Texture is classified by the spatial distribution of gray levels in a neighborood. It also helps in surface and shape determination. Gray level co-occurrence matrix is used to calculate different texture features [28]. There are two methods that can be used to calculate the texture feature of an image. One is the statistical texture analysis; the other is the structure of texture analysis. The former is the most conventional. Statistical texture analysis methods include spatial autocorrelation method, Fourier power spectrum method, Co-occurrence matrix method, gray level difference statistics method and trip length statistics method. Color mapping co-occurrence matrix (CMCM) is used to extract the texture information from a skin image. Gray level co-occurrence matrix (GLCM) is used to extract texture features in an image. It represents the form of tabulation which contains different combinations of pixel brightness values (gray levels) that occurs in an image. To calculate the different texture features like entropy, energy, homogeneity and dissimilarity, a gray level co-occurrence matrix is created.

## III. Classification Process of the Orange Defects

The European Union defines three quality classes (*extra*, *class I* and *class II*) for the fresh oranges with the tolerances of 5% and 10% by number or weight, respectively. The oranges in the *extra* class must be of superior quality with no defects or irregularity in shape, whereas the *class I* and *class II* can contain defects up to 1 cm$^2$ and 2.5 cm$^2$, respectively. All defect types in oranges contribute roughly equally to the final grading decision as local color, structural or textural variation of oranges.

In our classifier the defect detector uses a set of masks to recognise regions on the orange image. The defect is characterised by a discontinuity in the skin pigmentation. The features extracted from the orange images in either spatial or frequency domain can be used for classification. The external surface quality is directly related to the marketing and sales. Our automatic grading system can significantly improve the accuracy and consistency, while at the same time eliminating the subjectivity of manual inspection. The defects that we are able to detect on the external surface are caused by two reasons:

- Pre-harvest and Post-harvest diseases, like: diplodia and phomopsis stemend rot, splitting, pitting, green and blue mold, sour and brown rots, anthracnose, etc.
- Mechanical damages during transportation.

The defects on the orange fruit are characterised by different textures. Among various textures, we categorised defect types like:

- Pitting, which is caused by mechanical damage or reduced gas exchange during transportation. Pits can coalesce to form irregular patches and brown to black blemishes.
- Splitting is caused by the inability of the outer skin to hold the weight of the whole fruit. The outer skin of the citrus fruit splits and the inner pulp gets exposed. The defective region is usually brighter when compared with the normal skin.

For the research we used a data set obtained after processing high quality orange images and defective quality orange images, for a total of $400$ acquired images that are obtained by rotating and rearranging fruit samples. Color values (RGB-channels) as local features, are directly related with the images, so in our classifier they were introduced into the system without any change.

## IV. Proposed technique for orange feature extraction

The foreground region (orange) then can be segmented out from the background by using the Hue and Saturation histograms of the image. In order to extract the features, the pictures have been firstly segmented and the background removed. This latter stage is very fast and its computational weight can be neglected, since it only uses the saturation histogram and a saturation threshold having value $0.049$. Figure 2 shows an orange with several surface defects and the segmentation result, while Figure 3 shows the saturation and hue histogram of the same orange.

In addition to the segmentation using its HSV representation, we use color histogram and GLCM (Gray level co-occurrence matrix) to find quality classes corresponding to the orange qualities. For practical applications, the original input variables are typically preprocessed to transform them into some new space of variables where the pattern recognition problem will be easier to solve. This preprocessing stage is called *feature extraction*, see [29]. Preprocessing is performed in order to speed up computation and improve the classification performance [30]. We then selected useful features that are fast to compute and allow easy discrimination [31]. A feature set suitable for the classification should be insensitive to significant translations and have a very low correlation. Therefore, we base the extraction of features on the array of co-occurrence matrix, see [32]. Co-occurrence matrix is a single level dependence matrix that contains relative frequencies of two coordinate elements separated by a distance $d$. As you move from one pixel to another on the image, entries of the initial and final pixels become the coordinates of the co-occurrence matrix to be incremented, which in the end will represent structural characteristics of the image. Therefore, moving in different directions and distances on the image will lead to different co-occurrence matrices.

For each image we have calculated three co-occurrence matrices: one for each channel Hue, Saturation, Value. The obtained features represent the area of the orange, the background (the contrast, like gray level uniformity), gray level correlation between neighbours, sum average and sum variance. The features were calculated from the normalised co-occurrence matrix for $d = 1$ and four main directions: $0°$, $45°$, $90°$ and $135°$.

Since the use of the co-occurrence matrices leads to a course of dimensionality, we use five statistical descriptors of these matrices which use a co-occurrences gray level matrix. This is to calculate the number of adjacent pixels repetitions with the same gray level in the whole image. The statistical descriptors are the five textural features derived from the co-occurrence matrices.

*Angular Second Moment*: Consists of the sum of the squared elements in the co-occurrences matrix taken by pairs

$$\text{ASM} = \sum_{i=1}^{N_g}\sum_{j=1}^{N_g}\left[P_1(i,j)\right]^2 . \tag{4}$$

*Contrast*: The global contrast of the image (also known as variance or *inertia*) measures the contrast intensity between a pixel and its neighbours

$$\text{Contrast} = \frac{1}{(N_g-1)^2}\sum_{i=1}^{N_g}\sum_{j=1}^{N_g}(i-j)^2 P_1(i,j). \tag{5}$$

*Correlation*: Measures the relation of a pixel and its neighbours. The degree in which if the gray level of a pixel increases, its neighbour also increases

$$\text{Correlation} = \frac{\sum\limits_{i=1}^{N_g}\sum\limits_{j=1}^{N_g}(1-\mu_x)(j-\mu_y)P_1(i,j)}{\sigma_x\sigma_y}, \tag{6}$$

where the expected values are expressed as

$$\begin{array}{l} \mu_x = \sum_{i=1}^{N_g} i \sum_{j=1}^{N_g} P_1(i,j) \\ \mu_y = \sum_{j=1}^{N_g} j \sum_{i=1}^{N_g} P_1(i,j) \end{array} \tag{7}$$

and $\sigma_x$, $\sigma_y$ which are the variances of all the values of the class that feature belongs to

$$\begin{array}{l} \sigma_x^2 = \sum_{i=1}^{N_g} (i-\mu_x)^2 \sum_{j=1}^{N_g} P_1(i,j) \\ \sigma_y^2 = \sum_{j=1}^{N_g} (i-\mu_y)^2 \sum_{i=1}^{N_g} P_1(i,j) \end{array} . \tag{8}$$

*Gradient Module*: Is a measure of the degree of asymmetry of a distribution around the mean. It is obtained by calculating the third central moment of the distribution. If the obtained value is zero, it means that it is centered (like the normal distribution). If it is positive, it is asymmetrical to the right, and if it is negative, to the left

$$\begin{array}{l} \text{GM} = \sum_{i=1}^{N_g} \sum_{j=1}^{N_g} P_1(i,j) f(i)^2 \\ f(i) = i - N_g + 1 \end{array} . \tag{9}$$

*Intensity symmetry*: Is a measure of the variation of the texture if the grey levels are reversed

$$\text{IS} = 1 - \sum_{i,j=1}^{N_g} \left|P_1(i,j) - P_1(N_g-1-i, N_g-1-j)\right| . \tag{10}$$

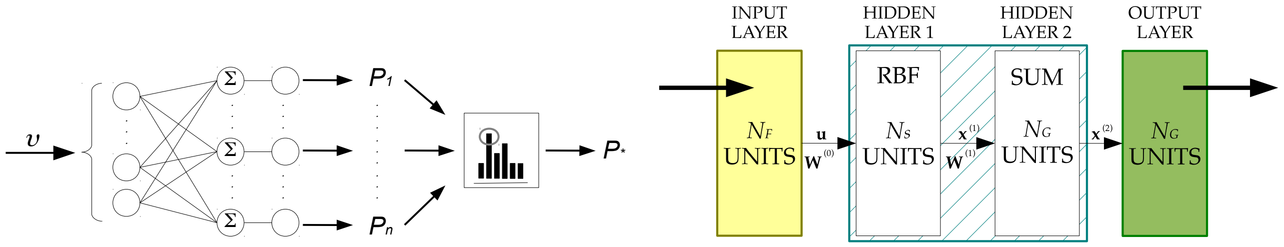

Fig. 4. A representation of our Radial Basis Probabilistic Neural Network (RBPNN) with maximum probability selector module. On the right the RBPNN layers model: $N_F$ is the number of features, $N_S$ is the number of samples and $N_G$ is the desired number defects to identify.

Firstly, we use the information from the co-occurrence matrices [33]. These matrices represent the spatial distribution and the dependence of the gray levels within a local area. Each $(i, j)$ entry of the matrices represents the probability of going from one pixel with a gray level $(i)$ to another with a gray level $(j)$ under a predefined distance and angle. More matrices are formed for specific spatial distances and predefined angles. From these matrices, sets of statistical measures are computed (called feature vectors) for building different texture models. In our case four angles, namely 0°, 45°, 90°, and 135°, are considered as well as a predefined distance of one pixel, in the formation of the co-occurrence matrices. Therefore, we have formed four co-occurrence matrices. A contrast equation (5) is used to calculate five parameters respectively, 0°, 45°, 90°, 135°, at limited distance one and 0° at a limited distance ten. This feature set extraction has a low dimensionality and a good discriminatory power. The features, e.g., mean and standard deviation, are extracted from each of the detail as well as the approximation sub-windows, and then fed into the Artificial Neural Network (ANN) classifier for defect classification. If the edges are not clearly defined, then the features extracted from such images are not useful. Training, testing, and validation of neural networks are performed using sample images.

## V. The Selected RBPNN

The proposed RBPNN (Fig. 4) is an implementation of a statistical algorithm called kernel discriminant analysis, see [34], in which the operations are organised into a multi-layered feed-forward network with four layers: an input layer, a pattern layer (the first hidden layer), a summation layer (the second hidden layer), and an output layer. Basically a RBPNN consists of an input layer, which represents the input pattern or feature vector. The input layer is fully interconnected with the hidden layer, which consists of the example vectors (the training set for the PNN [35], [36]). One other important element of the RBPNN is the output layer and the determination of the class for which the input layer fits. This is done through a winner-takes-all approach [37]. The output class node with the largest activation represents the winning class. While the class nodes are connected only to the example hidden nodes for their class, the input feature vector connects to all examples and therefore influences their activations. It is therefore the sum of the example vector activations that determines the class of the input feature vector. In RBPNN algorithm, calculating the class-node activations is a simple process. For each class node, the example vector activations are summed, which are the sum of the products of the example vector and the input vector, see [38]. Input neurons are used as distribution units that supply the same input values to all the neurons in the first hidden layer (such neurons are called *pattern units*). Each pattern unit performs the dot product $(\cdot)$ of the input pattern vector $\mathbf{u}$ by a weight vector $\mathbf{W}^{(0)}$. Then each pattern unit performs a nonlinear operation on the result. This nonlinear operation gives output $\mathbf{x}^{(1)}$ that is handed to the following summation layer. While the common sigmoid function is used for a standard FFNN, in our BPTA for presented PNN the activation function is exponential. Therefore for the $j$ neuron the output is where $\sigma$ represents the statistical distribution spread

$$\mathbf{x}_j^{(1)} \propto \exp\left(\frac{||\mathbf{W}^{(0)} \cdot \mathbf{u}||}{2\sigma^2}\right). \tag{11}$$

In the proposed model, while preserving the PNN topology [39], in order to obtain RBPNN capabilities, the activation function has been substituted with a Radial Basis Function (RBF). Moreover, there is the equivalence between the $\mathbf{W}^{(0)}$ vector of weights and the centroids vector of RBNN, which in our classifier are computed as the statistical centroids of all the given input sets. We name $\rho$ the chosen RBF, then the new output of the first hidden layer for the $j$ neuron is

$$\mathbf{x}_j^{(1)} \triangleq \rho\left(\frac{||\mathbf{u} - \mathbf{W}^{(0)}||}{\beta}\right), \tag{12}$$

where $\beta$ is the distribution shape control parameter, similar to $\sigma$ used in (11).

The second hidden layer in our RBPNN is a PNN. It computes weighted sums of received values from the preceding neurons. This second hidden layer is called summation layer with the output of the $k$ summation unit

$$\mathbf{x}_k^{(2)} = \sum_j \mathbf{W}_{jk}\mathbf{x}_j^{(1)}, \tag{13}$$

where $\mathbf{W}_{jk}$ represents the weight matrix. Such weight matrix consists of a weight value for each connection from the $j$ pattern unit to the $k$ summation unit. The summation units work as the neurons of a linear perceptron network. The training for the output in the applied model is performed similarly to RBNNs.

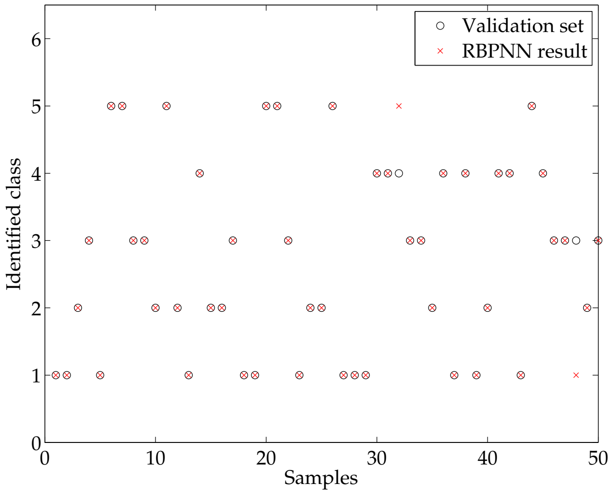

Fig. 5. The results of the identification proposed by our system at validation time: the circles show the effective class of the oranges, while the crosses show the identification output given by the implemented system.

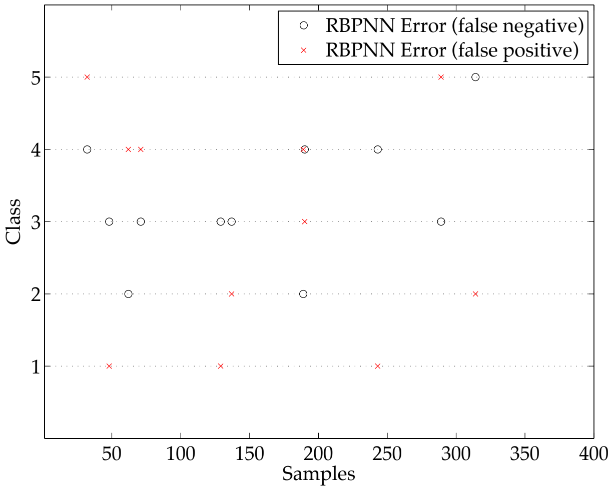

Fig. 6. The errors of identification of the proposed system: the circles identify the false negative results, while the crosses the false positive results.

## VI. Experimental results and conclusions

In our RBPNN classifier, defects were grouped into categories: surface defect as bruises (class 2), morphological defects (class 3), slight color defects (class 4), black mould (class 5) and a category of good fruit (class 1). The proposed classifier has been tested on a large number of image orange samples collected in a database. This section shows 400 samples of different defects of fresh orange surface include stab wounds, bruise, abrasion, sunburn, injury, hail damage, cracks and insect pest damage and good oranges. Fig. 6 shows the different recognitions. Our RBPNN model is able to correctly attribute the orange samples to the correct defect groups with an overall error of 2.75% (see Table I).

The proposed solution enabled us to obtain a fast and efficient automatic classification system for fruits defects. Although in an early stage of development, still such a system could be proposed on large scale for industrial applications, as well as for an implementation into programmable hardware.

TABLE I
A brief statistical analysis of the results by class.

| Class | Fruit condition | Number of samples | False negative | False positive |
|---|---|---|---|---|
| 1 | Normal fruit | 85 | 0 | 3 |
| 2 | Surface defect | 97 | 2 | 2 |
| 3 | Morphological defect | 71 | 5 | 1 |
| 4 | Color defect | 83 | 3 | 3 |
| 5 | Black mould | 64 | 1 | 2 |

| | Number of samples | Correctly classified | Overall error |
|---|---|---|---|
| **Overall classfication** | **400** | **389** | **2.75%** |

*Abstract*—**This paper describes a face recognition algorithm using feature points of face parts, which is classified as a feature-based method. As recognition performance depends on the combination of adopted feature points, we utilize all reliable feature points effectively. From moving video input, well-conditioned face images with a frontal direction and without facial expression are extracted. To select such well-conditioned images, an iteratively minimizing variance method is used with variable input face images. This iteration drastically brings convergence to the minimum variance of 1 for a quarter to an eighth of all data, which means 3.75-7.5 Hz by frequency on average. Also, the maximum interval, which is the worst case, between the two values with minimum deviation is about 0.8 seconds for the tested feature point sample.**

## I. Introduction

THERE are two major methods for face recognition [1]; one is the feature-based method which uses feature points at the endpoints of facial parts. The other is the holistic method, which processes the whole face region without decomposing regions into feature points. The former method has become unpopular because it is difficult to detect accurate feature points automatically. The latter method is now popular. However, Kathryn Bonnen and Anil K. Jain have recently proposed the effectiveness of a component-based method which uses facial parts in detail, rather than globally recognizing face information [2]. The holistic method conventionally analyzes the whole face region at once to achieve robust recognition. The component-based method utilizes separate regions of the eyebrows, eyes, nose and mouth, and performs dedicated recognition for each separate region, then integrates the results. The component-based method implies that it is now possible to detect facial parts before face recognition. The performance of the component-based method is better than that of the single holistic face recognition method.

The performance of face recognition has improved recently [3], and the results of various contests have been reported [4-6]. In those reports, recognition of frontal faces was considered as an easy task and more complicated conditions with age changes and with expressions are now targeted. Then, the basic face recognition technology is left in popular development activity. The recognition rate is now 97.5% for the frontal face without expressions [7], and it is still a difficult problem to realize 100% recognition for the frontal face without expressions.

One of the disadvantages of feature-based methods using feature points of face parts is that it is difficult to detect feature points correctly [1]. On the other hand, many devices are presented in the holistic methods with additional cases, such as faces with a non-frontal direction, under bad lighting conditions, and with facial expressions. However, for all cases, the recognition rate of the face is up to 99.90%, with a false acceptance ratio (FAR) of 1%. It is now difficult to reduce the FAR value since the recognition rate is at the upper limit.

In this paper, we consider the feature-based method because it provides high-precision results if the feature point detection works well and if its work successfully provides digital precision, while the holistic method views a whole face image with rough ambiguity at most. Recognition improves for a well-conditioned image from the frontal direction and without facial expression. We use moving video as the input and automatically extract the best shot from the frontal direction and without expression, and use the best shot images for registering the face image and matching input and registered face images. To obtain the best shot from an input video sequence, there are two methods using feature points. One involves maximizing the distance between feature points while viewing the input sequence. The other involves minimizing the variance of the distance between feature points. In this paper, the latter method will be described.

One of the methods using feature points of 3D presented by Drira et al. [8] performs 99.2% utilizing distances of 3D curves for faces without expressions. Another method using 3D mesh and the distance function in a wavelet-transformed domain under bad lighting conditions presented by Toderici [9] outperforms the 2D case. However, the recognition ratio is not so high. Guillaumin et al. presented an improvement using a learning method utilizing the nearest neighbor method to feature point distances [10].

## II. Previous Methods And Ideas For Improvement

In contests for face recognition, the recognition ratio for still pictures is reported to be 0.92 for rank 1 [4]. Further contests with age changes and with expressions are reported [5-6]. Also, most of these studies and reports settle some values of FAR (False Acceptance Ratio) or FRR (False Rejection Ratio), real distinguishing ability is not realized. From these results, the number of people that the face recognition system can distinguish without using any other information such as ID numbers is several hundred to a thousand. The so-called face-pass that permits a person to pass an authentication gate with only a face identification system without using an ID card does not make a service for more than thousand people. To improve the basic distinguishing ability of the number of people recognized and increase it above a thousand is the object of this paper.

To improve the recognition ratio, it is important to enhance the processing methods in the first stage of the system to acquire larger distances of feature values between people, not to incorporate additional conditions of age changes, expressions lighting conditions etc.

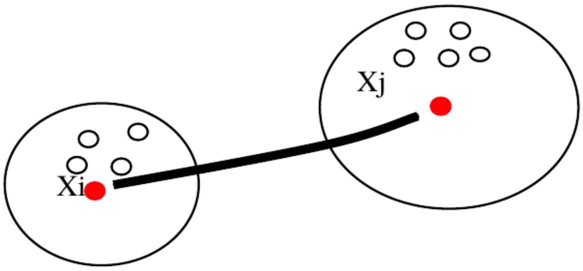

Fig.1 Feature points with the same name neighborhood[10].

## III. Face Recognition Using Feature Point Distance

### *A. Proposed system[11][12]*

Fig.2 shows the proposed face recognition system. Using input N frames, the best shot frame is selected by the method to be described in the following section. The best shot frame is registered in a database before recognition. At recognition, the best shot frame is selected and is verified using data in the database. The feature points of face parts are detected from the input face image. The detection is performed using software developed by Milborrow et al. [13] [14]. The software is based on the Active Shape Model and detects 77 feature points on the frontal face image. After detection of the feature points, two compensation operations of rotation and scale normalization are performed.

*A(1) Rotation compensation[12]*

The rotation compensation is to rotate at an angleθ which is a slope between the edges of both eyes. The rotation operation matrix shown in (1) is applied to the (x,y) coordinates of all feature points.

$$\begin{bmatrix} X \\ Y \end{bmatrix} = \begin{bmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} \quad (1)$$

After this rotation compensation, both eyes are aligned horizontally.

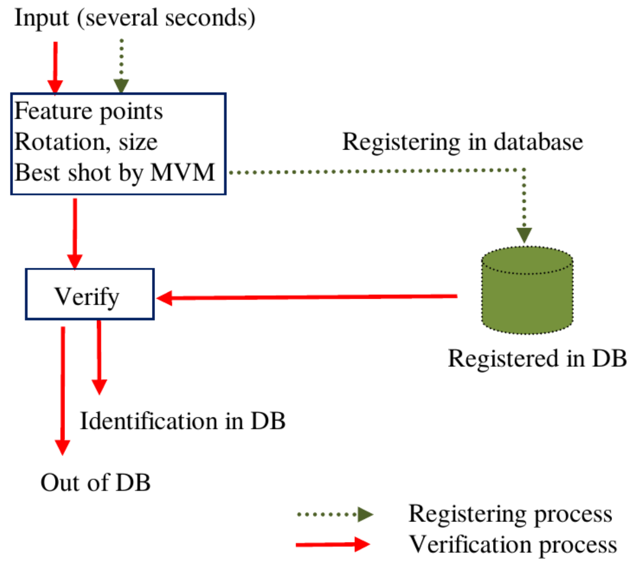

Fig.2 Face recognition system

*A(2) Size and position normalization*

Next, normalization according to the size is performed. This operation is applied to all feature points at the same rate as changing the size of a specified face part to a fixed size. In actual, let NF be

NF=sc/(X coordinate of the left edge of the left eye – X coordinate of the right edge of the right eye) (2)

Then, multiply this NF to all X and Y coordinates.

Position normalization is applied by moving all points in parallel after the size normalization. Let the input X and Y coordinate values of the first feature point be (In(0),In(1)) and the registered values be (Reg(0),Reg(1)), then the parallel movement value for X is Reg(0)-In(0), and for Y is Reg(1)-In(1)).

### *B. Best Shot Detection methods from video*

An advantage of using video for face recognition is that it can utilize well-conditioned data and discard poorly conditioned data. Therefore, video provides temporal continuity, so classification information from several frames can be combined to improve recognition performance [15]. Also, tracking of detected facial regions is possible and the system can be expanded to carry out facial expression detection [16].

Two methods of obtaining the best shot are considered. One is maximizing the length between the two feature points. Another is removing the value with greatest deviation to minimize variance.

*B (1) Maximizing Length Method*

A moving head in the input video shows a three- dimensional rotation pattern. Figure 3 is a face with a frontal direction and without a facial expression, which is the best shot. We will detect this kind of best shot image from all varying data. As for the Y and X axes rotations, the distances between feature points can be reduced by three-dimensional displacement and there is no data for compensation from the single camera environment. The Maximizing Length Method involves selecting a frame in which the distance between feature points is the maximum in all data.

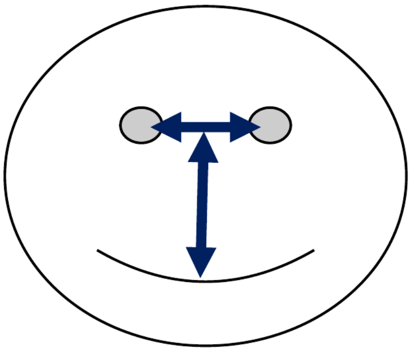

Fig.3 Regular face with frontal direction and without facial expression.

### *B (2) Minimizing Variance Method*

The Minimizing Variance Method is used to remove irregular data from the total data to obtain concentrated data with smaller variance. The method actually removes iteratively the largest value distant from the temporal average value and makes a new data set. Figure 4(a)-(d) shows the iterative removal status for the case of a pre-obtained time sequence data set of feature points. The asterisks in Figure 4(a)-(c) indicate the largest value at each stage. A removed value is replaced by a dotted line. From Figure 4(a) to (c), two values are removed one after another, and the third largest value is marked in Figure 4(c). The same processes are repeated to reach Figure 4(d), which shows a temporally small variance as if the iteration may converge to a fixed average with the smallest variance.

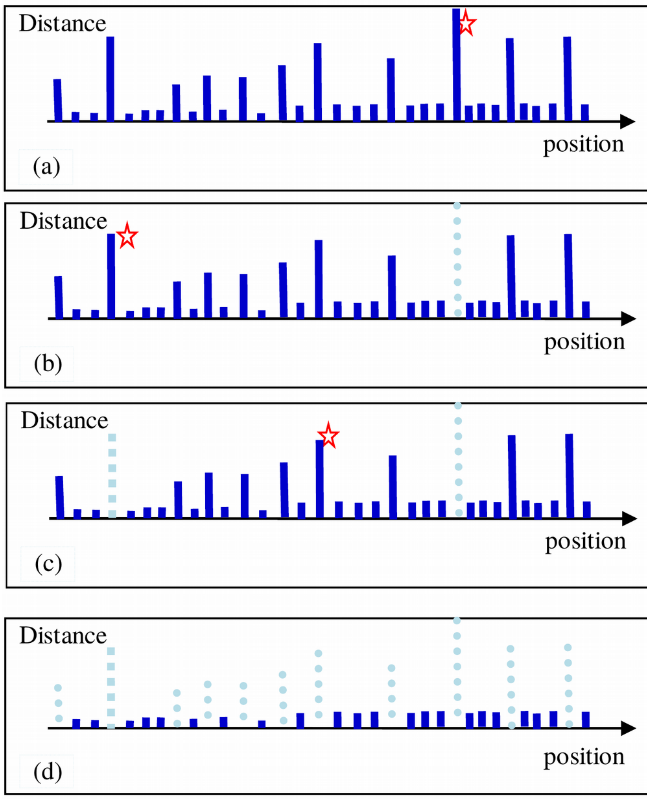

Fig. 4 Variance is reduced by removing the value with the greatest deviation.

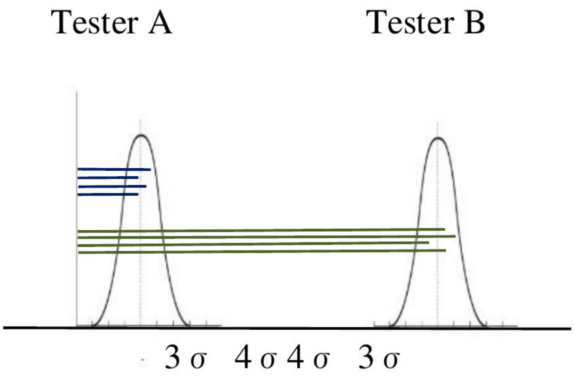

Fig.5 Distribution of two different persons.

### *C Estimation of the number of distinguishable people*

To distinguish one person from all the other persons using the detected feature points, the values should be clearly different to each other. To reduce the FAR and FRR, the detected feature point values should have meaningful distances. Here, we try to estimate the distance distribution for a larger number of testers from a smaller number of testers. The distance between two feature points on a face is a feature value. Let us consider a distribution of this feature values that are length data. We assume this distribution is normal with mean m and standard deviation σ.

Fig.5 shows a one-dimensional distribution for a feature value of a distance between two values. The distribution is made from the data of many testers. When this distribution is normal, the value of a sample taken from the data set randomly is considered to form a random sequence with this distribution.

Fig. 6 shows an example. This shows the minimum distance among data taken one after another from data with a distribution of mean m and standard deviation σ.When this minimum value goes below a threshold, i.e. 1, we cannot distinguish at least one person among the data using the feature value. When the minimum value remains larger than the threshold, we can distinguish all people in the taken samples. Fig.6 shows the case of m=16, σ=4, 8, 16, 32, 64. The horizontal axis is the number of samples taken. This graph shows that the minimum value goes below the threshold for more than 5-20 samples.

## IV. EXPERIMENTS

Four experimental items are carried out in the following sections. The Minimizing Variance Method (MVM) described in III B(2) is introduced in experiments to automati-

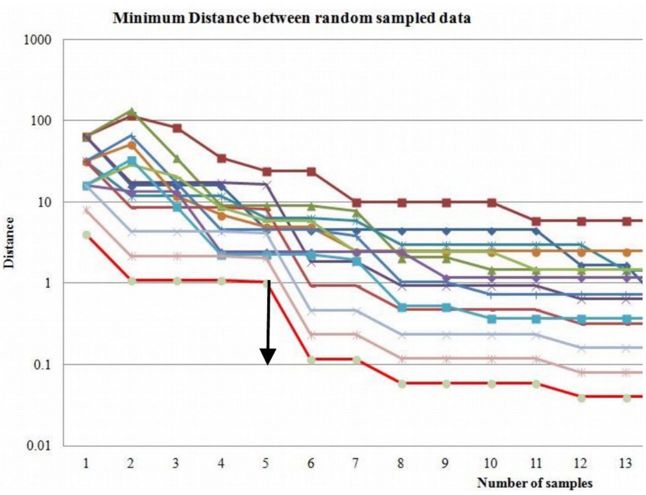

Fig. 6 Minimum distance among sampled random data. m=16, σ=64,32,16,8,4. This graph is based on a model generated by random samples from the normal distribution. Five values can be sampled keeping the distance values larger than 1 for all cases, which will be used in a later section, to allow taking samples five times. The width of windows is restricted to 13.

cally obtain frontal face images without expressions from input moving video of a person speaking for face recognition.

### A. Reducing variance by MVM

First, by adapting MVM described in III B(2) to use with a recorded part of a video with a length of about one minute, the convergence status of variances is investigated. The number of pieces of distances between feature points is the combination of two out of 77 feature points, that is $_{77}C_2=2926$ , where the total number of feature points is 77. For all this length data, let an initial value of the number of frames according to the time direction be “n”. The algorithm involves the following three steps;

a. Obtain the average length for time direction with the total number of the lengths of n.
b. Remove the largest value that is distant from the average value.

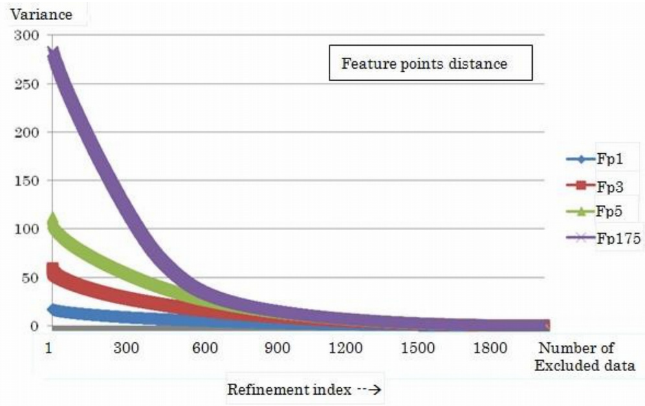

Fig.7 Variances of four distances between feature points converge as deleting iterations.

c. We get a new set of length data in which the number of lengths is subtracted by 1. (n=n-1)

This process is repeated until we get n=1.

Figure 7 shows four data which were randomly chosen from 2926 results with graphs of variances as the process above proceeded. The variances at the position of 1000 times of iteration, which is about half the number of total iterations are greatly reduced. Also, at the position of 1500 times, which is about a quarter of the total number, the variance is almost below 1-2. Other results show nearly the same tendency, as shown in the graphs.

### B. Variation by the positions of feature points

Figure 8 shows all 2926 distance values between feature points with well converging status according to the number of iterations. The numbers of iterations are from 500 to 1935, and their results are displayed overlapped. Figure 8(a) shows variances with the iteration numbers of 500 and above. Fig. 8(b) shows 1000 and above, Fig. 8(c) shows 1500 and above. These Figures show the variances reduce to small values after 1500 iteration. And after 1750, almost all variance data go below 2, and half of them seems to be below 1. A quarter to an eighth of all data seem to be below 1, which the input data are converge to stable values for register and recognition.

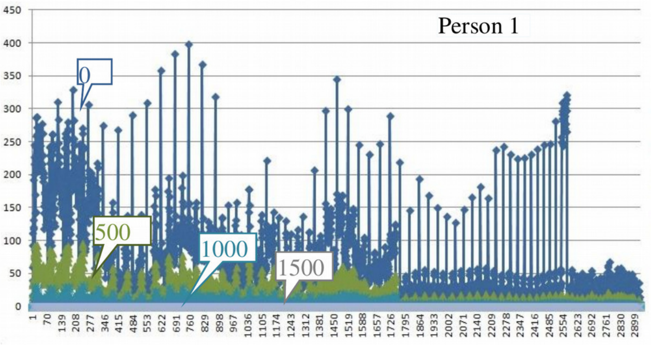

Fig.8 (a) Variances of distances between feature points converge as the number of iterations increases from 500 to 1935.

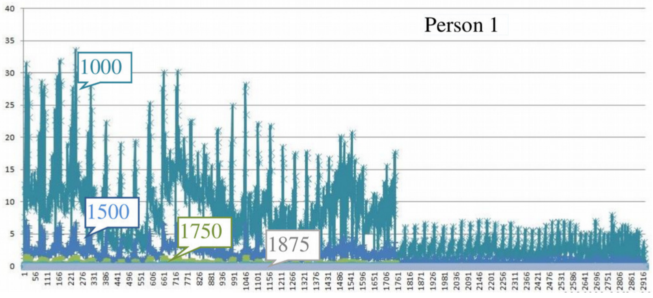

Fig.8 (b) Partial variances of distances between feature points converge as the number of iterations increases 1500, 1750, 1875, 1935. Enhanced in the vertical direction.

### C. Maximum interval between minimum variance data

After adapting the MVM to the length data, a quarter to an eighth of the resulting data forms a set with a small variance of 1-2. This quarter means 3.75-7.5 Hertz in the time

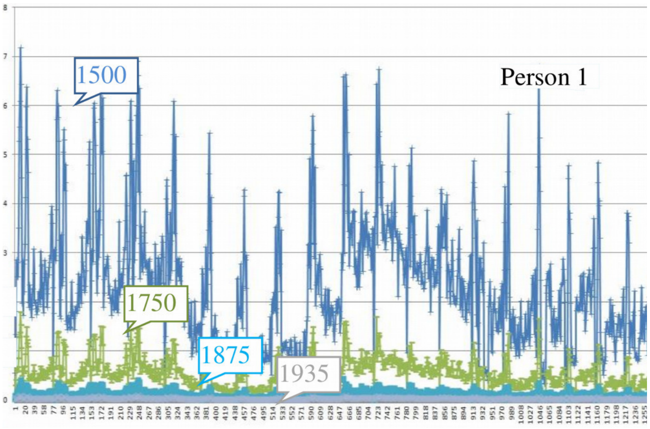

Fig.8 (c) Variances of distances between feature points converge as the number of iterations increases from 1500 to 1935. For the 1750 case, most feature values are below 2 and half of them are below 1.

direction because the original data was 30 Hertz. Face recognition can work at about 5Hz in the best conditions on average. But the value of 5Hz is average and we must consider the possible worst case. Then, the maximum interval between the converged data with small variances, which shows the worst case for detecting the best shot, is searched for. Figure 9 shows the maximum interval between the best shot frames vs. thresholds of deviation between the average value and the length value. The average values are the final values obtained by experiment III-A.

### D Estimation of the number of distinguishable people

For identification by face recognition, the number of distinguishable people will be estimated. The total number of feature values is 2926 as the pieces of distances between feature points. It is important to select feature values whose distance value is large enough to distinguish people. Fig. 10 shows a hundred feature values from the first number. The number of feature values that have a distance larger than 5 is 45. The distance value larger than 4 can be assumed to be the case of a standard deviation larger than 4 in Fig.6. From the curves of Fig.6, the number of valid samples to be distinguishable is 5. From this result, and if we take four more feature values (in total five feature values) we can find the number of distinguishable people is $5^5=3125$ [17]. If we take one more feature value it will be $5^6=15625$ .

We can estimate that there are at least five feature values from the different face parts of an eye, an eye brow, a mouth, a nose, and a contour, though the total 2926 data points may have correlations and are not independent of each other.

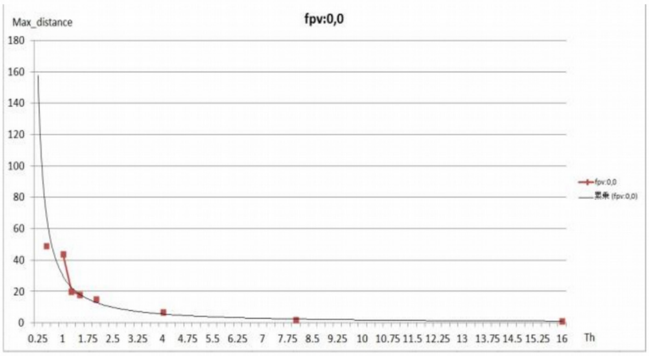

Fig.9 The maximum interval between the best shot frames vs. thresholds of deviation between the average value and length value. Dots are measured intervals. The value belongs to the best shot if it is smaller than the threshold.

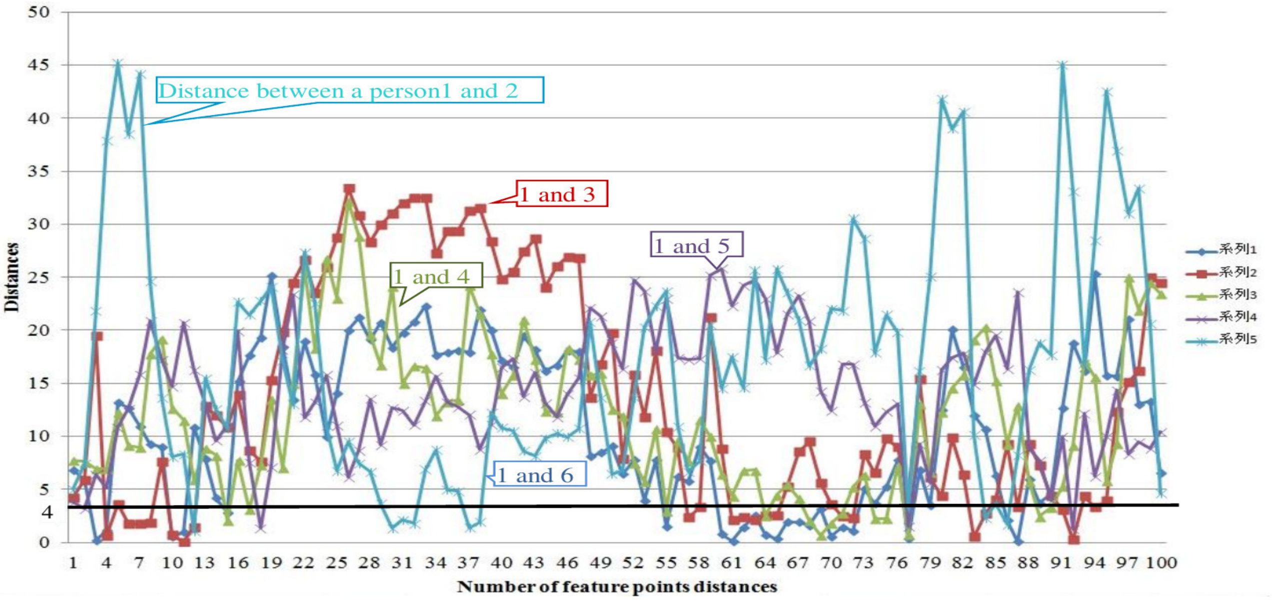

Fig.10 Five distance values obtained by six testers. The horizontal axis is the numbering of 100 feature values out of 2926. The feature values that have a distance of more than 4 are good distinguishable features for recognition.

## V. CONCLUSIONS AND FUTURE WORK

A new method of extracting the best shot from moving video input for face recognition is proposed. The best shot is obtained at the average probability of 1/4 to 1/8, which means 3.75-7.5 Hz in the time direction on average. The best shot can be obtained for all 2926 combinations of feature points. The maximum interval between the best shots is 0.8 second. According to Fig6, feature values larger than 4 can be used five times when sampling people. According to Fig.10, more than five feature values can be used. The number of distinguishable people can be estimated up to 3125 based on normal distribution. If we take six features, it implies the features distribute within 4σ.

In the future, how to select more reliable feature values for 5σ will be studied.

# Pedestrian tracking in video sequences: a particle filtering approach

Mateusz Owczarek, Przemysław Barański, Paweł Strumiłło
Institute of Electronics, Lodz University of Technology
Email: {mateusz.owczarek, przemyslaw.baranski, pawel.strumillo}@p.lodz.pl

***Abstract*—In this work we study the methods for pedestrian tracking in video sequences and indicate various applications of these methods ranging from surveillance systems to aiding the visually impaired persons. First, we define the general problem of object tracking that comprises the tasks of object detection, identifying the flow of object location in consecutive video images and finally analysis of the tracked trajectory data. We review the well known object tracking techniques i.e. the Mean-Shift and the CAMSHIFT algorithm and discuss their properties. Then we introduce the computational technique known as particle filtering (PF) and explain how we have applied it to the tasks of pedestrian tracking. We compare the PF approach against the Mean-Shift and the CAMSHIFT algorithms in terms of tracking robustness and the required computational demand. We conclude, that on the tested video sequences, the PF tracker outperforms the Mean-Shift and by a small margin the CAMSHIFT algorithm. The PF tracker requires more computational power, however, its tracking performance can be flexibly adjusted to the application requirements.**

## I. Introduction

HUMAN BEINGS, whether in a standstill or in motion, have an extraordinary visual capability of detecting objects and tracking them in the environment. This powerful property of the human visual system allows people, e.g. to manoeuvre in crowded pavements without bumping into other pedestrians. Implementation of object tracking functionality in computer vision systems is a challenging task and has attracted researchers' interest for decades. This is because there are numerous applications in which object tracking is important. They range from civilian applications (human-computer interaction, robotics, surveillance systems, crowd sourcing systems) to military applications (guided missile systems) [1], [2], [3]. Tracking of objects in video sequences is a particularly difficult task due to the following reasons:

- varying illumination of the monitored scene,
- loss of depth information in mono-camera image acquisition systems,
- varying size and shape of the tracked object (due to changes in orientation and distance to the camera),
- occlusions of the tracked objects,
- motion of the tracking camera (i.e. both the tracked object and the background move in reference to the camera).

The object tracking task can be subdivided into the three major steps:

1) Object detection in a scene and determining its location (i.e. applying methods for segmenting out the object of interest from the background).
2) Identifying object position changes in consecutive image frames, termed object tracking.
3) Analysis of the object tracking data (e.g. determination of the motion trajectory, path prediction, etc.).

The latter processing step strongly depends on the application. Our research goal is to develop a system that would serve as a vision based travel aid for the visually impaired. Although, a number of GPS-based navigation systems or remote guidance systems were designed especially for the visually impaired, they are expensive and offer poor position accuracy in urban environments [4]. Also, electronic travel aids in which ultrasound or laser sensors are embedded into white canes and also more advanced sensory substitution solutions (e.g. using auditory display techniques) have not found wider acceptance among the visually impaired users [5]. Our approach to aiding the visual impaired in mobility and travel is to track the position of a blind pedestrian in a city environment on the basis of video sequences. Then the positioning data will be integrated with the digital map data to work out the navigation instructions for the blind user. Such a solution does not require any additional hardware to be carried by a blind pedestrian except for a mobile phone that would serve as a communication device between the system and the user.

In this communication we report on our preliminary studies aimed at developing and testing robustness of the vision based object tracking methods with special focus on systems used for pedestrians' tracking. In Section II we review the related work and highlight the widely used Mean-Shift and CAMSHIFT object tracking algorithms. In Section III we introduce the particle filtering algorithm and explain how we apply this powerful computing technique to person tracking. In section IV we describe the experimental tests of the algorithms and evaluate their performance on example object tracking tasks.

## II. Review of related work

### A. Object detection methods

Every tracking method requires an object detection technique to distinguish the tracked object from the background and/or other objects. The result of tracking strongly relies on the applied object detection method. These methods can be subdivided into four categories [1]:

This work was supported by the European Union's Horizon 2020 Research and Innovation Programme under grant agreement No 643636 "Sound of Vision."

978-83-60810-66-8/$25.00©2015, IEEE

- **Point detectors** are used to detect characteristic points in a processed image (i.e. corners, edges). Among the most commonly used methods are: the *Moravec's operator*, the *Harris point detector* and the *Scale invariant Feature Transform* (SIFT). A comparative survey [6] provides more information on the topic.
- **Segmentation** leads to partitioning an image into characteristic regions (i.e. perceptually similar regions that can be used for tracking). The *Mean-shift* clustering [7], [8], the *Graph-cuts* and *Active contours* are within the most relevant image segmentation techniques.
- **Background modelling** is based on an assumption that moving objects appear on a very largely stable background [9], therefore the foreground can be obtained by "subtracting" the estimated background image from the current frame.
- **Supervised classifiers** that are based on a large collection of labeled samples composed of feature vectors. Samples are used as training data for the supervised learning method to generate a function that maps inputs (e.g. object features) to the desired outputs (e.g. class labels unambiguously binding the object with given features). These methods include neural networks, *adaptive boosting* (e.g. *Viola-Jones object detection* framework used to detect pedestrians [10]), *decision trees* and *Support Vector Machines* (SVM) in many variations [3].

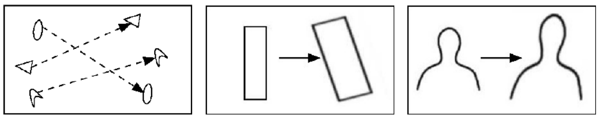
Among the image features commonly used in object tracking are [1], [11]:

- **Color** is used as a feature in histogram-based methods, where the object is represented by its appearance. Color spaces such as *L*a*b* and *HSV* (Hue, Saturation, Value) are more preferred in image processing, due to more perceptual uniformity.
- **Edges** are strong changes in the intensity or color in an image generated by object boundaries. Edges are less sensitive to illumination changes than color features.
- **Optical flow** defines the apparent motion of an object by a dense field of displacement vectors across consecutive image frames.
- **Texture** of an object described by a number of properties (such as lightness, density, regularity, linearity, directionality, smoothness, etc. [12]) is an excellent feature to track.

### B. Approaches to object tracking

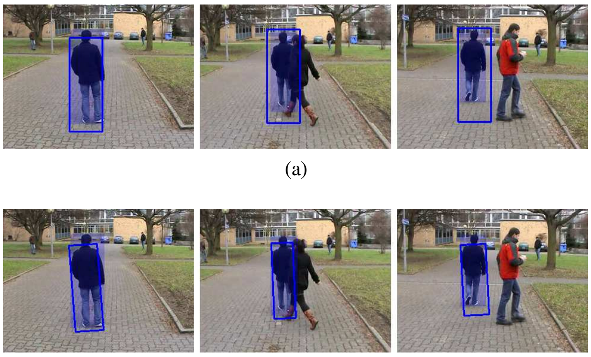
Object tracking techniques can be subdivided into the three major categories:

- **Point Tracking** relies on the positions and motion of points representing the target object in consecutive frames. Therefore, object tracking can be defined as the problem of finding points' correspondences (Fig. 1a).
- **Kernel Tracking** relies on the shape or appearance of the target object (referred to as *kernel*), which is represented by a geometric primitive (e.g. a rectangular patch or an ellipse), see Fig. 1b. The most popular representative of this category is the *Mean-Shift* [7], [8], [13] and its modification, the *CAMSHIFT* (*Continuously Adaptive Mean-Shift*) algorithm [14] (see Fig. 2).
- **Silhouette Tracking** relies on the information encoded inside the region of a tracked object which usually, due to the complexity of its shape, cannot be described well using simple geometric primitives (Fig. 1c).



(a) Multi-point correspondence (b) Parametric transformation of a rectangular patch (c) Contour evolution

Fig. 1. Different tracking approaches (source: [1])



(a)

(b)

Fig. 2. In the Mean-Shift algorithm (a) the search window size is fixed throughout the tracking session, whereas in the CAMSHIFT (b) the search window continuously adapts itself in size and orientation to fit the target object

The idea of applying particle filtering to object tracking was independently proposed by several research groups and is described in [15], [16] and [17] among others. Although the computational and probabilistic origins of the particle filter usually remains (more or less) the same, different approaches use different features to define the target model. Typically, edge-based image features are used [18], [15], [19], but color-based image features are also an option. The latter is even more robust against the out-of-plane rotations (e.g., when a person turns around), scale and rotation invariant [20], but more sensitive to the illumination changes (as indicated in Section II-A). For this reason, the color-based particle filter has become the object of our study.

Reference [2] presents recent trends in object detection, while [3] evaluates the state-of-the-art tracking algorithms.

## III. Application of Particle Filtering to person tracking

### A. Particle filter basis

Particle filtering, also called the *Sequential Monte Carlo* (SMC) [21] method, is a simulation-based technique which stems from the Monte Carlo method. The latter is a simple, yet effective, way of finding an optimal solution for multidimensional problems by randomly generating a large number of possible system states. This enables to observe the overall system behaviour and select the best solution.

In the particle filter approach, the distribution of the $\mathbf{s}_t$ is approximated by a set of so called particles. Every particle is represented by the vector:

$$\mathbf{c}_t^{(n)} = \left[\mathbf{s}_t^{(n)} \ \pi_t^{(n)}\right]^T \tag{1}$$

where the superscript $(n)$ denotes a particle number ranging from 1 to $N$ being the size of the particle set and $t$ denotes a time instant. Hence, the vector $\mathbf{s}_t^{(n)}$ represents the system state, that is the variables of interest, $\pi_t^{(n)}$ is a particle weight, i.e. a value that reflects how accurately a given particle approximates the system state.

The posterior distribution of $\mathbf{s}_t$ is approximated by the probability mass function:

$$p(\mathbf{s}_t|\mathbf{y}_{0:t}) \approx \sum_{n=1}^{N} \delta(\mathbf{s} - \mathbf{s}_t^{(n)}) \cdot \pi_t^{(n)} \tag{2}$$

where $\delta(\cdot)$ is the Dirac delta function.

The algorithm can be summarized in its basic form as follows [22]:

1) **Initialization**. At the algorithm's outset, all particles' states $\mathbf{s}_0^{(n)}$ are randomly initialized according to a given distribution. The weights $\pi_0^{(n)}$ are assigned equal values of $\frac{1}{N}$.
2) **Prediction.** New particle states are predicted on the base of the transition equation:

$$\mathbf{s}_t^{(n)} = \mathbf{f}\big(\mathbf{s}_{t-1}^{(n)}, \mathbf{u}_{t-1}, \mathbf{w}_{t-1}^{(n)}\big) \tag{3}$$

where $\mathbf{u}_{t-1}$ is a driving vector and $\mathbf{w}_{t-1}^{(n)}$ is the noise vector introduced to the state due to the measurement error of $\mathbf{u}_{t-1}$. Each particle is perturbed with an individually generated vector $\mathbf{w}_{t-1}^{(n)}$; $\mathbf{f}(\cdot)$ is the transition function that calculates a new state on the base of the previous one and the driving signals.
3) **Measurement update**. Each measurement $\mathbf{z}_t$ updates the weights of the particles by the equation:

$$\pi_t^{(n)} = \pi_{t-1}^{(n)} \cdot p\big(\mathbf{z}_t|\mathbf{s}_t^{(n)}\big) \tag{4}$$

where $p\big(\mathbf{z}_t|\mathbf{s}_t^{(n)}\big)$ is a conditional probability density of measuring $\mathbf{z}_t$ given the particle state $\mathbf{s}_t^{(n)}$. Particles that diverge in the long run from measurements will have small weights $\pi_t^{(n)}$.
4) **Weights' normalization.** For the sake of the next steps, the weights need to be normalized so that they sum up to 1:

$$\pi_t^{(n)} := \frac{\pi_t^{(n)}}{\sum\limits_{i=1}^{N} \pi_t^{(n)}}. \tag{5}$$

5) **State estimation**. The system state is the weighted average of all particles' states:

$$\bar{\mathbf{s}}_t = \sum_{i=1}^{N} \mathbf{s}_t^{(n)} \cdot \pi_t^{(n)}. \tag{6}$$

6) **Resampling**. After a number of algorithm iterations, all but a few particles have negligible weights and therefore do not participate in the simulation effectively. This situation is detected by calculating the so-called *degeneration indicator*, expressed by:

$$d_t = \frac{1}{N \sum\limits_{i=1}^{N} \left(\pi_t^{(n)}\right)^2}. \tag{7}$$

As the weights start to differ, the $d_t$ indicator decreases. If $d_t$ falls below a given threshold, then a process called resampling is evoked and a new set of particles is created. Resampling causes that the probability density function of $\mathbf{s}_t$ is refined in the next iterations of the algorithm. Thus, a better estimate can be found.
7) **Go to point 2**

### B. *Implementation of particle filter for person tracking*

The implementation of the particle filter tracker described herein is based on the idea behind the *ConDensation Algorithm* [15], once implemented in the OpenCV library, yet presently deprecated due to some imperfections in the resampling part.

Target object is represented by a rectangular patch (Fig. 4a). Such representation is suitable for representing simple non-rigid targets and works well in terms of kernel-based tracking methods [1]. Target model is defined by a (8×8×4 bins) HSV histogram of the target object's representation and an initial size of the representation rectangle (during the tracking process it is scaled in relation to its initial size). Reduced number of levels for the V-component of the histogram makes the method less sensitive to the changes in lighting conditions. The use of HSV histogram may, however, make the method more sensitive to noise [1]. Current version of the algorithm does not update the target model automatically, but a new target model can be built on-the-fly.

Due to the fact that the principle of operation of the particle filter was described in the preceding section, in the subsequent paragraphs we would like to limit ourselves just to the adjustments which make use of particle filter in object tracking.

*a) Initialization:* A set of $N$-samples is generated. Each sample represents the quantities of the target object's representation and is defined by a state vector and an initial weight:

$$\begin{aligned} \mathbf{s} &= [x, y, \frac{\mathrm{d}x}{\mathrm{d}t}, \frac{\mathrm{d}y}{\mathrm{d}t}, k]^T \\ \mathbf{s}_0^{(n)} &= [x, y, 0, 0, 1]^T \text{ for } n = 1, ..., N \\ \pi_0^{(n)} &= N^{-1} \text{ for } n = 1, ..., N \end{aligned} \tag{8}$$

where $(x, y)$ are the coordinates of the center of the representation rectangle, $\left(\frac{\mathrm{d}x}{\mathrm{d}t}, \frac{\mathrm{d}y}{\mathrm{d}t}\right)$ represents velocity vector (motion model), $k$ is the scale of the representation rectangle in relation to its initial size and $N$ is the number of samples.

*b) Evolution of the samples:* In every new frame a state of each sample is generated by a second order linear difference equation based on prior observations:

$$\mathbf{s}_t^{(n)} = \mathbf{A}\ \mathbf{s}_{t-1}^{(n)} + \mathbf{w}_{t-1}^{(n)} \tag{9}$$

where $\mathbf{w}_{t-1}^{(n)} \sim N(\mathbf{0}, \mathbf{Q}_t)$ is a vector of multivariate normally distributed random variates (stochastic component) and $\mathbf{A}$ is a *transition matrix* (deterministic component) defined for state vector (8):

$$A = \begin{bmatrix} 1 & 0 & \mathrm{d}t & 0 & 0 \\ 0 & 1 & 0 & \mathrm{d}t & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{10}$$

*c) Weighting the samples:* Each sample represents a hypothetical location of the tracked object. To weight the sample set, a histogram of each hypothetical target representation is compared to the target model. To quantify similarity between the two histograms, the *Hellinger distance* is used:

$$\begin{aligned} d_t^{(n)} &= \sqrt{1 - \frac{1}{M\sqrt{\bar{H}_1 \bar{H}_2}} \sum_{u=1}^{M} H_1(u) \cdot H_2(u)} \\ \bar{H}_k &= \frac{1}{M} \sum_{u=1}^{M} H_k(u), \end{aligned} \tag{11}$$

where $H_1$ and $H_2$ are the histograms to be compared and $M$ is a total number of histogram bins. The result is a score in range $[0, 1]$, where the first value indicates a perfect match and the latter a complete mismatch. The distance is used in the measurement equation to update the weights of the samples, according to:

$$\pi_t^{(n)} = \pi_{t-1}^{(n)} \cdot p(\mathbf{z}_t | \mathbf{s}_t) \tag{12}$$

$$\pi_t^{(n)} = \pi_{t-1}^{(n)} \cdot \frac{1}{\sigma\sqrt{2\pi}} \exp\left( -\frac{\left(d_t^{(n)}\right)^2}{2\sigma^2} \right), \tag{13}$$

where $\sigma$ is the standard deviation. The higher the weight, the higher chance that the particle will be drawn during the next iteration (particles with the lowest weights are to be replaced).

TABLE I
DETAILS OF THE TEST VIDEO SEQUENCE

| Parameter | Value |
|---|---|
| Format | 320 × 240 at 25 frames/s |
| Length | 1017 frames (∼ 41 sec.) |
| Target object | person |
| Keywords | moving cam, moving target, non-rigid target, rotation, similar distractors, full occlusion, outdoor |
| Link to dataset | [23] /datasets/seqI.zip |

The state of the tracked object at a time-step $t$ can be therefore estimated as the mean state [15]:

$$\bar{\mathbf{s}}_t = \mathrm{E}\left[\mathbf{s}_t^{(n)}\right] = \sum_{n=1}^{N} \pi_t^{(n)} \cdot \mathbf{s}_t^{(n)}. \tag{14}$$

*d) Re-initialization:* The process of propagation of samples is being continued until the mean state moves off the image or the probability of the mean state drops below a certain threshold. It usually means that the target object has been lost due to a mismatch between the predicted and actual motion. In such scenario, particles are redistributed in accordance with the continuous uniform distribution to re-acquire the target:

$$\mathbf{s}_t^{(n)} = \begin{bmatrix} x \\ y \\ \mathrm{d}x/\mathrm{d}t \\ \mathrm{d}y/\mathrm{d}t \\ k \end{bmatrix} \sim \begin{bmatrix} U(0, W_{image}) \\ U(0, H_{image}) \\ U(-0.05, 0.05) \\ U(-0.05, 0.05) \\ U(1.0, 2.0) \end{bmatrix} \tag{15}$$

where $(W_{image}, H_{image})$ is the size of the image.

## IV. Results of Experimental Tests

### A. Test results and performance measures

The implemented PF tracker has been tested and evaluated on a few short video sequences from the BoBoT benchmark on tracking dataset [23]. Here we present results obtained for one of the particularly difficult sequence which shows an individual walking along a pavement and is being followed by a camera (Fig. 4a). Ever and again a different person appears and passes by, shadowing the tracked pedestrian (so-called *occlusion*, cf. Fig. 4b), or is dressed in the same manner (so-called *similar distractor*, cf. Fig. 4c), trying to confuse the algorithm. Table I provides more details on the dataset.

The basic evaluation of the tracking algorithm relies on the overlap rate calculated every frame of the video sequence and defined as $\frac{\mathrm{area}(R_T \cap R_G)}{\mathrm{area}(R_T \cup R_G)}$, where $R_T$ is the rectangular region of the tracking result and $R_G$ denotes the ground truth [3]. If the overlap is larger than or equal to $1/3$, it is considered a hit (as shown in Fig. 5), otherwise a miss of target is denoted. Tests with a various number of particles show that $N = 100$ particles seems to be a good trade-off between accuracy and processing time of the algorithm (cf. Fig. 3). An interested reader is referred to the video sequence published at [25], which shows how the result of the tracking algorithm depends on the number of particles.

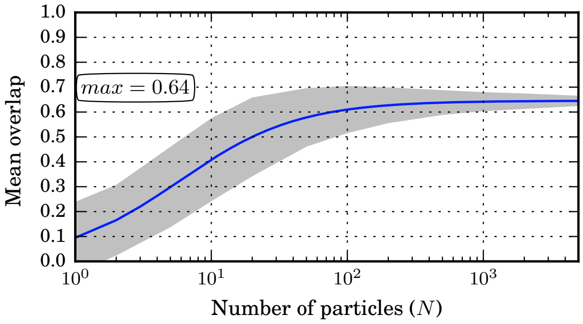


Fig. 3. The mean of ground truth and the tracking result overlap for $N = 100$ particles is equal to 0.62, which seems to be a trade-off between accuracy and processing time. Gray region is the standard deviation

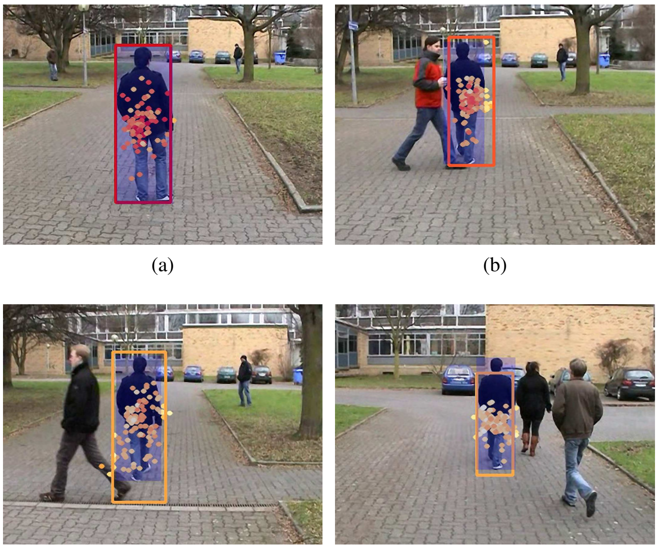

(a) (b)

(c) (d)

Fig. 4. PF tracker in action — tracked person is being followed by "particles" (each particle represents a hypothetical location of the tracked object). The tracking result is an outline around the target. Blue semi-transparent rectangle is the ground truth (source: [24])

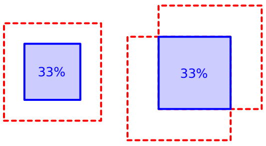

Fig. 5. Two examples of the ground truth (blue rectangle in the middle) and the tracking result (red dashed rectangle) overlap of 1/3

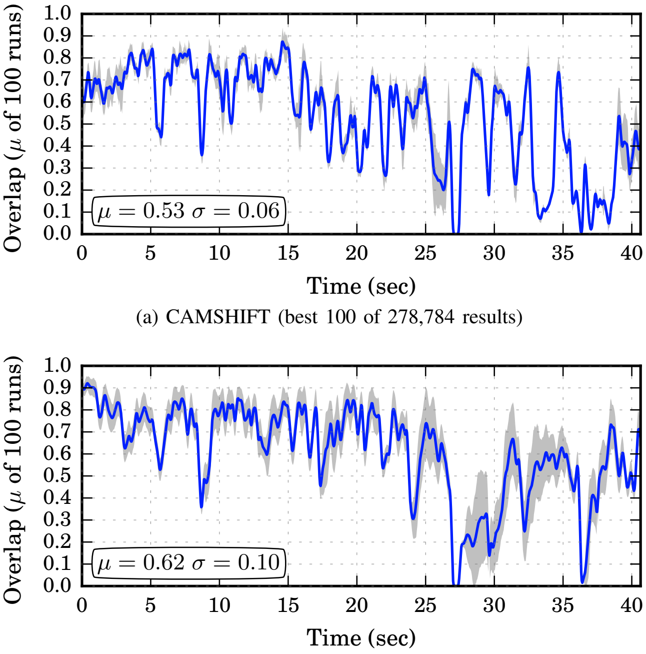

(a) CAMSHIFT (best 100 of 278,784 results)

(b) Implemented PF tracker (for $N = 100$ particles)

Fig. 6. The ground truth and tracking result overlap per frame for the test video sequence. Grey region is the standard deviation

Fig. 6b shows the overlap for each frame of the test video sequence (mean of 100 iterations) using $N = 100$ particles. At the beginning the overlap reaches up to 92% and oscillates around 80% for most of the time. Each drop below $1/3$ (a miss) is caused by a full occlusion, when the algorithm has lost the target and needed to be re-initialized. Slightly worse results in the last quarter of the video sequence are caused by the out-of-plane rotation of the tracked individual. After the person turned right, his right side is visible on the video instead of his back, on which the target model used to be built (as it was mentioned before, current version of the algorithm does not update the target model automatically, yet an adaptive approach is within the further work). Notwithstanding, the results are satisfactory — the PF tracker copes well with similar distractors and occlusions. A non-rigid target and motion of both the camera and the target also pose no problem.

### B. PF based tracker vs. the MeanShift and the CAMSHIFT

As indicated in Section II-B, color-based image features are robust against the out-of-plane rotations, scale and rotation changes. Additionally, the use of histogram matching results in relatively low computational cost. For this reason, color-based segmentation and tracking methods such as *Mean-Shift* and its extension *CAMSHIFT* (*Continuously Adaptive Mean-Shift*, cf. Fig. 2 upon the differences between these two methods), both within the OpenCV library, gained great popularity over the years.

CAMSHIFT is a parameter-free[1] tracking technique. It re-

[1] In the OpenCV library user can, however, define the maximum number of Mean-Shift iterations to converge

TABLE II
COMPARISON OF THE CAMSHIFT AND THE IMPLEMENTED PF TRACKER

| | **CAMSHIFT** | **PF tracker** |
|---|---|---|
| Mean of ground truth and tracking result overlap | $0.53 \pm 0.06$ | $0.62 \pm 0.10$ |
| Mean of hit ratio[a] | $0.79 \pm 0.02$ | $0.87 \pm 0.04$ |
| Mean number of Mean-Shift iterations per frame | $1.90 \pm 0.52$ | n.a. |
| Mean execution time per frame[b] | $0.73 \pm 0.03$ ms | $5.55 \pm 0.00$ ms |

[a] Hit ratio is the percentage of overlaps greater or equal to $1/3$.

[b] It should be noted that both the PF tracker and the evaluation script for the CAMSHIFT were implemented in Python, which tends to be slow.

quires a probability image of the target object (i.e. the back-projection of the object histogram) and an initial search window. Our test CAMSHIFT-based pedestrian tracker was based on the sample from the OpenCV library source code. It utilizes the HSV histogram of the target object masked with a binary image resulting from the thresholding of the initial image of the target object with different boundaries of colors. The purpose of masking was to extract as much of the target object from the background as possible to avoid false positives. A total number of over 270,000 different masks were used and only first one hundred results in terms of mean overlap were taken into account. The results are presented on Fig. 6a and tabulated in Table II.

As one can note, in several cases the CAMSHIFT-based pedestrian tracker performs marginally better than the implemented PF tracker, although the mean overlap and hit ratio of the former one are clearly lower. The CAMSHIFT-based tracker is also firmly faster. Please bear in mind though, that the result of the CAMSHIFT tracker strongly relies on the probability image of the target object. In this context it was selected carefully so as to correspond strictly to the video sequence used.

Finally, we encourage the reader to watch our short comparison video sequence available at [24].

## V. CONCLUSIONS

In this study we have undertaken the problem of object tracking in video sequences with a special focus on pedestrian tracking. Our objective was to compare the performance of the Mean-Shift and Camshift trackers to the powerful computation technique known as particle filtering. We have explained theoretical background of the PF and shown how we have adapted it for the purpose of pedestrian tracking. From the tests of the compared trackers on example video sequences (shot from a camera in motion) we conclude that the PF can outperform the the Mean-Shift and Camshift trackers. This is, however, at the cost of higher computational demand (cf. Table II summarizing quantitative comparison of the performance of the compared trackers). We argue, however, that the PF can be employed to track multi-modal distributions, i.e. that are not confined to Gaussian distributions. Finally, the strong advantage of the PF is that its computing implementations can be mapped to parallel processing architectures with a flexibly chosen number of particles. Our intention is to employ the developed tracking technique in a multi-camera video system aimed at aiding the visually impaired in mobility and navigation.

*Abstract*—**The paper presents a proposal of sensor fusion combining data derived from a Kinect device and high-precision sensors. The main idea was to enhance the tracking of a human arm in order to obtain precise coordinates. The Kinect plays the role of a calibration device and sensors' data are used in kinematics equations for enhanced tracking of the arm. This way the resulting information has less uncertainty and can be directly transmitted to another system, e.g. robotics one. The system has been implemented using kinematics-based approach with transformation operators as well as quaternions. In terms of accuracy the main result is that the Kinect performs very similar with sensors.**

## I. Introduction

THE idea of creating a device that allows to recognize human body shape in details without having to hold any remote controller on it inspired Microsoft to create the Kinect device (2010). It was a very novel and extraordinary approach to the challenge. Soon, the Kinect attracted researchers in many fields, especially from robotics and computer vision, as well as some communities that have released various SDK for Kinect allowing to use it as a kind of measurement tool. Since the lunch of the Kinect for Windows a lot of papers have been devoted to the scientific application of this device.

Some papers may serve as tutorials, e.g. for calibration of the Kinect imaging sensor [12], or help while building a new Kinect-based system [9], or source of references [4] for Kinect-based computer vision researchers, covering topics which include: preprocessing, object tracking and recognition, human activity analysis, hand gesture analysis, and indoor 3-D mapping, and many others.

In the beginning, researchers presented novel approaches to human detection using depth information taken by the Kinect [21], methods of obstacles detection where the Kinect was used as a capturing device [14], methods to quickly and accurately predict 3D positions of body joints from a depth image [17].

Later, considered problems became more complex or sophisticated. The Kinect was used to evaluate noise, accuracy, resolution, and latency of tracking skeletons; and measure the range in which the person being tracked must be in order to achieve these values [7]. Another tested application of the Kinect was a virtual bilateral Man-Machine interaction through the Kinect sensors, allowing the user to control and monitor Windows programs by gestures without a need of peripherals use [1].

There are even attempts to use the Kinect in the field of medicine or clinical rehabilitation as a monitoring device [18]. Another interesting use of the Kinect are methods for calibration using streaming information from depth cameras [19]. This is still a challenge in the case of hands generic precision and agility due to complexity of fingers joints.

As we consider the Kinect, the area of robotics is very popular in some purposes, for instance, enhancing the navigation of mobile robots, object detection and recognition, scene reconstruction, 3D inspection and others. The good example is an automated vehicles inspection by scanning and dynamically exploring regions of interest over an automotive vehicle body under visual guidance [11]. In such applications the very important aspect is quality of sensors [10] responsible for 3D data acquisition [13].

At present, there are many available solutions dedicated to context-aware robotics system [8], [16], e.g. for orientation determination of pedestrian motions by using an inertial measurement unit module and a complementary separate-bias Kalman filter [22].

In this paper we would like to propose a system based on the Kinect assisted by a set of high-precision sensors, that would be responsible for enhance movement tracking of a human arm with the accuracy suitable in the field of robotics. The idea of such a task is presented in Fig. 1, where we can see a man wearing sensors – one on the waistline and three on the natural links of his right arm. The arm’s configuration is mapped by the system. The Fig. 2. gives us a general view about the system and its components.

## II. Presentation of the System

The used computer vision system consists of an x86 computer equipped with the Kinect for Windows v2 device [23], which is supported by the YEI 3-Space sensors [24]. Microsoft Visual Studio 2012 and .NET Framework 4.5 are on the basis of applied software environment. Fig. 2 shows a visual conception of the used computer vision system.

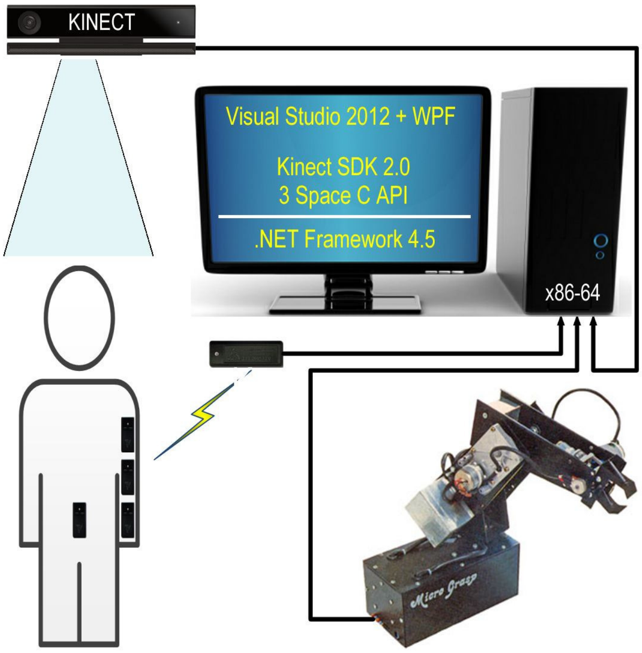

Fig. 2. The system conception

The presented system is based on the second-generation Kinect for Windows (well described in [3]) with an improved motion tracking functionality over its predecessor, a wider field of view, a high definition camera, and the ability to track up to six bodies at once. The Kinect can capture audio, color, and depth environment features, and process the depth data to generate skeleton data.

The YEI 3-Space Sensor (Fig. 3) is a miniature, high-precision, high-reliability, Attitude and Heading Reference System (AHRS) / Inertial Measurement Unit (IMU) with USB 2.0 communication interfaces in a single unit. The AHRS/ IMU uses a gyroscope, an accelerometer, and compass sensors in conjunction with advanced processing and on-board quaternion-based algorithms to determine orientation relative to an absolute reference or relative to a designated reference orientation in real-time. The gradient descent calibration process and high update rates increase accuracy and greatly reduce and compensate errors. The YEI 3-Space Sensor USB unit features are accessible via a well-documented open communication protocol that allows access to all sensor data and configuration parameters. Versatile commands allow access to raw sensor data, normalized sensor data, and filtered absolute and relative orientation outputs in formats incl. quaternions and Euler angles (pitch/roll/yaw). We a going to use both, Euler angles and quaternions, in order to compare results and also to verify our implementation this way.

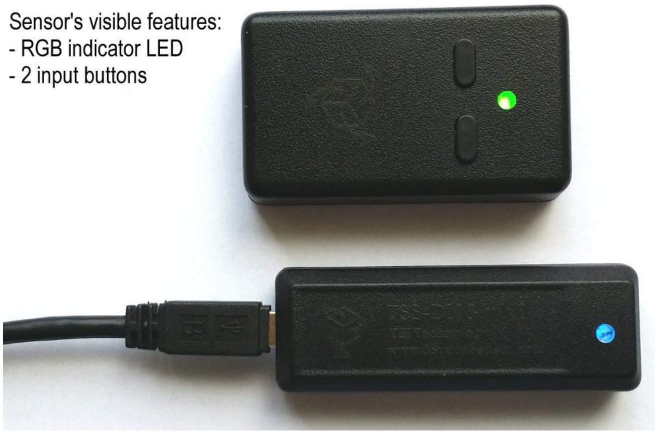

Fig. 3. The YEI 3-Space Sensor and the communication dongle

## III. Software Environment

Considering Visual Studio 2012 as the primal software environment we can distinguish three essential layers of the system: “application layer” on the top, “management layer” in the middle, and “data layer” at the bottom. The structure of the used software is presented in Fig. 4.

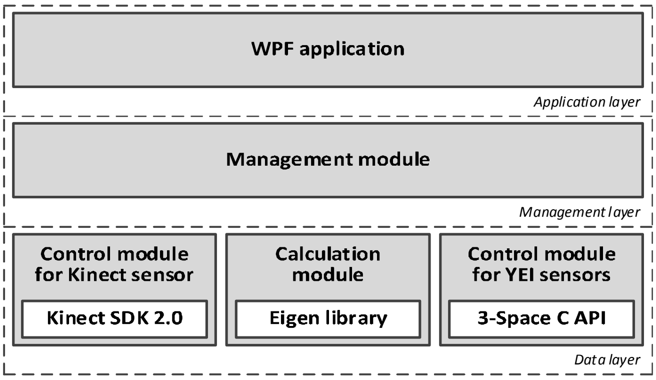

Fig. 4. The structure of the software environment

The application layer stands for the created WPF application [15]. It is the main element responsible for every activity aspect of the system, particularly for the GUI.

The management layer includes management control system tools placed in the management module library.

The set of libraries on the bottom layer includes: a control module for the Kinect sensor (it uses Kinect SDK 2.0), a calculation module (it uses the Eigen library ver. 3.2.2), and a control module for YEI sensors (it uses 3-Space C API ver. 2.0.6).

### A. Microsoft Visual Studio as a development tool

The use of Visual Studio 2012 as a development tool was involved by the possibility to fully utilize the Kinect for Windows SDK and assets of the Windows Presentation Foundation that provides a consistent programming model for building applications with a graphical subsystem. An additional aspect was the integration possibility of Microsoft .NET Common Language Runtime (managed code) with the 3-Space C API library and the Eigen library (unmanaged code).

### B. The Software Development Kit for Kinect

The Kinect for Windows SDK enables to create applications under Visual Studio 2012 (.NET Framwork 4.5 is required) that support advanced gesture and voice recognition using Kinect sensor technology on computers running modern Windows. To develop speech-enabled Kinect applications, the Microsoft Speech Platform SDK must be installed.

### C. The Eigen library

The Eigen is a high-level C++ open source library of template headers for linear algebra, matrix and vector operations, numerical solvers; this facilitates to achieve high performance of required calculations. In particular, the Eigen has also a possibility to solve linear systems using several types of decompositions, and includes several very useful classes and functions for image processing.

### D. The 3-Space API

The use of the 3-Space API was inevitable due to YEI sensors. This API is available for C/C++ and Python languages and can be used to write independent software for YEI sensors. Because of the chosen Visual Studio environment the 3-Space C API has been adopted.

## IV. Kinect's Role

As mentioned earlier and suggested in Fig. 1, the assumption is that the system is able to perform tracking of a human arm with the use of Kinect and sensors. To be exact, the Kinect is use mostly at the stage of calibration and later for verification purposes. In short, to perform the calibration of the system a person wearing four sensors have to take a posture shown in Fig. 5. (the arm must be aligned to ensure proper calibration), and next press a button on sensor $S_1$. At this moment sensors are reset, and the system reads coordinates of points $P_1$ to $P_4$ from the Kinect. Starting from this point, the Kinect plays the role of the secondary sensor, suitable for verification purposes.

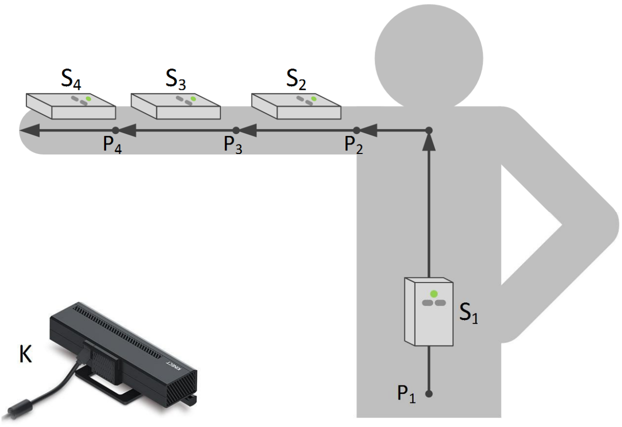

Fig. 5. The calibration of the system

## V. Kinematics Solutions

The use of sensors affixed to a human stature involves a need for an adequate mathematical instrument appropriate to perform required transformations on received data. The obvious one derives from robotics, where the kinematics plays the role of a fundamental description tool [6].

In order to describe the location of each link (a person's body part) relative to its neighbors a frame (a coordinate system) has been affixed to each link; see Fig. 6.

### A. Transformation operators

In the field of robot kinematics transformation operators allow simple and clear matrix representation of rotations and translations [2]. Let us start from coordinates of point $P_1$ (see Fig. 5) received from the Kinect during calibration procedure:

$$ {}^{K}P_1 = [p_1^x, p_1^y, p_1^z, 1]^T . \qquad (1)$$

Next, we can use other coordinates (points P$_2$, P$_3$, P$_4$) received from the Kinect to calculate crucial distances between sensors (see Fig. 6):

$$\begin{cases} x_{21} = p_2^x - p_1^x \\ y_{21} = p_2^y - p_1^y \end{cases}, \quad x_{32} = p_3^x - p_2^x, \quad x_{43} = p_4^x - p_3^x. \qquad (2)$$

Now, we can create transformation operators that are adequate to the situation presented in Fig. 6. The assumption is, that we are able to receive Euler angles $(\alpha,\beta,\gamma)$ from sensors. The next thing is that we use differences of corresponding angles, e.g. $\alpha_3 = \alpha_{S3} - \alpha_{S2}$.

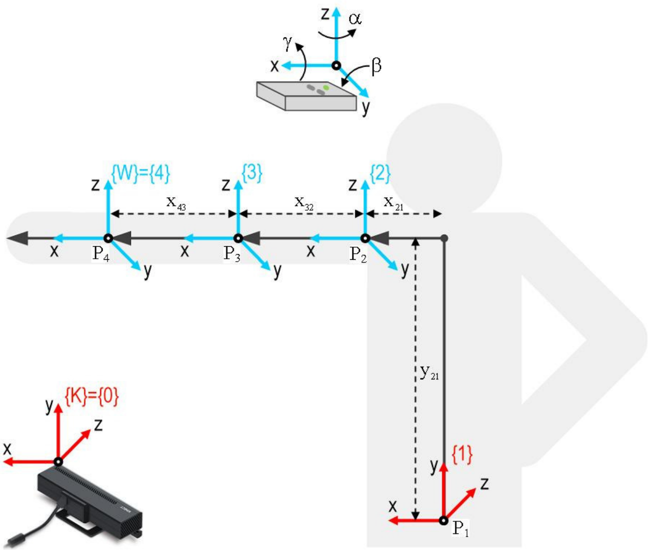

Fig. 6. A model of the human skeleton as a kinematic chain (see Fig. 5)

Taking into account our assumptions as to angles the set of transformation operators is as follows:

$${}^0_1T = {}^K_1T = \begin{bmatrix} 1 & 0 & 0 & p_1^x \\ 0 & 1 & 0 & p_1^y \\ 0 & 0 & 1 & p_1^z \\ 0 & 0 & 0 & 1 \end{bmatrix} \qquad (3)$$

$${}^1_2T = \begin{bmatrix} 1 & 0 & 0 & x_{21} \\ 0 & \cos(-\pi/2) & -\sin(-\pi/2) & y_{21} \\ 0 & \sin(-\pi/2) & \cos(-\pi/2) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

$$\cdot \begin{bmatrix} c\alpha_2 c\beta_2 & c\alpha_2 s\beta_2 s\gamma_2 - s\alpha_2 c\gamma_2 & c\alpha_2 s\beta_2 c\gamma_2 + s\alpha_2 s\gamma_2 & 0 \\ s\alpha_2 c\beta_2 & s\alpha_2 s\beta_2 s\gamma_2 + c\alpha_2 c\gamma_2 & s\alpha_2 s\beta_2 c\gamma_2 - c\alpha_2 s\gamma_2 & 0 \\ -s\beta_2 & c\beta_2 s\gamma_2 & c\beta_2 c\gamma_2 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \qquad (4)$$

$${}^2_3T = \begin{bmatrix} c\alpha_3 c\beta_3 & c\alpha_3 s\beta_3 s\gamma_3 - s\alpha_3 c\gamma_3 & c\alpha_3 s\beta_3 c\gamma_3 + s\alpha_3 s\gamma_3 & x_{32} \\ s\alpha_3 c\beta_3 & s\alpha_3 s\beta_3 s\gamma_3 + c\alpha_3 c\gamma_3 & s\alpha_3 s\beta_3 c\gamma_3 - c\alpha_3 s\gamma_3 & 0 \\ -s\beta_3 & c\beta_3 s\gamma_3 & c\beta_3 c\gamma_3 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \qquad (5)$$

$${}^3_4T = \begin{bmatrix} c\alpha_4 c\beta_4 & c\alpha_4 s\beta_4 s\gamma_4 - s\alpha_4 c\gamma_4 & c\alpha_4 s\beta_4 c\gamma_4 + s\alpha_4 s\gamma_4 & x_{43} \\ s\alpha_4 c\beta_4 & s\alpha_4 s\beta_4 s\gamma_4 + c\alpha_4 c\gamma_4 & s\alpha_4 s\beta_4 c\gamma_4 - c\alpha_4 s\gamma_4 & 0 \\ -s\beta_4 & c\beta_4 s\gamma_4 & c\beta_4 c\gamma_4 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \qquad (6)$$

Thus, the link transformations can be multiplied together to find the single transformation that relates frame {W} to frame {K}:

$${}^K_W T = {}^0_4 T = {}^0_1 T \, {}^1_2 T \, {}^2_3 T \, {}^3_4 T \qquad (7)$$

Finally, we can calculate coordinates of points from P$_2$ to P$_4$ with respect to frame {K} in the following way:

$$\begin{cases} {}^K P_2 = {}^0_1 T \, {}^1_2 T \cdot [0,0,0,1]^T \\ {}^K P_3 = {}^0_1 T \, {}^1_2 T \, {}^2_3 T \cdot [0,0,0,1]^T \\ {}^K P_4 = {}^K_W T \cdot [0,0,0,1]^T \end{cases} \qquad (8)$$

In the case of a robotics system we will prefer coordinates of point P$_4$ (i.e. for the wrist) with respect to frame {1} that can be calculated in the following way:

$${}^1 P_4 = {}^1_2 T \, {}^2_3 T \, {}^3_4 T \cdot [0,0,0,1]^T \qquad (9)$$

This is the case when the arm is fully independent of the Kinect as long as the calibration is done.

### *B. The quaternions*

The quaternions [5], a number system that extends the complex numbers, are members of a noncommutative division algebra. Dual-quaternions may formulate and solve a problem more concisely, more rapidly and in fewer steps, with result more plainly to others, and practice with fewer lines of code effortlessly debugged. There is no loss of efficiency – dual-quaternions can be just as efficient (if not more efficient) than using matrix methods. Additionally, there are some very important reasons for using dual-quaternions: singularity-free, un-ambiguous, shortest path interpolation, etc. This mathematical tool becomes very popular in the computer world, especially in computer graphics – even the used Kinect and sensors are quaternion-based devices. In a general case dual-number quaternions [20] allow compact representation of both rotations and translations. This mathematical tool was integrated into the current system with little coding effort.

In short, a dual-quaternion consists of two quaternions: $q_r$, $q_d$ (eight elements). These two quaternions are called the real part and the dual part:

$$q = q_r + q_d \varepsilon \,, \qquad (10)$$

where $\varepsilon$ is an additional dual number.

The dual-quaternion can represent only rotation by angle $\varphi$ if the dual part is set to zero:

$$q_R = [\cos(\frac{\varphi}{2}) - (\hat{v}_x i + \hat{v}_y j + \hat{v}_z k)\sin(\frac{\varphi}{2})][0,0,0,0]\,, \qquad (11)$$

where $\hat{v}$ is a unit axis.

Analogously, to represent only translation by vector $[t_x, t_y, t_z]$, the real part is set to an identity and the dual part represents the translation:

$$q_T = [1,0,0,0][0,\frac{t_x}{2},\frac{t_y}{2},\frac{t_z}{2}]\,. \qquad (12)$$

Now, combining the rotational and translational transforms into a single unit quaternion to represent a rotation followed by a translation we get:

$$q = q_T \times q_R \,. \qquad (13)$$

The following equation defines how we can transform point $p$ into point $p'$, using the received unit dual-quaternion:

$$p' = q \cdot p \cdot q^* \,, \qquad (14)$$

where $q$ and $q^*$ represent a dual-quaternion transform and its conjugate.

In the considered system we can directly use quaternions received from the Kinect and sensors. However, if we have only Euler angles $(\alpha, \beta, \gamma)$, there is an easy way to receive the quaternion responsible for the rotation (see Eq. 11):

$$\begin{cases} q_x = \cos(\gamma/2) - i\sin(\gamma/2) \\ q_y = \cos(\beta/2) - j\sin(\beta/2) \\ q_z = \cos(\alpha/2) - k\sin(\alpha/2) \end{cases}$$

$$q_R = [q_z \cdot q_y \cdot q_x][0,0,0,0]\,. \qquad (15)$$

## VI. Results

Results we obtained seem to be quite satisfying. Both tools, transformation operators and quaternions, were independently implemented and gave exactly the same values, what may be considered as a confirmation of a proper solution (implementation). Additionally, the coordinates received from the Kinect are concurrent with those calculated by the system – this has been checked in many cases; a sample is presented in Fig. 7–9, respectively for coordinates X, Y, and Z. The considered figures present wrist coordinates (the values are in metres) received during a person activity for an example period of 8 seconds.

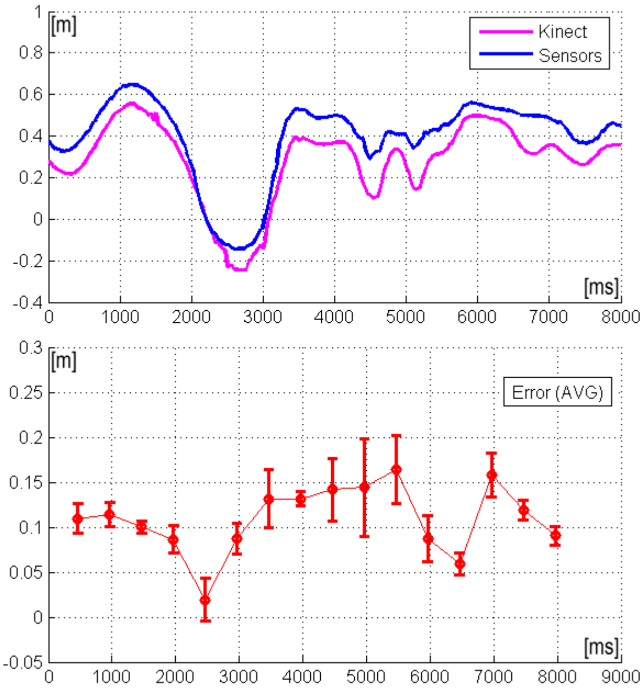

Fig. 7. Wrist coordinate X – values and the average error

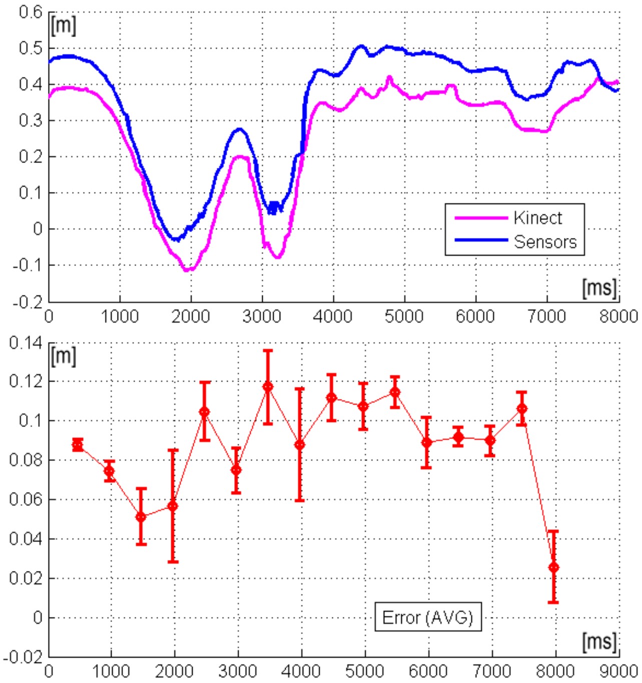

Fig. 8. Wrist coordinate Y – values and the average error

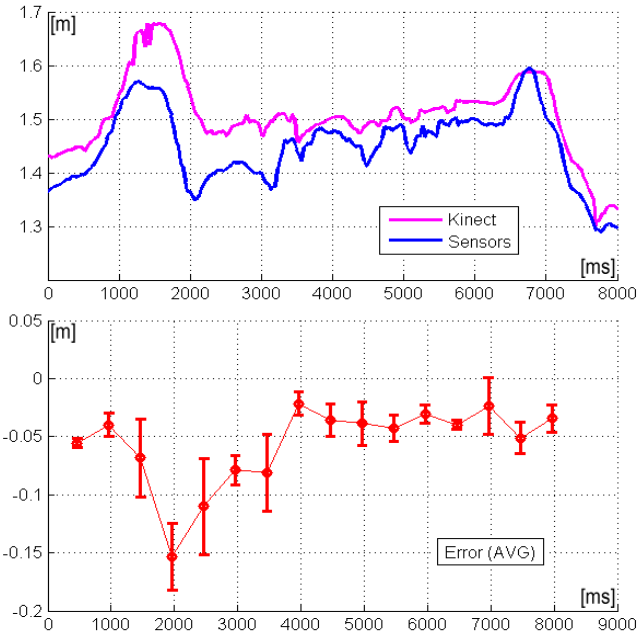

Fig. 9. Wrist coordinate Z – values and the average error

## VII. Conclusion

Authors are aware that the idea of the Kinect device supported by additional sensors is a strong negation of the Kinect nature. Nevertheless, we need to accent that the Kinect served mainly as a fine calibration device and for some verification purposes. Additionally, the Kinect fails for some "configurations" of a human posture, environment objects are serious obstacles, and the space range of the device is very narrowed. This set of adversities has been reduced by the use of the set of four high-precision sensors.

Some gains of the work are worth to be mentioned as advantages of the system: a high level of accuracy limited mainly by the process of calibration, immunity to terrain obstacles, and wide operating range.

We plan to improve the system accuracy, further simplify and revamp the process of calibration, and remove some technical limitations. We want to use only quaternions, even in the case of data received from the Kinect and sensors as they are native for these devices. We would like to perform some robotics experiments in order to face unknown.

***Abstract*—Sound attack is meant as the initiation of the tone. Good attack involves the simultaneous start of exhalation along with the emission of sound. This situation is known as a soft attack. Much more common is a hard type of attack, which is normally used while speaking. It involves tightening of the vocal cords before the expiration. Unfortunately, this state is tiring for the ligaments and can cause damage to the voice. The idea was to propose a method to analyse this problem, which in the future would become a part of set of methods for computer analysis of the singing voice. This article presents a method of the extraction of attack parameters. The estimation of these parameters is carried out with the recorded audio samples. In the study sound sample of 'a' registered several times for each pitch will be used.**

***Index Terms*—singing voice, sound attack, ADSR, quality of singing**

## I. Introduction

The motivation for taking up the research on the attack in the singing is the need of assessment of singing quality. The problem is to find some criteria of evaluation of the sound attack while singing. The goal is to find the criteria of automatic evaluation and involve computer methods to evaluate the attack in singing using these criteria. If properly defined, they allow for self-correction of selected voice parameters. It may be useful for training lessons of voice production. It can be useful to help singers make a progress. It can be very important for the choirs constantly working on the voice. Some criteria of evaluation, if properly defined, may allow for self-correction of selected voice parameters. The considered methods should evaluate these features in a similar way as human experts. To achieve that it is necessary to propose a computer method to analyse this feature and its parameters.

It should be noted here that it is difficult to find scientific publications which present the approach to computer evaluation of singing carried out in similar way as described in this article. The approach presented here reflects expert's evaluation in the computer aided assessment.

The singing voice is produced by the vocal instrument consisting of three basic components: the respiratory apparatus, the oscillating vocal folds and the vocal tract. Breathing has decisive influence on all activities related to the voice emission. Vocal folds open and close during breathing, but during speaking and singing, they start to oscillate with the fundamental frequency of sound which comes out of the mouth. At the interface between these two phases (open and close) of the sound generation the musical phenomenon known as an attack on the sound occurs.

The ADSR envelope is a practical model that describes a single sound (note). It can be used for sound analysis [1], [2] and synthesis [3]. It is the essential description of the sound waveform in the MIDI standard [4]. In terms of sound synthesis attack is interpreted as a part of ADSR envelope. The attack is used for modification of a first phase of amplitude envelope [5] of generated sound in which sound gains the highest amplitude. In most basic models it's followed by decay section, during which amplitude is decreased. After that there is a stage of a sustain which is characterized by a stable amplitude. The ADSR envelope is finished then by a stage of release. During this part amplitude is completely decreasing . The ADSR sections are illustrated in fig. 1.

The word "attack" is probably too strong description of the release of air through glottal folds. Anyway it is the term commonly used in the literature. Some other, related terms used in literature are: initiation, onset [6] or transient. To be precise it is needed to define some terms related to each other: onset, attack, transient. The reason for making these distinctions clear is that different applications have different needs. The similarities and differences between these key concepts should be considered. Referring to the definitions found at [7] the attack is the time interval during which the amplitude envelope of the sound increases.

The transients are short intervals during which the signal evolves quickly (increases and decreases quickly) in some nontrivial, unpredictable way. It is often connected to the situation where the excitation of the sound is applied and then damped (leaving only a slow decay). So the transient would be a part of the amplitude envelope starting from the onset, including the whole attack and the most important part of decay (the strongest one). The onset [3], [8] is a single instant chosen to mark a transient. In most cases it is connected with the start of transient (also start of attack) or with the earliest time when the transient can be detected.

The sound attack in the singing is related to the breathing. During vocal development care should be taken to teach the attack on the breath [9]. Proper breath preceding the phonation

978-83-60810-66-8/$25.00©2015, IEEE

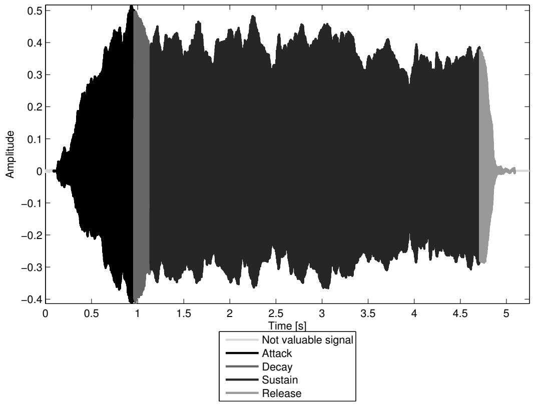

Figure 1. Example of the typical split of a sung phrase divided into sections ADSR (Attack-Decay-Sustain-Release)

phase will result in a good beginning of each phrase. It is especially important in phrases which begin with a vowel sound. Attack is more precise in the case of professional singers. Choral singers are less precise in that stage of voice production. It has to be noticed that practice can clear up that problem. Choir members are usually developing their voice in groups. Thus the vocal abilities are similar in a group of choir singers. It should be recalled here that the presented investigation concerns choir voices.

There are three known kinds of attack on sound depending on moment of tightening vocal cords in relation to the beginning of exhalation and on how strong the tightening of vocal cords is in the early stages of sound production:

- soft - when the vocal cords tightening moment coincides with the beginning of exhalation. This is the most favourable attack.
- hard - tightening of the vocal cords begins before the expiration. Unfortunately, this state is tiring for the ligaments and can cause damage to the voice.
- exhaling (aspirated) - short exhaust ahead of tightening of the vocal cords. Vocal cords do not close completely and the remaining gap influences the sound.

In this paper attack part of a signal is defined as first part of the sung sound. It ends by either stabilisation of amplitude (sustain) or total decrease of amplitude (decay).

In the article [10] an attempt to identify fast attacks has been presented. Fast attack transients are named there simply as attacks. The authors have defined the attacks as zones of short duration (a few ms) and fast variation of the signal short time spectrum with an abrupt increase in energy particularly noticeable in high frequencies since energy is usually concentrated in the low frequencies. The attack detection and modelling method developed there was based on the following requirements: the method should not use additive analysis results, in order to be usable for other purposes (segmentation, instrument recognition, etc.), it should succeed in every type of sound (particularly polyphonic sounds) with good time accuracy, it should be simple to use: the analysis parameters should, as much as possible, be adjusted automatically, it should be tested on a data base of sounds including polyphonic mixtures of percussive and non-percussive sounds.

## II. Research Conditions

The database consisting of representative samples presenting the abilities of choir singers is important point of that study. The database used here is the extension of the database created under the research project of West Pomeranian University of Technology: "Computerized methods of supporting the process of training choir voices" [11]. The recorded singers are singing in the choir of the same university. The samples in the database are divided into categories reflecting different aspects of the singer's practices. The content of the database allows to extract the selected parameters of singing voice. The exercises were selected from a set usually used during the voice production training. It is possible to investigate for example intonation [12], vibrato feature, tremolo, sonority, noise [13] and other features. It is possible to perform some more general investigations over the database as, for example, singing voice quality assessment [14], [15]. For that study the exercise containing the vowel "a" sung at one pitch for a few seconds was chosen. In fact, the most interesting part here is situated at the beginning of voiced part of the sample.

The recordings used in this article were taken in the specially arranged room, with proper conditions for the recording session. All of the sound material was recorded with a 24 bit resolution, with the sampling frequency of 48 kHz. Higher recording parameters give some wider possibilities of editing of the recordings. The sessions were recorded as a whole for each singer. The division into elementary parts, called sequences or phrases (piano, singer), was done with use of a program with a tool for automatic segmentation. The process was performed under supervision of an expert to provide the possible best prepared samples.

Eight males, representing baritone voice, were subjects for the experiment. They were chosen as representative voices from the group of singers. Each person was in good vocal and health condition. The samples were recorded twice to have the possibility to compare the results. The sound pitches selected for the study were chosen to be comfortable to sing for all of the singers. The pitches covered the range from pitch number 10 in octave 2 (sound A) to pitch number 5 in octave 4 (sound e2). There were 2 sets of the samples for each singer. The sets consisted of 5 samples, so together there were 80 samples available to analyse (8 singers, 2 sets, 5 samples for each set).

## III. Research Idea

The idea of the research was to develop a descriptors of attack on sound. Those descriptors should map experts' evaluation of analysed signal. For this reason, the evaluations of attack on sound were carried out parallelly by three experts. Evaluation marks given by the experts will be presented in the following part of this publication. Finally both results, obtained by computer methods and given by human experts, will be compared to decide whether the similar conclusion can be drawn.

### A. Experts' Assessment

Three experts were asked to assess the sound attack in the samples of singing. They were instructed about the definition of the attack on sound defined in this study. They had a possibility to listen to the voice examples before they started the evaluation. It was done to teach the experts the rules of the assessment and to make sure the samples would be evaluated in the same way by all of the experts. The experts had to assess the attack feature using 1-3 scale, where 1 meant so called soft attack, 2 meant medium attack and 3 meant hard attack. The experts were also evaluating the quality of the attack on the sound. To assess the quality they used a rating scale 1-5 where 1 was bad quality and 5 meant very good quality. It should be reminded here that every expert had to evaluate 2 sets of samples for each singer. Every expert was assessing the set of the samples according to the procedure:

- at first they were able to listen to 6 different, randomly selected, samples,
- 1st set of samples was played as first and then it was evaluated by the expert,
- 2nd set of samples was played in the random order.

The experts did not see the ratings of each other. During the assessment process three experts have assessed 8 male singers. There were 2 sets for each singer. Each set consisted of 5 samples. Concluding, samples were assessed 240 times. Taking into account there were 2 marks for each sample (the type of the attack and the quality of the attack) it gave 480 marks.

### B. Computer Aided Evaluation

During the preliminary studies, it has been established that the attack on the sound will be analysed according to the definition described in the first section of the article. At the beginning of the study it was assumed that the factors will be applied to three areas of the voice signal: time, amplitude and pitch [2]. Parameters of time have been given in seconds. The generalized Hilbert envelope was used to describe the characteristics of the amplitude. To illustrate each envelope the following parameters, which are also described in fig. 2, were selected:

- angle of attack on volume - directional factor of linear function of approximation for the amplitude envelope (fig. 2b),
- mean square error between the linear approximation and the actual envelope (fig. 2b),
- ratio of the energy of attack in relation to the energy of the entire signal represented by equation 1,
- values of derived envelope calculated by eq. 2 - the total sum of values and the number of values above and below zero (fig. 2c).

According to the theory, if both the first and the second parameter has a low value, we should be dealing with perfectly soft attack. Other parameters were selected as complementary ones, in order to test the possibility of their use.

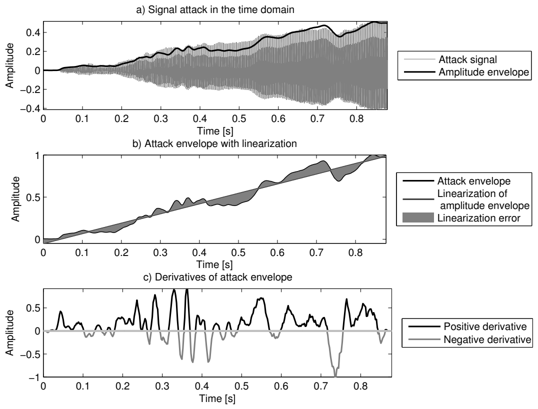

Figure 2. Presentation of some attack parameters based on amplitude values

$$E = \frac{\sum(Attack^2)}{\sum(Signal^2)},$$

where $E$-is energy parameter,

$Attack$-fragment of signal during the attack phase,

$Signal$-whole signal.

(1)

$$f'(x) = \begin{cases} 0 & : x = 1 \\ f(x) - f(x-1) & : x > 1 \end{cases}, x \in \mathbb{N}_+,$$

where $f'(x)$-is derivative in point x,

$f(x)$-is base signal

$x$-is index of element in vector.

(2)

The third set of analysed parameters concerned the pitch. This set meant to show how the singer sets the pitch during the attack on the sound. The parameters are displayed in fig. 3, and include following sets of data:

- angle of attack on pitch - directional factor of linear function of approximation for the pitch track (fig. 3b),
- mean square error between the linear approximation and the actual pitch track (fig. 3b),
- maximum pitch value registered with the upper pitch limit given by the value of expected tone plus 200 Hz,
- values of derived pitch track calculated with eq. 2 - the total sum of values and the number of values above and below zero (fig. 3c).

If the first parameter is less than zero that means the singer is attacking the sound from a higher frequency and trying to reduce the frequency to match the sound with the referenced tone. In the opposite case the singer increases the frequency in order to match the tone. Other parameters were selected as complementary ones, to test the possibility of their use.

## IV. The Results

As it was mentioned before, the investigation consisted of two parts. In the first part experts were asked to assess

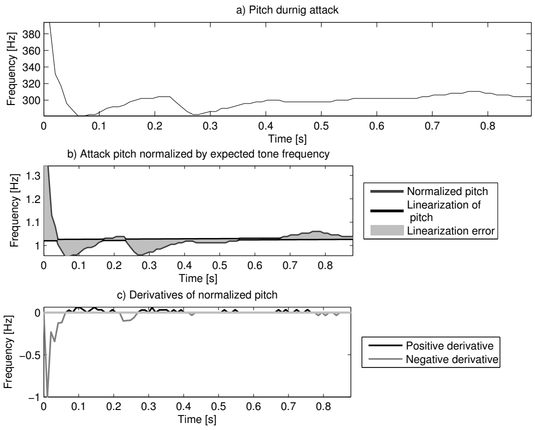

Figure 3. Presentation of some attack parameters based on pitch values

the samples from the database. In the second part a set of calculations over the samples was performed. After that, correlations between the results were searched.

### A. Computer Aided Evaluation Results

As it was planned before, the special calculations over the chosen samples were performed to obtain information about the attack on the sound. One of the most natural parameters of the attack calculated on the sound sample was the angle of attack calculated over the volume envelope. The parameter is interpreted here as a directional factor of a linear function which is an approximation of the amplitude of the envelope (fig. 2b). The values obtained for 5 samples for each singer are presented together in fig. 4. It can be seen in the graph that the angle of the attack is higher in case of the boundary samples. It is because these pitches are too high or too low to be enough comfortable for singing. It can be observed that in the tested group there are singers having problems at every sample and the singers having some discomfort only at boundaries. It is apparent from the graph that the best are singers s21 and s27, as the angle is generally lower for those singers.

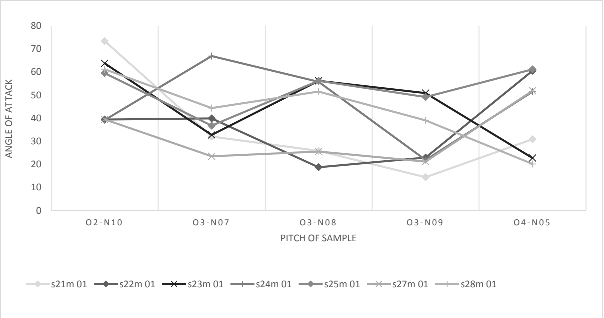

Figure 4. Angle of amplitude attack parameter (version 1 of set of samples)

The results obtained for mean square error between the linear approximation of the sound attack and the actual envelope (fig. 2b) are presented in fig. 5. Analysing that graph, and comparing to the previous one it should be noted that the parameter for singers s21 and s27 differentiate the singers. The singer s21 has higher values of these parameters than s27 and for this reason it can be stated that s27 is better, more stable, than s21 (although, considering the second attempt, s21 became more stable). Combining those two parameters together it is possible to obtain a decision rule better describing the abilities of the singers.

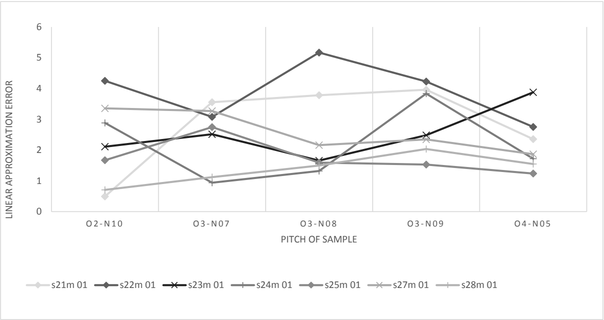

Figure 5. Mean square error parameter for the actual attack envelope (version 1 of set of samples)

Another example of the calculated parameter is ratio of the energy of attack in relation to the energy of the entire signal (represented by equation 1). The results visible in fig. 6 again highlight the singers s21 and s27. Those singers have greater energy values for the attack than the others. Especially if the energy values for each of the samples are summed up the differences between those singers and the others become really clear. The other results will not be described here in details, as the ones presented above sufficiently illustrate the general idea.

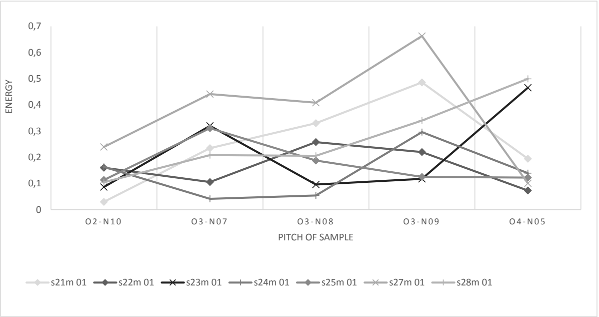

Figure 6. Energy parameter calculated over attack envelopes (version 1 of set of samples)

### B. Experts Results

Experts were asked to assess the feature of sound attack of the sung samples. They were instructed about the rules adopted in this study. They had a possibility to listen to the voice examples before evaluation of the process. The procedure was set to guarantee the assessment of the samples in the same way. The experts evaluated, among others, whether the sound attack in the recorded sample is soft, medium or hard. Those marks have been counted for each singer. That gave an entry information about the approach of the singer to the sound initiation. To illustrate that the figures 7 and 8 characterising the results of a good singer are presented. He was, generally, evaluated in the same way by all the experts. Some problems were observed on both ends of the analysed range. Additionally, from figure 8 one can see that the second trial (every singer was recorded twice) was better than the first one. Each expert has generally evaluated the initiation of the sound as soft, in this case. It should be noticed that all the samples lying in the middle range of the pitch were evaluated as soft. This is a result consistent with expectations of the experts.

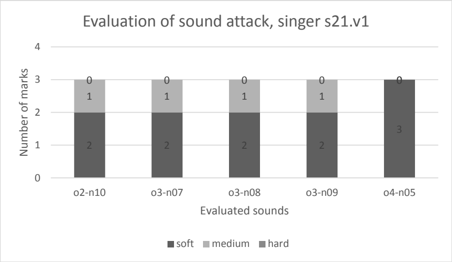

Figure 7. Evaluation of the singer s21 (sample version 1)

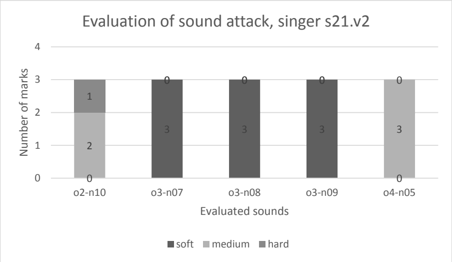

Figure 8. Evaluation of the singer s21 (sample version 2)

Another situation is presented in figure 9. The singer's results presented in that figure are not stable. This may be connected with some evaluation problems or, on the other hand, with low abilities of the singer.

All evaluation results were collected in one table and compared with the results obtained in an automatic way.

### C. Correlation of The Results

The results, both given by the experts and obtained from computer calculations were compared to find an answer to the question - whether the computer methods proposed here are able to evaluate singing samples in the similar way as human experts do. To this end the relation between the vector containing experts' decisions and the vector containing values of each previously calculated parameters for each singer was estimated. The example provided here shows comparison of the expert marks given to each singer with the calculated angle parameters.

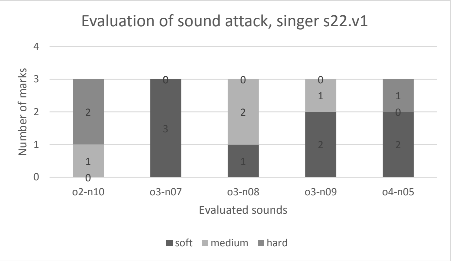

Figure 9. Evaluation of the singer s22 (sample version 1)

The upper part of the table I ("Summary of weighted expert's evaluation marks") summarize the marks given by the experts. The marks given by three experts were summed up and weighed to obtain general mark for each singer. For each mark (obtained in the previous step) it has been assigned an adjective describing the type of the attack according to the rule: mark 1-3 meant hard attack, 4-6 meant medium, 7-9 meant soft attack. The numerical marks were also averaged to give the average adjective mark. Similar operations were carried out on the second part of the table consisting of the values calculated using previously described procedure. The bottom part of the table contains the comparison of the marks, both, calculated and given by the experts. The row "Consistent values" shows how many values are consistent in both sets (expert's marks and calculated values). Taking into account all 5 samples (for each singer) it gives the mean value of consistency at the level of about 60 percent. Taking into account only the three middle samples the average consistency level between experts and computer evaluation also gives the value of about 60 percent. It leads to the conclusion that to achieve better results other parameters should be also involved.

The approach presented here is based on the expert's way of assessing the singing. The parameters proposed and calculated here are directly connected to the singing signal and can be easily observed in the signal. In the present article an example application of one of the parameters has been described. Therefore, further improvement of efficiency of computer assessment using the remaining, previously mentioned, parameters seems to be possible.

## V. Conclusion

The article focuses in general on the problem of the sound attack in singing. Sound attack is understood here as an initiation of the sound. This characteristic is very subjective in perception, but it can be used as a criterion of singing quality evaluation. The attack on sound can be divided into several types. One of the types is a soft attack. This is identified with the beginning of the sound in a soft, fine, smooth manner. Much more common is a hard type of attack, which is normally used while speaking. Unfortunately, this state is tiring for a singer and can cause damage of the voice. That is why the hard attack is not advised while singing for a long time. The goal was to involve computer methods to evaluate

Table I
THE ANGLE OF THE ATTACK

Summary of weighed experts evaluation marks - 1-3: hard, 4-6: medium, 7-9: soft

the attack in a singing to help the singer make progress. The methods should evaluate that feature in a similar way as human experts. To achieve that it was necessary to propose a method to analyse this problem. The results of the above automatic computer evaluation were compared to the marks given by the human experts. For the purpose of automatic evaluation it was assumed that the attack on the sound can be represented by objective parameters of signal describing subjective human impression. There was a need to answer the question whether among the calculated parameters were such that reflect experts' evaluation and thus can be useful to construct computer aided assessment system. The evaluation of the sound attack would be a part of that system. The investigation consisted of two parallel parts. In one of them the experts were assessing recordings of singing. In the other part a set of signal parameters was calculated for each singer in the context of sound attack. Among others the following parameters were calculated: the angle of attack calculated over the volume envelope, mean square error between the linear approximation of the sound attack and the actual envelope, the energy of attack in relation to the energy of the entire signal. During the study it has been found that among estimated features angle parameter, mean square error parameter and energy parameter can construct feature vector applied in a computer method of a sound attack quality assessment. The results concerning sound attack presented here may be useful for constructing a singing quality assessment system.

A large number of the results obtained for this study requires further, deeper analysis and may lead to subsequent applications.

## ACKNOWLEDGMENT

The authors would like to thank the members of The Jan Szyrocki Memorial Choir of West Pomeranian University of Technology for their cooperation in building database of singing voices. The authors would also like to thank the experts who spent a lot of time listening to and evaluating the singing samples.

***Abstract*—This paper presents a method to recognize a robotic arm in space using the Hough circles method. The robotic arm has colored bottle stoppers glued at the joints, which are recognized with color filtering. After this step, the biggest colored spot is detected and marked using the Hough circle method. The joints are numbered, this way each joint's position is known. The joints can be united with lines and this way a skeleton of the robotic arm can be drawn which can be loaded in a PC to create a control application.**

## I. Introduction

THIS paper presents a robotic arm detection and control using the Hough circles algorithm.

The control of a robotic arm is very useful in the industry, because in today's consumer world only robotic arms can do all the tasks precisely and with high speed [1]. The robotic arms need to be automated as much as possible, because this way, they can do even more tasks with less human intervention, which will lead to higher productivity [2].

Mostly in the industry, robotic arms are blind; they don't have vision system [3]. Vision system adds artificial intelligence and more autonomy to a robotic arm [4]. Mostly in the industry robotic arms are programmed previously, they know exactly all the movements which need to be executed [14]. This way, the robotic arms are not very flexible for today's dynamic world. If the robotic arm has a vision system added, than it can change its tasks during execution, this way there is no need to stop a production line [15]. A vision system can also make auto calibration for the robotic arm, this way the robotic arm can make small adjustments during execution, this way there is no need to stop the production line and this will save money and time [16].

In this experiment a robotic arm detection and control method was made. The robotic arm has glued colored bottle stoppers, the image has applied color filters and the joints are detected with the Hough circles method [8].

The joints are numbered, so exact position of them it's known. The joints can be united with straight lines, this way the skeleton of the robotic arm can be created and this way the movement of the robotic arm can be loaded in a PC [9]. With this information a control algorithm can be created just based on the images of the robotic arm taken with the connected cameras [10].

## II. Problem Formulation

The laboratory from the university had two Lynxmotion AL5 type robotic arms, the AL5A and the AL5B. These robots had no cameras or some other control system connected to them. The idea was to create a smart control system with image recognition, where the position in space of the robotic arm can be detected and to have a possibility to control the robotic arm using this information [11]. The intention was to implement the control system in C/C++ with the OpenCV library and run it on the Linux operating system. The used cameras were the Logitech C270 cameras which are compatible with a wide range of operating systems, including Ubuntu Linux 12.04 LTS which was used in this experiment. The Linux operating system is also a very good choice, because the system can be ported, with only a small amount of effort on other embedded devices which can run the Linux operating system.

## III. Problem Implementation

### *A. Used Equipment*

The experiment was made with the Lynxmotion AL5B robotic arm (Fig. 1). This robotic arm is used mainly for teaching purposes, but it can be also used for tasks which reflect industrial behavior of a robotic arm, because it copies exactly the characteristics of an industrial robotic arm.

The used robotic arm is controlled with the SSC-32 servo control board (Fig. 2). The communication with the servo control board can be done from a master control system, like a PC, via the RS-232 serial interface. The SSC-32 servo control board can generate PWM signals up to 32 motors; the used robotic arm has only 6 motors, so the servo control board is more than enough. The movement angle of each motor from the robotic arm is proportional with the PWM signal's duty cycle [12].

978-83-60810-66-8/$25.00©2015, IEEE

The motors from the robotic arm are special Hitec servomotors with gears for increasing the torque; they have also a special circuit board which moves the motors proportionally to the PWM signal generated by the SSC-32 servo control board [13].

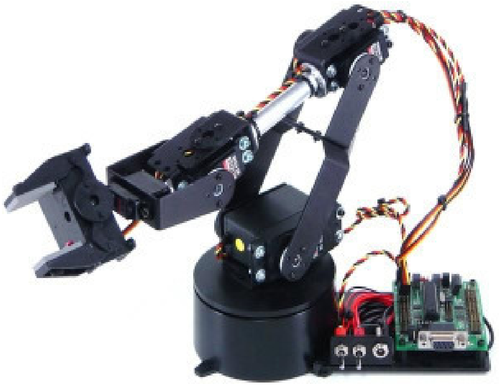

Fig. 1 Lynmotion AL5B robotic arm

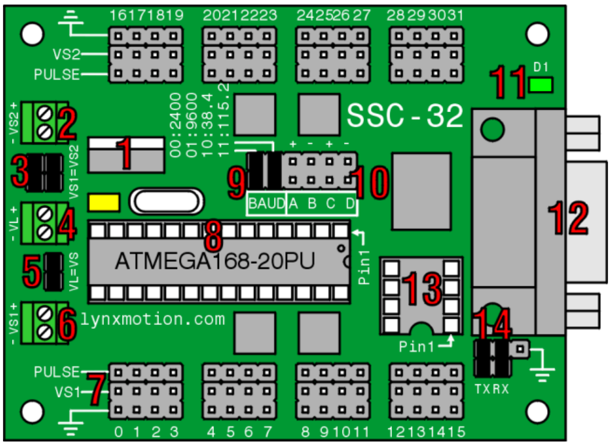

Fig. 2 SSC-32 servo control board

### *B. Theoretical Background*

For controlling the robotic arm, SCPI (Standard Commands for Programmable Instruments) commands are sent through the serial interface from the PC to the SSC-32 servo control board. These commands were captured using the HHD Free Serial Port monitor program (Fig. 3).

Fig. 3 HHD Free Serial Port Monitor

Next it will be presented the SCPI commands for controlling the robotic arm.

The first command is the version reading command, which is used for establishing connection over serial interface between the master control computer and the SSC-32 servo control board.

The commands after are the commands which initialize the motors. Actually these commands test all the digital ports from the SSC-32 servo control board. There are tested all 32 digital ports, even those which have no motors connected to them. This is a self test before controlling the robotic arm; this way is known if the system runs normally.

The “ALL SERVOS 1500” command places all servos in the position 1500. The position 1500 is the middle position of each motor. The motors are mechanically blocked to be able to make a maximum rotation of 180°, so the middle position is at 90°. The robotic arm is assembled mechanically in such a way, when all motors are in middle position, it can be said that the robotic arm woke up. The robotic arm it’s in a position which resembles a Greek capital gamma letter (“Γ”). The “ALL SERVOS 1500” command places the robotic arm in the home position, a position which is well known by the system, because all the motors are at the position 1500.

The last commands are used to control each motor of the robotic arm. The first number after the “#” it’s the motor number. The second number after the “P” letter it’s the motor position. If it’s 1500, than the motor it’s in the middle position. The last number which is after the “S” letter is the execution time, which is usually set to 1000 ms. If this number is 0, than this means that the motor is set to the maximum possible speed, so this way the execution of the movement will be made at the maximum speed which can be executed by the motor.

  // BASE
  #0P1500S1000\r
```

If the minimum robotic value (500) and maximum robotic value (2500) is known, than equation (1) can be obtained.

$$\alpha = \frac{\Delta\omega}{180° - 0°} = \frac{2500 - 500}{180° - 0°} = \\ = 11,(1)\ robotic\ values \qquad (1)$$

Equation (1) implies equation (2).

$$1°\sim 11,(1)\ robotic\ values \qquad (2)$$

In Fig. 4 there is the block diagram of the experiment. As it can be seen, we have a PC, the Logitech C270 webcam and the Lynxmotion AL5B robotic arm. The system is made for 2D control of the robotic arm, but for 3D control, the camera and the algorithm needs to be duplicated. The software part is a little bit more interesting. First it’ s used a HSV (Hue, Saturation Value) filter. After this, the Hough circle detection it’s made.

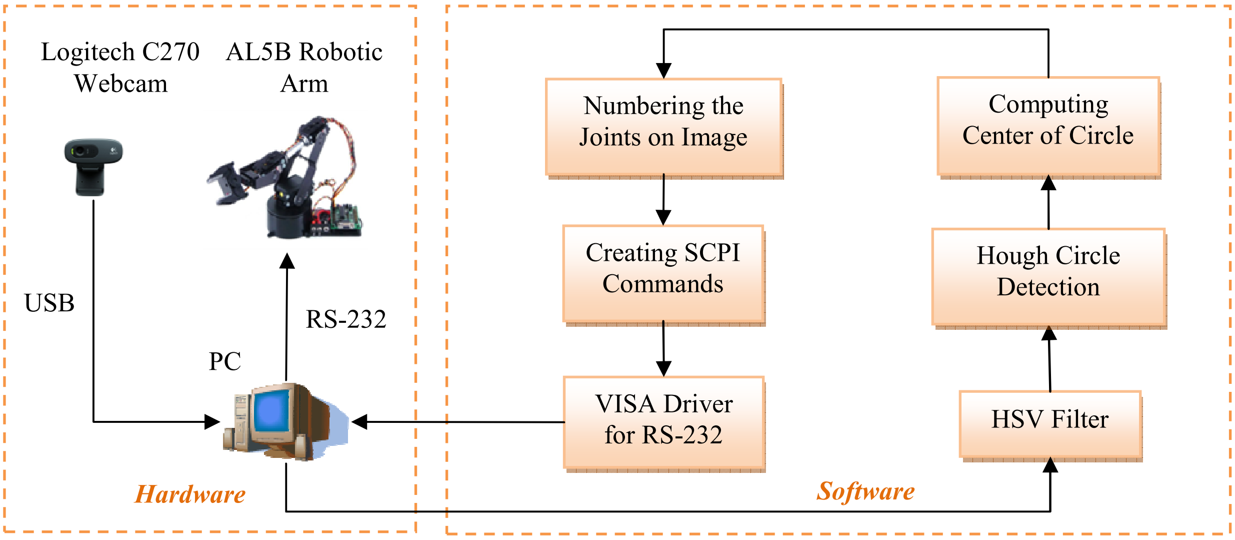

Fig. 4 Block diagram of the experiment

The Hough circle algorithm can detect round spots in an image. Round spots are present on the image after color filtering. The biggest round spot will be chosen, which will be a colored bottle stopper on a joint of the robotic arm. The Hough circle algorithm draws a circle around this detected colored spot.

After this step, the center of the circle is detected, which is actually the coordinate of a joint of the robotic arm and also is the place where the number of the joint will be placed. After this step, the joints can be united and this way the position of the robotic arm in space is known. After knowing the position of the robotic arm, SCPI commands are created and sent using the VISA RS-232 serial driver from National Instruments.

### C. Software Implementation

The software was implemented in Ubuntu Linux 12.04 LTS operating system using the C/C++ programming language with the OpenCV library and the Qt GUI. As it can be seen on the first image, the joints are recognized with the circles around the colored bottle stoppers glued to them. The joints are numbered.

The second image is the HSV filter of the original image.

The next four images are the color filters for blue, yellow, red and green with the sliders for the HSV values.

As we can see the joints were recognized, the only task is to unite the joints with straight lines, which is quite easy because the coordinates are known. They are exactly at the center of the circles. The numbers are drawn at the centers of the circles. The only task is to write the equation of a segment which goes though two points in space. After the step when the joints are united, the skeleton of the robotic arm is created. This data can be loaded in a PC and the position of the robotic arm will be known. Based on this info SCPI commands can be sent to the robotic arm to place its gripper in the desired position.

Fig. 5 Robotic arm control application under Ubuntu Linux 12.04 LTS in C/C++ programming language with OpenCV library using the Hough circles method for joint position detection

## IV. Conclusion

It was presented a system which can recognize the joints of a robotic arm using the Hough circles algorithm.

The robotic arm recognition is useful in the industry because it can ease the maintenance of the production line. There is no need to program previously or to calibrate the robotic arm, these operations are done on-the-go during execution.

The Hough circles algorithm works flawlessly for joints detection. There was also made a test with the Hough circle algorithm to follow a bouncing ping-pong ball. The test was done with no errors. After this test it could be told that the Hough circles algorithm can follow any movement of a robotic arm, it can even follow a bouncing ping-pong ball.

The Hough circles algorithm is implemented in OpenCV, so it can be used with ease.

Further enhancements would be to port the robotic arm control application on an embedded system.

The first step would be to port it on a Raspberry PI with Raspbian Linux "Wheezy" v7.0. After this it can be ported on FPGA boards which can run Ubuntu Liunx 12.04 LTS like the ZYBO or the ZedBoard development boards from Digilent.

On all the three systems the code can be ported directly as it is written in C/C++ or in Python. All the boards have the possibility to install OpenCV, so all the algorithms can be implemented with just minor changes.

The final task is to actually create the ASIC with Linux running on it and the code written in C/C++ with the OpenCV library. This would recognize the robotic arm's joints using the Hough circles algorithm. The task to create an ASIC is not the most complicated one, because there are tools from Mentor Graphics which can convert the VHDL codes in Verilog and after it can create the layout of the chip. This ASIC will behave similar to a PC or to a development board, but it will be a compact embedded IC which will be portable and will have the possibility to be placed in on PCBs with reduced size.

This idea to do everything portable and embedded came due to the tendency of the industry and consumer electronics predictions. This fact is described also in the German factories in the "Industrie 4.0" standard which explains that in the future the PC will not exist and it's no more needed. The task is to have many small smart devices like smart phones, tablets, smart watches and embedded devices which can do the same task as a PC, but they are much more flexible and much more compact. These devices are all connected in a big wireless network, all the devices communicate with each other in a smart manner and everything is more automated and works better, faster with less human intervention. This big wireless network became possible with the introduction of IP v6 which gave more IP addresses to the continuously growing devices connected to the big internet and to the intranets.

Kraków, Poland
Email: {mitu, werewka, sztandera, rogus}@agh.edu.pl

***Abstract*– Software systems are constructed using many different solutions. In practice it is important to assess different software systems. The most effective method of comparing software systems is to use a predefined reference architecture model as the basis for comparison. In this paper an ECORAM presentation layer reference architecture model is proposed. ECORAM is an extended common reference architecture model which contains a crucial number of elements used in systems investigation. The reference architecture is described using ArchiMate notation. For each element of the reference architecture a search for a mapping to the selected solution architecture is performed. When mapping fails it is assumed that a given feature of the reference architecture doesn't exist in the target system. Comparisons can be based on different aspects and the quality of metrics for predefined aspects may be defined. In this paper a comparison examples of different visualization solutions of business intelligence and game systems are presented.**

## I. Introduction

SOFTWARE systems are characterized by different architecture solutions. The solution architecture should be based on a reference architecture which is a template for a family of software systems or specific domains of interest.

The reference architecture [1] models the abstract architectural elements in the domain of interest, independent of the technologies, protocols, and products that are used to implement a specific solution for the domain, and represents the essence of the architecture of a collection of systems [2]. The purpose of the reference architecture is to provide guidance on developing architectures for new versions of a system or extended families of systems and products.

The reference model [1] describes the important concepts and relationships in the domain, focuses on what distinguishes the elements of the domain, and the reference architecture elaborates further on the model to show a more complete picture.

One of the main perspectives on Reference Architecture Models is that they are knowledge repositories which facilitate knowledge transfer and communication. However, they can also serve as frameworks, lexicons of terms and naming conventions, as well as structural relationships. One of the main challenges is to make the inherently abstract Reference Architecture Model concrete and understandable by providing sufficient specific information and guidelines.

When building software solution architecture in a given domain it is very important to have reference architecture. When obtaining software reference architecture it is important to have domain concepts and architecture reference models.

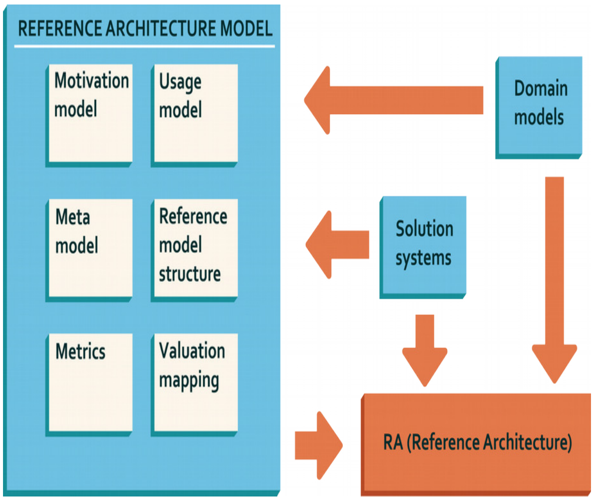

Fig 1. A reference architecture model in a reference architecture building context.

Domain models and solution systems may be used when building reference architecture models (fig. 1). The reference architecture model consists of the following elements:

- Motivation to build the reference architecture
- A usage model based on services (how the reference model will be used)
- A meta model defining the relationship in the set of related models.
- A reference model structure, consisting of elements and their descriptions.
- Metrics for defining the values of the reference model features.
- Valuation mapping. The elements of the reference architecture model can have different values for different stakeholders.

The reference architecture is developed based on a reference model, domain models and solution systems.

## II. Related works

The related works concerning the development of reference architecture models and the visualization capabilities of business intelligence systems are as follows.

Publication [3] describes a so-called RAModel (Reference Architecture Model) for reference architectures which can be included in reference architectures and presents all possible elements, broken down by type and relationship. The RAModel guides and improves productivity when new reference architectures are built and can offer effective support in the use and evolution of existing architectures. The RAModel also provides information on the elements and associated relationships which could be contained in reference architectures, independently from the application domains or purposes of such architectures. In the paper [4] a ProSARA process is presented for building reference architectures, focusing on how to design, represent, and evaluate such architectures. Publication [5] provides a framework for classifying software reference architectures. This framework is based on three dimensions: goals (why something is defined), context (where it will be used, who defines it, when it is defined), and design (what it describes, how specific and detailed this description is, how is it represented).Two purposes for using reference architecture are distinguished to standardize specific architectures (aimed at the interoperability of systems/components) and to enable the design of specific architectures (aimed at providing guidelines for the design of systems in the form of blueprints, patterns, etc.).

The question arises concerning to what extent reference architecture can be used for general application. In [6], CORA (COmmon Reference Architecture) is described for general use, and examples of its utilization are given, but the work proposes more of a reference model than a reference architecture.

In Business Intelligence Systems Presentation Layer solutions start to play an important role. In paper [7], which concerns big data analytics, two views of data presentation are described:

- Data visualization. The goal of data visualization is to communicate information clearly and effectively. In BI systems data volume is increasing, so it is important to use new visualization solutions.

- Analytics of data originating from different sources. The goal of web analytics is to automatically retrieve, extract, and evaluate information for knowledge discovery from web services and documents. Web content involves several data types such as text, symbolic data, metadata, hyperlinks and multimedia data including image, audio, and video. Multimedia analytics has to deal with multimedia data. Social media content contains text, multimedia, locations and comments.

Paper [8] indicates that using more interactive visual methods in BI would be beneficial for users. The paper contains confirmation of the following statements: Most visual methods currently applied in Business Intelligence are static or employ only very limited forms of interactivity; Increasing the interactivity of visual methods is desired by users. According to users, interactivity helps them gain information and knowledge in business data analysis.

In article [9] the visualization capability of BI systems in terms of developing effective visualization for addressing business problems is crucial to the success of BI. To amplify decision makers' perception and cognition of business data, BI systems often deploy a variety of visualization techniques. In the paper a Context Adaptive Visualization (CAV) framework is proposed which can guide the design and implementation of the visualization systems to be integrated into or used together with BI systems. The system requirements for flexible visualization development are based on visual solutions like creation, modification enhancement, integration and transformation.

## III. ECORAM presentation layer

Presentation plays a crucial role in IT systems. Historically, the presentation layer was separated from the application logic in order to enable different presentations without redesigning the whole application [10]. The presentation layer, especially the Graphical User Interface (GUI), has become a very important part of software for both users and developers [11]. There is a set of specific applications that relies mostly on User Interface (UI) and Human–computer interaction (HCI), with games and game controllers being among the most important representatives of this kind of application. From a design perspective, the presentation layer represents a specific set of problems that lead to a number of different solutions. The general idea of presentation layer design is to keep the presentation-related code separate from the domain-related code. The domain code should be completely unaware of the presentation logic in order to create reusable objects and components that are easy to test and maintain. The purpose of the presentation layer is to manipulate the presentation medium, give the user the look and feel experience (e.g. manipulate UI controls, present multimedia content), provide output to and receive input from the user.

The ECORAM (ECO Reference Architecture Model) is constructed from architecture building blocks (ABBs) that are comprised of information about the styles and architectural templates or features used [12]. The ECORAM is based on a layered model described in ArchiMate [13], so ABBs are grouped and presented in layers to emphasize their common properties. ArchiMate is an architecture description language (ADL), which is very suitable for communicating solutions among business and technology staff. The established approach assumes the developing of a new presentation model designed for product managers and system architects. This model should enhance understanding of user viewpoint dependencies and technical needs related to the entire service delivery in corporate architectures.

The main reason for developing the ECORAM was to express all system endpoint characteristics. Firstly, there is a need to classify the device held by the user. The first branch of the ECORAM is extremely simplified, adjusted just to describing the general device type. Then, on a deeper level, a feature set must be considered. The user endpoint may be full-featured, reduced or extremely basic.

Once the presentation platform is ready, another matter should be considered, namely the general type of information processed. This information may be current or historic, concurrent or object-based, fully verified or possibly damaged, complete or only partial, and so on.

The final branch should be a broad classification of the interaction with the user. Here, all kinds of HCI, content exchange or presentation services will be considered.

As long as the system has a user interface, it can be classified using the ECORAM. Finally, after a long period of discussions and fixes, a basic model branch list was established. All model branches have been included in a compact set.

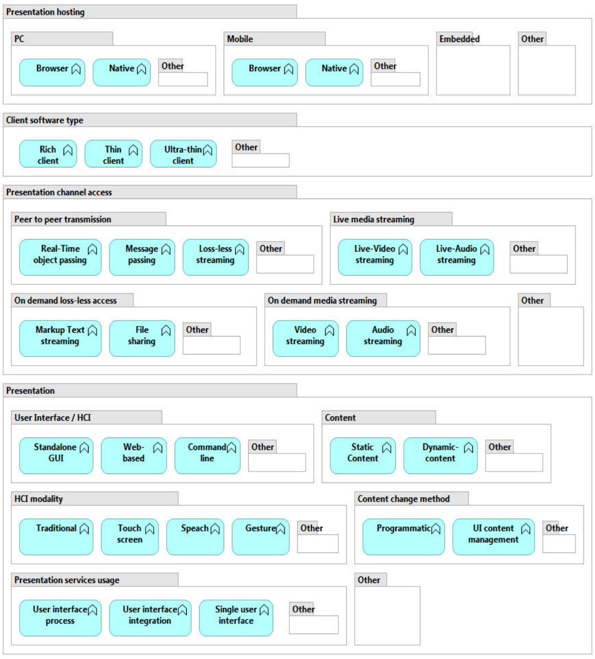

Fig 2. ECORAM presentation layer components in full set.

### *A. Presentation Hosting*

The first selected group of entities concerns presentation hosting. It represents three types of physical devices used to display information:

- PC – Any kind of personal computer (desktop, netbook, notebook, etc.): Browser – an application running in a Web browser on a PC; Native Client – a native application running on a specific OS.

- Mobile – Any kind of mobile device working on a specific OS (mobile phone, smart phone, tablet, etc.): Browser – an application running in a Web browser on a mobile device; Native Client – an application running on a mobile device.

- Embedded – a system with specific hardware dedicated to performing a computing function within a mechanical or electrical system (Real Time Systems, controllers, MP3 players, traffic lights, etc.). For embedded systems native, headless and other solutions can be used.

### *B. Client Software Type*

This division specifies the set of features and capabilities available in the solution and the degree of its dependence on the operating system. Most importantly, client types can easily be divided into three kinds:

- Rich Client – a typical standalone application deployed on a user's machine (Workstations, i.e. desktop UI, etc.) or a RIA (Rich Internet Application) running in a Web Browser, usually with a graphical user interface displaying data using a range of controls. Suitable for disconnected and occasionally connected scenarios.

- Thin Client – an application that depends heavily on a server in order to provide functionality. All the computing is performed on the server side, which distinguishes this type of software from rich clients.

- Ultra-thin Client – Server Based Computing (Independent Computing Architecture), delivering only presentation data and/or sending user actions.

### *C. Presentation Channel Access*

The next section specifies an abstract information flow between the user and the system. It should answer the question: "How do we deliver the presentation content?". Information can either be stored or retransmitted to a final user, or passed without any storage involvement. It can also be just a plain object, or possibly an infinite stream. Each user can also order just a part of a steam previously stored. Consequently, we propose the following list of presentation channel components:

- Peer to peer transmission - a transmission established for data generated in a real time. ECORAM assumes three kinds of such communication. 1) Real-Time object passing, occurring when an object is passed from the sender to the receiver in real time. These objects are based on patterns or classes and their size is limited. Objects can be cloned and sent to an unlimited number of receivers. (SOAP, REST etc.). 2) Message passing, messages can be read later (so storage is required). Messages may be cloned and delivered to a number of receivers without being deleted from storage (SMS, EMAIL, PAGER etc.). 3) Loss-less streaming, when a stream of data (taken in real time from a sensor or some such) is sent. It is encoded using dedicated protocol. The data size in this case is undefined.

- Live media streaming – a media stream does not require the use of any rigorous data quality assurance mechanisms. A stream may be defective or contain misrepresented data. In the case of this kind of stream, delay reduction is of the greatest importance: Live-Video streaming – Video content streaming; Live-Audio streaming – Audio content streaming.

- On demand lossless access – a stream with storage (on demand) – a limited size stream stored in data storage (similar to messages). Encoded using dedicated protocols: Markup Text streaming – a structured text described with mark-ups exchanged on demand between the sender and the receiver (RSS, TELETEXT, etc.); File Sharing – Files exchanged on demand between the sender and the receiver.

- On Demand Media Streaming – a media stream with data storage – on receipt, no type of rigorous data quality assurance mechanisms is required. Video Streaming – Video content streaming; Audio streaming – Audio content streaming.

### *D. Presentation*

A presentation mode, applied in a system interface, must deal with a user's (or human's) influence on that interface, and subsequently on the system itself. The following list divides interface presentation possibilities considering the type of user interaction:

- User Interface/HCI – The user interface is a part of a software program that allows the user to interact with computers and run their tasks. Human–computer interaction (HCI) describes the interaction between users and computers: Standalone GUI – a UI separated as a standalone application; Web-based – a User Interface based on a web application and characterized by request response navigation (interaction with the user); Command Line – Console-based applications offering an alternative text-only user experience, and typically run within command shells such as a Command window or a Power Shell. Most suitable for administrative or development tasks.

- HCI modality – the HCI modality is a general class of a sense through which the human can receive output from or give input to the computer: Traditional – Keyboard, mouse or touchpad; Touch Screen –Touch (multi-touch) or gestures on a Touch Screen; Speech – AUI (Audio User Interface) equipped with speech recognition solutions; Gesture – An interaction based on head and body movements

- Content – Describes whether the presented content will be changed by the user (dynamic content) or not (static content): Static content – content doesn't change, e.g. a static web-page; Dynamic Content – Presented content generated dynamically.

- Content change method – Describes how the presented content will be changed by the user: Programmatic – content refreshed or generated automatically, independently from the user's actions; UI Content management – Refreshed or generated depending on a user's actions, including Content Management Systems (CMS). A CMS is a computer program that allows content to be published, edited, modified and maintained from a central interface, and provides procedures to manage the workflow in a collaborative environment

- Presentation Services Usage – Describes the usage of different presentation services and user interactions between them: User Interface process – Synchronizes and orchestrates user interactions between presentation services for one actor and a one-time execution span [6]; User interface integration – Integrates different user interfaces and existing presentation services by offering various presentation integration services (i.e. WSRP, WS rendering); The User Interface Integration itself behaves like a User Interface, providing a presentation service by integrating a 'real' presentation service [6]; Single User Interface – One user interface – no need for integration

As we can see, the ECORAM is optimized to just four main sections, enabling the quick classification of a system. On the other hand, internal section granularity will support the expressing of all vital differences between two or more presentation layer structures, even those used in completely different kinds of IT systems.

## IV. ECORAM presentation layer application in Business Intelligence

ECORAM may be used for analyzing and developing human interactive computer systems (HICS). It is assumed that in BI systems interaction is performed in a timely manner. This means the reaction time is in accordance with human reaction. The application of an ECORAM for BI systems can be explained briefly as follows:

- The motivation is to use the reference model for a broad spectrum of applications. In particular, the model should be useful for BI systems.

- The model can be used in constructing BI systems , and also for investigating multimedia systems as potential data sources.

- The metamodel can be used as a default template for an application layer framework in an IT system of any kind. It shows meta-relations and meta-entities (here sections) that can be used or affected.

- Reference model structure, which is a composition of reference model elements. The description of model elements is also included here. The proposed structure can be applied for BI systems.

- Metrics defining the importance of the model features for BI systems.

- Valuation mapping – feature values important for BI System stakeholders.

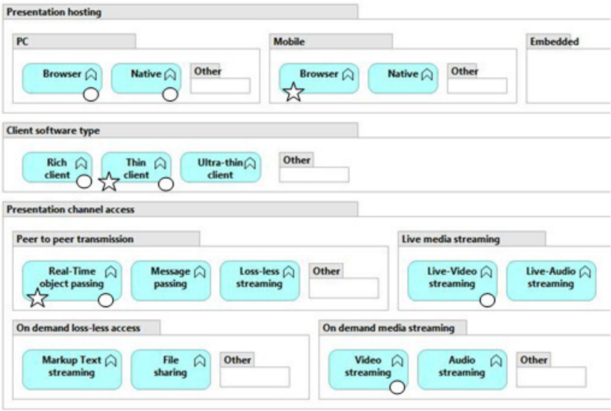

Fig 3. Sample mapping of asset usage: Taxi service management BI system (star symbols) and Integrated DVR Monitoring BI system (circle symbols).

Assessing software solution architecture is not an easy task. For the presentation layer some quality metrics can be distinguished, e.g. usability, user experience, and playfulness. ISO Standards 9126-3 [14] describe usability as product quality. According to ISO 9241-210 [15], "user experience represents a person's perceptions and responses resulting from the use or the anticipated use of a product, system or service". In terms of user experience, playfulness can come from a design that engages people’s attention or involves them in an activity for play, amusement, or creative enjoyment.

Fig. 3 shows the features used by two different BI systems and displays only a part of the ECORAM diagram. A full ECORAM diagram can be used to compare even totally different types of system, including different system domains Each component in a solution’s architecture is checked for features (assets) which also exist in the ECORAM. Various icon symbols are used to distinguish particular solution architectures (see Fig. 3). The diagram is used for a comparison of different systems. In a taxi business intelligence system [16] the customer uses a mobile device to connect to online taxi booking services and track the route of the approaching taxi. Additionally, by collecting information for many BI systems we can obtain statistical data which will give insight into how systems in a given domain are built. In [17] a Laboratory Management System (LIMS) delivering Real-Time Manufacturing Intelligence monitors a wide range of variables of both the manufacturing and the laboratory databases

## IV. ECORAM PRESENTATION LAYER VIDEO GAMES APPLICATION

ECORAM may be used for game systems comparison. Finally, three different popular game systems were considered: Angry Birds, the World of Tanks, and Kinect Sports.

Angry Birds is a puzzle video game developed by the Finnish computer game development company Rovio Entertainment. Inspired primarily by a sketch of stylized wingless birds, the game was first released for iOS in December 2009. Since then, over 12 million copies of the game have been purchased from the iOS App Store, which has prompted the company to design versions for other touchscreen-based smartphones, most notably those using the Android, Symbian, Windows Phone and BlackBerry 10 operating systems. It has since expanded to video game consoles and for PCs.

The World of Tanks is a multiplayer online game developed by a Belarusian company called Wargaming.net, featuring mid-20th century fighting vehicles. The focus is on player vs. player game play with each player controlling a tank or an armored vehicle. The World of Tanks debuted as an eSports game at the World Cyber Games 2012. On 10 June 2013, it was announced that the World of Tanks was coming to the Xbox 360 in summer 2013 as the World of Tanks Xbox 360 Edition. Xbox 360 players will use servers separate from those playing the Windows version and players of each version will have separate accounts.

Kinect Sports is a sports video game developed by Rare and published by Microsoft Game Studios for Xbox 360. The game is a collection of six sports simulations and eight mini-games, designed to demonstrate the motion-sensing capabilities of Kinect. The six sports included are: Bowling, Boxing, Track & Field, Table Tennis, Beach Volleyball and Football (Soccer in North America). Standing in front of a Kinect sensor, players compete by mimicking actions performed in real-life sports, such as throwing a javelin or kicking a football. The game received generally positive reviews from critics and sold over three million units as of April 2011.

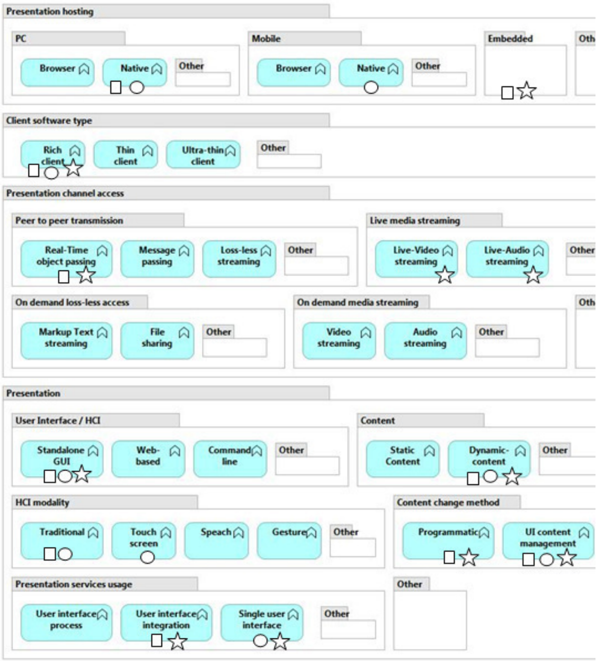

Fig 4. Sample system comparison: Kinect Sports (star symbols) and Angry Birds (circle symbols), World of Tanks (rectangle symbols).

The features used in the games can be evaluated from different viewpoints. The example considered here is playfulness. Playfulness motivates one to use the product and learn new features and technologies of the device. Paper [18] provides user interface characteristics influencing playfulness: creative enjoyment, challenge, curiosity, ability to customize the user interface, fun-in-doing, exploration, feedback, fantasy, metaphor and social interaction. A different perspective for understanding social game design is given by SoPlay heuristics [19]: accessibility – easy to approach, to understand and play; interrupt ability –spontaneous and irregular play sessions; continuity –a game world attracting the player to come back; discovery –new experiences and surprises; virility – growth in the player’s social network; narrativity –elicits curiosity; expression –self-discovery and customization; sharing – collaborating with friends, sociability among friends, social competition with others.

We have selected the following key aspects for a playful user interface: Creative enjoyment, challenge, feedback; Accessibility – making the game easy to approach, understand and play; Ability to customize the user interface; Social interaction.

$$PF(selected\ aspects) = \Sigma_{i=1}^{CE\ aspects}(\alpha_i CE_i) + \Sigma_{i=1}^{C\ aspects}(\beta_i C_i) + \Sigma_{i=1}^{SI\ aspects}(\gamma_i SI_i) \qquad (1)$$

For the selected games, a weighted quality factor can be determined to assess the play ability of the presenta-

TABLE 1.
KEY ASPECTS OF A PLAYFUL (PF) USER INTERFACE

| Key Aspect | Positive influence aspects (make use of) |
|---|---|
| Creative enjoyment (CE) | Touch screen, Speech, Gesture |
| Customization (C) | Dynamic content, UI content management |
| Social interaction (SI) | Live Video Streaming, Live Audio Streaming, User interface integration |

tion layer solution. Assuming that all coefficients αi, βi, γi are equal to 1, the playfulness of each game stemming from the presentation layer (fig. 4) can be determined in conjunction with Table 2. The results are as follows: PF(Angry Birds aspects)=3, PF(World of Tanks aspects)=4, PF(Kinect Sports aspects)=6. The simplified calculation demonstrate that the Kinect Sports game is characterized by the highest playfulness. The calculation of quality factors demonstrate only an approach to comparing different systems based on a proposed model.

## V. CONCLUSIONS

The process of ECORAM model development may be a part of knowledge management in a software development company [20]. The cooperative knowledge discovery model [21] including communication, coordination and cooperative decision making could be applied for developing and assessment of software solutions.

Reference architectures should accelerate work, reduce operating expenses and improve the quality of software system development, mainly due to reuse. Before reference architecture is designed it is important to develop an architecture reference model. To prove the flexibility of the model, a multiple system comparative analysis has to be performed, including system domains for auctions, games and BI. Each system chosen usually consists of many different presentation layer components that can be compared and placed in an ECORAM diagram. The diagram is capable of expressing all the differences with a sufficient level of detail.

Another possibility is to investigate the popularity of model elements in terms of usage by different user groups. For different kinds of users, we can now identify the presentation layer components used. The constant monitoring of a user group's activities and the system service counters will generate important statistical data for investment planning for future software line development. The solution will also make common feature exploration processes easier and will help system developers to design and refactor system architecture.

Finally, an ECORAM diagram can also be useful as a presentation tool during any kind of system requirements-establishment discussion with customers. The ECORAM diagrams are also used by computer science students when presenting their solution architectures, with the aim of quickly identifying the class of a developed software system.

It is possible to provide a development time-line in ECORAM diagrams (by creating a diagram set with timestamps) - and express a product line development regarding particular presentation layer components gradually involved. Building time-lined ECORAM diagrams for a set of similar products can easily express trends in product developments of that kind – helping to make a proper investment decisions in own product.

# 5th Workshop on Advances in Programming Languages

PROGRAMMING languages are programmers' most basic tools. With appropriate programming languages one can drastically reduce the cost of building new applications as well as maintaining existing ones. In the last decades there have been many advances in programming languages technology in traditional programming paradigms such as functional, logic, and object-oriented programming, as well as the development of new paradigms such as aspect-oriented programming. The main driving force was and will be to better express programmers' ideas. Therefore, research in programming languages is an endless activity and the core of computer science. New language features, new programming paradigms, and better compile-time and run-time mechanisms can be foreseen in the future.

The aims of this event is to provide a forum for exchange of ideas and experience in topics concerned with programming languages and systems. Original papers and implementation reports are invited in all areas of programming languages.

## Topics

Major topics of interest include but are not limited to the following:

- 
- Automata theory and applications
- Compiling techniques
- Domain-specific languages
- Formal semantics and syntax
- Generative and generic programming
- Grammarware and grammar based systems
- Knowledge engineering languages, integration of knowledge engineering and software engineering
- Languages and tools for trustworthy computing
- Language theory and applications
- Language concepts, design and implementation
- Markup languages (XML)
- Metamodeling and modeling languages
- Model-driven engineering languages and systems
- Practical experiences with programming languages
- Program analysis, optimization and verification
- Program generation and transformation
- Programming paradigms (aspect-oriented, functional, logic, object-oriented, etc.)
- Programming tools and environments
- Proof theory for programs
- Specification languages
- Type systems
- Virtual machines and just-in-time compilation
- Visual programming languages

***Abstract*—User interfaces (UIs) are advancing in every direction. The usage of touch screen devices and adaptation their UIs lives its boom. However integrated development environments (IDEs) that are used to develop the same UIs are oversleeping the time. They are directed to developing usable software, but forgot to be usable by themselves. Our goal is to design a new way of user interaction for common IDEs with the help of touch. The target group are hybrid devices formed by a physical keyboard and either an integrated, or separate, touch screen display. In this paper we describe a set of general purpose and domain-specific gestures which represents a language for working with a touch-driven IDE and provide a method their design. We performed two studies with developers from industry and university and developed a prototype of a gesture-driven IDE to evaluate the usability of the presented approach.**

## I. Introduction

The accessibility of alternative devices such as wearable gadgets, smartphones, tablets, tablet PCs, wall-sized displays, touch-enabled displays, kinect and others, has given a rise to different design guidelines for application user interfaces (UIs) which, though still young and imperfect, become more and more dominant. According to the world statistics a large part of interaction has moved to touch devices and the vast majority of mobile devices now supports touch control. Touch interfaces are natural and easy to get used to and they also affect the way people try to control other devices such as common PCs or notebooks. Therefore, *hybrid devices*[1] have emerged and operation systems try to adapt their UIs and functionality to touch.

Although touch control support has moved a large leap forward, it still has its disadvantages. Touch gestures are not entirely uniform on all platforms and in many cases, a touch display alone is not sufficient to fully handle all desired functionalities. A typical example is *writing on a virtual keyboard*. Vriting on a virtual keyboard is slow, imprecise and the keyboard occupies a large part of the screen [1]. Still, the situation is much better than before and the rise of platform guidelines for touch devices with different screen sizes helps the situation.

Despite the disadvantages, the situation is much better than in case of integrated development environments (IDEs). They are made to improve developer productivity as much as possible [2] but it is as if developers were primarily focusing on making UIs and interaction better just for their users while forgetting about themselves. The support of touch for the most common IDEs literally overslept the time. Not only the current IDEs are not ready for advanced work on touch displays, they are not even prepared for everyday touch use stereotypes and are largely limited to interaction via traditional hardware devices (e.g., the ubiquitous keyboard and mouse) [3]. It is not possible to use swiping to scroll, pinch to zoom or tapping the same way as in every other touch-enabled UI. From the IDEs we have analyzed, the only IDE ready touch is Eclipse, statistically the most used IDE for Java language. However, it still offers just fundamental features. As for the second in line, IntelliJ IDEA, despite marked innovative and usable, does not even support the most fundamental ones. Instead of browsing or scrolling through code, the swipe gesture selects text, infringing the common interaction stereotypes and adjustment of panel sizes or zooming by using pinch gesture is not possible at all.

Programming requires the speed of interaction and creativity, touch support is unambiguously a step forward because it brings a different form of user experience and according to Greene [4], supports creative thinking. Our goal is not to force the work exclusively via touch gestures but to create a symbiosis of keyboard, touch and, alternatively, mouse. Begel [5] experimentally verified that programmers are so used to physical keyboard that it would be disadvantageous or at most impossible for them to explicitly use virtual keyboard, which, in addition, has a low precision and does not enable writing by ten fingers.

Supporting common general gestures in IDE may not be enough to speed up the developer work. A specific solution is necessary to not just support the basic gestures, but enable advanced interaction adjusted for a specific IDE platform and programming language. In this paper, we show a method of designing a set of gestures for such advanced interaction as a way of designing the lexical part of a visual language. The focus is mainly on usability [6], [7], [8], domain usability and specificity [9], simplicity of use, learnability and compliance with standard design patterns and guidelines.

The main contributions of this paper are:

- Definition of more complex general-purpose gestures in the context of IDEs.

[1] In this paper, the term *hybrid devices* will be used to refer to devices with a keyboard and a touch display such as tablet PCs or combinations of desktop PCs/notebooks with an external touch display.

978-83-60810-66-8/$25.00©2015, IEEE

- A method of collecting, identifying and designing a set of domain-specific gestures via multiple user surveys and interviews including industry programmers and gesture recorder.
- Verbal definition of a domain-specific language of gesture patterns to support highly specialized work with code and consequently a design and realization of drawn gesture input and recognition in a form of a gesture-driven IDE for Android. When compared to a physical keyboard, we hypothesize that touch gestures are *more learnable and memorable than key shortcuts*.
- Evaluation of the proposed approach by means of usability evaluation.

Although our prototype is designed for Android devices, we do not focus on touch devices explicitly (although they may be a possible target), our target group are hybrid devices.

## II. A Touch-Enabled IDE

Here, we will describe a design of fundamental gesture interaction for touch devices related to IDEs. Elementary gestures are based on usability guidelines [10], [11], analysis of existing desktop and touch-based IDEs and discussions with industrial developers. Primarily, we followed the Google Material design guidelines [12] that also define the most common gesture patterns (Fig. 1).

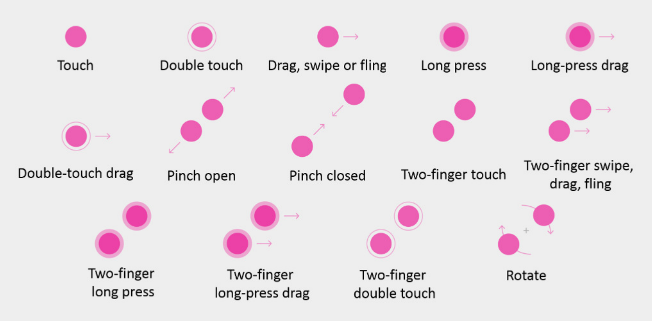

Fig. 1. The mechanics of touch gestures according to the Google Material Guidelines

We identified the following two fundamental categories of gestures related to their design:

1) *General-purpose gestures (GPGs)* - used for standard interaction. They can be used in different context, however their meaning is always the same or at least very similar. The most common GPGs are touch, double-touch, swipe or pinch. This category can be considered platform-independent although according to Wroblewski [13], not all gestures are applied on all platforms consistently to the same functionalities.
2) *Drawn gestures* - a specific type of gestures that have no standard or specification indicating their form, purpose or semantics. For example, drawing a circle can be used for restoration, rotation or selecting multiple items in a list. The design of semantics of drawn gestures is often intuitive and closely linked to the context of their use.

Breaking the stereotypes of *GPGs* can cause serious usability issues, mainly in the case of advanced or experienced touch device users. Therefore it is good to abide the standard interaction in case of this category. In case of an IDE, it is advantageous to design additional gestures similar to general-purpose ones by using multiple fingers to support more action shortcuts. When designing the set of GPGs, we primarily followed the guidelines of the Android platform and we were also inspired by the iOS platform guidelines for multi-touch gestures [14].

Based on the simple gestures displayed in Fig. 1, we further designed the following additional multi-touch gestures for common IDEs:

1) Double-touch to *select words*.
2) Tripple-touch to *select lines*.
3) Two-finger horizontal swipe for *undo/redo* inspired by the usage on Apple trackpads [14].

## III. Domain-Specific Language for a Gesture-Driven IDE

IDEs are used in the domain of programming and to be able to support at least the standard interaction with an IDE, we need to design *domain-specific gestures*.

The set of gestures supported by an application can be perceived as a *sign language*, which the user has to learn to be able to communicate effectively. A correct conceptual model helps users to better understand actions performed upon a UI, thus speeds up the learning process.

From this point of view, the list of domain-specific gestures (both general-purpose and drawn) described further in this paper can be perceived as a *domain-specific language* of the touch-enabled IDE:

1) Concrete syntax is defined by the *gestures* themselves: touch or movement, finger count, touch count and movement directions.
2) Abstract syntax is defined by the *actions* that the gestures *cause*.
3) Semantics is defined by their *type and implementation*.

Because of the limited space and for we design a simple visual language (the set of gestures is kept small), we will not formally describe the semantics of the gesture DSL in this paper. We expect that common language constructs, such as loops, conditions, comments or class and method declarations are known to common programming language designers. Therefore we expect the semantics to be clear from the purpose of the gesture. For each gesture, the semantics is a generated programming language construct. We use templates to generate the constructs similar to the ones used in common IDEs using the Velocity template engine. Concrete and abstract syntaxes are described verbally.

### A. General-Purpose Gestures

We designed the following GPGs for touch-enabled IDEs:

1) Swiping:
   a) Two-finger swipe for *"stuck shift"* - gradual shift from method to method by swiping two fingers.

   b) Three-finger swipe to the *end/beginning of the file*.
2) Code folding:
   a) Three-finger pinch for *method folding*.
   b) Four-finger pinch for *"semantic zoom"*.
   c) Five-finger pinch to *fold all class members*.

"*Semantic zooming*"[2] is a way of grouping content into specific predefined categories. In case of an IDE it would be a combination of related methods or blocks of code such as getters, setters, void methods, public methods, imports, nested classes, etc., into a single group. After performing the gesture, the user is promted to select a semantic group. After selection, everything else not belonging to the selected group is folded. This enables to focus only on the important parts of the code.

In case of pinch gestures, the action of pinching-in standardly folds class members and the opposite direction of pinching-out causes unfolding action.

### *B. Drawn Gestures*

As we stated in section II, drawn gestures are not subject to any specifications or conventions. Therefore their design needs to be approached with caution. They are specific for the target domain of use, therefore *domain experts should be included* in the design and development process. A domain analysis was performed to determine the way how programmers interpret different language constructs visually. We interviewed multiple developers from industry and their claims were supplemented by a survey. In the next subsections we will describe the results of the survey that was performed in two iterations.

*1) First Survey - Collection of Patterns:* In order to elicit the correct conceptual model most effectively, a support application for Android touch devices called *"Gesture Recorder"* (Fig. 2) was created. The whole survey process was performed in the application, using a Google Nexus 7 tablet, which asked users to interpret given programming language constructions by directly inducing gestures on touch screen. We used a standard Android tablet for the survey.

We wanted to cover a wide spectrum of programmer experience, therefore we included 68 participants, from which 8 considered themselves advanced programmers, 38 intermediate and 22 were beginner programmers. During the survey, each participant performed the survey independently to prevent influence and was assisted by one member of our research team in order to be able to correctly work with the survey application.

The survey application prompted the participants to interpret the following constructs by a drawn gesture: class declaration, comment, variable declaration, loop statements (both for, while and do-while), condition statement, method declaration and deleting a line.

For each prompt, an example of a language construct was displayed in the application to help the user to better connect his/her mental model with a new gesture. After all language constructs, participants were given a possibility to add their own idea for a new gesture and language construct. Then they were to fill a questionnaire about their programming experience. The results for each participant were sent to a distant server, manually checked and analyzed.

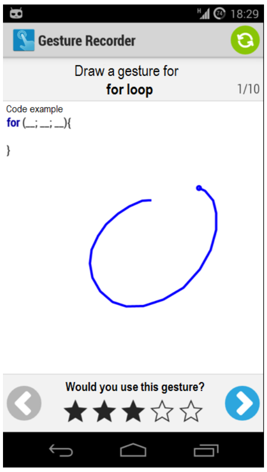

Fig. 2. The GestureRecorder survey application

*a) Evaluation Method:* Similarity of gesture shapes was taken into account via their abstractions into patterns. Differences in size, shape and format were abstracted into a single unified pattern while the direction of drawing was preserved. Differences were neglected only if the conceptual model of the gesture interpretation remained unchanged. The patterns with low repetition rate were omitted. Fig. 3 shows the simplified survey results. Each group represents one language construct and indicates the most common gesture pattern and the number of participants that used the pattern. The direction of drawing is indicated by the small circle representing the final point of drawing.

*b) Results:* The results in the case of a class were influenced by the fact that the respondents come from Slovakia, where class is called "trieda" and begins with the letter "T". Many of the participants also included "N" as in "new", but the number was not as significant. Both were mainly beginners or at least advanced programmers and from our experience, sooner or later older and more experienced programmers begin to in English language explicitly and do not perceive the class declaration and instantiation as the same concept anymore. In case of variable declaration, the results were unclear, therefore we decided not to include the gesture without further research. In case of cycles, as for the shape, the results jointly indicate a circle, as for the direction, the results are unclear.

*2) Second Survey - Suitability of Collected Patterns:* Because the results from the first survey were very variable, we decided to perform a second survey. The goal was to determine which shape of the previously identified ones was the most appropriate for the given language construct.

The second survey was performed on 65 new participants. In the first survey we covered different levels of programmer experience to get universal results but this decision has proven to be wrong. In the second round we rather decided to target

[2] More information about semantic zooming can be found in Microsoft official guidelines: https://msdn.microsoft.com/en-us/library/windows/apps/hh465319.aspx

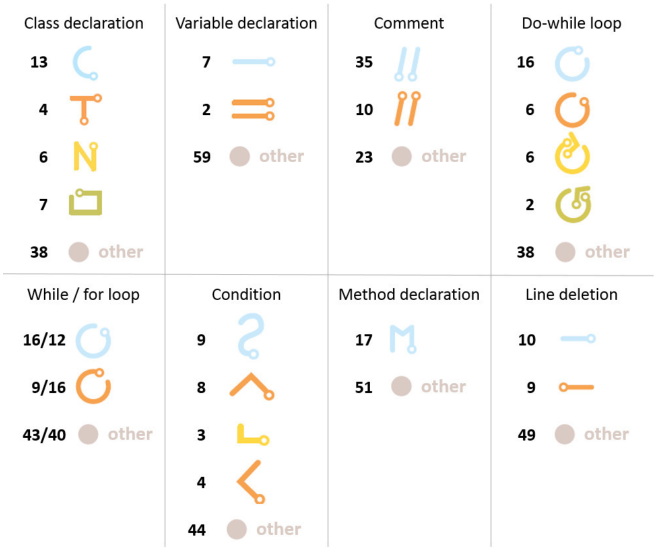

Fig. 3. The results of the first survey

the survey explicitly to last-year master students of informatics to achieve more relevant results. We used a questionnaire that contained only questions related to gestures. We included the most frequent answers from the first survey so the users could select from existing choices.

*a) Results:* The results of the second survey were much clearer. In case of class declaration, a significant number of 69% respondents have chosen the shape of the "C" letter which indicates it is an appropriate representation of a the gesture. In case of loops, the results indicate that the direction of drawing is not significant. There are multiple research papers that try to reveal the reason of the direction. A cross-cultural study by Amenomori et al. [15] identified a direct impact of culture and learning methods on the direction. Based on the facts we conclude that the gesture should be unified for all three loop constructions and should support both drawing directions. To unify all loop types, we need to add an additional step after gesture drawing, where the user selects the particular loop construction (while, do-while or for) according to his/her choice.

The results for condition statement were not as definite as in the case of class gesture, however a slightly more significant number of users selected the shape resembling a question mark. Since branching can again be noted by multiple constructs such as if, if-else, switch or shortened if-then-else statement (:?), the gesture can unify all possible constructs and enable a choice after, similarly to the loop gesture.

As for the final question, most of the respondents agreed on a horizontal line for line deletion.

## IV. Implementation of the Gesture DSL

At this point we will describe one of the ways of implementing recognition of the described gestures. We chose Android as a model platform mainly because of its accessibility, openness and good support of developing and recognizing custom gestures. However, the mechanics of gestures and the described procedures are common for any platform. The goal is not to point out to the details but to show the method of developing a gesture recognition engine.

We developed two prototypes of a simple gesture-driven IDE with the goal to design the gesture recognition algorithms and tested it with industrial developers. We focused on maximal usability. We deesigned and implemented recognition of both complex GPGs and drawn gestures.

Recognition of GPGs is implemented via native platform libraries. Recognition of drawn gestures is more complex and uses machine learning and recognition probabilities. Due to the limited space, we will only describe the implementation of domain-specific *drawn gestures*.

### A. Recognition of Drawn Gestures

To recognize drawn gestures we used the Android `com.android.gesture` package containing classes such as `Gesture`, `GestureOverlayView` and `Prediction` enabling possibilities to record, store, read and recognize gestures. The package is undocumented, therefore we will describe the design in more detail. `GestureOverlayView` is a graphical component that enables the actions of gesture recording and displaying it as curves. The recorded and predefined gestures are stored in a binary file located in application memory and contain a list of points and a single name may be assigned to each gesture.

Recognition works on the principle of comparing a drawn gesture with the whole file content and the result is a list of identified patterns with assigned probabilities. However, the default recognition is not very accurate, especially if the stored patterns are slightly similar to each other or if the drawn gesture did not imitate the target pattern too precisely. The more patterns are stored in the database, the less precise is the recognition. In case there are multiple gesture patterns, the recognition rate can be less than 40% which is unacceptable. Taking this fact into account, we needed to adjust the default recognition process so that each pattern could have a *database of multiple possible shapes*. We recommend to create the databases by recording pattern shapes from different users and multiple times and also to record the gestures drawn by the IDE users during their first use by means of a tutorial.

The *recognition probability* $p$ of match is determined by a positive number. The exact meaning of $p$ was not clear since the package is documented, thus the value was determined empirically for each pattern as stated below. In general, the gesture is successfully recognized $p > 1$ and the highest probability is considered as correctly recognized. This applies only after verifying the number of traces forming the gesture. If a circle is recognized after drawing two mirror-inverted C characters, the result will not be considered correct, even though it has the highest $p$ value.

The database for each pattern was created by drawing multiple slightly deformed shapes and in both drawing directions. Because of significant differences between probabilities for patterns with different complexity, an optimal $p$ interval was determined empirically for each pattern as follows:

- *Loop gesture* - is considered to be recognized if $p > 4$.
- *Condition gesture* - the most complex shape of all because of two changes in the direction. Recognized when $p > 3$.
- *Class gesture* - a higher value has proven to be optimal. This gesture is recognized if $p >= 5$.
- *Comment gesture* - a simple gesture of two consequent lines. Recognized if $p > 10$
- *Line deletion gesture* - the most simple gesture, almost identical to comment, but with only one line and different direction. Valid recognition if $p >= 10$.

The values were determined by re-entering gestures multiple times and observing the $p$ value after recognition. We verified both positive and negative cases and with the stated $p$ values, we achieved almost 100% success rate.

Since the recognition database is built using a simple form of machine learning and the recognition thresholds are determined empirically by applying probabilities, it is important to consider the number of available patterns in the database. Low number of predefined gestures that are not very complex and similar to each other is optimal. Also, it is very important *not* to continue the machine learning process during application use, because the user might draw incorrect shapes and hinder the recognition of the predefined gestures. Instead, we recommend to allow the user to create his/her own gestures and teach the correct and incorrect shapes to the recognition algorithm. This is also a problem of many systems for recognizing handwritten text. Each person has his/her own writing style and when supporting as many characters as the whole alphabet, the recognition can be incorrect multiple times and lead to reluctance and rejection of using the system. Moreover, the user is only able to remember a limited number of gesture shortcuts and forcing his/her to remember a whole database of patterns can reduce usability.

## V. Gesture DSL - Usability Test

To evaluate the gesture DSL, we created a prototype of a simple gesture-driven IDE for Android according to the design described in this paper and performed a usability evaluation.

Our target group were Java programmers, experienced in using IDE and minimally in using a touch-enabled smartphone or a tablet. For the reasons indicated by Nielsen [16], [7], we performed the usability evaluation with five participants and we targeted at qualitative evaluation. The participants were given tasks related to tutorial, GPGs and 2 tasks targeted at general work with the IDE.

Each testing was performed in the presence of one member of the research team. The sample was represented by five experienced developers with 1-5 years of practice in industry, using mostly IntelliJ IDEA. To avoid influence, the test was performed separately with each participant. In all cases we used Google Nexus 7 tablet and each time the application was reset to its original settings. Two of the respondents were given an external keyboard.

At the beginning, the participants were briefly familiarized with the research and with the testing process and they were given an in-app introductory tutorial. After finishing the tutorial, the participants were to perform the tasks on a sample class and to express their opinion.

### A. Observations and Conclusions

Gesture discoverability was 100%, each participant was able to perform the tasks successfully. The feedback received from the subjects indicated that almost all participants liked the idea of manipulating with the editor using GPGs and generating parts of code using drawn gestures. However, the idea of using it on a tablet was not accepted, each participant expressed the wish to use the gesture language on a common IDE which indicates the potential of our approach on hybrid devices. We concluded that the negative opinion towards tablets is related to writing code using a virtual keyboard. The results were definitely better in case of participants that used an external keyboard.

The gesture for folding all methods was marked most useful, however the users expressed the idea of subsequent use of the gesture multiple times to fold methods to regions. All of them liked the semantic zoom feature and indicated that it could replace the common IDE feature of code structure preview. They suggested to add a filter for constructors, member variables and a filter for displaying all method names.

The possibility to define custom gestures was described as a feature with high potential. Each developer mentioned an example of use, such as definition of custom predefined code parts and templates or combining with macros.

The design of new gestures is a major challenge. The gestures have to be simple, easy to learn and quick to write. This holds for the set presented in this paper, but with a growing number of gestures, their complexity might rise significantly, which could complicate their use. It might be beneficial to explore multiple combinations of gestures and patterns [17] [18] of their use.

## VI. Related Work

Biegel et al. [19] propose an inspirational approach to "touchifying" an IDE. They highlight multiple issues of common IDEs related to supporting touch handling in general. Authors present a solution on Eclipse IDE. Compared to our gesture set, they used already existing GPGs to support multiple functionalities. In their study, they did not include domain-specific drawn gestures. The fact that programmers rather prefer the combination of a traditional PC, touch display and a mouse shown in their paper *supported our findings* and confirms that this approach has a potential to be used on hybrid devices.

There are multiple works that focus on code refactoring triggered by gestures, such as the works by Murphy-Hill et al. [20] and Raab et al. [21]. Compared to their solution, we use a small set of gestures for commonly used features and for the sake of usability we never use multiple composed gestures to trigger a single operation. Lee et al. [22] propose a solution where refactoring can be triggered via drag-and-drop gestures but in contrast to our work they optimized the gestures for using a mouse.

Hesenius et al. [23] introduced an environment for tablets with advanced features but focused primarily on creating a new environment, not adaptation to hybrid devices. Delimarschi et al. [3] describe a natural UI for graphical IDE using a Kinect voice and physical gesture commands. Although we favour the potential of voice commands as means to speeding-up the developer work, voice recognition is still not mature enough to fully support multiple languages. As for physical gestures, the potential is less definite. Edwards and Barnette [24] unsuccessfully used tablet PCs with a pen in a laboratory programming course without adapting the software to this novel device.

Begel et al. [5] mentioned that it is possible that developers are less efficient by using a natural interface instead of typing. This is related to the fact that typing on a physical keyboard is already ingrained in every developer's habits, while more natural interaction might not be as standard in the development process. We agree that in the case of IDEs, not each natural interaction type is beneficial, however we argue for touch input being advantageous based on our observations and user feedback. Direct manipulation characteristics of touch helps to reduce the cognitive load [19]. Further investigation is needed to support this claim.

## VII. Conclusion

We introduced the concept of a DSL of gestures in the context of IDEs. We performed multiple studies to explore the visual representations of conceptual models of programming constructs and developed a prototype tool which served to conduct a pilot study to assess the feasibility of our approach. Despite the challenges and current limitations, we believe that it has the potential to improve and speed-up development and ease of use. To make the approach more accessible and verifiable in the context of hybrid devices, we have set forth the following goals: 1. Implement a prototype into a common desktop IDE such as Eclipse, IntelliJ IDEA or NetBeans in form of a plug-in. 2. Integrate learning capabilities that would allow the system to adapt to the user and his/her drawing style and allow the user to add new custom gestures via the existing IDE-native code template engine. 3. Generalize the approach beyond Android and Java, for a variety of operating systems and programming languages. 4. Experimentally identify the optimal number, complexity and combinations of drawn gestures.

***Abstract*—Visibly pushdown automata are pushdown automata whose pushdown operations are determined by the input symbol, where the input alphabet is partitioned into three parts for push, pop and local pushdown operations. It is well known that nondeterministic visibly pushdown automata can be determinised. In this paper a new algorithm for the determinisation of nondeterministic visibly pushdown automata is presented. The algorithm improves the existing methods and can result in significantly smaller deterministic pushdown automata. This is achieved in a way that only necessary and accessible states and pushdown symbols are computed and constructed during the determinisation.**

***Index Terms*—Pushdown automata, visibly pushdown automata, deterministic pushdown automata, determinisation of visibly pushdown automata.**

## I. Introduction

PUSHDOWN automata, which accept context–free formal languages, are one of the fundamental models of computation of the Theory of formal languages and automata [8]. Every nondeterministic finite automaton, which accepts a regular language, can be determinised and the theory of the determinisation of finite automata is simple and well–researched: states of an equivalent deterministic finite automaton represent so–called deterministic subsets of states of a given nondeterministic finite automaton [8]. The general determinisability does not hold for the case of all types of nondeterministic pushdown automata. The class of deterministic context–free languages is a proper subclass of context–free languages, ie for some nondeterministic pushdown automata their equivalent deterministic versions do not exist. Generally, it is not known how to decide for a given nondeterministic pushdown automaton whether there exists a deterministic equivalent or not. There is a lack of results in the theory of the determinisation of nondeterministic pushdown automata, although such results would be usable, eg when constructing practical deterministic algorithms from nondeterministic pushdown automata.

Visibly pushdown automata [3] are an important and well motivated subclass of pushdown automata, where pushdown operations are determined by the input symbol: the input alphabet is partitioned into three parts $A_c$, $A_r$ and $A_l$ for push, pop and local pushdown operations, respectively. This relates to function calls, for example. A function call is represented by push operation, local operations executed in the context of the called function are represented by local transitions, and, finally, the return from the function is represented by pop operation. The push, pop and local operations are sometimes referred as call, return and internal operations. Visibly pushdown automata are widely used, researched and known to be used in many practical applications, such as XML processing for example [1], [2], [5], [6], [7], [11].

It is well known that nondeterministic visibly pushdown automata can be determinised [3], [12]. These determinisations use principles that are also used in the well-known determinisation of finite automata: states of the equivalent deterministic automata are represented by so-called deterministic subsets [8]. Alur and Madhusudan [3] presented the proof of the determinisability of a given nondeterministic visibly pushdown automaton with $n$ states by creating a cartesian product consisting of all possible states and then creating deterministic subsets, which resulted in $2^{n^2+n}$ states of the deterministic version of the pushdown automaton. This was improved in [12], where the upper bound for the number of states was lowered from $2^{n^2+n}$ to $2^{n^2}$ and the upper bound for the number of pushdown store symbols was lowered from $|A_c|2^{n^2+n}$ to $|A_c|2^{n^2}$.

In this paper a new algorithm of the determinisation of nondeterministic visibly pushdown automata is presented. The algorithm improves the existing methods and can result in significantly smaller deterministic pushdown automata in many practical examples. Only necessary and accessible states and pushdown symbols of the deterministic pushdown automaton are computed and constructed during the determinisation, which is done by analysing which states are used in transitions on the same level of the nesting of pushdown operations and which pushdown store symbols can appear at the top of the pushdown store for each state.

The paper is organized as follows. Section 2 defines basic notions. Section 3 contains information on related works. Section 4 presents the new incremental algorithm for visibly pushdown automata determinisation. An example of the use of the presented algorithm is presented in Section 5. Finally, the conclusion of the paper is in Section 6.

This research has been supported the Czech Science Foundation as project No. 13-03253S.

## II. Basic notions

Basic notions are defined as in standard texts, such as [8].

### A. Alphabet, string

An *alphabet* $A$ is a finite nonempty set of *symbols*.

A *string* $s$ is a sequence of $n$ symbols $a_1a_2a_3\dots a_n$ from a given alphabet, where $n$ is the length of the string. A sequence of zero symbols is called empty string. Empty string is denoted by symbol $\varepsilon$ and its length is 0.

### B. Language

$A^*$ denotes the set of all strings over an alphabet $A$ including the empty string. Set $A^+$ is defined as $A^+ = A^* \setminus \{\varepsilon\}$. A *language* $L$ over an alphabet $A$ is a set $L \in A^*$. Similarly, for string $x \in A^*$, symbol $x^m$, $m \geq 0$, denotes the $m$-fold concatenation of $x$ with $x^0 = \varepsilon$. Set $x^*$ is defined as $x^* = \{x^m : m \geq 0\}$ and $x^+ = x^* \setminus \{\varepsilon\} = \{x^m : m \geq 1\}$.

### C. Pushdown automata

A *nondeterministic pushdown automaton* (nondeterministic PDA) is a seven-tuple $M = (Q, A, G, \delta, q_0, Z_0, F)$, where $Q$ is a finite set of *states*, $A$ is an *input alphabet*, $G$ is a *pushdown store alphabet*, $\delta$ is a mapping from $Q \times (A \cup \{\varepsilon\}) \times G^*$ into a set of finite subsets of $Q \times G^*$, $q_0 \in Q$ is an initial state, $Z_0 \in G$ is the initial pushdown store symbol, and $F \subseteq Q$ is the set of final (accepting) states.

Triplet $(q, w, x) \in Q \times A^* \times G^*$ denotes the configuration of a pushdown automaton. Top of the pushdown store $x$ is written on its left hand side. The initial configuration of a pushdown automaton is a triple $(q_0, w, Z_0)$ for the input string $w \in A^*$.

The relation $\vdash_M \subset (Q \times A^* \times G^*) \times (Q \times A^* \times G^*)$ is a *transition* of a pushdown automaton $M$. It holds that $(q, aw, \alpha z) \vdash_M (p, w, \beta z)$ if $(p, \beta) \in \delta(q, a, \alpha)$, where $z, \alpha, \beta \in G^*$. The $k$-th power, transitive closure, and transitive and reflexive closure of the relation $\vdash_M$ is denoted $\vdash_M^k$, $\vdash_M^+$, $\vdash_M^*$, respectively.

A pushdown automaton $M$ is a *deterministic* pushdown automaton (deterministic PDA), if it holds:

$$\forall q \in Q, \forall a \in A, \forall z \in G, \delta(q, \varepsilon, z) = \emptyset : |\delta(q, a, z)| \leq 1,$$
$$\forall a \in A, |\delta(q, \varepsilon, z)| \geq 1 : \delta(q, a, z) = \emptyset.$$

### D. Visibly pushdown automata

Visibly pushdown automata are defined as in [3], [12].

Let $A = A_c \cup A_r \cup A_l$ be a partition of $A$. The intuition behind the partition is: $A_c$ is the finite set of call (push) symbols, $A_r$ is the finite set of return (pop) symbols, and $A_l$ is the finite set of local symbols.

A *visibly pushdown automaton (VPA)* $M$ over $A$ is a seven-tuple $(Q, A, G, \delta, Q_0, \perp, F)$, where $Q$ is a finite set of *states*, $A = A_c \cup A_r \cup A_l$, $G$ is a finite *pushdown store alphabet*, a special symbol $\perp \in G$ represents the bottom-of-pushdown-store, which can be popped from the pushdown store unlimited number of times, $\delta = \delta_c \cup \delta_r \cup \delta_i$ is the transition mapping, where $(Q, G \setminus \{\perp\}) \in \delta_c(Q, A_c, \varepsilon)$, $(Q, \varepsilon) \in \delta_r(Q, A_r, G)$, and $(Q, \varepsilon) \in \delta_i(Q, A_l, \varepsilon)$, $Q_0 \subseteq Q$ is a set of initial states, $\perp \in G$ is initial pushdown store symbol, and $F \subseteq Q$ is a set of final (accepting) states.

## III. Related works

Visibly pushdown automata were introduced in [3]. Moreover, it was shown that any nondeterministic visibly pushdown automaton can be transformed into an equivalent deterministic one. The determinisation principle is similar to the the determinisation principle of finite automata [8].

In [3], states of the resulting deterministic visibly pushdown automaton consist of two components $(S, R)$. Component $R \in \mathcal{P}(Q)$ is an element of powerset of the states of the original automaton. Component $S = \mathcal{P}(Q \times Q)$ is a powerset of pairs of states of the original nondeterministic pushdown automaton that keeps tracking beginning states on path from push transitions to all states listed in $R$ component. We note that, given the union of states in second parts of pairs in $S$ component is equal to $R$ component, the $R$ component can be omitted but for keeping the automata hierarchy simple we maintain this $R$ component in the following definition as a connection to finite automata [12], where the states of the determinized automata correspond to the $R$ component.

Let $M = (Q, A, G, \delta, Q_0, \perp, F)$ be a nondeterministic VPA. For $A = A_c \cup A_r \cup A_l$, an equivalent deterministic VPA $M' = (Q', A, G', \delta', q'_0, \perp, F')$ can be constructed as follows: $Q' = 2^{Q \times Q} \times 2^Q$, $q'_0 = (Id_{Q_0}, Q_0)$ where $Id_X = \{(x, x) | x \in Q\}$, $F' = \{(S, R) | R \cap F \neq \emptyset\}$, $G' = 2^{Q \times Q} \times 2^Q \times A_c \cup \{\perp\}$, the transition relation $\delta' = \delta'_l \cup \delta'_c \cup \delta'_r$ is given by:

Local: For every
$l \in A_l, ((S', R'), \varepsilon) \in \delta'_l((S, R), l, \varepsilon)$ where

$$\begin{aligned} S' = \quad & \{(q, q') | \exists q'' \in Q : (q, q'') \in S, \\ & (q', \varepsilon) \in \delta_l(q'', l, \varepsilon)\}, \\ R' = \quad & \{q' | \exists q \in R : (q', \varepsilon) \in \delta_l(q, l, \varepsilon)\}. \end{aligned}$$

Push: For every
$c \in A_c, ((Id_{R'}, R'), (S, R, c)) \in \delta'_c((S, R), c, \varepsilon)$ where

$$R' = \quad \{q' | \exists q \in R : (q', \gamma) \in \delta_c(q, c, \varepsilon)\}.$$

Pop: For every $r \in A_r$,

- if the pushdown store is empty : $((S', R'), \varepsilon) \in \delta'_r((S, R), r, \perp)$ where $S' = \{(q, q') | \exists q'' \in Q : (q, q'') \in S, (q', \varepsilon) \in \delta_r(q'', r, \perp)\}$ and $R' = \{q' | \exists q \in R : (q', \varepsilon) \in \delta_r(q, r, \perp)\}$.
- otherwise: $((S'', R''), \varepsilon) \in \delta_r((S, R), r, (S', R', c))$, where

$$\begin{cases} R'' & = & \{q' | \exists q \in R' : (q, q') \in U\}, \\ S'' & = & \{(q, q') | \exists q_3 \in Q : (q, q_3) \in S', (q_3, q') \in U\}, \\ U & = & \{(q, q') | \exists q_1 \in Q, q_2 \in R : (q_1, q_2) \in S, \\ & & (q_1, \gamma) \in \delta_c(q, c, \varepsilon), \\ & & (q', \varepsilon) \in \delta_r(q_2, r, \gamma)\}. \end{cases}$$

The equivalent deterministic automaton has at most $2^{n^2+n}$ states and at most $|A_c|2^{n^2+n}$ pushdown store symbols. The size of the transition relation can be at most $|A_l|\left(2^{n^2+n}\right)^2 + |A_c|\left(2^{n^2+n}\right)^3 + |A_r||A_c|\left(2^{n^2+n}\right)^3$.

In 2009 an improved upper bound of the number of states has been found by Nguyen Van Tang [12]. In that paper two optimizations for Alur-Madhusudan's determinisation of visibly pushdown automata were introduced. First, the set of summaries $S$ component of a state pair for some special cases concerning initial states was minimized. Second, $R$ component of the state pair was removed. By removing $R$ component of determinised visibly pushdown automaton the upper bound for the number of states was lowered from $2^{n^2+n}$ to $2^{n^2}$ and there were at most $|A_c|2^{n^2}$ pushdown store symbols. The optimization is based on the observation that information stored in $R$ component of a state pair is already contained in $S$ component of the state pair [12]. However, that determinisation algorithm is still not practical. As pointed by Nguyen Van Tang in its implementation of visibly pushdown automata determinisation library, named VPAlib, the determinisation was performed in an exhaustive way. Therefore, their determinisation easily gets stuck with visibly pushdown automata of small size [12].

## IV. Determinisation algorithm

This section presents our new algorithm for the determinisation of nondeterministic visibly pushdown automata. The algorithm improves the original determinisation algorithm [3], [12]. As stated in the Introduction our algorithm computes and constructs only necessary and accessible states and pushdown symbols of the deterministic pushdown automaton. The basic idea of this improvement is analysing and tracking pushdown symbols that can appear on the top of the pushdown store for a particular state. With this information the explored pop transitions for the state can be reduced to only those that correspond to the possible pushdown store top symbols. Also, it is shown below that this information on the possible pushdown store top symbols for a state has certain interesting properties, which can be exploited for an effective way of calculation and storing this information for all states in the automaton.

We will use $\mathcal{T}_q$ to denote pushdown store top symbols. The *pushdown store top symbols* of state $q$, $\mathcal{T}_q \subseteq G'$ are the set of all pushdown store symbols that could appear at the top of the pushdown store for a state $q \in Q'$.

We will also use symbol $\lambda$ for a local connection: State $q'$ is locally connected to $q''$ if there is a sequence of transitions from state $q''$ to state $q'$, the pushdown store depth in both states is the same and the pushdown store depth for all other states along the sequence of transitions is greater than the pushdown store depth in $q''$. This relation between two states is not symmetric but is transitive. See Figure 1 shows an example of various local connections. Note that for example the path $1 \rightarrow 7 \rightarrow 8$ is not a local connection. The notation $a|\alpha \mapsto \beta$ denotes a transition that reads symbol $a \in A$ and replaces $\alpha \in G'^*$ with $\beta \in G'^*$ on the top of the pushdown store. This notation will be used in figures throughout the paper.

It can be easily seen that the pushdown store top symbols are shared between locally connected states.

With local connection from $q'$ to $q$ and local connection from $q$ to $q''$, the $q'$ is locally connected to $q''$ by transitive closure. If $\mathcal{T}_q$ is the set of pushdown store top symbols of state $q$, then $\mathcal{T}_{q'} \subseteq T_q$ and $\mathcal{T}_q \subseteq \mathcal{T}_{q''}$ and also $\mathcal{T}_{q'} \subseteq \mathcal{T}_{q''}$.

The local closure of state $q$ is $\lambda^*(q)$. See Figure 2 as an example of a local closure. See Figure 1 and note that the path $1 \rightarrow 7 \rightarrow 8$ mentioned before is in fact a local closure.

Closing all states under the $\lambda^*(q)$ connects all $\mathcal{T}_q$. See Figure 3.

We define these notions formally:

*Definition 1:* A local connection $\lambda(q)$ of state $q$. Given a deterministic visibly pushdown automaton $M' = (Q', A, G', \delta', q'_0, \bot, F')$, where $A = A_c \cup A_r \cup A_l$, states $q, q' \in Q'$, then $\lambda(q) = \{q' : (q, uw, \gamma_0) \vdash^k (q', w, \gamma_k), u \in A^*, w \in A^*, \gamma_0, \gamma_k \in G'^*, 1 \leq k, |\gamma_0| = |\gamma_k|, |\gamma_0| < |\gamma_i|, 1 \leq i < k\}$.

*Definition 2:* A local connection closure $\lambda^*(q)$ of state $q$. The local connection closure $\lambda^*$ is defined by these equalities:

$$\lambda^0(q) = q, \tag{1}$$

$$\lambda^{i+1}(q) = \bigcup_{\forall q' \in \lambda^i(q)} \lambda(q'), \tag{2}$$

$$\lambda^*(q) = \bigcup_{i \geq 0} \lambda^i(q). \tag{3}$$

*Definition 3:* A set of pushdown store top symbols $\mathcal{T}_q$ of state $q$. Given a deterministic visibly pushdown automaton $M' = (Q', A, G', \delta', q'_0, \bot, F')$, where $A = A_c \cup A_r \cup A_l$, states $q, q', q'' \in Q'$, then $T_q = \{g : (q', g) \in \delta(q'', c, \varepsilon), c \in A_c, g \in G', q' \in \lambda^*(q)\}$.

Due to convenient properties of $\lambda^*(q)$, $\mathcal{T}_q$ can be stored in a space optimal way. Given $q, q' \in Q'$, then $\forall q' \in \lambda^*(q)$ holds that $\mathcal{T}_{q'} \subseteq \mathcal{T}_q$, ie parts of $T_q$ can be shared between locally connected and locally closed states. See Figure 4 as an example of this process.

Further, we show by induction on the length of an input sentence that pushdown store top symbols are given by the $\lambda^*(q)$ and states that are source and target of the appropriate push and pop transition.

Step one:

$$\varepsilon : \bot \in \mathcal{T}_{q'_0}. \tag{4}$$

Then, assume that pushdown store top symbols are given by the local closure for first $i$ symbols of input word. Symbol $a$ is a $(i+1)$-th symbol of input word. Given $q_1, q_2, q_3, s_1, s_2, s_3 \in Q', a \in A_c$, then we have three distinct cases:

$$\lambda(r_1) = \{q_1 : (q_1, aw, \gamma) \vdash (r_1, w, \gamma)\}, \tag{5}$$

$$\mathcal{T}_{r_2} = \{(q_2, a) : (q_2, aw, \gamma) \vdash (r_2, w, (q_2, a)\gamma)\}, \tag{6}$$

$$\lambda(r_3) = \{q_2 : (q_3, aw, (q_2, a)\gamma) \vdash (r_3, w, \gamma)\}. \tag{7}$$

Notice that $\gamma$ does not change between states $q_1$ and $r_1$. Pushdown store top symbol $(q_2, s)$ was pushed in state $q_2$ and popped in state $q_3$ so $\gamma$ does not change between states $q_2$ and $r_3$ either. Pushdown store top symbols are given by the $\lambda^*(q)$ and states that are source and target of appropriate push and pop transition for first $i+1$ symbols of input word. The induction holds for $i+1$.

More informally: The deterministic automaton is constructed from the initial state. The deterministic subset of the

initial state is created from all initial states of the original automaton. Initial pushdown store symbol $\bot \in \mathcal{T}_{q'_0}$ forms the pushdown store top symbols set.

In every iteration, all local and push transitions are explored for the known states. Base set of possible pushdown store top symbols $\mathcal{T}_q$ of the pushdown store for given state $q \in Q'$ is given by push transitions. Then, we track pushdown store top symbols for each state.

Any two states $q$, $q'$, where a local transition exists from state $q'$ to state $q$, share part of $\mathcal{T}_{q'}$ in form of that everything from $\mathcal{T}_{q'}$ is in $\mathcal{T}_q$.

Any two states $q$, $q'$, where a pop transition popping symbol $(q', r)$ exists from state $x$ to state $q$, share part of $\mathcal{T}_{q'}$ in form of that everything from $\mathcal{T}_{q'}$ is in $\mathcal{T}_q$. Given $q, q', q'' \in Q', l \in A_l, c \in A_c, r \in A_r$, then for $\mathcal{T}$ the following properties hold:

$$\bot \in \mathcal{T}_{q'_0}, \tag{8}$$

$$\forall (q, \varepsilon) \in \delta(q', l, \varepsilon) \Rightarrow \mathcal{T}_{q'} \subseteq \mathcal{T}_q, \tag{9}$$

$$\forall (q, \varepsilon) \in \delta(q'', r, (q', c)) \Rightarrow \mathcal{T}_{q'} \subseteq \mathcal{T}_q, \tag{10}$$

$$\forall (q, (q'', c)) \in \delta(q'', c, \varepsilon) \Rightarrow (q'', c) \subseteq \mathcal{T}_q. \tag{11}$$

The algorithm of the determinisation is formally described by Algorithm 1. Given $q, q'' \in Q'$, its main part can be written in an abstract way as follows:

Fig. 4. Connecting $T_q$ between locally connected states.

1) create the initial state,
2) while $\nexists(q', \varepsilon) \in \delta(q, r, \gamma)$, where $r \in A_r$ and $\gamma \in \mathcal{T}_q$, do create pop transition $(q, r, \gamma)$,
   while $\nexists(q', \varepsilon) \in \delta(q, l, \varepsilon)$, where $l \in A_l$, do create local transition $(q, l, \varepsilon)$,
   while $\nexists(q', \gamma) \in \delta(q, c, \varepsilon)$, where $c \in A_c$, do create push transition $(q, c, \varepsilon)$,
3) set final states.

Only a pair of states $(q', q)$, where $q' \in \lambda^*(q)$, can appear as an element in $S$ component. As it is described in II, the new pairs of $S$ component are only created from push and local transitions. The push transitions only yield elements of $S$ component based on identity. On the other hand, the local transitions yield exactly the pairs that conform to local closure, because they connect appropriate targets of push and sources of pop operations.

Let $L$ be the set of all distinct pairs of locally closed states of the nondeterministic automaton. Then, $2^{|L|}$ is the maximum number of states of the deterministic automaton. The $|L|$ is at most $n^2$ when all states in the nondeterministic automaton are locally closed.

## V. Example

In this section the determinisation of a simple nondeterministic visibly pushdown automaton is demonstrated. For the sake of clarity, the component $R$ of states and pushdown store symbols is omitted, because the information it holds is already contained in the component $S$ (it is the second value of each pair), as it was described in [12].

*Example 5.1:* The nonderterministic visibly pushdown automaton $a_1$ is shown in Figure 6.

Let $a_1 = (Q, A_c \cup A_r \cup A_l, G, \delta, Q_0, \bot, F)$ be a nondeterministic visibly pushdown automaton. An equivalent deterministic visibly pushdown automaton $d_1 = (Q', A_c \cup A_r \cup A_l, G', \delta', q_0', \bot, F')$ can be constructed as follows.

The initial state is constructed as powerset of all identity pairs of initial states of automaton $a_1$, so $q_0' = \{(0, 0)\}$.

The push and the local transitions can be easily deduced from determinisation rules from Section IV. All transitions are shown in Figure 5.

In each push transition, the pushdown store top symbol is tracked for target state of the push transition. When a local transition occurs, all pushdown store top symbols are shared from a source state of the local transition to a target state of the local transition and all other locally connected states. The tracking of all locally connected states could be achieved by creating virtual transitions serving as a transitive closure.

Then, the pop transitions are created based on known input symbols (from the nondeterministic automaton) and tracked pushdown store top symbols. The transitions are created according to the determinisation rules from Section IV.

For an illustration of the determinisation see Figure 5. The pushdown store top symbols are tracked as follows. Push, local and pop transitions are marked green, gray and red, respectively. Arrows describe movements of tracked tops of the pushdown store. Dashed arrows represents source of top pushdown store symbols that are shared with target state when local transition occur.

The resultant deterministic PDA $d_1$ is shown in Figure 7.

The resultant deterministic PDA can be also reproduced by running Algorithm 1.

Given the nondeterministic pushdown automaton from the example above, the VPAlib algorithm [9] constructs a deterministic pushdown automaton with 45 states and 1206 transitions. We note that 45 (states) is not a power of 2, which is caused by the fact that the implementation of VPAlib library does not consider states in which components $R$ or $S$ are empty sets (in this way, it performs another optimization of the determinisation algorithm [12]). For comparison, our algorithm constructs an equivalent deterministic pushdown automaton with only 3 states and 8 transitions. This is a significant improvement over the previously existing determinisation algorithms.

## VI. Conclusion

A new incremental algorithm of the determinisation of nondeterministic visibly pushdown automata has been described. The algorithm creates only necessary states and pushdown symbols by analysing and tracking which states are achievable by computing transitions on the same levels of pushdown operations nesting. Possible tops of the pushdown store are stored for each state when a pop transition is in progress and then they are shared through local transitions with states on the same levels of the nesting. The behavior of the algorithm

is inspired by the behavior of the incremental construction of the deterministic finite automaton.

The algorithm has been implemented as a part of an experimental automata library [13].

Although the number of states of the deterministic automaton for the worst case is still $2^{n^2}$ for a given nondeterministic visibly pushdown automaton with $n$ states, it has been shown that the upper bound of the number of states of the deterministic automaton is dependant on the number of distinct pairs of locally connected states. For those and other reasons in many practical cases our algorithm provides significantly smaller deterministic automata than the previously existing determinisation algorithms.

Furthermore, a similar approach can be adapted for the determinisation of Height-deterministic pushdown automata [10].

Further information can be found on [4].

Technical University of Košice
Letná 9, 0420 00 Košice, Slovakia
Email: {jan.juhar, liberios.vokorokos}@tuke.sk

***Abstract*—The term Projectional editor is commonly used for tools that can work directly with the program's abstract syntax tree. They are able to provide different views of the program, according to the specific editor used. The ability to look at the program from multiple views is often requested as a mean to simplify program comprehension. During their evolution, the Integrated Development Environments were equipped with tools that provide such possibilities. Many of them already work with the parsed abstract syntax tree of the code and thus can be considered for projections. In this paper we review projections available in 6 widely used IDEs. The review categorizes existing projections and shows that significant number of IDE tools depend on the knowledge of program structure, but also that data from other integrated tools are used to enhance the projections.**

## I. Introduction

THE ability to evolve a software system depends on the programmer's ability to comprehend its source code. The source code comprehension (also program comprehension) is a cognitive process that involves analysis of the source code and retrieval of information and knowledge about the analyzed system. This process tends to take up to a half of a programmer's time during the software development and maintenance [1], [2].

The main hindrance that programmers face while comprehending the source code is the wide semantic gap that exists between the problem domain and the solution domain. Due to this gap, the mapping of a specific program feature to the code that implements this feature (or vice versa) is not straightforward. Factors like programmer's personality, experiences and skills, combined with the nature of the task at hand have a strong influence on this process [2]. Program represented as a source code enforces the single structure chosen by its author onto all programmers that will work with it later, regardless of whether they will intend to reuse, extend or modify it. This is the reason why the tools that are able to provide different, context-driven views of the code are requested during the comprehension process [3].

The goal to aid programmers in the program comprehension process stands behind many tools. The Integrated Development Environments (IDEs) represent the most complex toolset for working with a source code. The ultimate purpose of an IDE and all of its tools is to cover all phases of the software life cycle and to increase the productivity of programmers. For this reason, an IDE typically contains code editors, browsers and analyzers, refactoring and build automation tools, debuggers, and other tools. The research on the comprehension strategies of professional programmers by Maalej et al. [2] points out the importance of integrated environments: comprehension tools that are not a part of the IDEs are virtually not used at all in the practice.

The main advantage modern IDEs have over pure text editors (even the advanced ones) is that they can "understand" the structure of the source code. After loading the source code contained in text files, they parse it into an abstract representation of the code – a form of its abstract syntax tree (AST). Many operations that IDE performs, e.g., refactoring or contextual code completion, are performed against this AST [4]. Whenever the code or the AST changes, the other is accordingly updated to stay in sync.

There are IDEs that take this idea to the next level and use an AST as a base program representation. The program is stored in the files as a serialized form of this AST, e.g., using XML notation. After loading such file into the editor, a *projection* of this base representation is presented to the programmer. There is no need for parsing and when the programmer is editing the program, he or she is basically directly editing the AST [5]. Such base representation abstracted from concrete language notation can be presented through projections in multiple forms and consequently the notation that programmer deals with can be tailored to best suit a particular domain. Editors of such IDEs are therefore called *projectional editors* [4], [5]. The most notable example of such IDE is the JetBrains Meta Programming System (MPS) which is used not only to develop programs in domain specific languages, but also to create these languages along with the appropriate language notations and editors.

In the case of MPS-like tools the idea of projections is well-defined. It is the core of their functionality. As we already hinted, modern source-based IDEs also operate on the abstract representation of the code, even though it needs to be parsed from the textual notation and it exists only during code editing. Yet, this gives an opportunity to exploit the idea of projections even by these IDEs.

We believe that source code projections are used by source-based IDEs on a large scale. However, the term *projection* is not well established in their context. This may be the reason why tools that use them are seldom recognized or referred to

978-83-60810-66-8/$25.00©2015, IEEE

as projectional. Our goal in this paper is to identify, review and categorize projections that are used by popular IDEs.

## II. Integrated Development Environments and Projections

There are many tools that programmers can use during development for code editing. They range from pure text editors that provide the basic text manipulation operations, through the advanced ones that add support for syntax highlighting or word completion, to fully featured IDEs with all the tools mentioned in the previous section. However, there is no generally recognized definition of what exactly is an IDE. Due to a great number of existing tools and an effort to differentiate themselves, there is no clear boundary between what is still "only" a text editor and what is already an IDE.

For our purposes, we have already laid out some requirements on what we consider for an IDE, mostly with regard to projections we want to explore. We will understand an integrated development environment as an application that is designed to support the majority of the software development life cycle – that is, at least the implementation, testing and maintenance phases – by providing an environment for programmers that includes tools for the associated tasks. In addition, we will require that the included tools (not necessarily all of them) are able to take advantage of the program structure – they should operate on the abstract representation of the source code.

As for the term *projection*, in the context of the MPS-like projectional editors it is used to represent an interactive, customizable rendering of the AST [5]. This can be true even for the source-based IDEs that operate on a parsed AST, though possibilities are limited here by the need to preserve parsability of the base source code. Through projections, source code can be conveyed in multiple views. The source code projections can be thus considered for a mapping between a set of base source code structures and a set of dynamically created views [6]. Such views usually focus on some aspect of the system and convey it in a concise way. Different projections can be useful in different contexts, but generally they can have positive effects on program comprehension by providing a higher-level view of the system.

## III. A Review of Source Code Projections

In order to select which IDEs will be used for the review of existing code projections, we referred to their popularity ranking *Top IDE Index*[1] that was compiled from Google search trends as of April, 2015. We focused on the first ten ranks of the index, as listed in the table I.

However, the criteria according to which the tools were added to the index were less strict than our understanding of an IDE. As a result, the index also contains tools like Vim, Emacs and SublimeText. Although these are very flexible and extensible tools for programming, we consider them for code editors, because they work with the source code only at the textual level. Thus, these were ruled out of the review. Additionally, we had to exclude XCode as it is available only for Apple Mac platform, to which we did not have access. Six remaining IDEs marked in the "reviewed" column of the Table I were used in the following review of existing projections. The reviewed versions of used IDEs are also listed in the table.

TABLE I
Selection of IDEs for the review

| Rank[1] | Name | Category | Reviewed | Version |
|---|---|---|---|---|
| 1 | Eclipse | IDE | ✓ | 4.4.2 |
| 2 | Visual Studio | IDE | ✓ | 2013 Ultimate |
| 3 | Vim | Editor | – | – |
| 4 | NetBeans | IDE | ✓ | 8.0.2 |
| 5 | XCode | IDE | – (n/a) | – |
| 6 | SublimeText | Editor | – | – |
| 7 | Komodo | IDE | ✓ | 9.0 |
| 8 | IntelliJ IDEA | IDE | ✓ | 14.1 |
| 9 | Emacs | Editor | – | – |
| 10 | Xamarin | IDE | ✓ | 5.9 |

The review of projections was conducted by evaluating features of main application menu and code editor of each selected IDE for projectional properties. Within the single IDE, the features were checked for multiple languages and project types.

Four categories of projections were identified. In the following subsections we describe these categories and list the relevant projections along with their requirements.

### A. In-editor Projections

The code editor is a very significant part of each IDE. It was already mentioned that it projects editable representation of the AST constructed by parsing the source code. Of course, this projection will work only for languages that are supported by the IDE. Code editor displays the loaded file with exactly the same content as persisted on the storage medium. The projectional properties manifest themselves in the additional features that augment the text, and these are reviewed below.

The first is the *code highlighting*. It is able to convey information not only about the code syntax (e.g., by highlighting the keywords of the language), but also about its structure. It takes into account the scope of the variables – it distinguishes between local and global ones even if they have the same name. Furthermore, it can highlight all occurrences of the same program element (see fig. 1), identify unused statements and more. This is where the structural information provided by the parsed AST are exploited. However, the level to which the IDE is capable of these features depends on the detailness of the parsed AST and also on the language properties. The more a language has "dynamic"[2] properties, the less complete (or reliable) knowledge about actual program structure during

[1] http://pypl.github.io/IDE.html, accessed April 2015

[2] Dynamic languages are mostly defined by support for dynamic typing or powerful reflection that allows extensive run-time modifications of a program behavior.

runtime can be obtained from the static structure of the AST. These properties have influence on all projections that utilize the AST.

A related projection is the *error highlighting*, which brings another informational layer to the code editor. The simplest to detect are syntax errors. Strongly-typed languages can benefit from possibility to check type assignment and visualize the errors.

Another common in-editor projection is the *code completion*, visualized as a pop-up list of available program elements in the specific context. Yet again, the knowledge of structural relations of elements in the edited source code is required for realization of this feature and the level of list completeness depends on the AST detailness and language properties.

Apart from above described in-editor projections that are available in every selected IDE, there are some that exist only in one of them. IntelliJ IDEA is able to project method or class implementation in the pop-up window over the selected class or method name with action called *Quick Definition* (see fig. 1). It is a different form of the *go to definition* projection (described in section III-C) that causes less navigational overhead, as the pop-up can be easily closed and user does not need to switch to other editor tab or window. The projected code is, however, not editable. Visual Studio provides feature called *Peek definition*, which creates a projection with similar purpose. This one is inserted directly in-line within the editor, as can be seen in fig. 2, and is fully editable. The use of this projection recursively inside the in-lined view replaces the whole view and adds so-called “breadcrumbs” for switching among the already opened views.

Source code in the editor can be further augmented by metadata available in the AST. To give an example, the presence of documentation annotation `@deprecated` in a Java code can be projected by crossing out any usage of the annotated element in the editor to visually warn the programmer about usage of a deprecated API.

In-editor projections are also used to project information not obtained from the AST. While running the debugging session, the IntelliJ IDEA projects the actual values of the variables next to their occurrences in the code editor as the user steps through the program execution. *CodeLens*, a feature of Visual Studio, decorates declarations of methods with a reference counter, as displayed in fig. 2. In addition to this, it can show a unit tests passing score and a code changes history, if the data are available. Only the reference counter value can be obtained by analyzing the AST of the program. The later two pull required data from the integrated test runner and version control system, respectively.

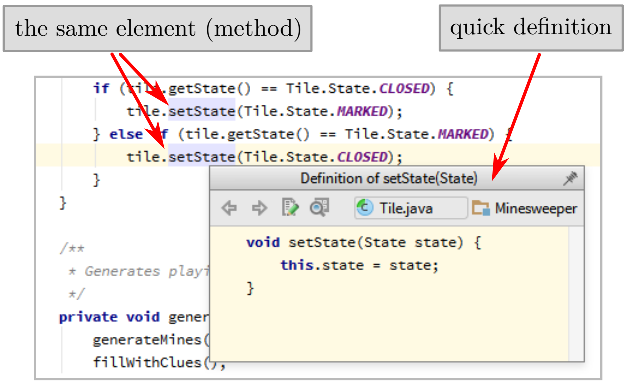
### B. Structure Projections

Each of the selected IDEs contains tools that provide overview of the project structure. The most basic one – the file browser – can be considered for an *identity* projection of the project’s files, with exactly the same structure as stored on a storage medium.

With the exception of the Komodo IDE, the selected IDEs contain panels that show hierarchical, tree-like project structure according to packages, namespaces, modules, classes, or other structural elements of the programs. These high-level views of the program structure are augmented with graphical symbols, informing the user about the visibility of the structural elements or distinguishing their type (class, abstract class, interface, and others).

The view of the same tool in a particular IDE differs depending on the used language or the project type. For example, in IntelliJ IDEA, *Project* panel shows more detailed structure in the case of Java files than, say, Python or JavaScript files. When working on a web project in the NetBeans IDE, the *Projects* panel extends the tree structure to include even the remote files that are linked from inside of the HTML pages.

Individual IDEs also differ in the level of the details displayed by these tools. Particularly detailed is the Package Explorer of Java projects that is available in the Eclipse IDE. As shown in fig. 4, it goes down to the level of individual class members and also provides their signature. At the file level the view is further extended with repository information of the latest edit. Another tool that goes deeper into the program structure is the *Architecture Explorer* in Visual Studio. In addition to listing the class members, it can recursively show



```
    if (tile.getState() == Tile.State.CLOSED) {
        tile.setState(Tile.State.MARKED);
    } else if (tile.getState() == Tile.State.MARKED) {
        tile.setState(Tile.State.CLOSED);
    }
}

/**
 * Generates playi
 */
private void gener
    generateMines(
    fillWithClues();
```

```
void setState(State state) {
    this.state = state;
}
```

    ApplyFilter(false);
```

```
        private void ApplyFilter(bool preview)
        {
            if (previewBitmap == null || cmbEdgeDetection.SelectedIndex =
            {
                return;
```

Fig. 2. *codeLens* and *peek definition* in Visual Studio all the methods called inside the implementation of a particular method. Moreover, it allows to create a graph that represents the selected call hierarchy.

Apart from tools projecting structure of the whole projects, all selected IDEs contain more focused tools that display detailed structure of the file currently viewed in the editor. This is intended to speed-up the navigation inside a single file. A related to this projection is the *breadcrumbs* panel that shows context of the currently edited part of the file based on the position of the caret in the editor. Eclipse and IntelliJ IDEA contain also projections that can display *type hierarchy* of classes and *call hierarchy* of methods.

### C. Search and Go-to Projections

The next group of projections relate to searching for specific program elements across the project. The simple text-based search is by the IDEs extended to take into account the source code structure. This helps to connect related elements and distinguish between the different elements represented with the same name (the same text).

One of the tools providing this kind of projection is used to search for all references of the same program element. This tool is called differently in each IDE, with names like *find usages* or *find all references*. It is useful for quick navigation and for discovering code dependencies. Another related tool deals with the comments. It displays all code locations where comment starts with the word "todo", or other configured pattern, which makes possible to track tasks across the project (see fig. 4).

Similar are tools for quick navigation between different program element occurrences and within the inheritance hierarchy. These include tools with self-explanatory names like *go to declaration*, *go to implementation*, *go to super implementation* and *go to type declaration*. If they can navigate to only one place in the source code, there is no "view" created and the action implied by the tool's name is immediately performed.

### D. Domain-specific Projections

The projections reviewed so far drew the required information for their construction from the parsed AST. Many general-purpose IDEs (in our case Eclipse, IntelliJ IDEA, NetBeans and Visual Studio) have support for a number of software frameworks. And there are IDEs that are built specifically to support some frameworks (e.g., Xamarin for mobile application development). These IDEs take advantage of common application structures, conventional configurations and domain-specific APIs in order to simplify development of applications with supported frameworks. As a result, code projections that support specific framework features were found in the reviewed tools as well.

Fig. 4. TODO tasks in Eclipse

Applications that use a particular framework have (to some extent) common structure and this is exploited by these IDEs. Based on the known structure, program element across different languages can be interconnected. Web applications created with the Spring or Play frameworks in IntelliJ IDEA or with ASP.Net framework in Visual Studio can have code completion working for dynamic segments of page templates because the IDE "knows" which program element represents the context of the template.

An example of a projection based on a framework configuration is the ability of IntelliJ IDEA to view and edit classes annotated with the Java Persistence API's annotations in the form of entity relationship diagram.

The common example of domain-specific projection among the reviewed Java-supporting IDEs – Eclipse, IntelliJ IDEA and NetBeans – is the graphical user interface builder for the Swing framework. Eclipse can project class inheriting from one of the Swing window components directly to its graphical representation and any edits made in this graphical view are reflected back to the code. To achieve the same functionality, IntelliJ IDEA and NetBeans use intermediary XML file that represents the layout of user interface components. Graphical representation is the result of projecting this XML file. In the other direction, the source code is generated from the XML. IntelliJ IDEA by default postpones this code generation to the compile time, while NetBeans updates code on each change of the design. Similar projections are available also in Visual Studio for Windows Forms framework and in the Xamarin IDE for creating graphical layouts for mobile applications. All these projections require the IDE to "understand" the API of the particular framework.

## IV. Projectional Tools in the Research

The research in the area of projectional tools is mostly associated with the tools like the already mentioned JetBrains

MPS. In their work [5], [7], Voelter et al. focus primarily on this language workbench. They discuss the concept of projections and possibilities they brig to the domain-specific language development, but also the associated issues of direct AST manipulation. They also deal with projections in the context of composition and extension of programming languages.

There is an ongoing endeavor in the research community to create tools that supports program comprehension. Few of those are generally viewed as projectional tools. However, many of the tools are implemented as IDE extensions and have projectional properties similar to those we described in the review.

Among these tools, the *Fluid source code views* [8] tool implemented for the Eclipse IDE is similar to the *peek definition* feature of Visual Studio that was reviewed in this paper. *Registration-based abstractions* presented by Davis et al. [9] are another example of IDE projections – in this case they change language syntax in the Eclipse IDE editor to achieve easier comprehension of frequently used coding patterns.

Another type of tools deal with the program concerns. The *Sieve Source Code Editor* [10] for the NetBeans IDE uses the structured code comments to create concern-oriented views of the source code. The *Code Bubbles* [11] and the *Code Canvas* [12] are alternative code editors for the Eclipse and Visual Studio IDEs, respectively. These provide projections of the source code that are abstracted from traditional file-based views and allow programmers to create free-form arrangements of the code they are working with.

## V. Concluding Remarks

In this paper we presented a review of code projections that are available in today's integrated development environments. We identified four main categories of the tools that feature projectional behavior.

The *in-editor* projections enhance the textual notation of the source code with code highlighting or completion. The *structure* projections are available as a separate panels that create views of the system concentrated on its structure, providing thus higher-level view that is easier to grasp than the full source code with all of its details. The *search and go-to* projections are provided by the tools for searching the related program elements or navigating the class hierarchies. In the most cases, these three categories require for their functionality a knowledge that can be extracted from abstract syntax tree analysis. We found also projections that use other information sources, exploiting advantages of the tools that are available in the integrated environments. There are data projected from debuggers, version control systems or test runners. The last category contains *domain-specific* projections that rely on conventions of supported frameworks, such as common application structures and APIs designed for a particular domain. As a result, they can provide code completion across languages, project annotated classes as relational diagrams or enable graphical builders of user interfaces.

We have shown in the review that the projections are not only a matter of projectional language workbenches as they are extensively used in many aspects of modern source-based integrated development environments. Their infrastructure is well-prepared for such functionality, which is also exploited by many research tools that are implemented as extensions of these IDEs. And as the MPS is approaching the usability of the standard source-based editing [5], the distinction between the AST-based and the source-based editors is becoming less apparent.

## Acknowledgment

This work was supported by the project KEGA 008TUKE-4/2013 and by the Slovak Research and Development Agency under the contract No. APVV-0008-10.

# Profile-driven Source Code Exploration

Emília Pietriková, Sergej Chodarev
Technical University of Košice, Department of Computers and Informatics
Letná 9, 04200 Košice, Slovak Republic
Email: {emilia.pietrikova, sergej.chodarev}@tuke.sk

***Abstract*—The following study deals with static analysis of Java source codes and it is dedicated to those readers who are interested in techniques aiming at evaluation of programming abilities of job candidates or students. In our case, the goal of the static analysis is to assemble the most significant and interesting data about source code author (programmer). If properly visualized, such assembled data may form programmer's profile which, to impartial observer, may further determine author's real programming abilities and his/her habits, both good and the bad ones. The present study represents first experiments attempting to form programmer's profile by static analysis of language element frequency. Conclusion offers a broader view, combining also other techniques as a future plan to generate knowledge profiles more precisely.**

## I. Introduction

KNOWLEDGE, skills and their level are often the focus of attention in many disciplines. In order to be successful, people are often compared with each other. In the area of programming it is similar, however, the range of skills-tracking possibilities is quite limited. In the following study, we present early stages of profile-driven source code analysis where our interest is focused on source code exploration with the intention of knowledge profile generation. Such a profile represents an objective evaluation of current knowledge and skills, individual progress compared to the past, or possible deficiencies to be addressed.

Knowledge profile may be beneficial for both beginners and experienced programmers as well as for lecturers. Profiles can be helpful during overall student assessment, moreover, they can be used when identifying course drawbacks towards improvement of the course. In labor market, job candidates may find programming profile generators beneficial as well. That is, this study is dedicated to those researchers who deal with source code analysis, focusing on author of the code.

There exists a large variety of automated tools dedicated to source code analysis. These tools deal with code from various perspectives, e.g. security evaluation, quality, design etc. Outputs of such tools mostly include reports reflecting various metrics, graphs or warnings. They, however, do not collect a profile of the programmer knowledge [1], [2]. More from the related work can be found in Section V.

In this study, our intention is to generate a programming knowledge profile from source code with a possibility of its comparison with different profiles. This includes comparison of the current profile with a profile which was actual in the past. This way, the profile report may point out author's progress. Profiles of the group of programmers can be compared with each other to reveal possible differences in their knowledge. It should be also possible to compare a personal profile to some explicitly defined knowledge level (e.g. needed to fulfill specific task). We consider tracking and comparing source code in the form of summarizing profiles as a contribution to a new view of knowledge, to a better analysis and filtration of irrelevant data. Yet, to our best knowledge, such a profile-driven tool has not been developed.

In the following sections, we describe the concept of knowledge profiles (Section II) and we introduce an initial prototype proposed and developed as a source code exploring tool (Section III). This tool operates on the basis of static analysis and it represents a partial solution of the presented task. The tool works with Java language constructs and it visualizes knowledge profiles based on various statistics and metrics. We discuss results generated by the tool on a medium-sized project as well as on a large project (Section IV).

## II. Knowledge profiles

In general, we understand knowledge profile as a description of knowledge and bindings between its elements necessary to handle a specific task.

In our study, we focus on knowledge profiles in an area where it is possible to formally define such a profile and to construct it automatically from particular input artifacts. Primarily, we deal with an area of programming where the artifacts are represented by source code and a profile is formally defined over a language in which the source code is created. We distinguish two types of profiles: subject and object profile.

*Subject profile* represents an expression of what the subject (author of the code) knows, how deep is his/her knowledge, what kind of issues is the subject capable to solve. In programming, this means that the subject (programmer) knows, for example, how to use `if` command, how to call or declare a function, how to use generic programming [3]. That is, the subject profile represents the range of tasks actually solvable by the programmer.

*Object profile* represents a profile of knowledge necessary to handle a specific task (or tasks) over some object. A programming book may define knowledge profile of prerequisites, i.e. what any reader should know before reading the book in order to understand its contents. There can even be a differential object profile determining what is the reader supposed to learn (know after understanding the book contents). Such a differential profile can be determined for each book chapter

978-83-60810-66-8/$25.00©2015, IEEE

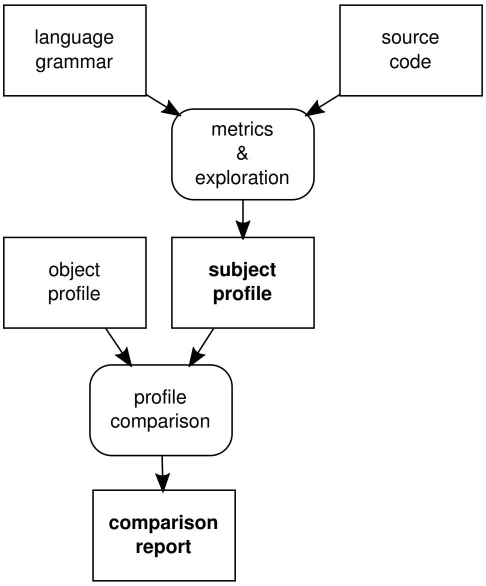

Fig. 1. Simplified knowledge profile generator scheme

as well. That is, the object profile represents the range of tasks which are supposed to be known by the programmer (but the actual state may be different).

The profile should allow to verify whether a specific programmer has sufficient knowledge to solve a task. Moreover, it should identify missing knowledge. For this reason, the profile needs to be structured. Such an assumption is supported by the fact that each programming task or its solution are structured as well [4]. In other words, if an actual (incomplete) task solution is structured than it is possible to assume that the same or similar knowledge, which has already been applied, will be necessary to complete the task.

In an early stage of our research the profile prototype is represented by a simple table, later we assume its transformation to a tree or a graph with annotated nodes or edges [5].

### *A. Profile Construction*

A profile can be constructed manually, however, an important part of our research is to generate profiles automatically from artifacts (source code). That is, one profile is supposed to be constructed after processing a finite number of source code files through their analysis. This way it is possible to generate an object profile and also a subject profile provided source code created by the subject is available. For experimental purposes, object profiles may be created manually. In order to construct a subject profile, it is necessary to analyze source code synthesized (created) by the subject.

The idea is depicted using the scheme in Fig. 1. The object profile is optional, so it does not have to be necessarily present. However, language and source code are compulsory. Without these two artifacts, subject profile cannot be generated. If both subject and object profiles are present, a comparison profile can be generated. Such a profile can be bind to a specific task through the object profile.

Source code analysis can be performed through parser of a particular language. An assumption is that particular grammar rules define concepts and the rules used by the code author mean that the programmer understands language constructs describing and defining the language. Complete language syntax is not necessary when processing source code, however, syntax definition should be accustomed to required knowledge expression. An appropriate form of rules should be as expressed in Eq. 1 not 2.

$$If \rightarrow \text{"}\texttt{if}\text{"}\ \text{"("}\ Expression\ \text{")"}\ Statement \tag{1}$$

$$A \rightarrow \text{"}\texttt{if}\text{"}\ \text{"("}\ B\ \text{")"}\ C \tag{2}$$

That is, the form should be human-interpretable, e.g. in order to understand *if*, one should understand expressions and statements.

Obviously, such a naive approach is not sufficient when creating a complex profile. The fact that the code author who called a function might indicate that he understands it, however, one function call does not provide a clear evidence that the subject perfectly understands every detail related to this function. This is why there is a need for metrics definition, based also on empirical observation. In the metrics, we may take into account multiplicity of one method use assuming the more is one method used, the more the subject understands it. Moreover, we may assess method complexity (code length and documentation length) [6]. Such metrics definition represents a separate part of the research regarding knowledge profile generation.

### *B. Use cases*

Presented approach towards knowledge profiles generation can find its practical benefits in the following:

- book profile (object profile) – based on subject profile, one may select the most helpful book,
- candidate selection (subject profile) – regarding a task or group of tasks (object profile) supposed to be solved,
- determination of skills necessary to handle some task (object profile) – based on subject profile,
- statistical evaluation of what people frequently use/not use – may indicate the difficulty of use (subject profiles)
- determination of language constructs complexity or library complexity.

The verification of the proposed method of knowledge profile generation can be done within the educational process, e.g. by creating a record of changes in student profile after passing a programming course. Such a record may be beneficial during the exam, indicating student improvement.

As stated in [7], static analysis tools generate lots of data. Therefore, in addition to appropriate techniques of profile creation, two other topics are related and represent a separate part of the research: usability and visualization of knowledge profiles. Assembled data regarding subject or object profile cannot be beneficial if the way of their visualization as well as the user interface are disarranged or too complicated to make any sense.

## III. Prototype

To evaluate the concept, a prototype has been implemented, that allows to analyze program source code written in Java language. The prototype represents only the first iteration of our research in the area. It uses the counts of language constructs used in the code to generate a profile. The profile itself is represented as a table containing the counts for each source code file and also summary data. The table is serialized in JSON format.

The data are then visualized in different ways to allow their further examination and comparison.

The tool provides four ways to display profile data:

1) *Detailed tables* — display counts of the used language constructs for each source code file. Constructs are divided into several logical groups (e.g. arithmetic operators or control flow statements) that are displayed in separate tables.
2) *Summary tables* — display summary counts for all files with values of statistical variables like arithmetic mean, modus, median, standard deviation etc, that characterize distribution of a language construct between source code files.
3) *Heat maps* — represent a matrix with total counts for each language construct, where cells of the matrix are colored according the counts (darker color means higher occurrence) and additional statistical data is displayed in a tooltip window (see Fig. 2 that displays comparison of several profiles).
4) *Box plots* also called box-and-whisker plots [8] — visually display summary data together with their distribution (see Fig. 3).

The tool can display simple profiles – data collected for some set of source code files that are produced by single person (subject profile) or are part of a single project (object profile). In addition, there are two compound types of profiles that consist of several simple profiles:

- *group profiles* that display data for several profiles and allows to summarize and compare them,
- *comparison profiles* that allow to compare several profiles with a single master profile.

For the comparison purposes, the most valuable type of display turned out to be *the heat map*. It allows to display a large set of data in a compact form which is easy to explore and therefore allows to visually find anomalies that may indicate significant results.

To implement the parser of Java language, ANTLR parser generator [9] was used. The visualization is based on web technologies such as AngularJS framework[1] and HighCharts interactive graph plotting library[2].

## IV. Experiments

We have performed several experiments regarding the developed tool.

### A. Analysis of language constructs used in large projects

The tool has been tested on several existing projects, both medium and large. The goals was to assess how Java language constructs are used in them and to test extraction of object profiles.

The results show that in medium-sized projects there is a lot of language constructs that are not used at all. For example, one of the tested projects – YAJCo parser generator [10] – did not adopt any bitwise and bit shift operators, a large part of the arithmetic operators and some other constructs.

Even in a large project, like Google Guava library[3], there are constructs that are never used, including some bit shift operators, try-with-resource blocks, and a default argument for annotation parameters. Bit shift operators, however, have been used in a form of compound assignment operators. On the other hand, try-with-resource was added to the language in version 7, so it has probably been avoided for compatibility reasons.

On the other hand, in the large project most of the Java language constructs was used at least once. This means that profiles based solely on language construct counting would not be comprehensive enough for such projects. For this reason we plan to extend the prototype with advanced analysis and additional metrics.

### B. Comparison of student assignments

To evaluate the comparison of profiles, we planned to compare projects of similar size and in the same domain. For this reason we have chosen source code developed by our students as part of their assignments. We used the assignments from the Object-Oriented Programming course. For most students, this course is a first introduction into Java language and object-oriented methodology. This way we were able to compare subjects with similar starting knowledge working on the same problem. We also added a solution developed by a teacher to the comparison.

Fig. 2 shows a fragment of the comparison results. Rows correspond to different language constructs, for example *break* statement or *try* block. Columns represent different projects. Students' projects are identified by numbers while teacher's project is called *master*. The table contains a total number of construct occurrences within analyzed codes. After pointing to some table cell, a tooltip window appears containing statistical parameters that represent distribution of the language construct per source code file (see return statement for student 6 in Fig. 2).

The comparison has show that in general the results of both students' and teacher's solution are quite similar. There are, however, some notable differences. For example, student 3 used the largest number of different language constructs,

even the ones not used by the teacher. Student 7, on the other hand, probably encountered problems with understanding the principles of object-oriented programming, since he used the *static* modifier much more often than the other subjects.

Some students missed language constructs used by all the others. For example, student 1 did not use *float* and *long* types, student 5 did not use *switch* statement. This may indicate that they did not understand these types or constructs, or they simply selected a different implementation strategy. Therefore, exploration of the source codes themselves is needed in both cases.

On the other hand, the fact that student 6 did not use *final* modifier quite clearly indicates that he does not understand the importance of immutability in programs.

## V. Related Work

There is a number of studies dealing with source code analysis. Most of them are focused on software security, detecting bugs, defects and potential vulnerabilities. Two of such studies are [11] and [12], both dedicated to static analysis of C/C++ source code. Static analysis tools which are the most popular usually explore static code and identify a large variety of bugs and bad programming practice [13].

Usually, static analysis refers to methods of automated determination of a program behavior during compile time. Static analysis tools have become part of modern compilers, however, these tools can only identify elementary errors [14]. E.g. traditional tools cannot identify the presence of deadlocks, having their own research branch [15], [16], or breaking mutual exclusion in concurrent applications [17], [18].

A method dedicated to collecting, comparing, and combining program semantics is refered to as abstract interpretation and it has been successfully used to derive run time properties of a program which can be used for program optimization. Other objectives of static analysis tools are mostly concept location [19], [20], code transformation [21], [22], security [23], [24], or reverse engineering [25].

When dealing with techniques of the static analysis, one may refer to [26], published a decade ago but still actual, focused on various approaches in software testing based on automata theory. One may also refer to a newer publication

[27], of which authors claim that empirical code evaluation plays an important role in software analysis.

A technique presented in [28] locates computational units typical for a set of related features through execution profiles. In order to detect the most feature-specific computational units, concept analysis is performed [28]. This is combined with static analysis using the feature-specific computational units to detect additional units along with the dependency graph.

Static software analysis has been also covered by a number of surveys, e.g. [29] or [30].

An interesting source of data for programming profile generation may be software repositories, produced and archived throughout software development [31]. In order to explore and examine software repositories, mining software repositories (MSR) have been created. As stated in [32], MSR exploration used to be subjected on industrial systems in the past. However, with an extensive increase of open-source software, this research has become a new challenge. MSR researchers mostly focus on clearer understanding of software evolution [33], development of tools, methods and processes.

Metadata analysis differs with particular exploration objectives and software repositories. The most common issues addressed by MRS researchers are [34]:

- detection of change patterns,
- prediction of changes,
- detection of bugs,
- analysis of bug-fixing change,
- source code exploration,
- identification of software developers.

All of the mentioned issues have one main objective in mind: To augment traditional software engineering techniques in order to guide decision processes in modern software projects [35]. That is, while MSR researchers focus on programming targets (programming result – software), our attention is paid to the source (software author). Since the aim of this study is to assess quality of the code author, source code exploration and developer identification [36] are the most related issues.

## VI. Conclusion

Having been first described as a prototype, this study has dealt with an exploration tool aimed at the Java code of various programmers. The main objective is to automatically generate programmer assessment profile. The analysis indicates the topic is quite extensive and little explored. This is why we described only a few of the potential methods for the profile generation.

The proposed tool has been developed and experimentally evaluated on several code samples including a medium-sized and large software project. The tool is intended to analyze knowledge through counting the language constructs. In order to clarify the results, the method utilizes elements of the descriptive statistics [37]. Within the experiment, various possibilities of source code processing have been implemented. For all the processing types, results are available in JSON meta-form as well as in various types of graphical web-based representation.

Since we are still in early stages, the described code-exploring tool and its continuing maturation will include the capability of treating more complex code solutions and utilization of additional metrics. The future plan is to detect and evaluate more advanced language usage e.g. nested loops, or programming idioms [38]. The tool should also track used library classes and method in addition to built-in language constructs. In order to support this, it would be required to implement processing of references in a programming language [39]. In distinction to general search-based techniques, future work will also involve model-based deductive evaluation, similar to [17]. Moreover, if combined with automated code-functionality evaluation during the educational process [40], knowledge profiles may become a significant contribution to student assessment.

Even with the current implementation it is hard to manually analyze and compare large number of profiles. This means that growing amount of data in the profile would require advanced methods of its visualization and automated analysis.

Apparently, automated knowledge evaluation might not be completely accurate. In order to achieve more precise profile results, it will be necessary to perform a lot of experiments over a large group source code and to combine several types of metrics or statistics. However, interesting results will be visible immediately.

***Abstract*—*Native functional-style querying extensions for programming languages (e.g., LINQ or Java 8 streams) are widely considered as declarative. However, their very limited degree of optimisation when dealing with local collection processing contradicts this statement. We show that developers constructing complex LINQ queries or combining queries expose themselves to the risk of severe performance deterioration. For an inexperienced programmer, a way of getting an appropriate query form can be too complicated. Also, a manual query transformation is justified by the need of improving performance, but achieved at the expense of reflecting an actual business goal. As a result, benefits from a declarative form and an increased level of abstraction are lost.***

***In this paper, we claim that moving of selected methods for automated optimisation elaborated for declarative query languages to the level of imperative programming languages is possible and desired. We propose an optimisation method for collection-processing constructs based on higher-order functions through factoring out of free expressions in order to avoid unnecessary multiple calculations. We have implemented and verified this idea as a simple proof-of-concept LINQ optimiser library.***

## I. Introduction

SINCE the release of LINQ (Language-Integrated Query) for the Microsoft .NET platform in 2007, there has been a significant progress in the topic of extending programming languages with native querying capabilities [1]. Programming languages are mostly imperative; their semantics relies on the program stack concept. They operate on volatile data and the meaning of collections is rather secondary. On the other hand, query languages are usually declarative and their semantics often bases on some forms of algebras or logics; these languages operate mostly on collections of persistent data. Declarativity of a query language reveals itself mostly when considering operators for collections. In the case of an imperative language, operating on a collection takes a form of an explicit loop iterating over collection elements in a specified order, while in query languages one declares a desired result (e.g., a sub-collection containing elements of a base collection matching a given selection predicate) and an algorithm of filtration itself is not an element of an expression representing the query. Based on characteristics of data structures, a database state and existence of additional auxiliary structures (e.g., indices), an execution environment can choose the most promising algorithm (a plan) for evaluation of the query. Declarativity allows one to postpone selection of an algorithm even to the moment of an actual query execution. In this paper we discuss to what extent solutions for processing of collections within programming languages are actually declarative. To do so, we made an extensive research on query optimisation. In databases it is a crucial process that allows a programmer to be relieved from thinking about details of a processing control flow, auxiliary data structures and algorithms.

LINQ seems to be the most robust solution introducing a promise of declarative collection processing within an imperative programming environment. It is commonly used for direct processing of collections and as a mapper to resources devoid of a robust declarative query API or query optimisation. When encountering performance issues, developers are forced to manually optimise LINQ expressions or partly resign from declarative constructs in favour of an imperative code.

```
var ikuraQuery =
  from p in products
  where (
    from p2 in products
    where p2.productName == "Ikura"
    select p2.unitPrice).Contains(p.unitPrice)
  select p.productName;
```

Listing 1. Example 1 – query expression syntax.

Consider a LINQ query expression in Listing 1 (the database diagram including the Products table is available at *http://northwinddatabase.codeplex.com/*) whose purpose is to find names of products with a unit price equal to a price of a product (or products) named Ikura. If the query addresses a native collection of objects, its execution is severely inefficient as the nested subquery, searching for prices of products named Ikura, is unnecessarily evaluated for each product addressed by the outer query. Although this task could be resolved in a time linearly proportional to the collection's cardinality, the LINQ engine induces an outer loop and a nested loop, both iterating over the products' collection. Using this example, in further sections we show that manual optimisation of complex LINQ queries is not an easy task.

LINQ enables to express the same goal in many different ways. However, evaluation times of two semantically equivalent queries may differ by several orders of magnitude. In particular, in the context of the LINQ query

978-83-60810-66-8/$25.00©2015, IEEE

expressions' declarative syntax, it violates the declarative programming principle. Without knowledge on how a query engine works in a context of given data, the optimisation process is too complex and time-consuming. This is particularly true if a programmer wants to preserve semantics and properties of his query construct.

To the best of our knowledge, the problem of automated global optimisation of LINQ queries for direct processing of collections of objects has not been addressed in the literature so far. By global optimisation we understand the ability to define an efficient query execution plan based on the whole query structure as opposed to the local optimisation that usually only targets a single operator. Below we prove that global optimisation can be done automatically making LINQ genuinely declarative.

Nonetheless, the problem that this paper deals with is not limited to LINQ. Surprisingly, it extends to dozens of programming environments that support functional-style operations on collections of elements, such as filter, map or reduce. Pipelines and streams introduced in Java 8 are a solution equivalent to LINQ to Objects [2]. The main difference lies in the naming convention of new operators corresponding to their functional prototypes (e.g., *map* and *filter* instead of LINQ's *Select* and *Where*). Furthermore, list comprehension constructs are examples of a shorthand syntax for specifying operations of projection and selection (filtering). Consequently, discussed issues concern many imperative languages exploiting this feature (e.g., Python). Fowler summarises such a functional-style programming pattern using a term collection pipeline [3]. Examples given in LINQ can be expressed in many imperative and functional programming languages. While we extend the conclusions of our work to the universe of imperative programming, they do not directly apply to functional languages (e.g., Haskell) since their principles of program evaluation are significantly different [4].

The rest of the paper is organised in the following way. First, we present a brief description of the state of the art followed by characteristics of language-integrated query constructs. Next, we describe issues with nested independent subqueries and free expressions revealing a huge optimisation potential. Finally, we present our solution followed by measured results and principles of our optimisation approach, being the core of the paper. The paper is concluded with a short summary.

## II. Related Work and the State-of-the-Art

Databases are the area of the computer science where declarative programming and query optimisation have developed extensively. Over 40 years of the research on relational systems resulted in various optimisation techniques [5][6] and numerous solutions are incorporated in available commercial products. Our research presented in the paper particularly addresses query optimisations analogous to query unnesting, dating back to the early 80s [7]. This topic is constantly appearing in the context of arising database technologies. Different approaches to handle nested queries evaluation have been proposed for object-oriented databases [8][9] and XML document-based stores [10]. However, NoSQL solutions marginalise the topic of query languages and usually rely on a minimalistic programming interface and domain-specific optimisations, mostly implemented by high redundancies and storing data in the form matching assumed queries. Most attention from the scientific community concentrates on the topic of distributed data-parallel computing using the Map/Reduce paradigm (like Hadoop or Dryad for Azure). This paradigm can be transparently used in declarative collection processing. The Dryad programming environment based on LINQ [11] takes advantage of mechanisms similar to Map/Reduce in order to write scalable, parallel and distributed programs. To increase sharing of computations in a data centre, Dryad can benefit from the Nectar system [12]. It is able to cache results of frequently used queries and incrementally update them. The use of cached results is achieved through automatic query rewriting. Robust query and program optimisations have been developed for solutions based on the functional paradigm. According to Fegaras [13], an optimisation framework for a functional lambda-DB object-oriented database relies on mathematical bases, i.e. the monoid comprehensions calculus. It generalises many unnesting techniques proposed in the literature.

Glasgow Haskell Compiler (GHC) for the Haskell non-strict purely functional language introduces many methods based on code rewriting. They range from relatively simple rules that can be used to improve efficiency of programs through modifications on a high syntactic level to more complex low-level core language transformations (e.g., let-floating, beta reduction, case swapping, case elimination) [14]. In particular, a procedure called full laziness (or fully lazy lambda lifting) has been proposed to avoid reevaluation of inner expressions for which result could be pre-calculated only once [15][16].

Currently, due to introduction of lambda abstractions into object-oriented languages, functional style of programming became ubiquitous. Stream and collection processing constructs derived from functional languages can be naturally evaluated in parallel using multiple processor cores. Therefore, the most popular solutions, like Java 8 streams, LINQ or ScalaBlitz, enable such optimisation through various libraries or frameworks [17].

In the field of functional-style queries integrated into a programming language, the topic of query optimisation seems the most advanced in LINQ. A LINQ provider library can implement direct processing of data (e.g., LINQ to Objects, LINQ to XML) or delegate processing to a remote external resource by sending a translated query (e.g., LINQ to SQL, LINQ to Entities). To be precise, a mixture of both approaches can be used, e.g. when the query language of a remote resource cannot completely express the semantics of a LINQ query. In the case when LINQ sends a translated query, it also delegates the responsibility for query optimisation. Consequently, if the external resource engine provides optimisation, developers can fully rely on a declarative style of programming. However, in the context of LINQ to SQL, the problem of analysing and normalising of LINQ queries in order to provide minimal and cohesive mapping to SQL has drawn attention of the scientific community. This is caused mostly by some drawbacks of the original Microsoft's solution that in some cases may fail or produce a so-called "query avalanche" [18][19].

The issue of performance deficiencies while processing collections of objects has not passed unnoticed by the LINQ community. In order to cope with the shortage in optimisation comparing to database engines, the i4o project (abbr. index for objects) solution adapted the idea of indexing to native objects' collections [20]. It is implemented as an alternative for the LINQ to Objects provider library. Utilising the concept of secondary access structures, i4o can produce several orders of magnitude of a gain in performance for queries filtering data at the cost of a data modification overhead.

Another examples of LINQ query optimisation tools are Steno [21] and LinqOptimizer [22] provider libraries. Their authors focused on a significant performance deficiency of LINQ queries in contrast to the equivalent manually optimised code that can be several times faster. Experiments have shown that Steno allows one to obtain up to 14-fold increase in processing of sequential data and 2-fold comparing to a problem processed by the DryadLINQ distributed engine [11]. The main idea behind Steno is to eliminate the overhead introduced by virtual calls to iterators that are the fundamental mechanism used by the LINQ engine. This problem has been solved by automatic generation of an imperative code omitting iterators. The optimisation addresses mainly implementation of individual operators. This also concerns the case of nested loops' optimisation when Steno has to analyse a series of operators only to preserve the order of iteration induced by the LINQ to Objects library implementation. This is justified by the loop fusion efficiency and consideration of side effects that are allowed in LINQ. Steno is also capable of higher-level optimisation giving an example of the GroupBy-Aggregate optimisation. It involves a local term rewriting, addressing a pair of neighbouring operators, i.e. GroupBy followed by Aggregate. When encountering such a sequence of operators, Steno replaces it by a dedicated GroupByAggregate operator that saves memory by storing per-key partial aggregates instead of the whole collection of group values. This optimisation takes advantage of LINQ declarativity by changing the course of evaluation. As a result, introducing side effects would cause its incorrectness. Being aware of a difficulty of automatic reasoning about side effects within queries, Steno's authors suggest developer-guided optimisation. Optimisation similar to GroupBy-Aggregate is considered in the SkyLINQ project [23] that develops an alternative operator called Top. This operator can be used to substitute a sequence of OrderBy and Take method calls (i.e. an operation to get top k elements). The significance of LINQ grew up with introducing LINQ to Events, an extension enabling declarative programming according to the reactive paradigm [24]. The solution derives from Functional Reactive Programming and is well suited for composing asynchronous and event-based programs [25]. Recently, this approach has attracted attention of commercial and scientific communities and, as a programming paradigm, faces efficiency issues indicating possible areas for optimisation [26][27].

Other current research on LINQ strives to allow seamless integration of heterogeneous data sources [28]. As a result, users can transparently process and modify data shared among contributing resources. Because of complex multilayer architecture, such an environment is not efficiency-oriented. LINQ is generally focused on local optimisation performed at a data source layer. In processing of heterogeneous and distributed data, it is unlikely that such optimisation is provided by each contributing resource. Therefore, it raises a need for global optimisation performed at the level of a LINQ query itself.

Declarative functional-style constructs in general-purpose object-oriented languages are not pure. As a result, decisions concerning optimisation have to be made by programmers. Transparent and aggressive compile-time optimisations can be achieved by introducing a query language extension into a programming language compiler [29].

One of numerous examples of extending compilers of existing languages with declarative constructs is SBQL4J [30]. It enables seamless integration of SBQL queries with language instructions and executing them in a context of Java collections. SBQL4J is based on the Stack-Based Architecture (SBA) approach instead of the functional approach and offers capabilities comparable to the LINQ technology [31][32]. What distinguishes it from other programming language-integrated queries is incorporation of several automatic optimisation methods developed for SBA. One of these methods, i.e. factoring out independent subqueries [8], enables SBQL4J to cope with optimisation of queries equivalent to examples discussed in this paper. It belongs to the group of optimisation methods that are based on query rewriting. Factoring out concerns a subquery (that in SBA represent any subexpression) that is processed many times in loops implied by so called non-algebraic operators despite that in subsequent loop cycles its result is the same. In SBQL4J rewriting is applied at a compile-time and a resulting performance improvement can be very significant, sometimes giving query response times shorter by several orders of magnitude.

## III. Characteristics of Language-Integrated Query Constructs

Declarative style programming (especially in the context of databases) is often associated with the select-from-where syntactic sugar known from SQL that was adapted into LINQ. The query in Listing 1 is expressed using the LINQ query expression syntax. That form lacks explicit information on an order of performed operations and virtually a compiler could translate it to any semantically equivalent lower-level code that could be considered a query execution plan. Consequently, programmers must be particularly careful about potential side effects within declarative constructs in order to avoid the risk of unpredicted violations. Technically, query expressions are syntactic sugar over the implementation layer using lambda expressions, higher-order functions and, so called, extension methods [33]. An executable query, after removing the LINQ syntax sugar, will take the form presented in Listing 2.

```
var ikuraQuery = products.
  Where(p => products.
    Where(p2 => p2.productName == “Ikura”).
    Select(p2=>p2.unitPrice).Contains(
      p.unitPrice)).
  Select(p => p.productName);
```

Listing 2. Example 1 – de-sugared.

The translated query uses the traditional, non-declarative object-oriented programming syntax. When processing collections or XML documents directly, the most crucial LINQ library extension methods (e.g., Select and Where) expose iterators that perform a specified operation on elements of a given collection. Lambda expressions are used to express details concerning such an operation, e.g. the selection predicate for the Where operator. Despite of similarity of Listing 2 to the original query expression, such composition of method calls on the products collection determines the order of evaluation.

Due to the specific implementation based on iterators and lambda abstractions, the execution strategy of LINQ queries is deferred. Execution is performed in presence of functions or instructions forcing iteration over elements specified by a query. However, a result of an iteration is not saved or cached, so each execution reevaluates a query against a given (current) data state.

The approach used in the LINQ to the objects' library implementation is generally ubiquitous (however, not uniform) in numerous programming languages (e.g., Python, Java 8, Elixir, Ruby) [3]. A good summary describing the possible set of properties of functional-style constructs can be found in the documentation of Java 8 streams [2].

The functional nature makes a language construct a good candidate for optimisation due to intelligible querying. All operations in a query processing chain produce a new queryable result instead of modifying original data; hence they do not introduce side effects. For example, during filtration on a list, no element is actually removed. Even though filter and map (common functional-style operators) are often used to directly process elements of a local in-memory collection, in reality elements can be obtained one by one from any so called queryable data source, e.g., a data structure, a generator function, an iterator, an I/O channel and a chained pipeline of collection operations. Such generality allows, usually time-consuming, querying of remote data sources, additionally making optimisation desirable.

The above properties are common in implementations of language-integrated query mechanisms. However a programmer must be sensitive to possible differences in various programming languages. For example, some languages implement consumable evaluation of queries. In such a strategy, elements of a queryable data source instance can be visited only once during its life. As a result, each query instance can be evaluated only once. The last property is present in Java 8 streams whereas LINQ operators are not consumable. The laziness-seeking property has the most profound impact on evaluation and semantics of language-integrated queries. It is connected with the lazy evaluation strategy assuming that a next element is returned for further processing only if necessary. Usually, a place of a lazy construct definition does not determine an actual moment of query execution (i.e. deferred execution strategy). Actual query execution occurs when its result is required, for example elements referred by a query are iterated or counted. Operations like selection, projection, and removal of duplicates are often implemented lazily. Consequently, to ensure coherence execution of eager constructs (e.g., grouping or ordering) is also deferred. Lazy evaluation usually results in better performance. It is cache-friendly since an element is processed by a chain of collection pipeline operations before proceeding to the next element. Moreover, in cases when the desired query result has been reached before visiting all elements it is not necessary to continue iterating (e.g., a query finding the first product with name “Ikura”).

In the context of query optimisation, it is important to preserve properties of optimised constructs. In a general case, any change in this matter can affect semantics of application code. Switching an expression evaluation strategy from lazy to eager or forcing immediate execution can have serious consequences. Only laziness-seeking constructs can deal with possibly unbounded data sources. Eager evaluation of selection and projection operators on an infinite data source would require infinite computational resources and time, while lazy evaluation can return partial results.

In the next section, we show that preserving deferred execution, which is implied by the lazy evaluation strategy, is the factor impeding query optimisation.

## IV. Performance Pitfalls

### A. *Evaluation of Independent Subqueries*

Analysing the expression from Listing 2, it becomes obvious that the nested query selecting products named Ikura will be executed multiple times, since it is a part of a lambda abstraction (specifying a selection predicate) called against each product (the external *Where* operator induces a loop iterating over elements of products collection). This form is not efficient and makes the computational complexity quadratic (i.e. $O(n^2)$). However, searching for products named Ikura is independent of the parent query and could be evaluated just once. In order to improve query performance, a programmer must transform it. A natural way for optimisation seems to be factoring out the problematic subquery to a separate instruction and assigning it to a new variable (see Listing 3). The changes could also be presented on the LINQ query expression, but because the form with extension methods is actually executed, it will be a basis for this study.

```
var nestedQuery = products.
  Where(p2 => p2.productName == "Ikura").
  Select(p2=>p2.unitPrice);
var ikuraQuery = products.
  Where(p => nestedQuery.Contains(p.unitPrice)).
  Select(p => p.productName);
```

Listing 3. Example 1 – loops in separate instructions.

A result of the transformation shown in Listing 3 may seem effective; however, the expected goal will not be achieved. The problem lays in the execution strategy of LINQ queries. The *nestedQuery* variable holds an instance of a non-executed query that will be evaluated – like in the case of the non-transformed expression (Listing 2) – at every traversal of the loop induced by the *ikuraQuery Where* operator.

In Java 8 streams proper execution of corresponding queries generally would become impossible due to the consumable property of streams. After the transformation, the selection predicate of the *ikuraQuery* would share the same instance of a *nestedQuery* stream. Evaluation of the nested query would be performed only once, at the first traversal of the loop induced by the *ikuraQuery Where* operator, whereas the following iterations would result in terminating query evaluation and throwing an exception.

Solving the above problems requires eliminating deferred execution of the nested query. There exist several techniques to force immediate execution of a LINQ query. For example, the *ToList* method returns a list containing a materialised query result. Applying it to the nested query makes the solution more efficient (linear computational complexity) than the query in Listing 2. However, a part of the original query is executed and the other part remains deferred to the moment of an actual demand. It is possible that data in a collection may change between creation of a query and its evaluation. The original query form (and the programmer's intention) is insusceptible to it – the query is always completely executed on a current data state. After immediate execution of the nested query one cannot be sure about it – the *ikuraQuery* can be evaluated when data needed for calculating the *nestedQuery* subquery got already modified. As a result of the transformation, there occurred a change of the query semantics that is very difficult to detect by a programmer or tests. Ultimately, a programmer is forced to resign from deferred execution of the whole query, which is shown in Listing 4.

```
var nestedQuery  = products.
  Where(p2 => p2.productName == "Ikura").
  Select(p2=>p2.unitPrice).ToList();
var ikuraQuery = products.
  Where(p => nestedQuery.Contains(p.unitPrice)).
  Select(p => p.productName).ToList();
```

Listing 4. Example 1 – fully immediate execution.

Due to explicit materialisation, reusing the optimised query against a different data state becomes troublesome. For an inexperienced programmer, a way of getting an appropriate query form can be too complicated. Without deeper knowledge on the LINQ internal semantics in a context of object data, obtaining an optimal structure of code is a tricky, time-consuming and error-prone task. The example shows a lack of real independence of LINQ from a type of a data source. Despite the fact that LINQ allows unified processing on various types and sources of data, an actual execution plan relies on them. It seems that the basis for elaborating this layer of the language was mostly the integration of the object-relational mapping with a type system of a programming language (what also shows at the level of the LINQ query expression syntax and implementing providers [30]).

### B. Factoring Out Constructs Executed Immediately

Although LINQ queries execution is deferred, an execution strategy of some expressions comprising LINQ queries can be immediate. Such expressions are evaluated locally in the place of the definition. Some operator, like aggregate functions returning a single value instead of a queryable data source, force immediate execution of a query. The query in Listing 5 contains such an expression determining the greatest unit price in the products' collection. However, it will not be evaluated until the execution of the *maxQuery* since it is contained in a lambda expression defining a selection predicate for the *Where* method.

```
var maxQuery = products.
  Where(p => products.
    Max(p2=>p2.unitPrice) == p.unitPrice).
  Select(p => p.productName);
```

Listing 5. Example 2 – extension methods syntax
(quadratic computational complexity).

Similarly to the subquery determining the price of the Ikura product, it should be evaluated only once during execution of the *maxQuery* and therefore needs to be factored out. Let us call such constructs free expressions. Using the same procedure as presented in the previous section, we break the query into two instructions and perform immediate execution (see Listing 6).

The *ToList* operation does not need to be applied to the expression defining maxPrice (actually, it cannot be applied because it returns a value), due to its inherent immediate execution.

```
var maxPrice = products.Max(p2=>p2.unitPrice);
var maxQuery = products.
  Where(p => maxPrice == p.unitPrice).
  Select(p => p.productName).ToList();
```

Listing 6. Example 2 – immediate execution
(linear computational complexity).

### C. Consequences of Changing the Evaluation Order

There exist some subtle consequences concerning evaluation after the manual optimisation. In the original forms of example queries (Listing 2 and Listing 5), nested expressions would be evaluated only if the products' collection is not empty. In the optimised forms (Listing 4 and Listing 6) it will be unnecessarily evaluated also when the collection is empty. This is particularly important for performance when a nested query operates on a collection different than the external query does. The current example concerns just one collection, but it is easy to imagine a situation when collections are distinct (e.g., products from other shops kept in separate collections). In extreme cases, if calculation of a factored out expression is time-consuming, this can worsen overall query performance. Aside from performance issues, the transformation presented in previous sections can have dangerous impact on query semantics. In the second example (Listing 5) in the case of an empty collection of products, the selection predicate is not evaluated at all and the final result is simply an empty collection of product names. After optimisation (Listing 6), the expression *products.Max(p2 => p2.unitPrice)* is always evaluated at the beginning. The *Max* method applied to an empty collection throws an exception. Consequently, the behaviour of the optimised query is unsafe and inconsistent with the intent of a programmer.

To make optimisation immune to the described risk, the original order of evaluation should be restored. This could be achieved by applying the lazy loading pattern to the free expression determining *maxPrice*. In Listing 7 we introduce an improved transformation.

```
var maxPriceThunk =
  new Lazy<Double>(products.Max(p2=>p2.unitPrice));
var maxQuery = products.
  Where(p => maxPriceThunk.Value == p.unitPrice).
  Select(p => p.productName).ToList();
```

Listing 7. Example 2 – immediate execution (linear computational complexity).

A *Lazy* class instance is a simple thunk – an object in memory representing an unevaluated (suspended) computation, used in the call-by-need evaluation strategy. The argument of the Lazy constructor specifies a function that should be evaluated at most once, only if its value is requested for the first time. The request is signalised by accessing the *Value* property of the *Lazy* instance. Consequently, the original order of the query and the free expression evaluation are restored (except the free expression being processed at most once) making the optimisation semantically safe. It is achieved at the expense of overhead concerning access to the *Value* property.

In the next sections we present a general approach to optimisation that preserves semantics and characteristics of an original query while reducing its computational complexity.

## V. Factoring Out Free Expressions

The solutions presented for both examples share a common shortcoming; they do not preserve the deferred execution property. Our main aim is to propose a general query rewriting rule overcoming the problem. In order to keep the solution generic, additional constraints have been assumed: (1) transformation should not break a query into separate instructions (in contrary to what is shown, for example in Listing 7), (2) we express the rules in general terms rather than LINQ specific ones (e.g., operators common in functional programming). Obviously, we assume also that the intent of a programmer is simply to query and not to introduce side effects deliberately.

Generalisation of the factoring out procedure should take into account queries more complex than presented above. A nesting level of a lambda expression in the examples presented in Listing 2 and Listing 5 is shallow, but conceptually can be arbitrary with no need to modify the factoring out procedure. Free expressions can be bound either globally, i.e. to an environment independent from a query, or to a lambda expression at any nesting level lower than the lambda expression containing a free expression. The examples presented in Listing 2 and Listing 5 concern the former case. A generalising solution to the latter case can be achieved by treating any subquery as a separate query and the rest as a global environment.

The basic idea behind the transformation is, first, to identify free expressions that could be evaluated before a loop induced by an operator containing them, and next, to apply an appropriate rewriting rule. This is generalisation of the standard procedure called loop-invariant code motion known from the compilation theory [34]. An example of incorporating this idea to programming language-integrated queries can be found in the Stack-Based Architecture theory [8]. To optimise evaluation in functional languages, a similar procedure of fully lazy lambda lifting (called also full laziness) has been also proposed [16]. In both cases rewriting rules are straightforward and make use only of the basic set of language operators. Our attempt to generalise, in a similar manner, factoring out free expressions within LINQ queries using only methods supplied by LINQ has been unsuccessful. In particular, LINQ operators in presence of a queryable data source (e.g., a collection) cause iteration over elements, whereas factoring out requires treating empty, single or multiple elements as an individual result cached for reuse in further calculation.

### A. Formalising Optimisation

The procedure of factoring out free expressions can be applied to the following query pattern:

*queryUnoptimized* ::= *queryExpr*(λ(***freeExpr***))

where *queryExpr* denotes a query expression that includes a nested lambda abstraction λ(*freeExpr*) containing *freeExpr* that is free from any lambda abstraction within the query. Additionally, we assume that *freeExpr* should be evaluated several times during the execution in order to make factoring out profitable. This pattern is not restricted to a whole query. It can match any subquery.

The solution requires introducing transformation of factoring out a free expression before a loop using it and applying the lazy loading evaluation strategy. Several aspects need to be addressed to make such optimisation effective and general. (1) In imperative programming languages deferring execution is often achieved through enclosing code in a function or by introducing an iterator. In both cases, repeated execution (e.g., inside a loop implied by map or filter collection pipeline operators) causes repeated evaluation. If this applies to a factored out expression, then it is usually necessary to force materialisation of its result before entering a loop using it. (2) Moreover, materialisation solves the issue with factoring out consumable data sources since they cannot be evaluated more than once. Before factoring out, the problem does not exist since such constructs reside inside lambda abstractions (that are parameters of collection pipeline operators) and therefore are evaluated only once during single lambda call evaluation. (3) As stated earlier, it is possible that a free expression is skipped during evaluation of the original query. In a general case it is safe to preserve an order of evaluation by suspending materialisation of a factored out expression and prevent its immediate execution before entering a loop using it. (4) An instance of a mechanism used for suspending materialisation of a factored out expression should not be shared between query executions. To solve this problem, it can be additionally enclosed in a lambda abstraction. Otherwise, following executions would share a cached result determined during the first execution. (5) In order to prevent collection pipeline operators from iterating over a collection, it has to be nested into a new collection as a single element. The same procedure can be applied to a single result to enable usage of collection pipeline operators.

Let us denote the following abstract operations: ***Collection***(*arg*) – creates and returns a collection consisting of one element specified by an argument, e.g., if an argument is a collection it returns a nested collection), ***Immediate***(*expr*) – evaluates and materialises a result of an expression passed as an argument (except when the *expr* execution strategy is already immediate), ***Suspend***(*lambda*) – returns an instance of a mechanism for lazy loading of an expression specified by a lambda abstraction passed as an argument, ***Value***(*lazy*) – returns a lazily initialised value stored by a lazy loading mechanism instance specified by an argument.

Taking advantage of above operations, we introduce the following rewriting procedure:

*queryOptimized* ::=
***Collection***(() => ***Suspend***(() => ***Immediate***(*freeExpr*))).
map(*lambdaParam* => *lambdaParam*()).
map(*freeExprThunk* => *queryExpr*(
λ(***Value***(*freeExprThunk*)))).flatten()

where λ(***Value***(*freeExprThunk*)) is a nested lambda abstraction λ(*freeExpr*) with an occurrence of *freeExpr* expression substituted by ***Value***(*freeExprThunk*). This form ensures that execution of all components of the original query is deferred assuming that collection pipeline operators map and flatten have such an execution strategy.

The first part of the rewritten query
***Collection***(() => ***Suspend***(() => ***Immediate***(*freeExpr*)))
creates a collection consisting of a single element that is a lambda function creating an instance of a mechanism for suspended materialisation of the factored out free expression. The following map operator ensures execution of the lambda function. As a result, the following map operator will process
*queryExpr*(λ(***Value***(*freeExprThunk*)))
expression only once for *freeExprThunk* assigned the lazily loaded cached value of *freeExpr*. Therefore, the result of evaluation of *queryExpr*(λ(***Value***(*freeExprThunk*))) is equal to the result of evaluation of *queryExpr*(λ(*freeExpr*)). The flatten operator eliminates an outer collection implied by the *Collection* operator. Consequently, the final result of the optimised query is taken from evaluation of the
*queryExpr*(λ(***Value***(*freeExprThunk*)))
expression.

### B. Implementing Optimisation in C#

In C#, to simplify optimisation we introduce an auxiliary method *AsGroup* to take care of the *Collection* operation and suspended evaluation of a lambda expression returning a materialised value of the free expression. Listing 8 shows the implementation of the auxiliary operator.

```
static IEnumerable<TSource> AsGroup<TSource>(
                    Func<TSource> sourceFunc) {
  yield return new Lazy<TSource>(sourceFunc);
}
```

Listing 8. Auxiliary optimisation method.

The ***Suspend*** operation is achieved by a Lazy class constructor ***new*** *Lazy<TSource>*(*sourceFunc*). The ***yield*** return statement is a syntax sugar enabling creating a collection available through an iterator deferring any computations until iteration starts. In this way, a programmer avoids using a concrete type of a collection and enables a compiler to choose the best implementation on its own. *AsGroup* exposes an iterator that returns only one element, i.e. an instance of a mechanism for suspended materialisation of the factored out free expression. It is created directly before yielding replacing the projection *map*(*lambdaParam* => *lambdaParam*()). Consequently, the rewritten query in case of LINQ takes the following form:

*LINQ-deferredQueryOptimized* ::=
*AsGroup*(() => ***Immediate***(*freeExpr*)).
*SelectMany*(*freeExprThunk* =>
*queryExpr*(λ(*freeExprThunk.Value*)))

where the *SelectMany* LINQ operator substitutes map and flatten and *freeExprThunk.Value* realises the *Value*(*freeExprThunk*) operation.

The above transformation can be adapted to a situation when *queryExpr*(λ(*freeExprThunk.Value*)) is a construct executed immediately (e.g., when it returns a single value). In that case *SelectMany* needs to be replaced with two operations: Select realising projection and *First* responsible for flattening and immediate execution:

*LINQ-immediateExpressionOptimized* ::=
*AsGroup*(() => ***Immediate***(*freeExpr*)).
*Select*(*freeExprThunk* =>
*queryExpr*(λ(*freeExprThunk.Value*))).*First*()

The ***Immediate*** operation is required only in the case when *freeExpr* is a LINQ query deferred in execution. Explicit materialisation can be achieved using LINQ specific methods, e.g., *freeExpr.ToList*(). The transformation constitutes the general rewriting rule for optimisation of LINQ queries through factoring out free expressions. Applying it to the examples from Listing 2 and Listing 5 is shown in Listing 9 and Listing 10, respectively.

```
var ikuraQuery =
  AsGroup(() => products.
    Where(p2 => p2.productName == “Ikura”).
    Select(p2=>p2.unitPrice).ToList()).
  SelectMany(ikuraPriceThunk => products.
    Where(p => ikuraPriceThunk.Value.
    Contains(p.unitPrice)).Select(p => p.productName));
```

Listing 9. Example 1 – after factoring out suspended free expressions optimisation.

```
var maxQuery =
  AsGroup(() => products.Max(p2=>p2.unitPrice)).
    SelectMany(maxPriceThunk =>
      products.Where(p =>
            maxPriceThunk.Value == p.unitPrice).
      Select(p => p.productName));
```

Listing 10. Example 2 – after factoring out suspended free expressions optimisation.

The queries execution strategy after optimisation remains deferred and in the case of the second example (Listing 10), the problem of the exception while addressing an empty products' collection does not occur.

## VI. Performance Tests

We have evaluated the impact of factoring out of free expressions optimisation in C# by applying it manually to a number of problems: ***samePriceAs*** – given a collection of products, find products with the same price as the product specified by a name, ***maxPrice*** – given a collection of products, find products with the maximal price in the collection, ***promoProducts*** – given a collection of products, find names of products in the imaginary sale promotion, i.e. exactly *k* times more expensive than any other product, and ***pythagoreanTriples*** – from natural numbers between 1 and n find a number of triples satisfying the Pythagorean theorem.

In experimental tests, the collection of products ranged from 1 to 1,000,000 elements. The size of each product averaged to 175 bytes. Tests for ***samePriceAs***, ***maxPrice***, ***promoProducts*** and ***pythagoreanTriples*** problems have been conducted using queries in Listing 2, Listing 5, Listing 11, and Listing 12 accordingly. The problems have been solved relatively simply and each one has at least one free expression suitable for the factoring-out optimisation. Solutions to ***samePriceAs*** and ***maxPrice*** have free nested queries, whereas ***promoProducts*** and ***pythagoreanTriples*** introduce simple mathematical calculations that can be factored out. The tests include comparison with PLINQ and LinqOptimizer optimisation framework. We also combine them manually with our optimisation to explore limits and further opportunities.

```
var promoProducts =
  products.Where(p => products.
     Any(p2 => p2.unitPrice ==
             Math.Round(p.unitPrice / 1.2, 2))).
  Select(p => p.productName);
```

Listing 11. A query concerning the ***promoProducts*** problem before optimisation.

```
var pythagoreanTriples =
  Enumerable.Range(1, max + 1).SelectMany(a =>
    Enumerable.Range(a, max + 1 - a).SelectMany(b =>
      Enumerable.Range(b, max + 1 – b).Where(
        c => a * a + b * b == c * c))).Count()
```

Listing 12. A query concerning the ***pythagoreanTriples*** problem before optimisation.

We conducted our experiments on a workstation with a 4-core Intel Core i7 4790 3.6 GHz processor, 32 GB of DDR3 1600MHz RAM, hosting Windows Server 2012 R2. Benchmarks have been compiled for a x64 platform with enabled code optimisations using target .NET Framework v. 4.5. Tests results for following problems are presented in Fig. 1, Fig. 2, Fig. 3 and Fig. 4.

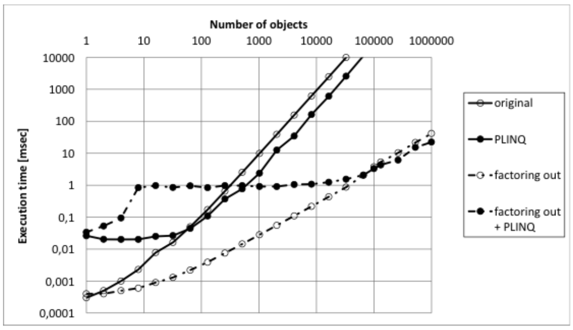

Fig 1. Query evaluation times for ***samePriceAs*** problem.

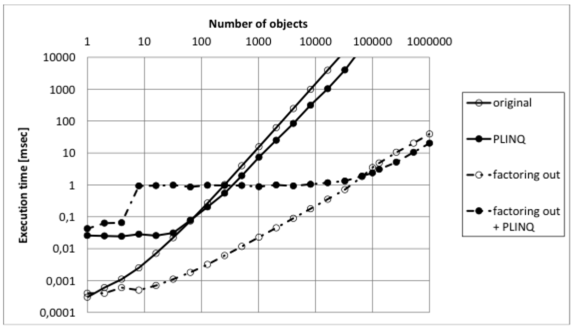

Fig 2. Query evaluation times for ***maxPrice*** problem.

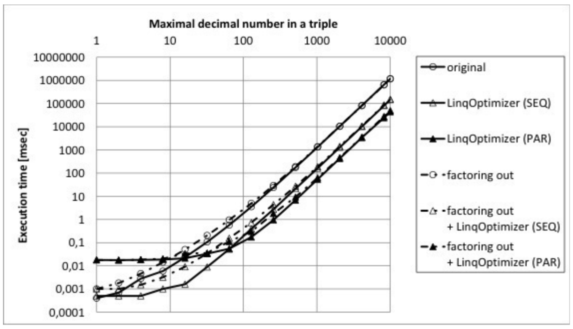

Fig 3. Query evaluation times for ***pythagoreanTriples*** problem.

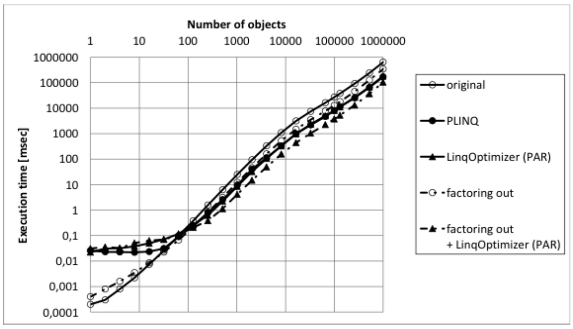

Fig 4. Query evaluation times for ***promoProducts*** problem.

The LinqOptimizer is used in two variants: sequential (denoted by SEQ) and parallel (denoted by PAR). The latter competes with PLINQ. Each query before and after factoring-out optimisation has been subjected to three further optimisation variants, i.e. PLINQ, LinqOptimizer sequential or parallel variant. The tests focus on query execution times and omit optimisation and compilation of a query. Most of the plots use logarithmic scales to more clearly reveal differences in performance for various collection sizes. To improve readability, the plots omit optimisation variants that are generally worse. In particular, the sequential variant of LinqOptimizer is shown only if it improved query performance in any collection size range, and the better alternative between PLINQ and parallel variant of LinqOptimizer is selected.

Results of the tests are as follows:

- Tests' results are consistent with an expected computational complexity. In ***samePriceAs*** and ***maxPrice*** problems it has been reduced from quadratic to linear, achieving a gain in orders of magnitude for large collections, e.g., in the case of the second example (Listing 5 and Listing 10) the query after factoring out is more than 30,000 times faster for 100,000 products (boost from ~115 s to ~3.8 ms).
- Except for the ***pythagoreanTriples*** problem, the profitability threshold of individual factoring-out optimisation is very low when comparing to PLINQ and LinqOptimizer. Even for a collection of 2 objects, optimised queries can work faster than original ones (e.g. ***samePriceAs*** and ***maxPrice***).
- The performance penalty in the case of a collection consisting of a single element is at most 0.6 μs which corresponds to a ~60% deterioration (the ***pythagoreanTriples*** problem).
- When processing large collections, the factoring-out transformation can give several times better performance by taking advantage of PLINQ (especially in the case of the ***promoProducts*** problem). For smaller collections, PLINQ imposes overhead significantly greater than factoring out.
- The ***pythagoreanTriples*** problem optimisation tests show that it may be difficult to obtain a significant gain when factoring out a simple expression (i.e. a * a + b * b). A ~3% gain is achieved for n equal to 10,000. • The LinqOptimizer framework seems to be designed for optimising queries involving numbers rather than complex objects. Only in the ***pythagoreanTriples*** problem optimisation, it outperforms both PLINQ and factoring out.
- In general, combining factoring out of free expressions with LinqOptimizer is not likely to produce the best solution. However, it seems that tuning of the LinqOptimizer algorithm should be possible. In the ***pythagoreanTriples*** problem, PLINQ is able to produce more efficient query after factoring out, whereas LinqOptimizer favours the original query. Unfortunately, the differences are too small to be seen on the plot.

C# libraries offer a *Lazy* class realising the Suspend operation, but considering performance, we have implemented our own lightweight version. We have experimented with different variants of performing *Collection*, *Suspend* and *Immediate* operations but the presented solutions generally resulted in performance better than others.

## VII. Automatic Optimisation

### A. Free Expression Detection

The transformation is justified by the need to increase effectiveness, which is achieved at the expense of reflecting the business goal. As a result, benefits from a declarative form and an increased level of abstraction are lost.

LINQ expression trees enable run-time analysing and dynamic building of LINQ queries [36]. This feature allows developing an optimisation method relying on rewriting of a LINQ abstract syntax tree. Automated detection of specified query patterns and transformation to an optimised form are required to make LINQ queries truly declarative. The previous part of this paper deals with the latter, i.e. the definition of efficacious rewriting rules for factoring out of a free expression. This section describes an algorithm for detection of free expressions within a query. The procedure does not address any details of implementation for the LINQ platform. It is general in terms of functional-style programming.

Let us establish a set of definitions concerning expressions and lambda abstractions (inspired by the definitions introduced by Hughes [16]):

- **Def. 1 (bound variables of lambda)**. An occurrence of a variable within lambda $\lambda_A$ is bound to $\lambda_A$ if and only if it is a parameter of $\lambda A_{A,}$
- **Def. 2 (bound expressions of lambda)**. An expression within lambda $\lambda_A$ is bound to $\lambda_A$ if and only if it contains a variable bound to $\lambda A_A$.
- **Def. 3 (native lambda of expression)**. The innermost lambda in which an expression *e* is bound is its native lambda. Let us denote this lambda *n*λ(e),
- **Def. 4 (free expressions in lambda)**. An expression *e* within lambda $\lambda_A$ is free in lambda $\lambda_A$ if $\lambda_A$ is nested in native lambda of expression *e*.
- **Def. 5 (maximal free expressions)**. A maximal free expression (MFE) is a free expression of some $\lambda_A$ that is not a proper subexpression of another free expression of $\lambda_A$.

Additionally, to simplify definitions and the algorithm description, we assume that names of variables are unique. Moreover, we implicitly treat a whole query as a lambda abstraction with all free variables (constituting a global environment) as its parameters. In the case of examples from Listing 2 and Listing 5 native lambda of each MFE is the whole query.

From the definitions above, it follows that any MFE e free in a lambda $\lambda_A$ can be determined before $\lambda_A$ evaluation. Precisely, it could be determined anytime during evaluation of *n*λ(*e*). The above statement is correct since:

1. *e* is a free expression (see definition 5).
2. $\lambda_A$ is inside *n*λ(*e*) (see definition 4).

3. *e* is not bound to $\lambda_A$ (see definition 3).
4. *e* does not contain variables bound to $\lambda_A$ (see definition 2).
5. $\lambda_A$ call does not introduce any variable (parameter) required by *e* (see definition 1) that makes *e* independent from $\lambda_A$.

Consequently, it is possible to factor out the expression *e* from $\lambda_A$ and evaluate it at the level of the *n*λ(*e*) lambda.

The algorithm uses the standard depth-first search approach and detects all MFEs during a single pass through a query expression tree. Expression visitation focuses on finding its bindings that we define as a set of lambda abstractions declaring variables (usually as lambda parameters) used in the expression. This information is further used to determine bindings of its parent. Usage of lambda abstraction parameters determines whether an expression is free or bound. Therefore, it is necessary to handle information about names of the parameters and lambda abstractions to which they are bound. This is a task of an auxiliary map called binders. To correctly manage parameters' binding, the procedure specifically handles lambda abstractions and terminal name binding expressions.

While visiting lambda abstraction, the binders' map is filled with its parameters. They are visible only within the lambda abstraction. This sets the right context for the recursive visitation of the lambda body in order to detect free expressions bound specifically to the current lambda. Finally, the bindings set is returned to the lambda parent except for the current lambda that is removed (information on binding to the current lambda is not relevant outside).

The binders' map is used when visiting name-binding terminal expressions. These expressions consist only of an identifier name. If a name is found in the binders' map, a corresponding lambda is returned (as a single-element bindings set). If a name is not bound to any lambda, then it is assumed to be a globally free variable.

The described behaviour does not concern a name on the right hand side of a member access operator (e.g., field names). Such a name is bound locally to its left side, therefore field member access bindings are inherited from their left side expression. In general, bindings for remaining types of expressions are simply inherited from their children (a sum of the sets).

In the implementation nesting level annotations for lambda abstractions and variables are introduced to simplify the binding analysis. Expression bindings provide sufficient information to determine all MFEs and their native lambdas.

To exemplify the algorithm let us consider the promoProduct problem shown in Listing 11. The query in its optimised form is presented in Listing 13. The expression determining a price *Math.Round*(*p.unitPrice* / 1.2, 2)) is unnecessarily evaluated multiple times during execution of the inner loop implied by the Any operator. What distinguishes this and previous examples is that the transformation applies not to the whole query but only to the *Where* predicate. Additionally, the predicate is not a LINQ query but an expression returning a Boolean value. Therefore, *Select* and *First* methods were used instead of *SelectMany*.

```
var promoProductsOptimized =
  products.Where(p =>
    AsGroup(() => Math.Round(p.unitPrice / 1.2, 2)).
    Select(priceThunk =>
      products.Any(p2 => p2.unitPrice ==
                   priceThunk.Value)).First()).
  Select(p => p.productName);
```

Listing 13. Example 3 – rewriting inside lambda abstraction.

[20, $\lambda_3$, {$\boldsymbol{\lambda_3}$}]

Fig 5. Example abstract syntax tree algorithm nodes annotations.

Partial results of the algorithm work for the unoptimised query are presented in Fig. 5. Each abstract syntax tree node of the query is annotated with three values: (1) a number indicating an order of visitation, (2) a lambda expression directly including an expression, (3) bindings set including the bolded element denoting a native lambda of an expression. Lambda expressions have been assigned unique numbers to facilitate their identification. Bindings that are removed at the end of lambda node visitation are indicated by a strikethrough symbol.

Free expressions have their native lambda (bolded lambda in bindings set) different from a nearest lambda (denoted by the second annotation), i.e. expressions with visitation order ranks 6, 11-17. After omitting terminal expressions such as literals (constant type nodes ranks 16 and 17) and name bindings (bind type nodes ranks 6 and 15), the only MFE left to factor out is *Math.Round*(*p.unitPrice* / 1.2, 2)). Its native lambda is $\lambda_1$. Hence, factoring out should be applied to its indirect parent: the *Any* node with a visitation order rank 5 (presented in Listing 11). It is an expression inducing iteration over the products collection at the highest level within $\lambda_1$.

### *B. Applying Factoring Out*

The factoring out rewriting rule can be applied during visitation of lambda expressions. However, not all MFEs should be factored out. The conditions under which the optimisation promises well are described in analogous solutions [15][8], namely: (1) a free expression cannot be too simple (e.g., names and literals), (2) a free expressions' result should be used more than once. They can be verified during preparation to the transformation.

First, the complexity of an MFE can be examined. An appropriate threshold for applying transformation could be introduced, e.g., based on an arbitrarily set weight of language constructs comprising an MFE. Performance tests on the ***promoProducts*** problem involving factoring out a relatively simple expression have proven improvement in the case of collections consisting of at least 30 objects. For over 250 products optimised query was about twice as fast.

The second condition concerns a number of times that a MFE result is used in evaluation. An additional analysis may be necessary for confirming that $n\lambda$(MFE) contains a method that causes iteration over some collection that may require repeated evaluation of the MFE. For example, in LINQ this concerns mainly operators parameterised with a lambda abstraction (such as *Select*, *Where*, *Max*, etc). Operators operating on sets (e.g., *Contains*, *Union*) or custom ones are not any indication for the optimisation. The more detailed cardinality analysis is doubtful in case of a programming language environment and a lack of a cost model.

We have implemented a prototype LINQ provider library realising the mentioned optimisation (available at *https://github.com/radamus/OptimizableLINQ*). The analysis and the transformation are performed using the LINQ expression trees' representation available at runtime. Access to expression trees is provided though the *IQueryable*<T> interface that does not allow direct query execution. Instead, it exposes an abstract syntax tree of a query (in a form of a type-checked expression tree) to a data store provider. The provider makes use of this representation to build a query in a form (language) dedicated for a given data model (e.g., LINQ to SQL) [36].

Implementing optimisation in the form of a LINQ provider library gives a developer possibility to resign from aggressive, global query optimisation, e.g. when the order of evaluation is important considering some planned side effects. To enable automatic optimisation, the *AsOptimizable* extension method should be applied to a source collection. It is shown in Listing 14 for the Ikura product example.

```
var ikuraQuery = products.AsOptimizable().
  Where(p => products.Where(p2 =>
                  p2.productName == "Ikura").
    Select(p2=>p2.unitPrice).Contains(p.unitPrice)).
  Select(p => p.productName);
```

Listing 14. Example 1 – automatically optimised.

As a result, a rewritten query is compiled and becomes available for multiple use. One-time overhead occurring at the site of the definition is about a millisecond. A developer should consider runtime optimisation with caution when a query is used only once over a small collection. In contrast to LINQ, Java 8 streams operators are consumable, which prevents multiple usages of the same query. We are not aware of any mechanism enabling rewriting optimisations of Java 8 stream queries at runtime; nevertheless, in the case of consumable constructs the cost of optimisation done at runtime would burden each query execution.

## VIII. Summary

The proposed solution proves that it is possible to provide programming languages offering functional-style access to querying data collections with resource-independent static optimisation mechanisms. We proposed a formal method – factoring out of free expressions – based on higher-order functions rewriting. Its essence is to avoid unnecessary recurring calculations. Factoring out of a free expression that is complex to calculate generally produces a robust performance gain. Such optimisation can be fully automated and does not require any interference or implementation-specific knowledge from a programmer. Using simple examples, we emphasise the significance of the order of evaluation implied by semantics of functional-style operators. Finally, we elaborate general and safe optimisation, considering characteristics of functional-style querying in imperative programming languages.

In contrast to the Nectar system [12], which also uses term rewriting to increase sharing of computations, our work addresses functional-style queries in general, i.e. without context of application which would limit our optimisation. We take advantage of the similar approach to optimisation as Steno [21], LinqOptimizer [22], or SkyLinq [23]. However, we make an attempt to explore more aggressive, global optimisations comparable to optimisations of database query languages.

The presented approach was verified in Microsoft .NET environment and its Language-Integrated Query technology. However, the automated solution has not been straightforward to elaborate due to necessity of considering several variants implied by execution strategies of constructs comprising LINQ queries and complexity of implementing LINQ providers.

Our optimisation for LINQ can be combined automatically with other ones as long as they preserve queries in an expression trees form. In other cases, fusion of optimisations has to be done manually. For example, PLINQ enables to take advantage of multiple cores and achieve several times better efficiency in processing of large collections. Moreover, the optimiser in some cases could automatically (or by a programmer's decision) resign from suspending evaluation of a factored out expression and remove overhead that it imposes. The tests showed that it results in further improvement of performance, up to ~18%. Finally, it seems that transformations would be the most profitable if incorporated in a compiler. Considering source-to-source transformations already performed by the C# compiler on LINQ query expressions [33] this solution imposes itself.

We believe that our work is as a real step towards genuine declarative language-integrated queries. We conduct further works on optimisation of functional-style constructs processing collections. One branch of our research concerns the elaboration of methods that are aware of operators semantics, e.g., addressing complex queries taking advantage of the selection operation, which exposes a huge potential for optimisation (e.g., pushing selection [37]). We also consider adapting other methods, such as revealing weak dependencies within queries that enable performing further factoring out [38].

***Abstract*—The purpose of this paper is to introduce and describe a new Ruby benchmarking tool. We will describe the background of Ruby benchmarking and the advantages of the new tool. The paper documents the benchmarking process as well as methods used to obtain results and run tests. To illustrate the provided tool, results that were obtained by running a developed benchmarking tool on existing and available official ruby benchmarks are provided. These results document advantages in using various Ruby compilers or Ruby implementations.**

## I. Introduction

RUBY IS A PURE OBJECT-ORIENTED interpreted language. The language itself has three major implementations: MRI written in C, JRuby written in Java, and Rubinius written in Ruby. These are often compared in different ways such as usage, performance, and memory requirements. The non-functional attributes of the implementations vary significantly.

Our goal was to develop a benchmarking tool for these implementations that would wrap all of the provided versions and run benchmarks against them. It is important to mention that this paper does not focus on developing benchmarks, but merely on providing a tool capable of taking any kind of existing benchmark, running it against all available Ruby versions, and testing its usability.

To ensure complete isolation of all tested Ruby versions, we used Docker [2] to pack each configuration inside a Docker container. Docker is a open-source tool that enables a Linux application and its dependencies to be packaged as a lightweight container. The benchmarking tool was then developed to handle these containers as well as to validate their content (correct versions, compilation flags, compilers used). It is also responsible for running selected benchmarks and storing their results. In section III, we describe the basic practices used while developing the benchmark tool as well as all of its responsibilities, methods used to collect data, and available Ruby versions.

In our research, we used official available benchmarks from the Ruby repository[1] and a parallelism benchmark from the Rubinius repository[2] to point out some basic characteristics of Ruby implementations and their power. The tool was run on a baremetal and virtual server to provide results from both environments. In section III-D, we describe both environments and their configuration in detail.

The results we present are also available online. The results are in three main areas:

- MRI Versions overview - we have compared multiple MRI Ruby versions to determine the progress mainly in memory usage as new MRI (2.2.0) has announced a new garbage collection algorithm.
- A comparison of MRI compilers determined the differences in using different C compilers to compile Ruby (2.2.0 used in benchmarks). Our results proved that the widely used, also default for a dominant group of linux distributions, version 4.8 of GCC is the best choice for prime performance.
- Running benchmarks on different Ruby implementations not only proved that MRI is best for short single-threaded executions (these tests were extremely short prohibiting to start the just-in-time compilers for JRuby and Rubinius) while JRuby and Rubinius are better for longer or multi-thread runs, but it also showed the progression and power of JRuby in handling parallel tasks and improving in performance from version to version.

## II. State of The Art

Ruby [1] is an interpreted object-oriented programming language which was designed and released by Yukihiro Matsumoto, known as Matz, in 1995. Ruby is a pure object-oriented language in which even values of primitive types (true, false, nil) are represented as objects. It is also suitable for functional programming and capable of powerful metaprogramming.

There are three major Ruby implementations.

The oldest - original implementation - is known as MRI ("Matz's Ruby Interpreter") or CRuby (since it is written in C). CRuby does support native threads, but it uses Global Interpreter Lock [3] (known as GIL) which allows data to be modified only one thread at the time, thus prohibiting true concurrency.

JRuby, as the title suggests, is a 100% Java implementation of Ruby. This allows for Ruby applications to be run on a Java Virtual Machine (JVM), thus utilizing its just-in-time (JIT) compiler, garbage collection, and mainly its concurrent threads. It also allows us to use any library that is compatible with JVM.

Access to the CERIT-SC computing and storage facilities provided under the programme Center CERIT Scientific Cloud, part of the Operational Program Research and Development for Innovations, reg. no. CZ. 1.05/3.2.00/08.0144, is greatly appreciated.

[2] https://github.com/rubinius/rubinius-benchmark

978-83-60810-66-8/$25.00©2015, IEEE

Rubinius is the Ruby version of Python's PyPy. Much of its source is written in Ruby making it easier to understand. It also includes a just-in-time compiler on a virtual machine written in C++.

In December 2013, Sam Saffron published a call for an official long-running Ruby benchmark [4]. At the beginning of development, in November 2014, Ruby still had no long term running benchmarks like Pypy speed center[3] for Python. At that time, there was just one Ruby benchmarking suite that was used by the community to test different configurations and experiment with their performance. The Ruby Benchmark Suite [5] by Antonio Cangiano was developed between the years 2008 and 2013. It uses a host OS and installed rubies to perform tests. During the development of our benchmark tool, Rubyfy.ME, Guo Xiang Tan[4] presented his own benchmark tool in cooperation with Sam Saffron. This became the official ruby long-term running benchmark[5]. His tool uses a single docker image containing all tested Ruby versions. It also provides tests for individual commits in the official Ruby repository acting more like performance CI (Continuous Integration) solution.

## III. Benchmark Tool

In this section we describe the benchmark tool that we have developed. The main aim during development was to ensure the separation of all Ruby versions so they did not share a library or resource that could affect the results. To ensure complete isolation, docker images were created for each Ruby version or compiler. Since this tool is written in Ruby, there are only two system requirements that are required to run the developed benchmarking tool:

- Ruby of version 2.0 or above
- Docker of version 1.0.1 or above

### A. Docker integration

Docker [2] is an open-source program which is capable of packing linux applications and their dependences as a container. Container-based virtualization isolates applications from each other. It runs in userspace on the host operating system utilizing resource isolation and allocation benefits while being much more efficient.

The tool automatically downloads all required docker images and validates a correct Ruby presence. This means that the correct Ruby version, the correct compiler and its version, and the correct compilation flags are present in each docker image. It is also responsible for running benchmarks in correct containers.

Table I lists Ruby versions and implementations that are present in the benchmarking tool.

### B. Running Benchmarks

All benchmarks must be located inside exactly one subfolder in the benchmarks folder. This hierarchy allows to track the origin or divide the benchmarks into groups. There is one special category of benchmarks located inside the benchmarks/custom folder (we will call them custom benchmarks from now) which is handled differently compared to the others. By default, official Ruby benchmarks are present in the benchmarks/ruby-official.

Every benchmark that is not from a custom category is, before its execution, wrapped inside an additional code that captures all of the needed information. Memory usage is stored before code execution. Then, using the official benchmark library for Ruby, time consumption is tracked. At the end, garbage collection is triggered manually and memory usage is tracked once more. This way, the needed time, used memory, and total executable memory are tracked for each benchmark.

Custom benchmarks do not undergo the described flow. Code is executed without modification and standard and error output is captured, thus allowing us to store any kind of information.

Rubinius and JRuby implementations of Ruby contain a just-in-time compiler which results in slower code execution during program startup. For these versions, it is important to warm up the virtual machine (JVM for JRuby) by running the code multiple times or for a short period of time before actually benchmarking. There is still no support because benchmarks need to be adapted to run in loops in order to ensure warm-up. For now, we do not use suitable benchmarks so all benchmarks are run without a warm-up, resulting in slower times for JRuby and Rubinius. However, we plan to add this feature after we ensure enough benchmarks that are able to run in loops.

### C. Storing and Publishing Results

Each run stores a record in a csv file named after the Ruby version used for that run. Each record contains information about the executable benchmark, Ruby version, compiler, and current time. Standard output and standard error output are stored for custom benchmarks while time and memory usage are stored for others.

After providing information about the web interface of this benchmark tool, the user is able to push results from csv files to Ruby on Rails application which provides complex results and graphs.

The feature to publish stored results allows us to build an easy and user friendly presentation. Using the highcharts[6] library, simple graphs were created to simplify collected results. These graphs were split into three main categories: an MRI versions comparison, an MRI C compilers comparison, and a Ruby implementations comparison. Overall, graphs were created for each category as well as for each benchmark.

This tool was developed for community use so its main characteristic is easy usability and extensibility allowing users

TABLE I
RUBY VERSIONS AND IMPLEMENTATIONS

| Implementation | Versions | Details |
|---|---|---|
| JRuby | 9.0.0.0.pre1 | OpenJDK 64-Bit Server, Virtual machine version 1.7.0_75-b13 |
| JRuby | 1.7.12, 1.6.8 | OpenJDK 64-Bit Server, Virtual machine version 1.7.0_65 |
| Rubinius | 2.2.10, 2.3.0, 2.4.0, 2.4.1 | |
| MRI Ruby | 2.2.0 | Multiple images with different compilers: GCC 4.8, GCC 4.9, Clang 3.3, Clang 3.4, Clang 3.5, all on both -O2 and -O3 flags |
| MRI Ruby | 1.6.8 - 2.1.5 (12 versions) | All compiled using GCC 4.8 -O2 |

to easily add new benchmarks, test their own code, or even add more Ruby versions. This tool also comes with its own Rails web application which allows users to see their results in no time. However, this approach makes it harder to specify or focus on some deeper characteristics of Ruby. For example, the user is currently unable to set or change runtime flags, but we are planning to provide this feature in the near future.

### D. Environment

Benchmarking was performed in two independent environments.

- Baremetal Ubuntu 14.04, kernel version 3.13.0-36-generic x86_64 GNU/Linux, with Intel(R) Core(TM) i5-2450M CPU @ 2.50GHz, 2x 8GB Samsung SODIMM DDR3 Synchronous 1333 MHz RAM located on an Intel Emerald Lake motherboard.
- A virtual private server provided by CERIT-SC, configured to 16GB RAM and 8 virtual CPU running Debian 3.16.7-ckt4-3 bpo70+1. This virtual machine is hosted on 2x Intel(R) Xeon(R) CPU E5-2620 0 @ 2.00GHz (12 cores) 96 GiB DDR3 1333 MHz. Center CERIT-SC (CERIT Scientific Cloud) offers computing resources and also participates in research and development activities.

Each Ruby implementation was run with its default settings. We did not use any runtime command flags as there is no support for this feature yet. The only exception was made during a parallelism test when JRuby and Rubinius were run with JIT disabled.

This tool was developed as an open-source project and its sources are publicly available on Github[7].

## IV. RESULTS

Using benchmarks from the official Ruby repository enables us to present results in the following categories:

- MRI Ruby Compilers - a comparison of Ruby compilers (Clang, GCC) tested on MRI Ruby Versions 2.2.0.
- Ruby Implementations - the difference between various implementations and between handling single-thread vs. multi-thread tasks.
- Ruby 2.2.0 Garbage collection - the progress of new incremental Garbage collection announced in Ruby 2.2.0.

Each benchmark was successfully run ten times to provide stable and usable results from both environments. During the benchmarking and development process, the most recent versions of selected implementations were: 2.2.0 for MRI, 2.4.1 for Rubinius, and 9.0.0.0.pre1 for JRuby.

### A. MRI Ruby Compilers

As MRI Ruby (also called CRuby) is written in C, the choice of a C compiler and its compilation flags can affect the performance of a Ruby interpreter.

In December 2014, Peter Wilmott published an article [6] about MRI Ruby compilers. All of his tests were run on AWS from an m3.medium EC2 instance and he used Ruby version 2.1. Using benchmarking suite developed by Antonio Cangiano, his results show a great performance increase from GCC 4.8 to GCC 4.9 and he also pointed out that optimization on level 2 works better than on level 3.

Running all of the official Ruby benchmarks on the Ruby version 2.2.0 on both a baremetal and a virtual server provided by CERIT-SC group resulted in our results being different than those obtained by Peter. Both sets provided us with the same result (Fig. 1 and Fig. 2), thus showing that GCC 4.8 on optimization level 3 (the default shipped for Ubuntu 14.04) is still ahead by a small amount (1-2% faster than GCC 4.9 -O3). The results also provided that level 3 optimization is currently faster for Ruby 2.2.0 (an almost 4% speed increase from GCC 4.8 -O2 to GCC 4.8 -O3).

### B. Ruby Implementations

The main difference between MRI Ruby and Rubinius, JRuby, is that MRI Ruby uses GIL (global interpreter lock) which makes single threaded tasks run faster, but does not permit real concurrency. This is why MRI Ruby is significantly better in overall results (official ruby benchmarks that are used for each category are single thread simple tests and often too short to start a JIT compiler on JRuby and Rubinius, thus making their results even worse) as is shown on Fig. 3 and Fig. 4

Although we used the parallelism benchmark provided in the Rubinius repository[8] to determine the differences in handling parallel tasks. In this benchmark we manually edited the tool to pass command line arguments disabling JIT compilers for JRuby and Rubinius (-X-C for JRuby and -Xint for Rubinius ) because this benchmark is built to run multiple times and provide the best results gathered. This would allow the JIT compilers to activate and radically reduce the execution times.

[7] https://github.com/Ryccoo/rubyfy-me-docker-suite

[8] https://github.com/rubinius/rubinius-benchmark/blob/master/parallelism.rb

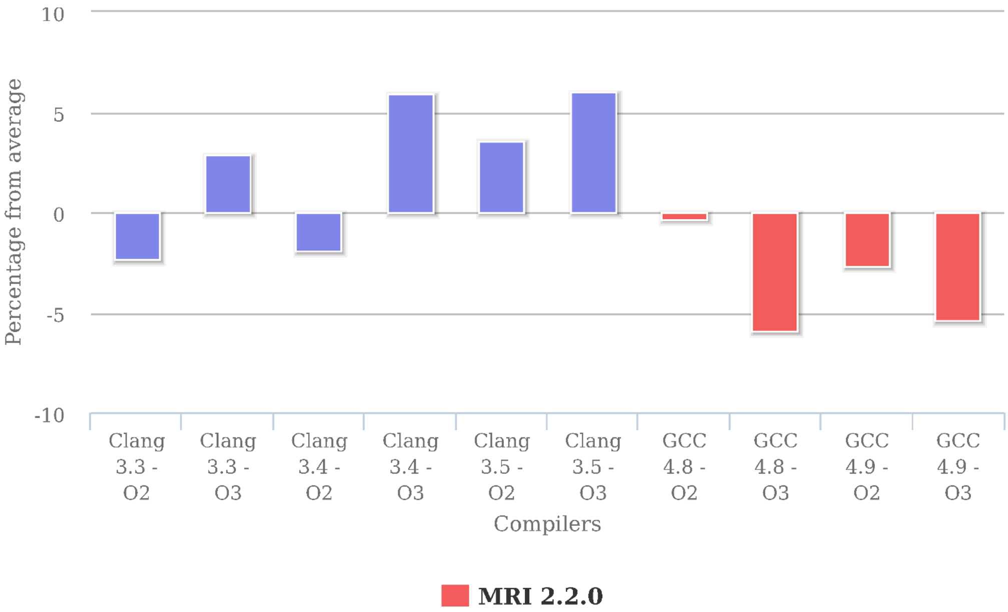

Fig. 1. Overall results for MRI compilers run on CERIT-SC virtual server

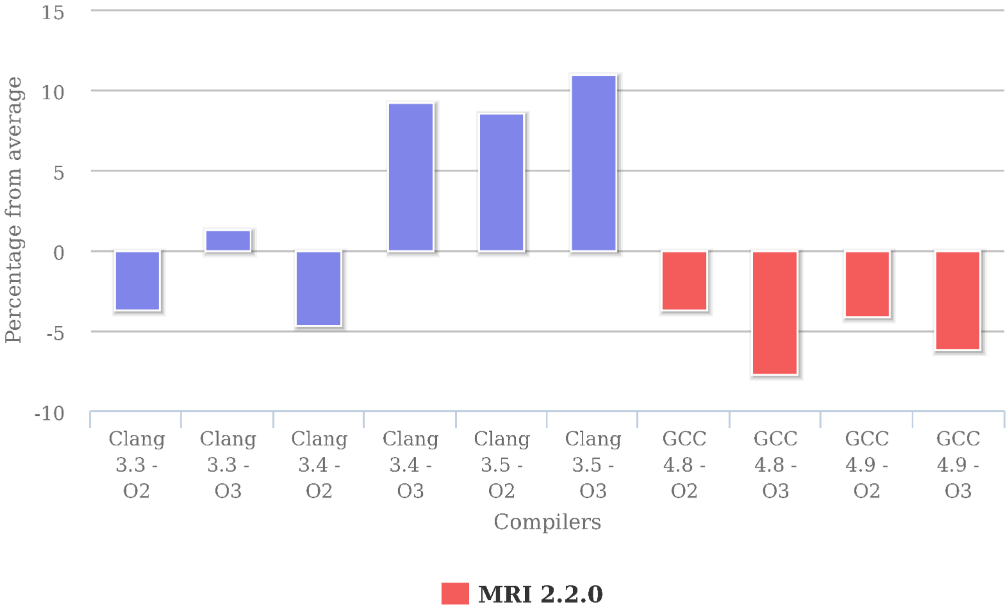

Fig. 2. Overall results for MRI compilers run on a baremetal Ubuntu machine

On Fig. 5 we can see the true power of JRuby parallelism as well as its progression.

The benchmark first computes the amount of work needed to keep the thread busy for two seconds, then runs the same amount of work on each of four threads. Because virtualization (the usage of virtual CPUs) makes it harder to compute and calibrate needed work amount, we present only results from the baremetal machine.

### *C. MRI 2.2.0 Incremental garbage collection*

The MRI Ruby version 2.2.0 has announced new incremental garbage collection. From this version, symbols are also garbage collectable. Symbols are now divided into two categories: mortal and immortal. Immortal symbols are defined inside code while mortal symbols are created dynamically during execution. MRI Ruby 2.2.0 now collects mortal symbols allowing to free up more memory. We were able to watch the decrease of memory usage compared to the previous version as shown on Fig. 6.

These tests were also run separately and aimed at the last

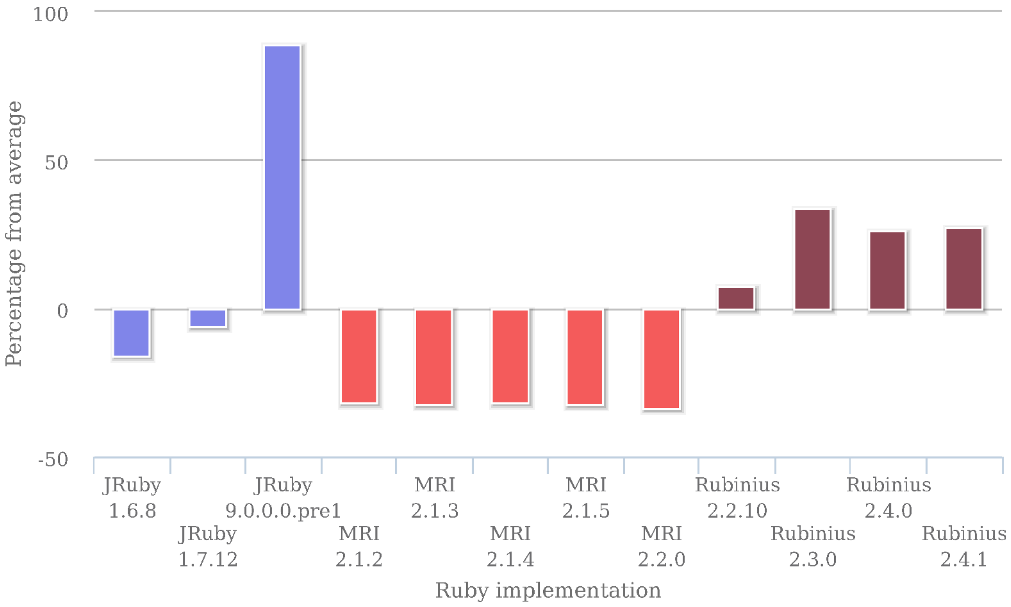

Fig. 3. Overall time performance on different Ruby implementations tested on a baremetal Ubuntu machine

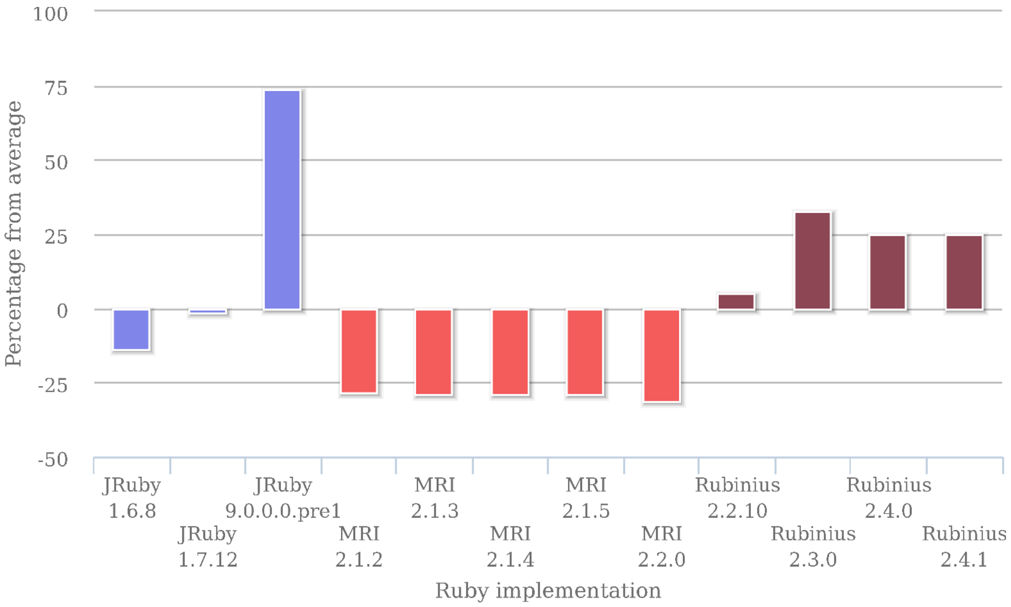

Fig. 4. Overall time performance on different Ruby implementations tested on a CERIT-SC virtual server

Ruby versions which confirmed the gap between ruby 2.1.x and 2.2.0 as shown on Fig. 7.

## V. Conclusion

Our results show that in the case of compiling the newest version of MRI Ruby (currently 2.2.0 during benchmarking) for normal, non-experimental or special use cases, the choice of GCC 4.8 with an O3 flag will provide the best available performance. While this version of a GCC compiler is the default for the predominant group of linux distributions, there is no need to make any changes during Ruby installation.

MRI Ruby is the best choice for computing single threaded simple and short tasks while the GIL (Global Interpreter Lock) is prohibiting to starting real concurrency. This is when the choice of other implementations like JRuby and Rubinius is important. As shown on Fig. 5, JRuby provides us with the best concurrency. This ability increases from version to version. Therefore, JRuby is the best choice for big cloud computations offering multiple virtual CPUs.

It is important to remind that used benchmarks and benchmarking techniques did not allow the warm-up required by JIT compilers, thus results with proper and long enough warming

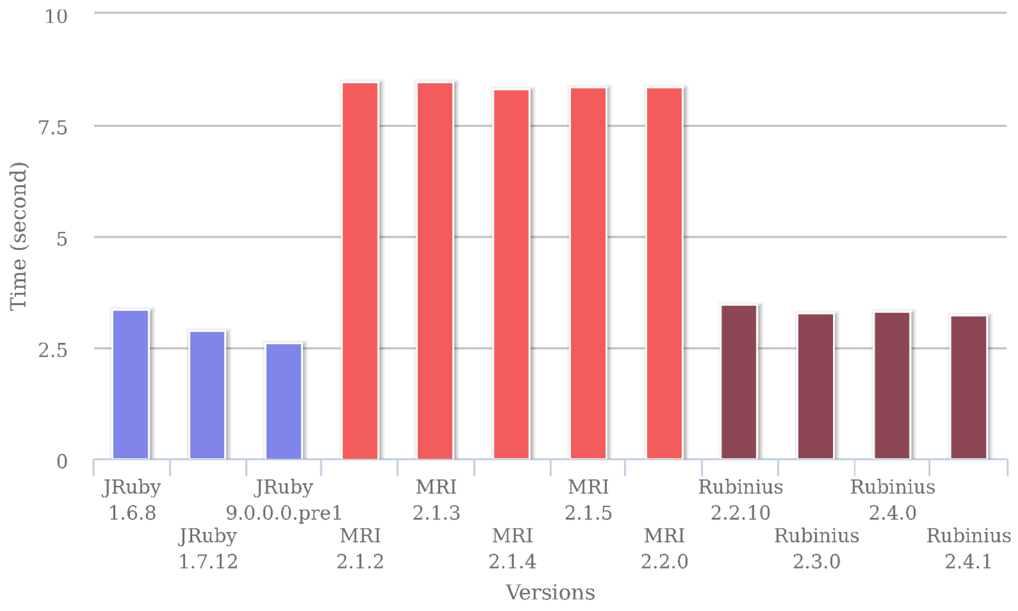

Fig. 5. Rubinius parallelism benchmark - running 4 parallel threads

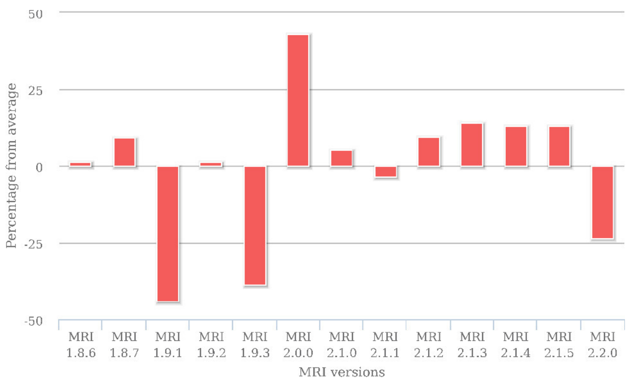

Fig. 6. Memory usage difference from the average

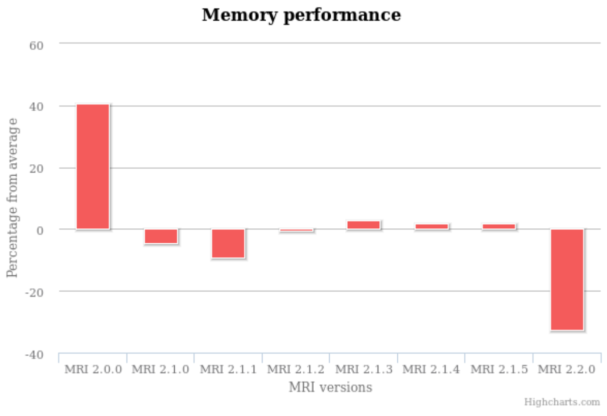

Fig. 7. Difference from average memory usage on recent Ruby versions

could differ on JRuby and Rubinius.

The introduction of new garbage collection in MRI 2.2.0 with the ability to collect mortal symbols can fix a common programmer mistake as a side effect. The problem occurred when the program was converting user inputs to symbols. These symbols were not garbage collectable and the program often drained the entire system memory and ended up freezing. Symbols converted from MRI 2.2.0 are tagged as mortal and garbage collected after being unused, thus not draining the entire memory.

# Source Code Annotations as Formal Languages

Milan Nosáľ, Matúš Sulír, and Ján Juhár
Department of Computers and Informatics
Technical University of Košice
Letná 9, 042 00 Košice, Slovakia
Email: milan.nosal@gmail.com, {matus.sulir,jan.juhar}@tuke.sk

***Abstract*—Attribute-oriented programming (source code annotations) is a program level marking technique that enables enrichment of program elements with custom metadata. In this paper we hypothesize that there is a correspondence between source code annotations and conventional formal languages in general. We analyze our observations about source code annotations from three aspects of language description: concrete syntax, abstract syntax, and semantics. The discussion provides evidence of the hypothesized correspondence and we use it as a basis for our definition of an *annotation-based language* (abbreviated: @L). However, the analysis also shows that compared to conventional formal languages, source code annotations have some specificities mainly connected to their binding to host program elements. The presented analysis contributes to the field of attribute-oriented programming by discussing the relationship between annotations and conventional formal languages, and by surveying relational idioms in annotations' usage that can be inspirational for annotations' authors.**

## I. Introduction

ATTRIBUTE-ORIENTED PROGRAMMING (abbreviated: @OP) as a technique of marking source code elements with source code annotations [1], [2] became quite popular during the last decade, as is manifested by multiple frameworks, such as the Spring Framework. The annotations as a metadata format found the same popularity in the academic environment as well. As an example we can mention an annotation-based parser generator YAJCo, which uses annotations with an object-oriented language model for syntax [3] and references definition [4]. We can also recognize a research field dedicated to annotations. Most important examples include a book about attribute-enabled software development by Cepa [5] that summarizes his research in the field, multiple research articles about enforcing annotations' dependencies in source code such as work of Noguera et al. [1], or one of the first articles on the topic of how to use (or how not to use) annotations by Correia et al. [6].

In our previous work [7] we analyzed the correspondence between annotations and XML in the scope of configuration languages. The main manifestation of the correspondence was the discovery of a set of mapping patterns between annotations and XML. Using the discovered mapping patterns we showed that annotations and XML can be considered equivalent in terms of their expressibility. Based on our previous work, in this paper we want to examine the relationship of annotations and formal languages deeper. A formal language is defined by an alphabet and a set of formation rules (grammar[1]). We will try to show that the same can be applied to annotations.

Our work presented in [7] can be considered a case study on correspondence between annotations and a representative of a generic language, XML. It indicates that there is probably a correspondence between annotations and formal languages in general, as well. Therefore in this paper we hypothesize that *there is a correspondence between annotations and conventional formal languages*. We will provide an analysis of our observations supporting this hypothesis and discuss the annotations from three language description aspects, concrete syntax (abbreviated: CS[2]), abstract syntax (abbreviated: AS), and semantics. The evidence presented in this work indicates that we can use the formal language theory when we are working with annotations. In consequence, the application of the approaches from the language theory can provide benefits for annotations' authors and users. In related work in section IX we will discuss several other works that connected annotations with languages, however, none of them considered this correspondence a hypothesis and tried to prove it. We will conclude the paper in section X with a brief discussion of consequences of proving this hypothesis.

The contributions of this work are as follows:

- observations of corresponding characteristics between source code annotations and formal languages (sections III, VI, and VII),
- discussion of discrepancies between annotations and formal languages (and thus identification of the main specificity of annotations in comparison with formal languages, section IV),
- survey (overview) of relational idioms between annotations and between annotations and their host language that can help annotations' authors during designing the annotations (sections III-B, IV-B, and IV-D),
- discovery of reversed code-wise relations between annotations and their target program elements that emphasize the significance of annotations relation to their host language (section IV-C), and

This work was supported by VEGA Grant No. 1/0341/13 "Principles and Methods of Automated Abstraction of Computer Languages and Software Development Based on the Semantic Enrichment Caused by Communication".
This paper shares contents with the first author's dissertation thesis.

[1] Grammar [8] described by concrete syntax (including also the lexical syntax) and abstract syntax. Abstract syntax describes the structural restrictions between language concepts (words). Concrete syntax describes the actual representation of the language sentences in the given alphabet.

[2] Not to be confused with Counter-Strike.

978-83-60810-66-8/$25.00©2015, IEEE

- definition of *annotation-based language* (abbreviated: @L) and its aspects from the viewpoint of formal language theory (throughout the whole paper with a summary in section VIII).

## II. Source Code Annotations

Before going into discussion about the correspondence we will clarify several essential terms connected with source code annotations. An *annotation-enabled language* (abbreviated: @EL) is any formal language that supports attribute-oriented programming. A language supports the attribute-oriented programming if its grammar (and therefore its parser too) allows adding custom declarative tags to annotate standard program elements. These tags have to be structured and therefore parsable by the parser (or by some additional tool, as in case of XDoclet[3] technology). An example of an @EL is Java programming language from version 1.5. In previous versions the attribute-oriented programming was supported by a 3rd party tool XDoclet. This means that if we add these tags to a valid host language sentence, it still *has* to be a completely valid host language sentence without any preprocessing or other manipulations. In other words, the @EL parser has to have an extension point, a grammar rule, that enables these tags. In case of Java annotations, they are a part of the Java language. In case of XDoclet, the XDoclet annotations are part of standard Java comments.

Annotations do not directly change the source code semantics. They only add metadata to source code. Annotations can be queried and processed on demand by frameworks or tools, or the program itself, thus indirectly changing program semantics.

Custom declarative tags supported by @EL are *source code annotations* (abbreviated: annotations). An annotation annotates an annotation-enabled program element[4]. E.g., a program element can be a method, a function, a class, a statement, etc., depending on language's programming paradigm. We will call the program element annotated by an annotation the *target host program element* (abbreviated: target element) of that particular annotation.

Source code annotations can be also dynamic as discussed by Noguera et al. [9] and Cazzola et al. [10]. Dynamic annotations can have properties that are evaluated dynamically when the annotations are processed (conventional static annotations are evaluated during compilation, just as constants). A dynamic annotation can have a property that is bound to some code property, e.g., a property that is bound to count of loop iterations cannot be evaluated during compile time. During runtime, when the loop is evaluated, the annotation will remember the iteration count and it can be queried. However, dynamic annotations cannot directly change program semantics as well.

The relation between an annotation and its target element has to be expressed by in-place binding. In-place binding requires that an annotation is placed next to or directly into its target program element declaration. The placement has strict rules that are dependent on the host @EL grammar. In General-Purpose Languages (abbreviated: GPL) it is usually expressed by prepending an annotation directly before the program element declaration. Our definition of annotations is presented in Definition 1.

**Definition 1.** *Annotations are custom declarative structured tags in host @EL that are bound to host program elements using in-place binding. Annotations have to be parsable by standard @EL parser (or a 3rd party tool) that allows implementing semantics in form of a plug-in.*

What follows is an analysis of the correspondence between annotations and formal languages.

## III. Abstract Syntax Correspondence

The main idea of the correspondence between a formal language and a set of related annotations stems from the fact that we can observe a structure (abstract syntax) in using annotations from the given set. The observed regularities are not accidental, and in all cases they are even enforced by the processing tools.

### A. Structural Correspondence Example

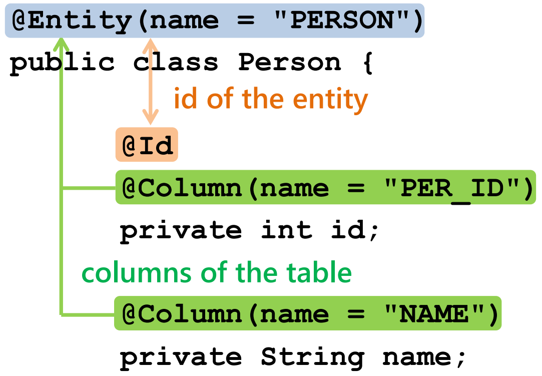
Let us begin with an illustrative example based on Java Persistence API (abbreviated: JPA) annotations. JPA is an object-relational mapping specification for Java. In JPA annotations are used to specify mapping between Java classes and a relational database. In a simple example presented in Figure 1 an `@Entity` annotation is used to specify that the `Person` class is going to be a persisted entity, and `@Column` annotations specify the mapping of fields to table columns. JPA specification requires the user to use the `@Entity` annotation to include the class in the persistence management setup[5]. Without the `@Entity` annotation all the `@Column` and the `@Id` annotations would not be processed by any JPA compliant object-relational mapping (ORM) tool. This relationship is represented by green arrows in Figure 1. Another requirement is that each entity marked with the `@Entity` annotation has to be annotated by the `@Id` annotation to specify which of the fields represent a primary key. This relationship is highlighted in orange in Figure 1.

Considering the example from Figure 1 one can easily notice that the `@Entity` annotation and the `@Column` annotations mimic an abstract syntax tree (abbreviated: AST). Annotations and their properties are nodes, thus modelling a tree. A sketch of such an AST is shown in Figure 2. We also added a simplified AST of the host language to illustrate the binding of annotations to their target elements.

[3] http://xdoclet.sourceforge.net/xdoclet/index.html

[4] Annotation-enabled program element is a program element that can be annotated. In some cases not all program elements can be annotated. E.g., in the Java language the `if` program element cannot be annotated by Java annotations (statements in general).

[5] One can alternatively use `@Embeddable`, or `@MappedSuperclass`, but those have slightly different semantics and are not important for the discussion.



```
@Entity(name = "PERSON")
public class Person {
    @Id
    @Column(name = "PER_ID")
    private int id;
    @Column(name = "NAME")
    private String name;
```

Fig. 1. Mapping of the Person entity class to database using JPA annotations

Now when we look at the given AST, we can easily devise a simple external domain-specific language[6] (abbreviated: DSL) that would to a degree copy the structure of these annotations. Snippet in Listing 1 can be an illustration of an external DSL that expresses the same information as annotations. Here we can see by an example that there is a correspondence between annotations and formal languages.

Listing 1. Person entity definition

```
Entity "PERSON" {
  Id Column   "PER_ID"
  Column      "NAME"
}
```

### *B. Idioms in Structural Relations*

The example shown in section III-A is just an illustrative example. In practice, however, we can find multiple structural stereotypes (idioms) in annotations' usage that support our hypothesis. Each *idiom specifies common structural relationship between annotations* (annotation-based language concepts) and as such defines a part of the annotation-based language's grammar. In this section we will provide a survey of commonly known and recognized structural idioms of annotations' usage. Although for the sake of the discussion about the correspondence a single example would be enough, this overview can be useful for annotations' authors in the process of designing an annotation-based language.

**Vectorial annotation** idiom described by Guerra et al. [12] enables us to add multiple annotations of the same type to the same target program element. An example showing vector of multiple `@Alternative` annotations is presented in Listing 2. Annotation `@Alternatives` has a single parameter of array of `@Alternative` annotations.

Listing 2. Vectorial annotation idiom example

```
@Alternatives(
   {@Alternative(B.class), @Alternative(C.class)})
public class A { ... }
```

**Composite annotation** idiom described by Guerra et al. [12] has annotations as its parameters as well. It allows creation of a tree-like structure of annotations, however, bound to the same target program element. A composite annotation example is shown in Listing 3. In the example there is the `@Author` annotation nesting `@Name` and `@Contact` annotations.

Listing 3. Composite annotation idiom example

```
@Author(
  name=@Name(firstName="Milan", surname="Nosal"),
  contact=@Contact(email="milan.nosal@gmail.com")
)
public class Person { ... }
```

**Inside relation** idiom requires an annotation @A to be inside scope of another annotation @B. E.g., if @A annotates a field of a class then a class (or its outer class or package) has to be annotated by @B. This idiom was described by Noguera et al. in [1] and also by Ruska et al. in [13], where they call it the Parent-child relation. This idiom is a special case of the Required attribute (annotation) idiom described by Cepa et al. [14] specifying that an annotation requires a usage of another annotation to be valid. In the Required attribute (annotation) idiom the scope is arbitrary. We have already seen an example of the Inside relation idiom in Figure 1 and it is reiterated in Listing 4. In it, the `@Id` and `@Column` annotations had to be used to annotate fields of a class annotated by the `@Entity` annotation. Annotated fields are inside the scope of the `@Entity` annotation annotating the enclosing class.

Listing 4. Inside relation idiom example

```
@Entity(name = "PERSON")
public class Person {

  @Id
  @Column(name = "PER_ID")
  private int id;

  @Column(name = "NAME")
  private String name;
  ...
```

**Neighbor** idiom specifies that a valid usage of annotation @A is only in case when its target program element is also annotated with another annotation @B. This does not necessarily mean that usage of @B requires @A (this relation is not commutative). This idiom is also a specialization of the Required attribute (annotation) idiom described by Cepa et al. [14]. Noguera et al. [1] describes this idiom as the Requires idiom. A variation of this idiom is described by Ruska et al. in [13] as the Occurrence of multiple annotations idiom that is commutative. In the following example in Listing 5 the `@Table` annotation requires the `@Entity` annotation annotating the same class in order to be considered for processing by the annotations semantics implementation. In this example only an entity class can be mapped to database.

Listing 5. Neighbor idiom example

```
@Entity
@Table("PERSON_TABLE")
public class Person { ... }
```

[6] A language focused on, and usually also restricted to a particular problem domain [11].

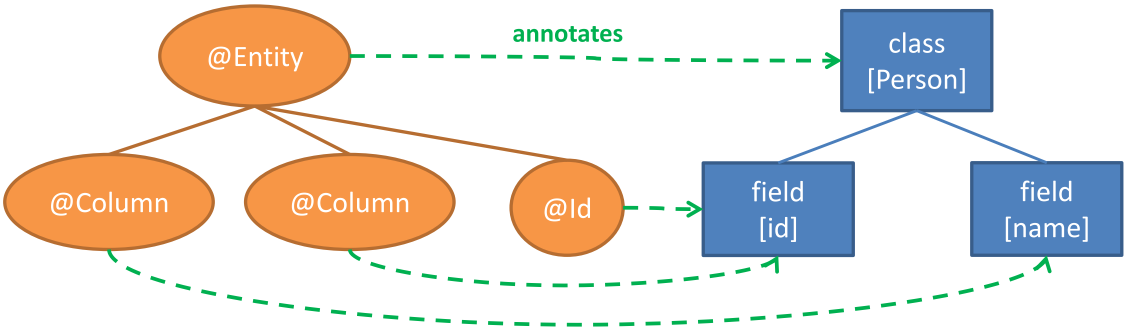


Fig. 2. AST model of the Person entity definition using JPA annotations

**Mutual exclusivity** idiom prohibits usage of an annotation @A if the target program element is annotated with @B (@A and @B are mutually exclusive). The idiom is described by Ruska et al. in [13]. Noguera et al. [1] call the same idiom the Prohibits idiom. This idiom is a specialization of the Disallowed idiom described by Cepa et al. [14] that can specify exclusivity on various scopes, not only on the same target program element. Following code sample from Listing 6 shows an example of invalid use of annotations that are mutually exclusive. In our annotation-based language a field cannot be annotated both by both `@Id` and `@Basic` because a column cannot be both identifier and regular column at the same time.

Listing 6. Mutual exclusivity idiom violation example

```
// incorrect usage of @Id and @Basic
@Id
@Basic
private String name;
```

**Unique annotation occurrence** idiom requires that only one instance of an annotation type can be present in a given scope of the host @EL. The idiom is described by Ruska et al. [13]. A variation of the idiom is mentioned by Noguera et al. [1] as the Unique idiom that can be applied to annotation parameters. This way an annotation-based language designer can specify that the parameter value of the annotation can occur only once in a given scope. In the example from Listing 7 there is a violation of the Unique annotation occurrence for `@Id` in the scope of the class. In this language there cannot be two identifiers for the same entity.

Listing 7. Unique annotation occurrence idiom violation example

```
@Table("PERSON")
public class Person {

  @Id
  private int id;

  // cannot be defined again
  @Id
  private String name;

  ...
```

**Refers to** idiom requires an annotation parameter to be a reference (usually implemented as a simple string) to a parameter value of another annotation. The idiom is described by Noguera et al. [1]. The code snippets in Listing 8 show a Refers to idiom where the `@Author` annotation from class `A` is reused for class `B` by using a reference. `@AuthorRef`'s `value` parameter[7] refers to the `id` parameter of the `@Author` annotation.

Listing 8. Refers to idiom example

```
@Author(
  id="milan.nosal",
  name=@Name(firstName="Milan", surname="Nosal"),
  contact=@Contact(email="milan.nosal@gmail.com")
)
public class A { ... }

@AuthorRef("milan.nosal")
public class B { ... }
```

## IV. Annotations' Abstract Syntax Specificities

We discussed an important observation about correspondence between a set of annotations and a formal language in terms of abstract syntax. However, there are also discrepancies between annotations and a common standalone formal language definition. These discrepancies stem from the very nature of annotations. Annotations are meant to annotate program elements of their host @EL. We have already seen it in the example from Figure 1. The `@Entity` annotation annotated the `Person` class. The `@Id` annotation annotated the `id` field. And so on. In Figure 2 these relations based on annotating are represented by dashed arrows from the AST of annotations to the simplified AST of the host @EL. The use of annotations in context of the host language creates an unusual aspect of abstract syntax that is not present in a standalone language – *relations between annotations and host program elements* that are annotated. In general, grammar defines restrictions for relations between concepts of the formal language. However, in case of an annotation-based language, there are also restrictions on relations between annotations (@L concepts) and host language elements (not @L concepts).

[7] If an annotation type declares a `value` parameter then the name of the parameter can be omitted from the annotation instance as in case of `@AuthorRef`.

These restrictions are characteristic for annotations and in language theory they correspond to language composition.

We distinguish two types of relations between annotations and host language program elements, based on the relation direction:

- *code-wise relations* define annotations' requirements posed on their target elements and the program they are used in, and
- *reversed code-wise relations* specify host language's requirements for the annotations to be used in a context of a given host program element.

In the following sections we will discuss in detail both types.

## A. Code-wise Relations

*Code-wise relations* are relations defining restrictions by annotations to their target program elements. Each annotation may specify some requirements for its target program element. These annotations cannot annotate arbitrary host language element, because the given restrictions have to be kept. Basically, code-wise relations specify on which program elements annotations can be used.

As a standard example of enforcing existing code-wise relations we can mention Java's `@Target` metaannotation (annotation that annotates annotation types). Using the `@Target` metaannotation we can specify what types of Java program elements can a given annotation annotate. E.g., we can use `@Target(ElementType.METHOD)` to restrict annotations to annotate only methods. In C# the support for this type of restrictions is even of a finer grain. However, there are still many useful restrictions that cannot be defined by standard tools. E.g., we cannot restrict an annotation to annotate only an implementation of some interface, such as restricting the `@WebServlet` annotation to annotate only an implementation of the `Servlet` interface.

To illustrate it on a real world example, we can take a look back at the JPA annotations. The code snippet in Listing 9 replays the Person entity mapping with an added field for the person's age. However, JPA does not allow mixing annotating fields and getters/setters. In this case, the last `@Column` annotation will not be processed by the JPA implementation. In case of the `age` field, the JPA `@Column` annotation annotates the setter method, not like in the case of the other fields, which violates JPA specification (we could say it violates the JPA annotations abstract syntax).

Listing 9. Incorrect JPA mapping

```
@Entity(name = "PERSON")
public class Person {
  // an annotated field - OK
  @Id
  @Column(name = "PER_ID")
  private int id;

  // another annotated field - OK
  @Column(name = "NAME")
  private String name;

  private int age;

  // an annotated setter - incorrect
  // (it should annotate the field)
  @Column(name = "FIRST_NAME")
  public void setAge(int age) { ... }
  ...
```

## B. Idioms in Code-wise Relations

There are common structure stereotypes in code-wise relations as well. They indicate that this aspect of annotations usage structure has to be considered a part of annotations abstract syntax. Again, listed idioms are not only an evidence of the discussed aspect of the abstract syntax, but also can be inspirational for annotations' authors. Following is a list of known code-wise relations idioms.

**Target restriction** idiom specifies which types of target program elements can be annotated by the annotations. This idiom is implemented both in Java and C# as a standard validation. Noguera et al. [1] introduces finer-grained validations of the Target restriction idiom on Java platform that they call AvalTarget. Kellens et al. [15] focus on designing a framework for declaring arbitrary requirements on annotations' target program elements. Code sample in Listing 10 shows a standard Target restriction implementation in Java. The `@Override` annotation can annotate only methods, because only methods can override a behaviour. In addition we would want to restrict `@Override` to methods that really override inherited methods. In Java this checking is implemented in standard compiler for the `@Override` annotation, but in general checking like this is left to the annotations author.

Listing 10. Target restriction idiom example

```
// compile-time error
@Override
public class Clazz {

  // valid use (toString overrides inherited method)
  @Override
  public String toString() { ... }
}
```

**Refers to element** idiom specifies that an annotation parameter is a reference to program element from @EL (other than annotations target program element). The idiom is described by Ruska et al. in [13] as Annotation values referencing other elements idiom. A specialized version of the idiom where the annotation refers to a class is described by Guerra et al. [12] as an Associative Annotation idiom. Code sample from Listing 11 shows a usage of the Refers to element idiom to refer to a specific validation implementation class for an annotation type through a parameter of the `@Validator` metaannotation. The `Validation` interface defines validation operation for a given annotation annotated by the `@Validator` metaannotation. The concrete `OverrideValidation` defines specific validation for the `@Override` annotation.

Listing 11. Refers to element idiom example

```
public @interface Validator {
  Class<? extends Validation> value();
}
...
@Validator(OverrideValidation.class)
public @interface Override { }
```

**Type** idiom requires that target program element yields or conforms to a specific runtime type in host @EL. An example might be the type of the field, or the interface of the class. This idiom is described by Noguera et al. [1]. One of the uses for the Type idiom is using annotations as type modifiers (e.g., `@NotNull` annotating only reference types). The following code in Listing 12 shows a valid use of `@WebServlet`. The `@WebServlet` annotation registers a servlet to the web container. Therefore the annotation is supposed to annotate only an implementation of the `Servlet` interface.

Listing 12. Valid Type idiom example

```
@WebServlet(urlMappings={"/MyApp"})
public class MyAppServlet implements Servlet {
  ...
```

### C. Reversed Code-wise Relations

*Reversed code-wise relations* pose restrictions on the host language according to the annotations that are present in the code. E.g., the same way as we can specify the type of the field of a class is the `Person` class, we could also require that the field type (in this case the `Person` class) has to be annotated by a particular annotation (e.g., `@Entity`). Or, we may want an argument of a method to be of a type that is annotated by a particular annotation. Basically, reversed code-wise relations specify how can host language use annotated program elements.

Such requirements we call reversed code-wise relations because they revert the direction that we use to look at annotations and their binding with the host language. Code-wise relations specify in which cases the annotations are not correctly used. Reversed code-wise relations specify in which cases the host language source code is not correctly used with respect to annotations. According to code-wise relations the annotation is invalid if its target program element (or some other program element of the host language) does not exhibit some characteristics. According to reversed code-wise relations the program element is incorrectly used if it or some related program element misses a particular annotation (or has an incorrect one). This kind of relations increases integration of annotations into the host language.

As an example of an error caused by violating this type of requirements is a quite common error in using dependency injection in Enterprise Java. Code sample in Listing 13 shows an invalid use of dependency injection. Both classes are marked as stateless beans and therefore should be managed by a container. `@EJB` annotation marks a server of a mail service implementation to be injected. However, then the `Notifications` class takes control of the `MailService` instantiation by using the `new` keyword. When the objects are created like this, the dependency injection annotations will not take effect and the server will not be injected. This is a case of reversed code-wise relation, because the annotations are used properly, however, the code that uses annotated program elements is not correct. The `MailService` instance should be obtained through the `InitialContext` to be correct.

Listing 13. Using `@EJB` for dependency injection

```
@Stateless
public class MailService {

  @EJB
  private Server server;

  public void sendMail(String mail) {
    server.send(mail);
  }

  ...
}

@Stateless
public class Notifications {
  public void notify() {
    MailService ms = new MailService();
    ms.sendMail(
       "This will throw NullPointerException.");
  }
}
```

### D. Idioms in Reversed Code-wise Relations

We have recognized and identified following two reversed code-wise validations:

**Annotated type** idiom poses a restriction upon entities[8] of the host @EL. It requires that an entity type has to be annotated by an annotation. E.g., a method argument might require an object of a type annotated with a specific annotation. This idiom can enhance the object-oriented dynamic binding of the @EL. Using this idiom a method could require object of any type but annotated with a particular annotation, or with particular annotations in its scope. In the code sample from Listing 14 we use the `serialize` method to serialize an object of the `Person` class. However, using the Annotated type idiom the method serialize requires that the type of the object to be serialized to be annotated by the `@Serializable` annotation (e.g., instead of Serialize marker interface). Therefore the `Person` class has to be annotated by the `@Serializable` annotation for the example to be valid.

Listing 14. Annotated type idiom example

```
public class Serializer {
  // serialize requires argument with
  // type annotated by @Serializable
  public static void serialize(
      @AnnotatedType(Serializable.class)
      Object object) { ... }
}

...

public static void main(String[] args) {
  Person person = new Person("Milan");
  Serializer.serialize(person);
}

...

// for program to be valid, the Person
// class has to be annotated with @Serializable
@Serializable
public class Person { ... }
```

[8] Method argument, variable, etc.

**Annotated program element** idiom requires that the program elements which exhibit some particular characteristics must be annotated by a particular annotation. This idiom is very close to the work of Kellens et al. [15] that uses dependencies like these for co-evolution of annotations with source code. As an example we can use the `@Override` Java annotation in Listing 15. If a method is overriding a method from a superclass it has to be annotated by the `@Override` annotation. If the annotation is not used the program should be incorrect (as in case of the `override` keyword in C#). Code in Listing 15 shows examples of both valid and invalid program elements.

Listing 15. Annotated program element idiom example

```
public class A {
  public void a() {}
  public void b() {}
}

public class B extends A {

  // invalid program element
  public void a() {}

  // valid program element
  @Override
  public void b() {}
}
```

## V. Abstract Syntax Correspondence Summary

According to the presented discussion we can summarize our conclusions as follows. Considering the abstract syntax (AS) of a language defined by source code annotations we have to consider following components of annotations' AS:

- relations between annotations – **structural restrictions**,
- annotations' requirements on @EL concepts – **code-wise restrictions**, and
- @EL concepts' requirements on annotations – **reversed code-wise restrictions**.

While the relations between annotations match the standard abstract syntax of a standalone formal language, the other two are specific for annotations. The code-wise and reverse code-wise restrictions can be in general compared to embedding as a form of language composition, but annotations tend to come with more complex constraints on their usage and in case of an embedded language the embedded portions are usually not dependent on each other (without structural restrictions). And, from the implementation viewpoint, embedded languages usually have own parser.

If we consider a set of related annotations an *annotation-based language*, then based on our discussion we will define the abstract syntax of an @L as in Definition 2. So far there is not a standard formal apparatus for describing the full AS of @L. However, there are several approaches to this problem in the academy that we will review in section IX.

**Definition 2.** *The abstract syntax of an @L is a set of structural, code-wise and reversed code-wise restrictions on @L annotations' usage. These restrictions represent formation rules that specify a valid @L sentence.*

## VI. Concrete Syntax Correspondence

Of course, the correlation between annotations and formal languages does not end with abstract syntax aspect of the formal language description. Clearly, the annotations themselves need to have a concrete way of presentation (and serialization). In this section we will take a look at how the concrete syntax of annotations is defined.

@L author can design the @L in terms of the abstract syntax as we have already discussed. Of course, it is only logical that she should be also able to specify how the annotations of the @L will be presented in the source code of the host language. In most common @EL the apparatus for the concrete syntax definition are *annotations type*s. A specific of annotations in terms of concrete syntax when compared to formal languages is annotations' binding to target program elements. Both of these aspects will be discussed in following sections.

### A. Annotation Types

Annotations are instances of annotation types the same way as objects are instances of classes in object-oriented programming. An annotation type is a definition of a structure of a set of annotations. It defines what parameters can an annotation have, what is the name of the annotation, etc. Using annotation types the @L author can specify what are the @L terminal symbols – annotations' and parameters' names, and their values' types. Just for illustration we can take a look at the code snippet in Listing 16 presenting a simple annotation in C#. This annotation type defines annotations with name "Configuration" and two parameters, the first an integer identified as "paramId", and thesecond a string identified as "paramValue". If the @L consisted only of annotations of this type, we could easily identify its lexical symbols - "Configuration", "paramId", "paramValue", integer value and a string. The Java version of the same annotation type is presented in Listing 17.

Listing 16. C# version of the `Configuration` annotation type

```
public class Configuration : System.Attribute
{
  public int paramId;
  public string paramValue;
}
```

Listing 17. Java version of the `Configuration` annotation type

```
public @interface Configuration
{
  public int paramId();
  public string paramValue();
}
```

Another interesting fact the reader might have noticed is that the annotation types can partially define abstract syntax. If one of the parameters accepted annotations[9], then the annotation would be an instance of the Composite annotation idiom.

However, even in CS there are discrepancies between annotations and formal languages. The CS of annotations is restricted to follow some rules in order to be parsable by the

[9] Currently, annotation nesting is not supported in C#, but there are implementations that allow it, e.g., Java annotations.

standard @EL parser (or the 3rd party tool). In @EL GPLs those rules are defined by the GPL grammar.

Let us take a look at a set of grammar rules[10] of Java 8 that specify the grammar for Java annotations that are listed in Listing 18.

Listing 18. Grammar rules for the Java 8 annotations

```
Annotation ->
   NormalAnnotation | MarkerAnnotation
   | SingleElementAnnotation

NormalAnnotation ->
   ’@’ TypeName ’(’ [ElementValuePairList] ’)’

ElementValuePairList ->
   ElementValuePair {’,’ ElementValuePair}

ElementValuePair -> Identifier ’=’ ElementValue

ElementValue ->
   ConditionalExpression
   | ElementValueArrayInitializer | Annotation

ElementValueArrayInitializer ->
   { [ElementValueList] [’,’] }

ElementValueList ->
   ElementValue {’,’ ElementValue}

MarkerAnnotation -> ’@’ TypeName

SingleElementAnnotation ->
   ’@’ TypeName ’(’ ElementValue ’)’
```

These grammar rules specify CS restrictions on Java annotations. As we can see, annotations have to start with the ’@’ sign, followed by the annotation name. Then there are optional annotation parameters enclosed in parentheses, and so on. Considering we had an Java annotation type for the `Configuration` annotation type presented in Listing reflst:javaAnnType, then a concrete Java annotation would look like the annotation in Listing 19.

Listing 19. Java `@Configuration` annotation example

```
@Configuration(paramId=1, paramValue="new")
public class A {
  ...
```

Of course, the different attribute-oriented programming implementations might have different restrictions. E.g., in C# the annotations are not prefixed by the ’@’ but enclosed with brackets, and have some other minor differences from Java annotations. The same `Configuration` annotation in C# (annotation type in Listing 16) would look like the code in Listing 20.

Listing 20. C# version of the `Configuration` annotation

```
[Configuration(paramId=1, paramValue="new")]
public class A {
  ...
```

In a conventional formal language the language author is usually not restricted by any such rules. In this aspect annotations resemble more generic languages[11], such as XML languages, and alike; that are built around a given syntactic skeleton.

### B. Binding Rules

@L CS has another specific aspect – *binding rules*. Each annotation *marks* (annotates) its target program element. This relationship is expressed by the relative position of annotation to its target element. Again, the binding rules for a specific @OP implementations might differ. These rules have to ensure that for each annotation there will be unambiguous mapping to its target language element and that for each program element there will be unambiguous way of finding its annotations. The most common binding for annotations is using annotations as prefixes[12]. E.g., the Java annotations are considered modifiers and therefore they prefix declarations just as Java modifiers do. The reader has seen already seen multiple examples of Java annotations usages. This can be also illustrated by Java grammar for class modifiers in the Java 8 grammar excerpt[13] in Listing 21. The excerpt shows that class annotations prefix the class declarations.

Listing 21. Grammar excerpt for class modifiers showing in-place binding of Java 8 annotations

```
NormalClassDeclaration ->
   {ClassModifier} ’class’ Identifier ...

ClassModifier ->
   Annotation | ’public’ | ...
```

Since Java 8, annotations are supported on types, too. Listing 22 is a grammar rule[14] for primitive types that shows type annotations allowing to annotate types.

Listing 22. Grammar rule illustrating type annotations

```
PrimitiveType ->
   {Annotation} NumericType
   | {Annotation} ’boolean’
```

There might be additional rules for binding, as for example a restriction in Java requiring that two annotations of the same type cannot annotate the same target program element.

### C. Summary

Each particular @EL defines its own concrete syntax skeleton for adding annotations to its source code. While the restrictions posed by @EL have to be kept, the @L author can use annotation types to define the rest of the concrete syntax. Therefore we will define the concrete syntax aspect of @L by Definition 3.

**Definition 3.** *The concrete syntax of an @L is specified by restrictions posed by the host @EL in combination with the*

*set of concrete annotation types of annotations that belong to the @L.*

## VII. Semantics Correspondence

According to Kleppe [18], a sound language description would not be complete without a semantics description. And of course, the same applies to annotation-based language. There are multiple ways of describing semantics of a language. An annotation-based language is usually described by dynamic semantics that is defined by the tool processing the annotations (the *reference implementation* [18]).

There are two approaches to @L reference implementation:

- **compile time processing** is implemented as a pluggable annotation processor plugged to the host @EL compiler, and
- **runtime processing** is implemented as a reflection mechanism.

*Compile time processing* is implemented as a pluggable annotation processor. The host @EL parser creates an AST with annotations and provides it to all registered annotation processors. The AST with annotations can be used to generate code or other software artefacts, to generate documentation or even to manipulate the AST. E.g., in Java there is a standard implementation of pluggable annotation processing API released under JSR 269 specification[15]. This standard annotation processing API does not support AST modification and can be only used to generate new artefacts. An alternative to JSR 269 is a Spoon API by Pawlak [19] that enables fine grained source code modifications.

*Runtime processing* is implemented as an API that allows some form of runtime reflection for querying annotations. Runtime processing is usually used to read configuration of frameworks and programs. Languages such as Java or C# provide standard Reflection API that can be used to query for annotations on program elements such as classes, method, etc. These can be used to find out whether there is a particular annotation annotating the chosen program element. However, these APIs do not enable searching for annotations in a set of program elements (e.g. finding all the occurrences of specific annotation on all the classes on classpath) and likewise operations. These types of queries common in compile-time annotation processors. The need for the same feature in runtime is reflected by commercial runtime APIs, such as Scannotation[16] or Google Reflections[17].

An interesting hybrid of the compile-time and runtime processing is aspect-oriented programming (AOP) with annotations. Annotations in AOP can be used to bind aspects to program elements. This way we can add, remove, or modify the code. The final weaving of the aspect may happen both during compile-time and runtime, depending on used AOP implementation.

Each annotation-based language defines its semantics using one of the discussed approaches. Thus, we define @L operational semantics by Definition 4.

**Definition 4.** *The @L semantics is described by reference implementation using a pluggable annotation processor or a GPL code using reflection API. Reference implementation may use convenience frameworks, such as Google Reflections.*

## VIII. Annotation-based Language

We presented our observations indicating a close correspondence between source code annotations and formal languages. We proposed definitions of the three main annotation-based language definition components - @L abstract syntax, concrete syntax and semantics. Based on the presented discussion we propose to define a term *annotation-based language* to describe a given set of annotations that are processed by the same reference implementation with the same goal. For example, if we have a set of JPA annotations used to describe mapping of Java classes to relational database that are processed by a JPA implementation (e.g., Hibernate), we can consider them an @L. Our formulation of the @L definition is presented in Definition 5. In it we assume that the same reference implementation implies the same annotations problem domain (e.g., object-relational mapping).

**Definition 5.** *Annotation-based language (@L) is a set of all annotations and their parameters (*alphabet*) processed by the same reference implementation. It is defined by the reference implementation (*semantics*), structural, code-wise and reverse code-wise restrictions (*grammar – abstract syntax*), and their annotation types (*grammar – concrete syntax*).*

For example, if we have a set of JPA annotations used to describe mapping of Java classes to relational database that are processed by a JPA implementation (e.g., Hibernate), we can consider them an @L. This @L is of course defined by all three language aspects of CS, AS and semantics according to definitions we have proposed.

We have also noticed that the main source of the discrepancies between @L and a conventional formal language is the binding of annotations to target elements of the host language. Therefore we will emphasize the importance of the binding in the @L. We can therefore identify two main components of the @L:

- @L **concepts** represented by annotations and their structural relations, and a
- *meaningful* **binding** between concepts from @L and host @EL (represented by code-wise and reverse code-wise relations).

These two @L components are illustrated on the example with JPA mapping of the Person class in Figure 3. @L concepts are the annotations themselves, the binding maps the annotations to host language program elements.

We expect the binding between annotations and their target elements to be meaningful. That means that changing the target element of an annotation should also change the meaning of

```
@Entity(name = "PERSON")
public class Person {

    @Id
    @Column(name = "PER_ID")
    private int id;

    @Column(name = "NAME")
    private String name;
```

Fig. 3. Illustration of concepts and binding @L components on JPA example

the @L sentence to which the annotation belongs. E.g., if we consider the example of JPA configuration in Listing 4, moving the `@Id` annotation from the `id` field to the `name` field would define a different object-relational mapping, although the @L sentence would consist of the same annotations.

## IX. Related Work

There are several works that aim at annotations' relations definition[18]. They either provide a framework to define and validate more-or-less arbitrary dependencies between annotations and their target elements or they provide implemented common stereotypes in @L structure that can be reused for validation. These idioms show common stereotypes in annotation-based abstract syntax definition. Most of the works were already referred throughout the paper, in this section we will provide a brief summary.

Darwin [21] devised a DSL for dependencies description. His aim, contrary to the other works, was to provide a framework for describing dependencies for third party @Ls. The author of rules was to be a user of @L and not its author. Ruska et al. [13] identify several structural idioms and provide a framework for checking dependencies. In their approach they store the source code model into a database and run SQL queries representing constraints. They designed a Prolog-like DSL for convenient rules writing. Although both of these works do not explicitly mention the term annotation-based language (or any synonym) they admit that annotations have some structured dependencies that we consider a recognition of abstract syntax of @L.

Kellens et al. [15] introduce so called Smart Annotations. Smart Annotations declare their sufficient and necessary requirements. Necessary requirements declare what characteristics the annotated element must exhibit so the annotation usage is valid. Sufficient requirements are dual to necessary and they declare that if there is an entity in the code exhibiting characteristics required by it then it should be annotated by the annotation. Their work is focused on code-wise dependencies and they aim to provide better control of evolution of annotated software. Their sufficient requirements exhibit characteristics of the reversed code-wise dependencies.

Cepa et al. [14] is one of the first works that concerns checking dependencies between annotations and the host @EL. Although their framework was quite limited in supported restrictions[19], in their work they also look at annotations as a form of a language framework. They realized that annotations can be used to enhance the host GPL with domain-specific concepts thus acknowledging @OP as a form for DSL-like language extensions.

Noguera et al. [1] went even further than Cepa et al. and stated that *"a set of annotations dedicated to a given domain-specific concern can be referred to as an Attribute Domain-Specific Language (AttDSL)"*. They therefore consider annotations a language and not only a language extension. They distinguished between structural and code-wise dependencies (we used their naming).

Song et al. [22] introduce metadata invariants that are not exclusive for annotations but work for XML languages, too. They use Metadata Invariant Language (MIL) to write invariants for annotations or XML documents. MIL can be used to check structural and code-wise dependencies. Their work assumes that for an @L there can be a standalone external language that shares part of the @L semantics (multiple concrete syntaxes). We have utilized the same property of a subset of @Ls in our previous work [23]. We designed a tool that is able to create AST for @L and combine it with concepts from a separate XML-based language that is an alternative notation for the @L. The tool takes a mapping between the two formats.

The furthest advance towards @L we consider the work of Noguera and Duchien [24]. Not only they recognize @L, but they also designed a method for creating Annotation Model, a UML model of annotation-based language. They use this model and its binding to code model (AST of the host @EL) to check annotations restrictions.

Cepa in his book about @OP [5] connects the annotations to languages too. He mentions that annotations can be seen as a convenient way of extending the grammar of the language. With the work of Noguera et al. [1] Cepa's ideas were the main inspiration for this work. However, in his work he considers the annotations only as an extension of the grammar and as an alternative for adding domain-specific abstractions to the source code, and only briefly mentions annotations as a restricted form of embedded DSL. He does not further examine the correspondence between annotations and languages.

[18] We focus solely on the source code annotations defined in section II as a language implementation strategy. Therefore we will not discuss works such as Bonenfant et al. [20], which also use the term *annotation language*. However, they use it in different context than us. In their work the annotations are any custom metadata (their *annotation language* is an XML-based language).

[19] E.g., it cannot check dependencies between annotations on program elements in the same scope in program model.

From the viewpoint of existing @Ls, we could find multiple sets of annotations defined for the same domain and processed by the same semantics reference implementation. There are sets of annotations defining GUI from data model [25], annotations used for plugin extension definition [26], @L for design patterns definition [27], @L for model checking [28], and so on.

There are not many works concerning @L design, however, one can find some inspiration in analysis provided by Mancini et al. [29]. They discuss options of using annotations and their design for data validation definition. All the above mentioned works about annotations usage restrictions define some annotations AS idioms that can be used for @L design as well. Guerra et al. [12] discuss solely annotations idioms both in CS and AS. Correia et al. [6] discuss bad smells that can be result of bad annotations design or their usage. They also provide a set of possible solutions to remove them. Correia et al. [6] show that annotations syntax can be as important as their domain usability [30].

## X. Conclusion

This paper presented our observations about correspondence between source code annotations and formal languages. The correspondence was illustrated on three definition aspects of formal languages – abstract syntax, concrete syntax and semantics. For each of these aspects also the discrepancies were discussed. While the correspondence indicates that we should look at annotations as a form of language (and therefore we define the term *annotation-based language* for a set of domain-specific annotations), the discrepancies identify the main specificity of annotations that separates it from conventional formal languages. This specificity is the binding of annotations to their host annotation-enabled language.

Realizing the correspondence between annotations and formal languages we can draw some consequences for future research directions. For example, XML generic language provides several mechanisms to define an abstract and concrete syntaxes of concrete XML languages, e.g., XML schema definition, Document Type Definition, etc. In practice we can notice notorious lack of similar mechanisms for @Ls. Annotation types are usually not sufficient to describe the relations that are common in @L. A common practice is to describe the grammar using natural language documentation. Considering the presented correspondence, then instead of natural language documentation, the formal methods of abstract syntax definition can be applied. Methods such as EBNF are commonly known and therefore their application can make the annotation-based language syntax more comprehensible. In section IX we discussed several academic works that implement frameworks for @L abstract syntax definition, but so far none of them became industrial standard. So a logical consequence of the correspondence is the *need for standard AS definition formalism/mechanism for annotations*. In this matter there was a small step further in Java 8 type annotations.

The standard AS definition formalism/mechanism for annotations cannot be restricted to mere @L AS validation. Another important feature is the ability to create a fully annotated AST. In Figure 2 we have sketched the AST with annotations' relations in mind. However, currently the @EL implementations do not support @L AS and therefore the AST nodes representing annotations have no explicit relations with other annotations (unless annotation types support it, such as in case of Composition annotation idiom in Java). Supporting these relations explicitly could prove beneficial for @L authors and their semantics implementation.

Another observation that is related to our discussion is the lack of unified API for semantics reference implementation in runtime and in compile time. Currently, standard @EL implementations provide two distinct APIs for annotation processing and for runtime reflection. This observation was authored by Cepa [5] quite a long time ago, but to our best knowledge no real advance was made in industry in this matter.

In general we can consider annotations a *generic embedded language*. They provide a syntactic skeleton that on one hand restricts @L author in concrete and abstract syntax, but on the other hand provides standard tools for their parsing (either the host language parser or a third party tool). But in contrast to generic languages they are restricted to embedding into the host language; they have to annotate its program elements. Based on this observation, in our future work we want to analyze options of using annotations for language composition. From the observations presented in section IV we learned that annotations' specificity is their binding to host language. In the future work we want to examine types of language composition that can utilize annotations as an implementation technique.

Email: peter.pigula@student.tuke.sk, milan.nosal@gmail.com

*Abstract*—**Java provides two different options for processing source code annotations. One of them is the annotation processing API used in compile time, and the other is the Reflection API used in runtime. Both options provide different API for accessing program metamodel. In this paper, we examine the differences between those representations and we discuss options on how to unify these models along with advantages and disadvantages of this approach. Based on this proposal, we design a unified Java language model and present a prototype tool which can populate a unified model during both compilation and runtime. The paper includes the designed API of this unified language model. To verify our approach, we have performed experiments to show the usability of the unified metamodel.**

## I. Introduction

SINCE the year 2004, when annotations were first introduced to Java, this programming technique is on the rise. More and more programs use annotations during compile time for code generation [1], [2], and in runtime for configuration and reflection [3]. In spite of the fact that usage of annotations in both instances is often very similar, means to access annotations and program model, as well as their representations, are different. If a developer needs to complete the same task in both compile time and runtime, she has to be familiar with both of them, and would have to create two different versions of the source codes. That is because code using annotation processing API cannot be used during runtime, and vice versa.

We came across this problem during our previous work. We designed a tool (*Bridge to Equalia* [4]) that provided an abstraction layer to two most common configuration formats in Java – XML and source code annotations. *Bridge to Equalia* (abbreviated: *BTE*) uses XML to annotations mapping patterns [5] to shorten the configuration interface code in cases when both annotations and XML should be accepted interchangeably. To query the annotations, *BTE* uses Java Reflection API in combination with the Scannotation [6] library. Therefore, it works only in runtime (Reflection API requires compiled classes). As we wanted to use *BTE* also in projects that work during compile time, we faced the problem of working with different APIs for annotation processing during in runtime and in compile time.

**Algorithm 1** Checking whether a field is public during runtime

```
boolean isFieldPublic (Field field) {
  if (Modifier.isPublic(field.getModifiers())) {
    return true;
  }
  return false;
}
```

**Algorithm 2** Checking whether a field is public during compile time

```
boolean isFieldPublic (Element field) {
  for (Modifier modifier : field.getModifiers()) {
    if (modifier == Modifier.PUBLIC) {
      return true;
    }
  }
  return false;
}
```

*BTE* is a medium size project with a complex implementation, therefore we will not use its source code as a case study for the illustration of the problem. Just as an example of the APIs' diversity we can take a look at the representation of the accessibility modifiers of Java program elements. During runtime, modifiers are encoded to a single integer value. Every bit of this integer represents one modifier. On the other hand, during compile time modifiers are represented as a set of enumeration types `Set<Modifier>`. Each element of this set represents one modifier. This means that for example a method, which checks whether a field is public or not, would be different in both runtime and compile time. Implementation of such a method during runtime is presented in the algorithm 1. Implementation of the same method in compile time is presented in the algorithm 2. We have to note that although both listings use the `Modifier` type, they are both different and belong to different packages. Of course, the *BTE* implementation works not just with modifiers, but many other types of metadata (program elements' names, annotations, annotations' parameters, code tree structures, etc.).

In this work we want to *share our experience with designing and implementing a tool that provides a unified API to Java source code model during runtime and compile time*. We will discuss challenges in the design that we faced, and we

This work was supported by VEGA Grant No. 1/0341/13 "Principles and Methods of Automated Abstraction of Computer Languages and Software Development Based on the Semantic Enrichment Caused by Communication".

978-83-60810-66-8/$25.00©2015, IEEE

will present the designed API (that was also implemented and can be found at https://github.com/mallynth/UModel). We conclude with a simple experiment that evaluates the tool's performance against standard APIs.

Since there is currently no unified representation in Java, developers who come across this problem are left with only a single option, which is to create two versions of the source code dealing with the same problem in different representations. In small tasks, this option is not that time consuming. But with increasing complexity of the processed annotations it may lead to code difficult to manage, maintain and evolve. In cases like this, unified representation could reduce the needed work by half, and apply the Single point of responsibility principle.

Having two versions of the code accessing annotations goes against *Single point of responsibility* principle. This leads to potential problems during evolution and maintenance (as we faced with the *BTE* tool). Suppose we have two programs that are used for the same purpose, but one of them is used during compile time, and the other during runtime. Degree of difference between these programs would not be very high, because they were developed using the same algorithm, and they just use different APIs. Now let us suppose that we need to implement a change of the base algorithm. That means we need to change both versions of the code separately from one another in order to implement the desired change. This increases the risk of a bug, e.g., when a developer forgets to make a change in one of the versions, or she misses an important difference in APIs. This leads to overhead in testing, because again, both versions need to be tested separately.

Cepa [7], [8] deals with similar problem about the representation of metamodel in programming languages. He recognizes the need for a generalized representation of the program by using a graph of metadata nodes that could be used in compile time, loading time and runtime. He then proposes a Generalized and Attributed Abstract Syntax Tree (GAAST), which is a syntax tree of the language enriched by annotations. The recognition for the need of GAAST support stemmed from his work on his framework MobCon [9], which is a framework used to generate mobile applications in Java. His work in combination with our previous work with *BTE* was the main inspiration for this work.

Contributions of this paper are following:

- we analyse options by which unification of both program model representations in Java can be achieved,
- we discuss and explain the pitfalls that need to be considered during the design and implementation of the unified model, and
- we present the designed API for projecting standard source code models into a unified Java program model during both compile time and runtime.

## II. Existing Program Models

Annotations in Java are used as a source code decoration mechanism. It means that they do not directly influence the control or data flow of the program that is annotated. A study [10] performed on the curated collection of programs Qualitas Corpus [11] showed that more than 60% of analyzed programs are using annotations. That includes systems developed before annotations were introduced to Java. This study provides evidence that annotations are an important part of Java.

**Algorithm 3** Declaration of annotation with source code retention

```
@Retention(RetentionPolicy.SOURCE)
public @interface SourceAnnotation {}
```

**Algorithm 4** Declaration of annotation with runtime retention

```
@Retention(RetentionPolicy.RUNTIME)
public @interface RuntimeAnnotation {}
```

Annotations can be used to express metadata of a program. They can be accessed by the developer in two different ways:

- during **compile time** using annotation processing API, and
- during **runtime** using Reflection API.

Both of these ways offer metadata to the developer in a different representation. Both representations are basically *program models* that include all metadata available at the given time. Program model available during compile time is represented by classes in a package `javax.lang.model.element` [12] and the model available during runtime is represented by classes in a package `java.lang.reflect` [13]. These models are accessed and queried using different APIs. When their difference is not important for the sake of discussion, we will refer to them simply as **basic models**.

Probably, the main reason of their difference is that they are used in a different phase of a program life cycle and different metadata are available during those phases. However, they are still similar since they represent the same program structure.

To illustrate the difference, we can mention annotations marked by the `@Retention` metaannotation. In the code fragment 5, the `SomeClass` class is annotated with two annotations `SourceAnnotation` and `RuntimeAnnotation` which are declared in code fragments 3, and 4 respectively. In this example, if we would access the metamodel during compilation, we would get both annotations. However, if we would access the metamodel during runtime, we would find out that the `SomeClass` class is annotated only with the `RuntimeAnnotation` annotation. That is because `SourceAnnotation` is marked with meta-annotation `@Retention(RetentionPolicy.SOURCE)` to indicate that it should be discarded after annotation processor finishes, and therefore it will not be available during runtime.

Another difference is the option for running methods of the code. In reflection, the developer can invoke methods unknown during compile time using reflection API. However, in compile time the API does not support invoking of processed code, since in that time the classes have not yet been compiled.

**Algorithm 5** Usage of annotations

```
@SourceAnnotation
@RuntimeAnnotation
public class SomeClass {
  ...
}
```

The differences do not end with different models. It is very common that the developer only needs some metadata that are present in both models, e.g., names of classes that are marked with a specific annotation. The problem is that the API for acquiring those metadata are different in both models, in spite of the fact that they are the same metadata. In some cases, in addition to the method of acquiring metadata being different, the representation of the metadata is also different (as in case of modifiers discussed in the introduction).

Examples of similar elements in both models can include names of classes, their methods or hierarchy of classes.

### A. Annotation Processing Program Model

Annotation processor is executed before compilation of the program and the execution itself is divided into separate rounds. Annotation processor can acquire metadata that are present in source code as well as metadata that were created in previous rounds of this processor execution.

Main class, that is used to represent entities in the program model for this API is the `Element` class. Instances of this class can represent multiple different entities, such as classes, interfaces, methods or fields.

*1) Accessing Metadata in Annotation Processor:* The main method that every annotation processor must have is the `process` method. As its name suggests, this method is doing the annotation processing. One of the parameters of this method is an environment of current round represented by the `RoundEnvironment` class. From this environment, the developer can acquire metadata that she needs.

One of the methods for acquiring metadata from round environment is by using the method `getRootElements`. This method returns list of all root elements of the program that are represented by `Element` class. The `Element` class has a field `kind` which defines what this element represents (class, interface, method etc.). By querying these elements, it is possible to find metadata that are needed.

Different way would be to use the `getElementsAnnotatedWith` method which returns a list of elements that are marked with a specific annotation. When using this method, there is a useful annotation `@SupportedAnnotationTypes`, which can be used to mark the annotation processor class. It specifies annotation types which annotations are supposed to be retrieved from the source codes during annotation processing.

### B. Reflection Program Model

Reflection can be used during runtime and it provides a way for accessing the metadata of the running program.

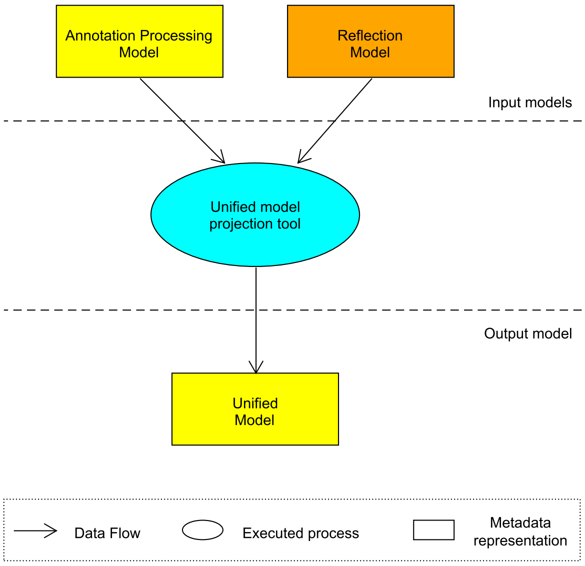

Fig. 1. Concept of the unified API idea

*1) Accessing Metadata in Reflection:* To gain access to metadata provided by reflection in a specific class, one can use `ClassName.class` parameter of every class which returns a `Class` class that represents a class with the name "ClassName". This class can be then used to retrieve metadata about the class and elements defined inside the class, such as methods, constructors, fields or annotations, or even inner classes. It is possible to retrieve lists of those elements or search for specific ones. For example retrieving the list of annotations by which the class is marked can be done by calling a method `getDeclaredAnnotations`.

By calling methods provided by classes of the reflection model, developer can acquire any metadata existing during runtime. One of the big differences in usability of the two basic models is that in reflection, methods can be executed, which is impossible in annotation processing.

## III. Program Model Unification

Due to the similarities in these models, we expected that it should be possible to design a tool that would be able to provide a unified API to data from both basic models. Simple overview of the idea is illustrated in Fig. 1. It is enough to note that input data used in the tool will always come from only one of the input models at the time. Which model it is depends on the time when the tool is used.

### A. Unified Model Projection Types

In order to create a unified model, first we need to determine how the unification tool will project basic models into the unified API.

We will illustrate the problem of unified model types on program trees. A node in the tree represents a program element (class, method, etc.) and annotations. The structure models the

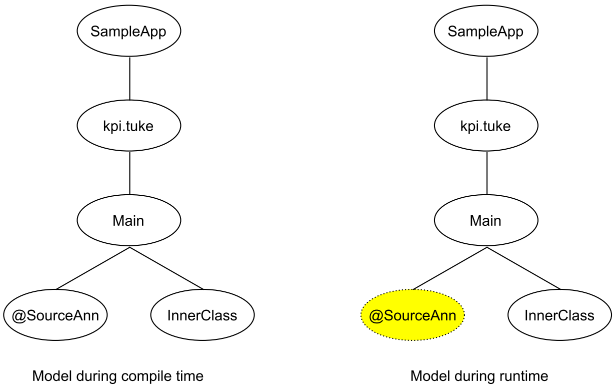

Fig. 2. Model comparison illustration

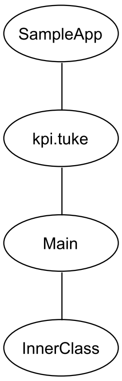

Fig. 3. Equality-based projection

encapsulation relationships of program elements. The tree's root represents Java project (library, application), its children are Java packages, the packages contain classes, or might be annotated by annotations, the nodes representing classes have children nodes representing variables and methods, and again annotations that belong to the classes, and so on. E.g., we might have a root node 'sampleApp' with a single child node 'kpi.tuke' representing package. The 'kpi.tuke' node could have a child node representing the 'Main' class, and this 'Main' node could have two child nodes: a node for the 'InnerClass' class, and a node for the '@SourceAnn' annotation, etc. Program elements and annotations are source code entities that the unified API should expose.

An illustration of both basic models for the discussed example is presented in Fig. 2. Nodes that are **equal** in both models are represented by ellipses with white color and solid border. Equal in this context means that both basic models expose the same metadata about the element in both models.

Node '@SourceAnn', which is represented by an ellipsis with yellow color and dotted border in a model during runtime shows a situation when element **does not exist** in runtime model, but exists in the compile time model. This is a result of using the `@Retention(RetentionPolicy.SOURCE)` meta-annotation that marks the `@SourceAnn` annotation to be discarded by the compiler during the compilation.

Projection to the unified model can be designed in different ways depending on which metadata would be included in it. There are three main approaches to design of a unified API:

1) **equality-based** projection,
2) **combined** model projection, and
3) **problem-specific** model projection.

First, the **equality-based** projection for the discussed example is shown in Fig. 3. In this type, the unified model includes only those elements and metadata, that are available in both basic models. That means node '@SourceAnn', which does not exist in runtime model, will not be projected to the unified model either (regardless whether created during runtime or compile time).

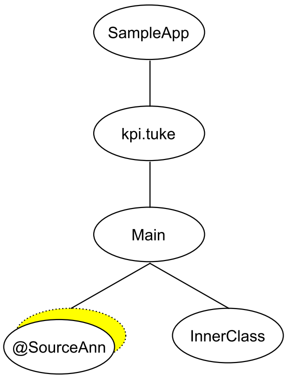

Fig. 4. Combined model projection

Second, the **combined** model projection is shown in Fig. 4. In this type the unified model exposes all the elements and their metadata that were included in the basic model. For example, if the unified model was created during compile time then the unified model would expose all the metadata that are available during compile time, including those that are not available during runtime. This projection type deals only with different APIs, and does not regard the differences of information exposed by basic models (the equality-based projection hides the differences in exposed information about the source code).

Third, the **problem-specific** projection covers cases when the projection is optimized for a given problem (something like a DSL [14] in languages). Basically it represents ad-hoc solutions for a family of problems. E.g., it might be a case of a simplified model, restricted in the tree depth to classes (therefore the only child nodes of the class nodes would be nodes for their annotations). We will not discuss this type of projections further, since its applicability is limited to a restricted set of problems.

### B. Conclusion

Both equality-based and combined model projection types can be used in our solution. Both of these types have their specific uses, but we decided to go with a model that is based on a **combined model** projection type. There is also an option of implementing both types and letting the user decide which model he needs at the time, but in current implementation we support only combined model. The reasoning behind the decision to use combined model over equality-based model is that it gives the user more information when using our tool, since the equality-based model hides metadata that are not available in both basic models.

## IV. Designing Unified Representation

When designing a unified representation, we faced several challenges. In this section we discuss some of the most important of those questions and problems.

### A. Ways to Access Metadata

One of the most important questions is how to access metadata in basic models in order to use them in a unified model. There are two possibilities how to achieve this:

1) **Direct access** to metadata with the use of an API that will unify the access methods in both basic models, and
2) **Model creation** and accessing metadata from the created unified model.

In the following sections, both of these ways are described in detail.

*1) Direct Access:* The most important thing when using **direct access** approach of accessing metadata is the interface that will be able to unify access to both basic models. In object oriented programming, this interface can be implemented using a adapter design pattern [15] [16].

In terms of accessing metadata, this design pattern can be expressed in such a way that class that needs metadata can access them by requesting them from the adapter, which handles acquiring metadata from basic model and transforms them into the unified model. Simplified example of this can be seen in Fig. 5, where the class `Client` calls a method `getMetadata` on a class `Adapter`. This method collects the requested metadata from one of the basic models which is available at the time, transforms them into the unified model that is expected and returns them to `Client`. The `Model` in this figure can represent either annotation processing model or reflection model. Which of these is currently represented depends on what part of the program life cycle it is currently in. Adapter therefore must be able to tell whether it is called during compile time or during runtime and will then choose how to retrieve metadata accordingly.

Using this method means that the ***basic model is accessed during every single call from the client***, because it has to retrieve the required metadata.

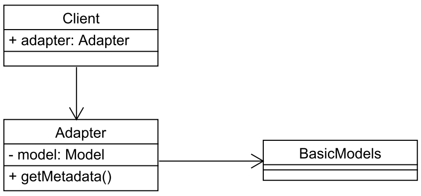

Fig. 5. Adapter Pattern

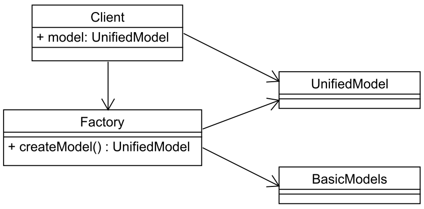

Fig. 6. Model Factory

*2) Model Creation:* The most important step when using **model creation** approach is the creation of the unified model itself. Unified model can be provided by a method similar to a factory method pattern [15].

In terms of model creation, this method will not be exactly the same as the factory method, because we know which type of class this method will return, but we do not know (and do not care) which basic model was used to create the class. Simplified example can be seen in Fig. 6, where once again the `Client` class needs access to metadata. Unlike the adapter patter, where the `Client` called a method which provided metadata, it now calls a method `createModel` on the `Factory` class. This method creates the unified model from one of the basic models and returns it to the `Client`. Same as with direct access, model that is currently represented by the `Model` class depends on what part of the program life cycle it is currently in. Therefore, just as Adapter had to be able to tell whether it was called during compile time or runtime, the `Factory` has to also be able to tell too. This method can also be compared to reverse engineering [17].

Unlike the direct access method, ***it is not needed to access basic model during every single call from the client***. Basic model needs to be only accessed once, when creating the unified model. Accessing metadata after the creation of unified model is handled by the unified model itself.

### B. Additional Costs of Accessing Metadata

In basic models, which are already part of Java, costs to access specific metadata can be easily analysed. During each request to access metadata it is required to search the basic model and find the metadata that were requested. After they are found, they simply are returned in the same format as the basic model defines. If we disregard implementation details of basic models, this process is the same for reflection model as well as annotation processing model.

*1) Direct Access:* Additional costs when using direct access method is created mainly because during every request to access metadata from basic model, it is needed to search this model, find metadata that are needed and then transform them into the specified unified metadata representation that is expected as an output of the request. In comparison to acquiring metadata from basic model, it has one additional step, which is transforming metadata to the unified model. However, this one additional step is executed during every request, and it increases the time needed to retrieve metadata.

*2) Model Creation:* Additional cost when using model creation method is the creation of the unified model itself, but this process is only executed once. After the unified model is created, all requests are handled through the unified model itself and results do not have to be transformed into the representation that is expected as an output, because they already are in form of the unified model representation.

Comparison of retrieving metadata from unified model and from basic models depends on the exact implementation of the unified model. In ideal circumstances, the access to metadata through unified model can be faster than accessing them through basic models (in case the unified model is better suited for specific requests). It is more likely, however, that accessing metadata through unified model will be slower than through basic models.

### C. Minimizing Additional Costs

In spite of the fact that reducing additional time costs to access metadata when using unified model is nearly impossible and it is not the purpose of this paper, we still have the possibility to employ some methods in order to minimize the performance impact of using unified model.

To help minimize additional costs we can use caching of results in both direct access and model creation methods.

Main idea of this in direct access method is that the results will be stored for use in another request during every request to access metadata. In every request after that, those metadata will already be at hand and it will not be needed to search the basic model for them again. Building on that method, we can make it so that it is very close to model creation method. That can be achieved by storing the cached data in such a way, that they would resemble the unified model created by model creation method. Downside of this is that we introduce a new step into the process of retrieving metadata: a step to check whether the requested metadata are already stored or not.

In model creation method, data would not be stored during requests, because even before the first request, the unified model was already built and put into memory. In this case, data would be prepared for most common requests during the model creation itself.

Because of the additional steps, caching of results runs into problems with small amount of requests and is getting better and better with more requests.

Different approach to minimizing additional costs is **selective model creation**. This method is based on the idea that user knows which metadata he or she will use and he or she can specify which parts of the model are required. User would be able to define which parts of the model will be created and which parts will be ignored. The disadvantage is that the user has to learn how to configure the tool in such a way, that it will provide desired results. If the configuration is too complicated then this disadvantage can be big enough to overshadow the biggest advantage of using a unified model, which is to make it easier for the user to gain access to metadata.

### D. Query Methods

As it was mentioned before, both of the basic models have different way of accessing the same metadata. The metadata can be queried via methods that help the user easily navigate through the model. Both basic models and their APIs provide query methods. They are primarily used to conveniently query metadata. Both API query methods and model accessor methods (getters and setter) differ in Reflection API and Annotation Processor API. Example of this difference can be the way how to retrieve list of annotations that class `A` is marked with. To retrieve metadata about these annotations in annotation processing model, developer has to call a method `getAnnotationMirrors` on the instance of the class `Elements` that represents class `A`. On the other hand, in reflection model, developer has to call a method `getDeclaredAnnotations` on the instance of the class `Class` that also represents class `A`. If both of these methods were called in the same program on the same class, their results can be different (disregarding the fact that they are represented in a different way), because some of them can be marked with meta-annotation `@RetentionPolicy.SOURCE` or `@RetentionPolicy.CLASS`, but **they represent the same metadata**, which are annotations of class `A`.

The simplest way how to design query methods is to support both names of the same methods from basic models. For the aforementioned example it would mean that there would be two query methods, one called `getAnnotationMirrors` and second one called `getDeclaredAnnotations`. These methods would always return the same results.

Better way, which is in the spirit of unification, would be to use only one method that would not have to be named exactly the same as the ones in the basic models, but it would be named name clearly enough that there would be no confusion what the purpose of that method is.

There is also a way which mimics the principles of XPath [18] for XML files. It is based on the fact that the unified model is represented in a tree-like structure that can be traversed much like XML[1]. This way is best used as an addition to the method of using one unified method, because it would provide the developer with better control over the search queries.

### E. Conclusion

For accessing metadata from basic models we decided to use the **model creation** approach. Main reason for this is that

[1] XML grammar [19] is commonly defined using XML schema [20].

in the direct access approach, searching through basic model during every request could be slow. Using the model creation approach pushes the additional time costs of using the unified API to a single point of the tool initialization.

On the other hand, the method of model creation can be designed in such a way, that when it comes to retrieving metadata from unified model, most common requests could be optimized so that they will be as fast as possible.

## V. Prototype Implementation

Based on previous analysis, in this section we present a prototype tool *UModel*[2] that can be used to create a unified model. The name *UModel* comes from the term Unified Model. Because this tool has to be able to create unified model from both basic models, it has to be able to recognize which of the models is available during that time. This is easily done, because both of the basic models have different context in which they are created and these context can be easily recognized from one another.

### A. Unified Model Creation

The abstract concept of unifying tool was illustrated in Fig. 1. In that figure, the process of creating unified model was not specified. Fig. 7 illustrates phases that are needed to create a unified model.

Model creation during runtime as well as compile time is divided into four main phases:

1) **Initialization phase**,
2) **Model creation phase**,
3) **Reference resolving phase**, and
4) **Finalisation phase**.

**Initialization phase** represents the phase in which the tool itself is initialized. That includes the initialization of structures that will be used during model creation as well as initialization of structures needed for result caching. Besides initialization of these structures, this phase also creates the basic structure of the model itself, which will be filled in during the next phase.

In the **model creation phase**, the unified model itself is created. Both runtime and compile time models are created by advancing through the provided basic model from top to bottom. Since metamodel can be represented as a tree structure, the tool starts with the root (topmost) element and gradually advances through its descendants to the leaves (bottommost elements). For every node in the basic model that the algorithm passes through, one node is created in the unified model. If the algorithm finds a reference to another element (e.g., method return type is a class included in the model), then this reference is only saved as a plain text. These references are resolved after the second phase finishes creating the whole model.

The model creation phase also saves the results for the queries encapsulated by the query methods presented in section V-D. These common queries, such as finding all the program elements annotated with a given annotation type, are this way cached and therefore should result in better time efficiency.

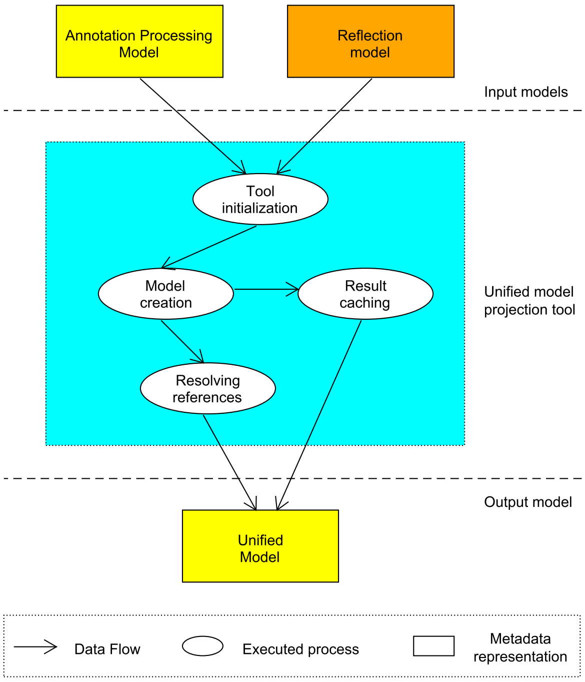

Fig. 7. Tool structure

After the second phase finishes, the **reference resolving phase** begins. During this phase, the tool resolves all of the references between the types that can be resolved (e.g., one class having a field of the type defined by another class). Reference that can be resolved is a reference to an element that is a part of the unified model. This kind of references can be used to easily traverse through the unified model. References that refer an element that is not a part of the unified model are not resolved and are left as a plain text. During this phase, the tool does not use the basic model, it works on the unified model created by phase two.

During the **finalisation phase**, the cache and the unified model (with resolved references from phase three) are joined together. After they are joined, the unified model is complete and can be passed to the tool's client.

### B. Unified Model API

This section contains description of the set of most fundamental classes representing the unified model API. All classes start with the letter U which represents their unification from both models.

The `UModelFactory` class is a factory class in a singleton design pattern which is used to instantiate unified model. It only has one factory method, the `createModel` method that returns an object of the `UModel` class.

[2] https://github.com/mallynth/UModel

*1) UModel:* This class represents the unified model that contains specific packages and classes for a given project (the 'sampleApp' node from Fig. 2). Main purpose of this class is to wrap the components of the unified model into a single root node object and to provide query methods that provide API with common queries. These query methods will be described in section V-D.

*2) UPackage:* The `UPackage` class represents a package in the source code.

Selected fields:

- `name` - full name of the package.
- `containingClasses` - set of classes implemented in this package.
- `containingEnums` - set of enumeration types implemented in this package.

Packages in the unified model *are not represented with a tree structure*. Instead of using tree structure that organizes packages into a tree with one root (as the file system does), we use a simple structure where every package is represented on its own (the standard Java model).

*3) UClass:* The `UClass` class represents a class, interface or declaration of new annotation type.

Selected fields:

- `classType` - enumeration type that defines which language element is represented by this class. Possible values are `CLASS` for classes, `INTERFACE` for interfaces and `ANNOTATION_TYPE` for declaration of new annotation type.
- `name` - name of the element.
- `enclosingPackage` - reference to an enclosing package.
- `modifiers` - modifiers represented by Integer.
- `parent` - reference to a parent element.
- `interfaces` - set of interfaces that are implemented by this class. If the `UClass` object represents an interface, then it represents which interfaces are extended and if the `UClass` represents declaration of new annotation type then this set will be empty.
- `annotations` - set of annotations represented by the `UClassAnnotation` class.
- `enums` - set of declared enumeration types.
- `constructors` - set of constructors represented by the `UConstructor` class.
- `fields` - set of fields represented by the `UField` class.
- `methods` - set of methods represented by the `UMethod` class. If `UClass` represents a declaration of new annotation type then this set contains parameters of declared annotation.

*4) UField:* The `UField` class represents a field (variable, attribute) of the class.

Selected fields:

- `name` - field name.
- `enclosingClass` - reference to a class where this field is declared in.
- `modifiers` - modifiers encoded to `Integer`.
- `annotation` - set of declared annotations represented by the `UFieldAnnotation` class.
- `type` - type of the field. It can be represented either by a string or by a reference.

*5) UMethod:* The `UMethod` class represents one method of a class. If it is included in annotation type declaration then it represents a parameter of the new annotation.

Fields:

- `name` - method name.
- `enclosingClass` - reference to a class where this method is declared in.
- `modifiers` - modifiers represented by Integer.
- `annotation` - set of declared annotations represented by the `UMethodAnnotation` class.
- `parameterTypes` - ordered list of arguments. They are represented either by a string or a reference.
- `returnType` - type of the return value. It is represented either by a string or a reference.

The `UConstructor` class is very similar to the `UMethod` class. The only difference is that it does not include a name.

*6) UAnnotation:* The `UAnnotation` class is an abstract class that represents an annotation of any language element. Classes that extend the `UAnnotation` are:

- `UClassAnnotation` which represents a class annotation,
- `UConstructorAnnotation` which represents a constructor annotation,
- `UFieldAnnotation` which represents a field annotation,
- `UMethodAnnotation` which represents a method annotation.

Selected fields:

- `annotationClass` - type of the annotation. It is represented by a full name of the annotation type. If this annotation type is represented in the unified model, then it is also represented by a reference to that annotation type.
- `annotatedElement` - represents an element which is annotated by this annotation. Type of this element depends on the element that is annotated. For example, in `UClassAnnotation` this element has a type of `UClass`.
- `parameters` - set of parameters of this annotation. Each parameter is represented by the `AnnotationParameter` class which includes three `String` fields: its `name`, `type` and `value`.

### C. Representation of specific elements

The fact that unified model is created from two existing model means that the representation of some language elements can be problematic, especially when it comes to elements that are represented differently in both basic models. One of them is the problem of representing modifiers, which were explained in the introduction of this paper. Other problem we had to face was how to represent references.

*1) Representation of References:* References, that are created during the second phase of unified model creation, are represented by the `AbstractMap.SimpleEntry` class. This class represents a key-value pair, which can for example be used in hash tables such as `HashMap`.

Key of this key-value pair is a full name of the element that is referenced. Key of every reference is filled in during the model creation phase. If possible, the value of this key-value pair is filled in during the reference resolving phase. The value is filled in only when the reference references an element included in the unified model. If that is the case, then the value of the key-value pair will be a reference to the element itself. If the reference references element that is not included in the unified model, then the value will be left as `null`. That means that every reference has a key, which represents the full name of the referenced class, but not every reference has a valid value.

*2) Representation of Modifiers:* As we mentioned before, one of the differences between annotation processing model and reflection model is the representation of modifiers. The difference is that modifiers in annotation processing are represented as a set of enumeration types `Set<Modifier>` and in reflection, they are represented as one integer.

In the unified model, we decided to use the representation identical to the one in reflection, which means all modifiers in unified model are represented by bits of an integer. When the unified model is created from annotation processing model, then the set of modifiers is converted into one integer by using bitwise OR.

### *D. Query Methods*

These methods provide API for convenient metadata queries. Most of these methods are related to annotations, since annotations are the main point of this model.

Query methods included in the class `UModel`:

- `getClasses` - provides all classes that are included in the unified model. Returns a set of `UClass` objects.
- `findClassByFullName` - provides a class specified by its name. Return type is a `UClass` class.
- `findClass` - provides a class specified by a class `Class`. Return type is a `UClass` class.
- `getPackages` - provides all packages included in the unified model. Returns a set of `UPackage` objects.
- `findPackageByName` - provides a package specified by its name. Return type is the `UPackage` class.
- `getEnums` - provides all enumeration types that are declared in the unified model. Return type is a set of `UEnum` classes.
- `getAnnotatedElements` - provides all elements that are annotated by at least one annotation. Return type is a set of classes that implement the interface `AnnotableElement`. This interface is implemented by all elements that can be annotated.
- `getElementsAnnotatedWith` - provides all elements annotated by a specific annotation. Return type is a set of classes that implement the interface `AnnotableElement`.
- `getMethodsAnnotatedWith` - provides all methods annotated by a specific annotation. Return type is a set of `UMetod` classes.
- `getFieldsAnnotatedWith` - provides all fields annotated by a specific annotation. Return type is a set of `UField` classes.
- `getConstructorsAnnotatedWith` - provides all constructors annotated by a specific annotation. Return type is a set of `UConstructor` classes.
- `getClassesAnnotatedWith` - provides all classes annotated by a specific annotation. Return type is a set of `UClass` classes.

Last five methods, which provide elements annotated by a specific annotation, have two alternatives. In one of them, the annotation is specified by a class that extends the `UAnnotation` class. In the other, the annotation is specified by the `Class` object representing the given annotation type. This is a convenience alternative that allows using `Class` objects in order to enjoy type checking.

Beside query methods that are included in the `UModel` class, there are query methods that check whether an element is annotated by an annotation of a specific type. This annotation can either be specified by a class that extends the `UAnnotation` class or by the `Class` class of that annotation.

## VI. Experimental Evaluation of Prototype

Although this paper does not deal with creating a faster way to access metadata when compared to basic models, it is still important that the time needed to access metadata by using unified model is not too demanding in comparison to basic models, otherwise the unified model would be unusable.

For the purposes of determining whether the created experimental tool is fast enough, we have conducted two experiments which are explained in this section.

### *A. Time Needed for Unified Model Creation*

In the first experiment, we tested how much time is needed to create the unified model when using the created tool. This metric is very important, since this time can be considered as **additional time** when compared to basic approach.

For the purposes of this experiment we chose two programs, one of them consisted of 122 classes and the other consisted of 1745 classes. Both of these programs have on average approximately 100 lines of code per one class.

We only tested how much time it would take to create the unified model. That means the difference between time of initialization of the tool and the time that unified model was returned.

*1) Results:* Times that are presented in the table I are average times after 100 runs. It is important to note there were quite big deviations, especially during the compile time.

From the times presented in the table, we can see that the time it takes to create unified model from a small program

TABLE I
TIME NEEDED TO CREATE UNIFIED MODEL

| | 122 classes | 1745 classes |
|---|---|---|
| **Compile time** | 42 ms | 670 ms |
| **Runtime** | 387 ms | 2043 ms |

is not that high, especially during compile time. Time needed to create unified model from a bigger project was naturally higher, because more metadata needed to be processed.

One important thing to note from this experiment is how the tool is scaling when it comes to bigger programs. Second program is approximately 14 times bigger then the first one which means that if the scaling of the tool was linear, it would take 14 times more time to create unified model from bigger program than from smaller program. Creation of unified model from bigger program in compile time took little over 15 times more time than creation of unified model from smaller program. Similarly, creation of unified model from bigger program in runtime took approximately 5 times more time than creation of unified model of smaller program. From these data we can see that scaling of the tool during runtime is much better than scaling during compile time. The fact that the scaling during compile time is worse than linear suggests it may be a good idea to try to optimize implemented tool for the use in compile time.

### *B. Overall Speed of Prototype*

The second experiment was designed to test the speed of the tool when performing a task. For purposes of this experiment, we used the same two programs as we used for the first experiment.

During this experiment we measured four ways in which a given task could be implemented:

- **Annotation processor model** - using metamodel available during compile time.
- **Reflection model** - using metamodel available during runtime. Helper libraries Scannotation [6] and Google Reflection API [21] were used for this measurement.
- **Unified model during compile time** - using the tool to create unified model during compile time and using this unified model to complete the task.
- **Unified model during runtime** - using the tool to create unified model during runtime and using this unified model to complete the task.

The task consisted of two parts (to make the test a little less trivial):

1) Find the names and types of all elements that are marked with the test annotation.
2) Retrieve all fields of a class that is specified by its full name.

For the first part of this experiment a simple test annotation was created and then added to source codes of the programs. In the program that consisted of 122 classes, 8 elements were marked with the test annotation and in the program that consisted of 1745 classes, 137 elements were marked with the test annotation.

TABLE II
OVERALL SPEED OF TASK COMPLETION

| | 122 classes | 1745 classes |
|---|---|---|
| **Annotation processing model** | 12 ms | 484 ms |
| **Reflection model** | 1154 ms | 2822 ms |
| **Unified model during compile time** | 47 ms | 949 ms |
| **Unified model during runtime** | 472 ms | 2245 ms |

*1) Results:* Results of the experimented are presented in table II.

Times that are presented in this table are the average times after 100 runs. Same as in the first experiment, some of the times that were measured when using the unified model were often very different when compared to the average, especially during the tests with the bigger program. During compile time, the lowest measured value was 477 ms and the highest measured value was 1189 ms. During runtime, the lowest measured value was 1823 ms and the highest measured value was 2480 ms. These fluctuations could have been caused by the fact that we used unordered sets in the unified model and the position of requested metadata is always different.

From the data we can see that the time needed to complete the task in unified model during compile time was more then double when compared to the time needed to complete the same task during compile time without the use of the unified model. This fact reinforces the idea of trying to optimize unified model creation during compile time.

We can also see that during runtime, the tool was actually faster in completing the given task. Main reason for this is that helper libraries Scannotation and Google Reflection API were used to make the task significantly easier in reflection model. These libraries made the task easier at the cost of additional time during execution, which is also the main reason behind the unified model.

## VII. RELATED WORK

As it was mentioned before, main inspiration of our solution to the problem we faced with the *BTE* [4] tool was the idea of Generalized and Attributed Abstract Syntax Trees (GAAST) proposed by Cepa [7], [8], [22]. In his work [7] he states that object oriented languages should support an explicit representation of the program as a graph of meta-objects that can be then accessed through a well defined API. He also shows, that usage of meta-model in a GAAST structure helps support model-driven development.

Noguera has a similar approach to Cepa in his tool AVal [23], [24], which is used to validate frameworks that are using annotations. Purpose of this validation is checking, whether the framework uses specific annotations in a correct way. Specification of how annotation is used correctly is designed through meta-annotations, which define constraints on the usage of those annotations. He uses two models for this validation. One of them is *annotation model*, which is a model derived from annotation types and second one is *code model*. Code model is very similar to an abstract syntax tree.

We used a similar approach to the unification of two models which was discussed in this paper in the tool Bridge To Equalia [4]. This tool is able to create a unified model of annotation-based and XML-based configurations using by extensible metamodel.

There are libraries that help querying metadata during runtime, such as Scannotation [6] and Google Reflections [21]. These libraries provide convenient APIs for annotations processing, however, they do not address the problem of runtime and compile time model unification.

## VIII. Conclusion

In this paper we explored differences between compile time and runtime models, explained the problem of their diversity and analyzed the approaches how to unify these models by providing their advantages and disadvantages. The discussion should provide a basis for consideration of providing a standard unified API for accessing metadata in programming languages. We presented the API we designed and implemented in our tool for unified model creation, which was used to support the analysis. The tool was evaluated by experiments to verify the usability of the proposed tool. They and showed that both the creation of unified model and its querying are reasonably fast. The paper can be considered a technical report that should be helpful for developers dealing with the same problem, or developers that are interested in either of the two existing approaches to annotation processing (reflection and annotation processing API).

*Abstract*— **Reengineering of an existing information system can be carried out: to improve its maintainability, to migrate to a new technology, to improve quality or to prepare for functional enhancement. An important phase of a data-oriented software system reengineering is a database reengineering process and, in particular, its subprocess – a database reverse engineering process. The reverse engineering process contains two main phases: data structure extraction and data structure conceptualization. In the paper we present a blueprint of a model-driven approach to database reengineering process that is one of the results of our research project on model-driven intelligent systems for software system development, maintenance and evolution. Within that process hereinafter we focus on the data structure conceptualization process and propose a model-driven approach to data structure conceptualization. Proposed process is based on model-to-model transformations implemented by means of Atlas Transformation Language.**

## I. Introduction

AN information system (IS) implemented to fulfill organizational information requirements would adapt to emerging business models and technology changes and innovations. Organizations are facing the problem of maintenance, evolution or even replacing of a part or whole legacy information/software system. A new system can be redeveloped from scratch, but in that case the knowledge captured in the legacy system is lost. Legacy system replacement or reengineering can be done with significantly reduced amount of effort and cost if the conceptual models are reconstructed from them. Summarizing the definitions of reengineering process presented in [1]–[5] it can be concluded that reengineering entails: (i) the reverse engineering activities aimed at creation of a more abstract view of the system; (ii) the restructuring of the abstract view; and (iii) the implementation of the system in a new form by means of forward engineering activities. A majority of software systems may be characterized as data-oriented systems. They are centered around a persistent data structure, like set of files or a database. The reengineering of a data-oriented software system makes up the code reengineering and the database reengineering processes that could be carried out almost independently one of another. In the paper we deal with a phase of database reengineering process.

The persistent structures, primarily databases, are at the core of most company information systems. The knowledge captured in them can serve as an important resource in a legacy information system modernization project and they are a common source of reverse engineering processes. The database reverse engineering (DBRE) is, according to Hainaut *et al.* [6], the process of recovering the conceptual schema of a database.

The emergence of Model-driven Software Engineering (MDSE) enables the building of more effective reverse engineering solutions. Model-driven Reverse Engineering (MDRE) is the application of MDSE principles, methods and tools to the reverse engineering process, relying on: meta-models, models and model transformations. The Model-driven Architecture (MDA) specified by the Object Management Group (OMG) [7] currently is the most mature formulation of MDSE paradigm.

The OMG has noticed a necessity to understand and evolve existing software assets and launched the Architecture-driven Modernization (ADM) initiative [8]. Within our research project on model-driven intelligent systems for software system development, maintenance and evolution, spanning throughout last past years we have developed a model-driven approach to database reengineering process, adhering ADM framework. In this paper we present just a blueprint of that approach using ADM horseshoe as a reference model. After that we focus on the database reverse engineering (DBRE) process within the database reengineering process.

Hainaut *et al.* in [9] have presented the general architecture of the DBRE process divided in two main phases: data structure extraction and data structure conceptualization. During the data structure extraction phase it is hard to fully apply model-driven principles. The main reason is the fact that some activities need user interaction and the process cannot be fully automated. Therefore, in the

Research presented in this paper was supported by Ministry of Education, Science and Technological Development of Republic of Serbia, Grant III-44010, Title: Intelligent Systems for Software Product Development and Business Support based on Models.

paper we propose a model-driven approach to data structure conceptualization phase of database reverse engineering process. It is implemented within the IIS*Studio development environment aimed at evolutive and incremental IS development and reengineering [10]–[14]. Our approach is mainly based on MDSE and Domain Specific Language (DSL [15], [16]) paradigms. The approach is purely platform independent and strictly differentiates between the specification of a system and its implementation on a particular platform. IIS*Case tool, as a part of IIS*Studio is aimed at IS forward engineering, while IIS*REE tool is aimed at IS reverse engineering. Model transformations implemented in these tools are based on several database meta-models and their classification will be presented at the very beginning of the paper.

Apart from Introduction and Conclusion the paper has 5 sections. In Section 2 the classification of IIS*Studio meta-models is presented. A sketch of a model-driven approach to database reverse engineering is proposed in Section 3. Detailed description of a data conceptualization process is given in Section 4. A case study is presented in Section 5, and related work is treated in Section 6.

## II. IIS*Studio meta-models classification

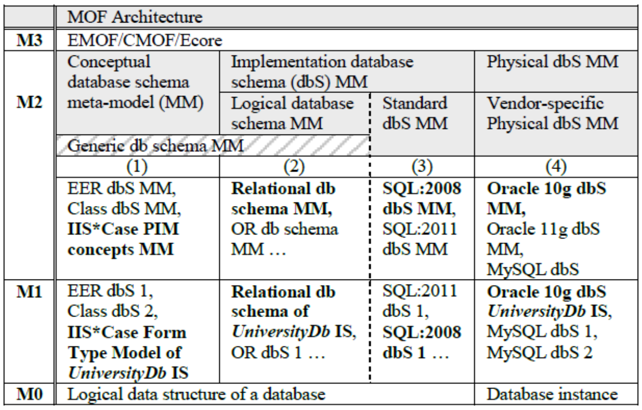
Software development process produces numerous models of complex application artifacts. In the paper we focus on models relating to databases. For these models we use the generic name **database models**. Numerous data models are proposed and they can be classified according to the types of concepts they use to describe the database structure, as follows: i) high-level or **conceptual data models**; ii) representational or **implementation data models**, and iii) low-level or **physical data models**. In the context of MDSE data models may be seen as meta-models. A database schema is expressed by means of the concepts of a selected meta-model. According to the MDSE terminology, such database schema is called database model and it should conform to the appropriate meta-model. An EER database model conforms to the EER meta-model, while a relational database model conforms to the relational meta-model.

Common examples of conceptual data models are (Extended) Entity-Relational (ER, EER) data model and Object-oriented (OO) (also called Class) data model. Relational and Object-relational (OR) data models are used predominantly for logical (implementation) database schema design and database implementation.

IIS*Studio uses form-type (FT) data model for conceptual IS and database design. Like EER and OO data models, it is conceptual data model. A *form type* is the main modeling concept in FT (data) meta-model. It generalizes document types, i.e. screen forms that users utilize to communicate with an information system. Using the form type concept, a designer specifies screen or report forms of transaction programs and, indirectly, specifies (i) an initial set of attributes, constraints and future database schema, (ii) basic functionalities of future transaction programs and (iii) components of their user interface. A form type concept, as well as related concepts of a domain and attribute, is platform independent. A form type is a named tree structure, whose nodes are called component types. Each *component type* is identified by its name in the scope of the form type, and has nonempty sets of attributes and keys, and a set of unique constraints that may be empty. Besides, to each component type must be associated a set of allowed database operations. A part of FT meta-model can be seen in the third row of the table presented in Fig. 4. A detail description of FT data model and FT meta-model may be found in [17].

In this paper, we use the MDSE terminology based on the four-layered architecture proposed by OMG common meta-meta-model Meta-Object Facility (MOF) standard [18]. System under study (SUS) is at the M0 level. The concept of a model is specialized depending on the level, in which a model is located: a model at M1 level, a meta-model at M2 level and a meta-meta-model at M3 level. An SUS is represented by a model at M1 level, which conforms to a meta-model at M2 level that is conformant with a meta-meta-model at M3 level. In [19] we have proposed a classification of database meta-models and distribution of database meta-models and database models across the MOF level stack. Adapted version of the classification is presented in Fig. 1 where can be seen different kinds of database meta-models that describe database models at certain abstraction level:

1. generic database schema meta-models:
   - generic conceptual database schema meta-models,
   - generic logical database schema meta-models;
2. standard physical database schema meta-models; and
3. vendor-specific physical database schema meta-models.



| | MOF Architecture | | | |
|---|---|---|---|---|
| **M3** | EMOF/CMOF/Ecore | | | |
| **M2** | Conceptual database schema meta-model (MM) | Implementation database schema (dbS) MM | | Physical dbS MM |
| | | Logical database schema MM | Standard dbS MM | Vendor-specific Physical dbS MM |
| | Generic db schema MM | | | |
| | (1) | (2) | (3) | (4) |
| | EER dbS MM,<br>Class dbS MM,<br>**IIS*Case PIM concepts MM** | **Relational db schema MM,**<br>OR db schema MM … | **SQL:2008 dbS MM,**<br>SQL:2011 dbS MM | **Oracle 10g dbS MM,**<br>Oracle 11g dbS MM,<br>MySQL dbS |
| **M1** | EER dbS 1,<br>Class dbS 2,<br>**IIS*Case Form Type Model of *UniversityDb* IS** | **Relational db schema of *UniversityDb* IS,**<br>OR dbS 1 … | SQL:2011 dbS 1,<br>**SQL:2008 dbS 1** … | **Oracle 10g dbS *UniversityDb* IS,**<br>MySQL dbS 1,<br>MySQL dbS 2 |
| **M0** | Logical data structure of a database | | | Database instance |

Fig. 1 Classification of database meta-models

In each field of the table in Fig. 1, that is on the intersection of column (**i**), where **i** ∈ {1, 2, 3, 4}, and row M**j**, where **j** ∈ {0, 1, 2, 3}, a list of exemplar models is given. In the column (1) at the M2 level there are several conceptual database schema meta-models: EER, OO (Class) and FT meta-model (so-called IIS*Case PIM concepts MM, where PIM stands for Platform Independent Model). Throughout the paper the names FT MM and IIS*Case PIM concepts MM will be used interchangeably. In the column (1) at the M1 level there are several conceptual database schemas (database models) that are conformant with an appropriate meta-model from the field in column (1) and level M2. For instance: IIS*Case Form Type Model of *UniversityDB* IS is a conceptual database schema of *UniversityDB* information system and it conforms to the IIS*Case PIM concepts MM (FT MM).

It could be noticed that models (meta-models) placed in the same field of the table are at the same abstraction level. In a way, EER database schema meta-model is at the same abstraction level as class database schema meta-model and IIS*Case PIM concepts meta-model. The abstraction level of the models (meta-models) throughout the columns of the same row is decreasing with increasing of the column number **i.** The models (meta-models) placed in column 1 are at the highest abstraction level, while the models (meta-models) placed in column 4 are at the lowest abstraction level. A relational database schema of *UniversityDb* IS is at higher abstraction level than its implementation under the Oracle10g database management system, represented as vendor-specific Oracle 10g database schema of *UniversityDb* IS.

Presented classification is very important for our DBRE approach and for understanding model transformations that are based on classified meta-models. Detailed description of meta-models that we use in this paper may be found in our papers [14], [17] and [19]–[20].

## III. A Model-driven Approach to Database Reengineering Process

Reengineering is one of the key concepts in software maintenance and evolution. It generally includes some form of reverse engineering followed by restructuring (optional) and some form of forward engineering. Previous researches on information system (IS) reengineering have made great achievements concerning: the forward engineering, the identifying of system's components and their interrelationships and the creation of representations of the system in another form. But, they have not yet been successful enough in creating representations of the system at a higher level of abstraction. A reverse engineering process (and consequently a whole reengineering process, too) can benefit of integrating the meta-modeling and meta-models in the process. In this section we present a blueprint of a model-driven approach to database reengineering implemented in IIS*Studio. In Fig. 2 we use ADM horseshoe model to illustrate main steps of proposed approach.

Database reengineering process begins with a legacy database. Relational databases are at the core of most company information systems and that is why, here in Fig. 2, we assume that legacy database is a relational database. Starting from a physical database schema, that is recorded in the relational database schema data repository, the conceptual database schema or logical database schema may be extracted. All of these database schemas represent models at different levels of abstraction.

Fig. 2 Horseshoe model of model-driven approach to database reengineering implemented in IIS*Studio

Reverse engineering phase covers steps 1–5, where steps 1–3 belong to the data extraction phase, and steps 4 and 5 make the data conceptualization phase. Step 6 is optional and represents restructuring phase. Forward engineering phase covers steps 7–9. Step 10 is not the step of database reengineering process and it is an activity of code reengineering process.

In the first step information about supported data types, tables, columns, check constraints, primary key and unique key constraints accompanied with foreign key constraints are captured from a legacy database repository and are placed in IIS*REE repository.

Additional information about the inverse referential constraints and homonym inconsistencies are discovered in the step 2 (Semantic Enrichment step). User interaction is required to control data extraction process at this stage. This interaction prevents full automation of data extraction phase and that is the reason why this phase is realized by means of traditional Java programming in OracleJ Developer environment. The similar problem arises again in step 6 (Restructuring step) of the reengineering process because this step requires user interaction, too.

Once it is captured, the physical database schema (model) may be transformed into desired conceptual database model. A designer may choose target conceptual meta-model among EER, Class and FT meta-models. In Fig. 2 FT meta-model is selected. Depending on selected target meta-model a model transformation or a chain of model transformations will be executed. These transformations are based on appropriate meta-models that can be at different levels of abstraction. The distribution of the model transformations and supporting meta-models across MOF and abstraction levels is given and explained in Section IV.

In the purpose of specifying and managing meta-models we have used the Eclipse Modeling Framework (EMF), Eclipse Juno 4.2.1. and OCL 3.2.1. Model transformations used in step 4 are implemented in ATL IDE (ATLAS Transformation Language Integrated Development Environment), version 3.3.1 [21]. Hereinbefore is mentioned that steps 1 and 2 are implemented in one technological space (OracleJ Developer), and step 4 in another one (EMF). Step 3 is used to bridge the technological gap and to export captured data by means of XML document conformant with XML meta-model. Step 6 is implemented in the same technological space as steps 1 and 2, due to the fact that it requires user interaction, too. Step 5, like the step 3, is used to bridge the technological gap, but in the opposite direction. Therefore, strictly speaking, it is not part of the data conceptualization phase.

In a forward engineering process, designers start with a high abstraction level model, abstracting from all kinds of platform issues. Through a chain of model-to-model (M2M) transformations, ending up with a model-to-text (M2T) transformation, the initial platform independent model transforms iteratively to a series of models with less degree of platform independency, introducing more and more platform specific extensions. Details of forward engineering process with activities in steps 7–10 are presented in some of ours already published papers, like [10]–[12], and we omit these details here.

In the next section we focus on the data structure conceptualization phase.

## IV. Data structure conceptualization phase

A complex system may consist of many interrelated models organized through different levels of abstraction. Each of them is conformant to a meta-model. In a forward engineering process a chain of M2M transformations should be completed starting from an initial model at the highest level of abstraction (Platform Independent Model, PIM), through the less abstract models, with different levels of platform specificity (Platform Specific Models, PSMs), and resulting in an executable program code that represents a model at the lowest level of abstraction (fully PSM). These M2M transformations transform a model conformant to a meta-model into another one conformant to a different meta-model. Conversely, in a reverse engineering process, the abstraction level of models and degree of platform independency are increasing throughout the chain of transformations.

In this section we present the activities of data structure conceptualization phase. Model transformations implemented in the conceptualization phase are presented in a rectangular coordinate system in Fig. 3. The abscissa represents MOF level of a model, and the ordinate represents abstraction level of a model in the context of its platform specificity. The input of the process is XML specification of captured physical database model. This XML specification conforms to XML meta-model. The data conceptualization phase is realized as a chain of three M2M transformations: 1. XML2RDBMS, 2. RDBMS2RM, and 3. RM2IISCase. The fourth M2M transformation presented in Fig. 3 is IISCase2XML transformation and it corresponds to the step 5 in Fig. 2, and, as it was explained in Section III, it is not part of data conceptualization phase.

The first transformation transforms a model conformant with XML meta-model into a model conformant with an SQL standard meta-model. It could be SQL: 2008 dbS meta-model, e.g., listed in bold style in column (3) and row M2 in Fig. 1.

The transformation RDBMS2RM transforms a model conformant with an SQL standard meta-model into a model conformant with generic relational db meta-model (bolded text in column (2), row M2 in Fig. 1). It is not possible to transform a model conformant with an SQL standard directly into a model conformant with FT (IIS*Case PIM concepts) MM. The reason lies in the fact that FT approach to database design is based on the Universal relation schema assumption (URS assumption). Physical database meta-models and database meta-models based on SQL standard do not support URS, while generic relational db meta-model does.

Both of aforementioned transformations are PSM2PSM transformations. The third one, RM2IISCase is a PSM2PIM transformation. It transforms a model conformant with generic relational db meta-model into a model conformant with FT meta-model (so-called IIS*Case PIM concepts MM). It is placed in column (1) and row M2 in Fig. 1. In a way the data conceptualization phase is finished and conceptual database model is generated from a legacy database. The obtained model is transformed in an XML document by means of the forth transformation IISCase2XML.

It is important to emphasize that model transformations in Fig. 3 are modeled as conformant with ATL meta-model. Each of them is based on two meta-models: source and target meta-model. The source meta-model of a model transformation is at lower abstraction level than the target meta-model of that transformation in a reverse engineering process. At M1 MOF level each transformation execution transforms an input database schema (model) into an output database schema (model). Although having the same name in Fig. 3, relational database schemas that are input models for transformations 1, 2 and 3, respectively, are not the same models and they are conformant with different meta-models. Their platform independency is ascending throughout the chain of model transformations.

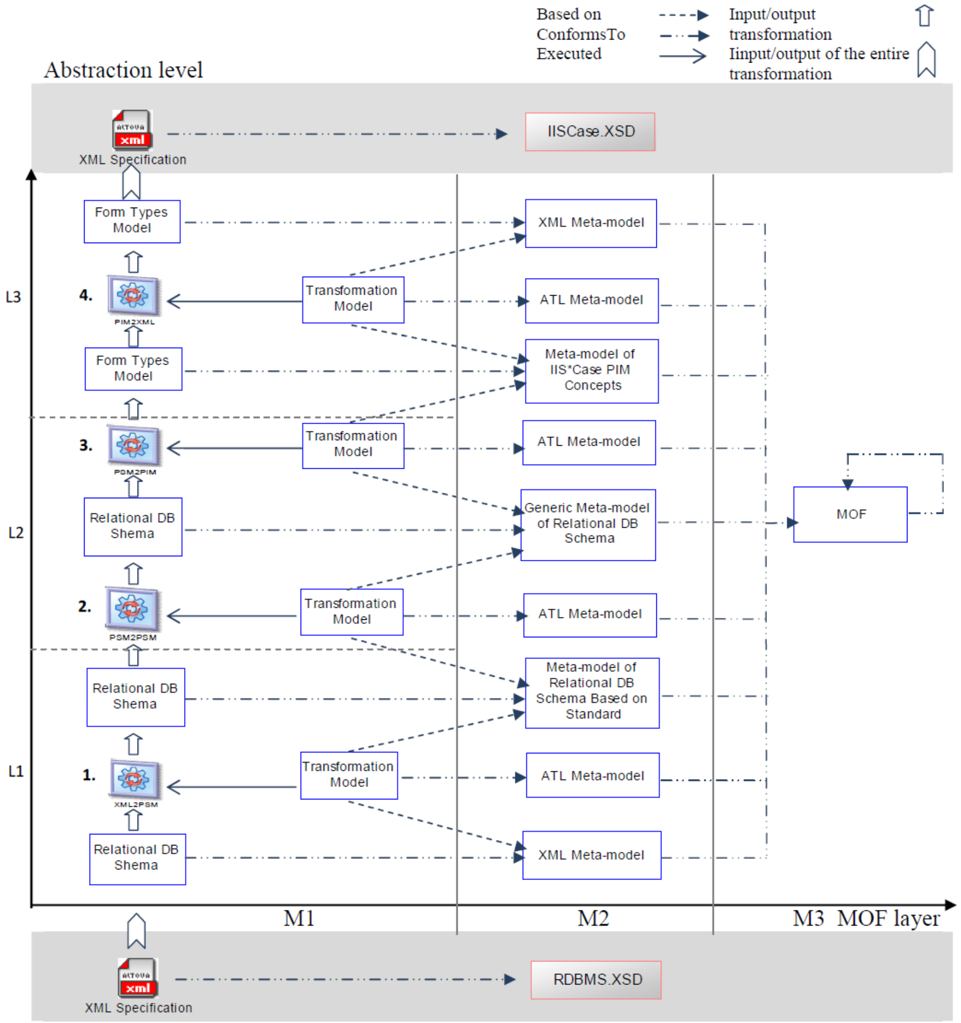

Fig. 3 Data structure conceptualization through a chain of M2M transformations

## V. Case study

In this section an example of a chain of model transformations that implements data conceptualization phase of database reverse engineering process is presented. *UnivesityDb* database instance is SUS consisting of two tables: *University* with columns *UniId*, *UniName* and *UniCity*; and *Faculty* with columns *UniId*, *FacId*, *FacShortName*, *FacName* and *Dean*. It is implemented under the Oracle database management system. In the data extraction phase vendor-specific physical database schema is extracted from legacy database repository and afterwards semantically enriched with the information collected from legacy database and through interaction with designers. The specification of vendor-specific physical database schema is written in an XML document that conforms to XML meta-model. At the very beginning of the process the transformation XML2RDBMS is executed and a SQL standard database schema is generated, conformant, in the particular case, with the SQL: 2008 dbS meta-model. By means of RDBMS2RM transformation the SQL standard database schema is transformed into a generic relational database schema. These two database schemas are not the same and they conform to different meta-models. In Fig. 4 a transformation RM2IISCase, from a generic relational database schema into a form type data model is presented in more details.

A database model conformant with IIS*Case PIM (FT) MM

Fig. 4 An example of RM2IISCase transformation

In the first row a part of the generic relational dbS meta-model and a database model conformant with it are presented. In the third row the target IIS*Case PIM concepts meta-model and a conformant form-type database model are presented. In the middle of the table, the second row contains an ATL rule for mapping concepts from the generic relational dbS meta-model to the concepts of IIS*Case PIM concepts meta-model. The model transformation gets the relational database model from the first row as input and transforms it into the form-type database model presented in the third row.

ATL rules presented in Fig. 4 are just the small excerpt from all ATL rules used to specify model transformations in IIS*REE. Presented rules are aimed at mapping concepts of source and target meta-models at the highest level of details. Mappings at the lower level of details alongside with belonging helpers are omitted here.

## VI. Related work

Hainaut *et al.* [6], [9], [22] describe main steps of database reverse engineering and several authors based their research on these proposals. Perez *et al*. [23] and Boronat *et al*. [24] create object-oriented (class) conceptual database schema from the relational data dictionary. Gogolla *et al.* [25] have sketched how syntax and semantics of the ER and relational data model and their transformation can be understood as platform independent and platform specific models. Beggar *et al*. [26] propose a reverse engineering process based on MDSE that presents a solution to provide a normalized relational database which includes the integrity constraints extracted from legacy data. In [27] a process is proposed to automatically generate Web Services from relational databases. SQL-92 meta-model has been used to represent the conceptual database model. Polo *et al.* [28] present the technical and functional descriptions of a tool specifically designed for database reengineering based on simplified relational and object-oriented meta-model.

Aforementioned approaches to database conceptualization are mostly based just on two database meta-models. Vendor-specific physical or standard relational meta-model mainly are found on the source side of M2M transformation. On the other side, EER, class or standard/vendor-specific relational meta-models occur on the target side of M2M transformation, depending on selected conceptual schema. Our approach supports transformations between vendor-specific relational, standard relational, generic relational, FT, EER, and class meta-models. Our classification and distribution of database models across the MOF level stack (Fig. 1) enables systematic approach for mapping specification between different models/meta-models and development of appropriate M2M transformations. To the best of our knowledge, there is no similar systematical overview of database meta-models.

Some authors obtain relational database schema as the final result of data structure conceptualization process. According to Hainaut *et al.* [22] relational database schema cannot be seen as a pure conceptual database schema. It is not fully platform independent due to the fact that it is compliant with the data model of a family of database management systems. In our approach FT database schema is obtained as the result of the data structure conceptualization process. FT specification is based on business forms, users are familiar with, and in that manner it models system as-is in a platform independent way. At the same time, the specification is platform independent prescription model of future screen and report forms and input for series of M2M transformations that ends up with M2T transformation generating application prototype.

Research work on database model transformations can be broadly classified as unidirectional model transformation algorithms and multi-model (multi-language) transformation algorithms. The examples of unidirectional model transformation algorithms, proposed by Lano and Kolahdouz-Rahimi and Beggar *et al.* can be found in [29] and [26], respectively. Multi-model transformation algorithms can be ranged from linking each model to a graph [30], or description logic language (like those presented in [31]–[33]) to transformations mediated by a dictionary of common terms [34]. These results we consider as important in the context of our future research on unifying of different data model meta-models.

## VII. Conclusion

When a legacy system become too costly to maintain, or when new technologies need to be incorporated, system need to be replaced or somehow reengineered. An important phase of a data-oriented software system reengineering is a database reengineering process and, in particular, its subprocess – a database reverse engineering process. In the paper we focus on the data structure conceptualization process and propose a model-driven approach to data structure conceptualization that is based on M2M transformations implemented by means of ATL.

The proposed framework offers a wide range of M2M transformations. IIS*Studio supports transformations between models conformant with EER, FT, relational and class meta-models. In the paper we present database conceptualization into a FT database schema. There are several reasons why we decide to support such kind of conceptualization. Firstly, the end users would participate in the restructuring of a conceptual schema during the database and IS reengineering process. The FT concept is closer to the end-users' perception of data, than the concepts of relational data model, that makes it easier to involve them in the restructuring process. Secondly, extracted FT specifications can be enriched with the specifications of the transaction programs and business applications and they can be used not only to support generation of a database schema of an IS, but to support the generation of an IS program code and appropriate graphical user interface (GUI). In that context, our future research can be directed towards improvement in the data extraction phase. Information captured from application GUI could contribute to the semantic richness of reverse engineered form-type model. Results presented in [35]–[38] support our idea. According to the future research in connection with data conceptualization phase we plan to specify meta-models of different data models and to unify different meta-models as the basis for platform independent modeling of M2M transformations between database meta-models conformant with different data models meta-models, bearing in mind results presented in [39].

*Abstract*—**We introduce the principles of symbolization and conceptualization of perceived reality. We show them as processes that are applicable inside of a computer mind. We derive those processes from principles of a human mind. We present process of higher order regular abstraction and state automata acceptance as possible machine reality realization mechanism. We present the algorithm for evolution of machine mind language. Verification of this algorithm is presented in functional language Haskell. On the output, we have obtained fine-grained parallel non-redundant structure. It is in super-combinator form and represents elements of a machine mind language. Count of elements applications highly exceeds the count of elements themselves. Instead of accumulating acquired information, they are dissolved in the language of a mind. Vice versa, the information can be reconstructed from this language. We show that non-redundancy of a machine language is the decisive criterion for restructuring the machine mind language in each moment of communication. It is like that, so we can achieve more powerful and abstract communication between humans and computers or between computers themselves.**

## I. Introduction

ABSTRACTION of the human-computer communication interfaces [1] can be increased by DSL development [2], coming out from the abstract syntax [3]. Grammatical and/or genetical language evolution [4], [5], [6] is more automated approach, but still oriented more to syntactic than to semantic facet of languages.

On the other hand, the development of thinking machine is a great challenge, which can be found in many works of historians, philosophers, psychologists and linguists. For example, Renfrew [7] characterizes humans as symbolic beings that language was evolved in a consequence of communication. Gardenfors [8] refers to the structured substance of concepts. Structured conceptualization for databases can be found in [9]. Chomsky's [10] hypothesis on the universal language of thought, innate to every human being is the subject of many discussions.

In this paper, we present the algorithm in which reality recognized by humans can be conceptualized and represented in the machine mind.

Our approach comes out from the empirical cognition of reality by humans and its reflection in the mind: our imaginations are structural, and our concepts that reflect the meaning of the reality are languages, since they are meaningful. In our opinion, no information acquired by human is being forgotten (it is just suppressed in our mind) and no information is stored multiplicity.

We deal with symbolization just marginally in this paper, more information can be found in [11]. We discuss conceptualization as a process of abstracting the language concepts in more detail, since differently abstracted concepts on input of the algorithm affect the evolved language of the machine mind.

We present the algorithm for the machine mind language evolution in eight subsequent steps. In this paper, we also introduce the principle of applicative deterministic automata, able to recognize reality incrementally.

Also another aspect of symbolized input processing is explored. We present possibility of higher order regular expressions creation.

Our results tend to distributed automata structures [12] and they conform with the principle of the determinism of systems [13]. The proposed solution allows us to separate process forming of language of the machine mind from the process of machine thinking reasoning on concepts. As we hope, this provides a perspective for cognitive and more abstract HC and CC communication.

## II. Symbols and perception

Human is a symbolic creature, i.e. the human communication is symbol based. He creates immaterial concepts inside of his mind that flow right from the symbols that have material substance. Concepts exist only inside of a human mind, i.e. his imagination. Symbols posses their informal meaning and at the same time they might be structured with high degree of complexity during the communication.

Symbolization is a symbol based reality representation process. Simple components of reality, such as the letter $A$ or an image of a square can be symbolized with simple symbols like $a$ or $b$. Therefore we are able to symbolize perceived reality, like the sequence (1), into the symbol sequence $aabababa$.

$$AA\Box A\Box A\Box A\Box A \tag{1}$$

The new structured symbol has been created. The relation between the reality and its symbolized form is bidirectional. It is not enough to symbolize reality at the input in order to communicate, as the reality needs to be reconstructible at the output from the previously obtained symbol structure.

This work was supported by project VEGA 1/0341/13 Principles and methods of automated abstraction of computer languages and software development based on the semantic enrichment caused by communication

978-83-60810-66-8/$25.00©2015, IEEE

The symbolization of the sequence (1) is expressed with the rule (2):

$$\frac{A \leftrightarrow a \qquad \Box \leftrightarrow b}{AA\Box A\Box A\Box A\Box A \leftrightarrow aabababa} \tag{2}$$

Section above line in the rule (2) tells us, that if we have already identified reality of simple facts $A$ and $\Box$ and symbolized them with symbols $a$ and $b$, then new structured reality (1) is going to be symbolized with the use of a new symbol. This is the structured symbol $aabababa$. The structure doesn't necessarily have to be a sequence as it is in our example, but may be any structure. Symbols are just abstractions of reality in our view, recorded and produced from inside of a memory during communication. In order for communication to be faultless, such records of reality are stored inside the memory. They represent reality inside a human or computer mind. Since a human does not think in symbols, we may need to imagine its relation to machine mind abstract symbols as a connective bidirectional links to records of reality. Since we do not posses an architecture of a machine that corresponds to human mind, we find no other way than to consider them as alphabet symbols - terminal symbols of a language, and to represent them in discrete way, like whole non-negative numbers.

The purpose of symbolization is not the same as recognition problem. A machine is able to register and reproduce reality. Cognition is tied with the language evolution and it is inherent property of a mind. The language evolution works together with symbol abstraction. It is based on conceptualization, whose substance is the concept creation inside of an internal machine language.

## III. Conceptualization

A mechanism of conceptualization is a higher form of language abstraction than symbolization is.

String (3) is a concept - language, identical with the symbol sequence perceived on input. An abstraction was not performed upon it.

$$aabababa \tag{3}$$

Sequence (1) is a concept or a language that has meaning if we consider process of symbolization defined in (2) being applied.

Consider a concept in a form of a regular expression (4), where $(r)^*$ is transitive closure of an expression $r$. This concept is created by performed abstraction that searches for repeating patterns, in our case the sequence $ab$.

$$a(ab)^*a \tag{4}$$

This concept is more abstract than concept (3) for there is a relation (5) between the languages (3) and (4).

$$aabababa \subset a(ab)^*a \tag{5}$$

A machine operating with the language (3) cannot effectively communicate with a machine that recognizes the language (4), since its language is less abstract. In automaton theory it means that an automaton derived from the regular expression (3) accepts only terminal symbol string $aabababa$. It can be generated from the regular expression (4) however. On the other hand, the human or the machine (3) can learn from its counterpart (4), since it is capable of producing the symbol set $aa$, $aaba$, $aababa$, etc. It can achieve level (4) by this process. We can say, that language (3) will mutate to the language (4). The premise for machine learning is a massive stream of structured symbols at the input. Language (3) mutation into more abstract form is based on such a stream.

A sequence of symbols at the input shown at (6) leads to conceptualization - the process of concepts creation shown in (7).

$$aa; aaba; aabababa \tag{6}$$

$$\begin{aligned} &1.\quad (\{\}, aa) \Rightarrow \{aa\} \\ &2.\quad (\{aa\}, aaba) \Rightarrow \{a(ab)^{\{0,1\}}a\} \\ &3.\quad (\{a(ab)^{\{0,1\}}a\}, aabababa) \Rightarrow \{a(ab)^{\{0,1,3\}}a\} \end{aligned} \tag{7}$$

In the first step, the mind is enriched by language $aa$ as there is the symbol $aa$ at the input and the mind is empty. This language is stored inside of the machine mind. Next, the symbol $aaba$ arrives at the input. The result of conceptualization is mutation of the language $aa$ inside the mind of a machine into the language $a(ab)^{\{0,1\}}a$ during the second step. Another symbol transforms the language into $a(ab)^{\{0,1,3\}}a$ during the third step. This language enables the machine to communicate in form of the symbols $aa$, $aaba$ and $aabababa$, since (8) holds.

$$\begin{aligned} &a(ab)^0a \Rightarrow aa \\ &a(ab)^1a \Rightarrow aaba \\ &a(ab)^3a \Rightarrow aabababa \end{aligned} \tag{8}$$

The conceptualization example (7) shows us, that symbols on the right side of (8) can be generated and then represented as records of reality from concepts on the left side. Those concepts are languages, since they are sub-languages of most general language (9). This language is a concept only when all symbols generated from it have meaning i.e. represent the reality.

$$a(ab)^{\{0,1\}}a \subset a(ab)^*a \tag{9}$$

Following facts about conceptualization are to be noted:

1) Conceptualization leads to language ambiguity, it expands exponentially, therefore a selection condition is necessary. For example, language $(a)^{\{2\}}$ could have been created in the first step of (7) instead of the language $aa$.
2) It is possible to represent single symbol with multiple languages. For example, if language $a(ab)^{\{0,1,3\}}a$ is created inside of a mind of one machine and language $aa(ba)^{\{0,1,3\}}$ inside of another, they will be equal in terms of inter-machine communication. Machines will "understand" each other.

We can conclude that the machine mind is non-redundant i.e. does not contain any two identical language components. The mind hasn't got an ability to forget and it is deterministic. Language structure of the mind has to be highly parallel, associative, and amount of interconnections between language components highly exceeds the amount of components themselves.

## IV. Structured symbols as regular expressions

We have shown, that reality can be symbolized as a structured symbol describable by a regular grammar. In this paper, we use regular expressions to describe concepts that were obtained by previously symbolized reality. Those expressions themselves provide interesting ways to describe concepts, as we will show in this section.

Regular expressions are usually an in-line way to describe regular grammars. In practice, we use them for string matching. Therefore, fundamental data type (the type of symbol that regular grammar itself is matching to patterns) for accepting is a character. Our expressions are composed of operators sequence, closure and sum. First two have been already described earlier. Sum operator is $n$-ary and designated as $|$ symbol.

Regular expressions represented as a string itself are not well executable. One of better executable solutions is to use a tree form that can be considered meta-executable, as described in [4]. All our experiments were performed in functional language Haskell. It allows easy creation of complex data structures, such as a tree. Definition is based on work [11] and is depicted below:

```
data REXp a = TERM a | SEQ [REXp a] |
    SUM [REXp a] | CLS (REXp a)
```

Data structure `REXp` contains four constructors. Constructor `TERM` represents fundamental type, `SEQ` is for the sequence, `SUM` represents the sum operation and `CLS` is for the closure. It is notable, that we are not using type `Char` as the fundamental type for regular expression. Current definition allows us to match expressions composed of an arbitrary data type. We will return to this proposition later on. Sum and sequence operators are $n$-ary.

Consider following regular expression:

$$a(b|c)^* \tag{10}$$

where $a, b, c \in \Sigma$, where $\Sigma$ is terminal symbol set. This expression matches string that begins with symbol $a$ and after that an arbitrary long string consisting of $b$s and $c$s is matched. Transformed regular expression into the tree form is shown bellow. Transformation is based on scheme described in [11], so we won't present it here for brevity.

```
SEQ [TERM 'a',
      CLS (SUM [TERM 'b',TERM 'c'])]
```

As mentioned earlier, fundamental type of regular expression does not have to be of type `Char`. Definition allows us to use arbitrary data type.

TABLE I
Meaning of regular expression elements

| symbol | meaning |
|---|---|
| $a$ | $d(e)^*$ |
| $b$ | $ef$ |
| $c$ | $(d\|f)$ |

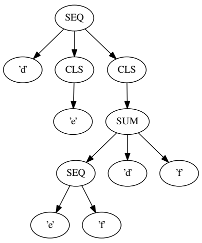

Fig. 1. Less abstract regular expression

Let us consider our regular expression data type as a form of abstract interpretation of another regular expression. Therefore elements $a$, $b$ and $c$ represent other regular expressions, and the resulting type will be `REXp (REXp Char)`. This can be considered a higher order regular expression.

Term "higher order" is used similarly as in functions, where higher order functions take a function as a parameter or return one. Since our regular expression takes another as a parameter, it can be considered higher order regular expression.

Definitions of symbols the $a$, $b$ and $c$ meaning is depicted in Table I. We use different symbols, $d$, $e$ and $f$, in this abstraction to make it clear on what level of we currently are. By substitution of the elements $a$, $b$ and $c$ we get less abstract regular expression:

$$d(e)^*(ef|(d|f))^* \tag{11}$$

Tree form of expression (11) is shown in Fig 1.

Fundamental data type can be arbitrary, even recursive. Question arises, what if we would be able to create data type that is going to be recursive and will contain `REXp a` type. Data type like that would need a terminating and recursive part. In our case, we will use type shown bellow. Regular expression itself would be of type `REXp RexChar`.

```
data RexChar =
      Ch Char | R (REXp RexChar)
```

Every element of regular expression can be either a character (the use of `Char` is not obligatory, we have chosen this type for example purposes) or regular expression of same type as the original expression. Purpose of recursive regular expressions is that they can contain themselves as their fundamental elements entering form of recursion.

In Haskell we can create those expressions statically as a source code or we might obtain them dynamically during execution by parsing input. Here is an example of a higher order regular expression in static Haskell code:

```
a,b :: REXp RexChar
```

```
a = SEQ [TERM (Ch 'a'),
      SUM [TERM (R b), TERM (Ch 'c')]]
b = SUM [SEQ [TERM (Ch 'b'),
      TERM (R b)], TERM (CH 'b')]
```

We can rewrite them as:

$$\begin{aligned} A &\to a(B \mid c) \\ B &\to bB \mid b \end{aligned} \tag{12}$$

If we consider the rules of CFG from Chomsky hierarchy, we can see that our recursive regular expressions (12) are written in format of a BNF rule. We can see, that our recursive regular expressions are corresponding with CFG rules and BNF grammars.

By definition of hierarchy of languages, for every regular language a finite state automaton can be constructed. Automata are efficient way for accepting or even generating phrases of regular languages. Next section discuses the idea of higher order state automata, that may not necessarily be finite, yet for all practical purposes, they will be usable.

## V. State automata derived from higher order expressions

As machine mind processes symbolized input and transforms it into concepts, it needs mechanism for structured symbols acceptance. This can be done with state automata. Deterministic automata can only have one transition for each symbol from one state to another and cannot contain empty transitions. Every nondeterministic automaton can be converted into deterministic. For practical purposes, it is always better to have control over choosing which step to take next.

To obtain state automata we need to have an expression first. We will use following example:

$$A \to aAb|ab \tag{13}$$

Expression (13) can be interpreted as a grammar of context free language that contains strings that have exact number of $a$s and $b$s in succession. This is typical illustration of a non-regular context free language, uninterpretable as a regular expression. However with our recursive expression it is possible. Resulting tree created from (13) will be infinite, depicted on Fig 2. We can see that second argument of sum operator, $ab$, is terminator part. We can conclude that if we consider our regular trees as executable, they are able to accept a context free language.

In work [11] is presented an algorithm that transforms regular expressions directly into minimum state automaton. Same can be applied to higher order regular expressions. Resulting automaton of expression (13) is depicted in Fig 3. This is an automaton corresponding to regular expression labeled as $A$.

There is a transition within body of an automaton in Fig 3 that accepts not a symbol but entire automaton. In this case it accepts itself. We can perceive this fact as a recursive jump to the higher level. For an input string "$aaabbb$", our automaton would have jumped twice into higher levels. We could see this as an automaton with infinite levels, as depicted in Fig 4. We see, that those automata are equivalent to recursive transition networks.

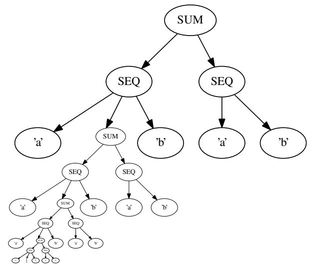

Fig. 2. Tree form of expression (13).

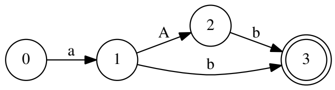

Fig. 3. Context free automaton

Final state on higher level does not always mean possible string acceptance, it can just represent return from a recursion, as depicted in Fig 4, where states 3 of all higher levels have transition into state 2 of lower level. Acceptance of string is achieved only in final states on base level. This does not mean, that higher level final states are not allowed to have transitions into final states of lower levels. In case like that, whole string of symbols can be accepted at higher level and then sequence of empty transitions into base final state will occur.

Consider following higher order expression written according to our rules, labeled as $B$:

$$B \to ba(Bb|(b)^1) \tag{14}$$

Closure in last symbol is parametrized and it designates zero or one repetition. Automaton for expression (14) is depicted in Fig 5. In this particular case see an example of higher order nondeterminism.

Automaton itself is deterministic, if we look at it as residing on one level, where $B$ transition is just another symbol transition. It is unfortunately not our case and $B$ means

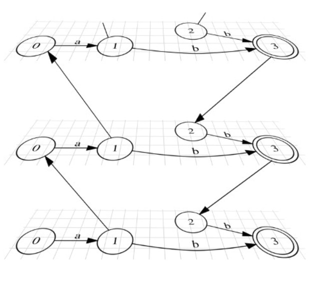

Fig. 4. Recursive infinite state automaton

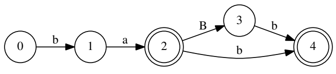

Fig. 5. Nondeterministic higher order state automaton

recursion, where automaton accepts itself. Consider execution where we are on non-zero level and are in the state 2. It is the final state, so execution on current level can terminate and we can return back. There is also a transition into the higher level and a normal transition with the symbol $b$.

Therefore exactly three transitions are possible at this moment. And all three are accepting one symbol, $b$. Jumping into the higher level causes jump into state 0 and here only $b$ is accepted. Returning one level down will get us into the state 3 and here $b$ is only acceptable symbol as well.

Application of automata inside machine mind is a possible solution for perceived reality acceptance, and as we have shown, symbolized structures do not need necessary be simply structured. The accepting part is but a small portion of a whole concept of the machine mind. The more important part is to deal with symbols and conceptualize them into the memory. We will continue to use only simple regular expressions further on for the sake of simplicity. Our focus is to get closer to human comprehension of concepts as possible. In the next section we will present the algorithm of abstract machine mind evolution that satisfies conditions of symbolization and conceptualization laid in previous sections.

## VI. Abstract language evolution algorithm

Let the language $a(ab)^*a$ be a result of conceptualization, that is also a concept, since symbolization process was bound to reality. This concept is composed of infinite amount of sub-concepts, where each of them has its own meaning. The most simple concept is $aa$ that symbolizes meaning of two uppercase letters $AA$. We can abstract from language semantics, since it is defined by separate process of symbolization. Therefore we can see them as simple regular expressions rather than complex languages.

An algorithm for abstract language evolution is composed of those eight steps:

1) Transformation of regular expression to metaexecutable form of (meta)syntactic tree, considering priority and associativity of metaoperations.
2) Selection of arguments  terminal symbols and transformation of each (sub)expression to the form of its application to selected arguments.
3) Abstraction of each expression  deriving the arity of lambda abstraction from number of arguments, selected in step 2. Elementary languages arise being still applied in the tree.
4) Decomposition of elementary languages (elementary language concepts). Elementary languages are dissolved in associative memory represented by a list and applied by the MATCH operation.
5) Abstraction of all applications (APP) to terminal symbols, i.e. replacing them by abstract applications (APPA) to lambda variables. The set of mutually applied abstract languages is formed.
6) Compression - removal of multiple occurrences of the same abstract languages, i.e. removal of redundancy of elementary languages.
7) Filtration - removal of sets of pointers to redundant languages. Manipulation phase.
8) The machine mind language extraction.

The sequential separation of steps is useful for the methodological purposes and also for verification of evolution on a sequential computer. But it can be noticed that sequential steps are executable potentially in parallel as pipelined processes.

## VII. Algorithm implementation using Haskell

In the Haskell implementation, meta-operations of sequence and transitive closure used in abstract concept $a(ab)^*a$ as well as sum (|) meta-operation were used. This allows us to apply the algorithm to the abstract language concept $a(b)^*|c$ as an input sample.

Each elementary language is in supercombinator form, i.e. lambda abstraction (LAM $n$ $e$), where n represents lambda variables $x_1, \ldots, x_n$ and $e$ is a meta-expression. Meta-expression $e$ in the form VAR 1 represents lambda variable $x_1$, otherwise it is the application of binary sequence metaoperation (SEQ), unary transitive closure metaoperation (CLS), and n-nary sum metaoperation (SUM), all being applied to the applications of elementary languages. These applications (APPA (MATCH k) $[x_1, \ldots, x_m]$) apply $k$-th elementary language of arity $m$ to bound lambda variables. By other words, k-th elementary language is a supercombinator, which can be accessed to be applied in a highly distributed associative memory of mind by operation (MATCH $k$) .

## VIII. Algorithm verification

We obtain the abstract language concept $a(b)^*|c$ represented in the machine mind by five elementary languages $L$ in supercombinator form (15).

$$\begin{aligned} L &= \{L_0, L_1, L_2, L_3, L_4\} \\ L_0 &= \lambda x_1.x_1 \\ L_1 &= \lambda x_1.L_0\ x_1 \\ L_2 &= \lambda x_1.(L_0\ x_1)^* \\ L_3 &= \lambda x_1.\lambda x_2.L_1\ x_1 + L_2\ x_2 \\ L_4 &= \lambda x_1.\lambda x_2.\lambda x_3.(L_3\ x_1\ x_2|L_0\ x_3) \end{aligned} \tag{15}$$

Each of elementary languages is applied to admissible abstract symbols, that sets have been derived in the algorithmic evolution. All possible applications (16) represent all meaningful sub-concepts acquired by the most complex input concept.

$$\begin{aligned} &L_0\ a,\ L_0\ b,\ L_0\ c \\ &L_1\ a \\ &L_2\ b \\ &L_3\ a\ b \\ &L_4\ a\ b\ c \end{aligned} \tag{16}$$

For example, we can verify that the applications of identity supercombinator $L_0$ yields concepts $a$, $b$, and $c$, that represent facts, and the application of supercombinator $L_4$, see (17), yields the most complex concept $a(b)^*|c$.

$$L_4\ a\ b\ c = a(b)^*|c \tag{17}$$

Abstraction in the process of conceptualization significantly decreases the amount of elementary supercombinators of the machine mind. For example, abstract concept $a(ab)^*a$, i.e. $a(ab)^ka$ would be represented by 6 supercombinators, for each $k \geq 0$. But if the algorithm is applied to non-abstracted concept (such as $aabababa$), the amount of supercombinators grows linearly ($2k+3$ for $k \geq 0$, i.e. 9 supercombinators for $aabababa$).

Summarization of structurally identical concepts yields no change of supercombinator form of languages $L$, just that amount of their arguments is increased. For example, (18) holds.

$$L(a(ab)^*a|c(cd)^*c) = L(a(ab)^*a|c(cd)^*c|e(ef)^*e) \quad (18)$$

Considering well abstracted conceptualization of large amount of symbols on input, we can await that the amount of application bindings exceeds the amount of elementary languages rapidly, preserving non-redundancy of the set of elementary languages.

## IX. Recognition by applicative automata

As can be seen, derived elementary languages are defined by regular expressions in that a single meta-operation is applied to elementary languages applications, instead of terminal symbols. Let us remind that:

$$L_4\ a\ b\ c = a(ab)^*c$$

In the first step of meta-computation we get:

$$L_4\ a\ b\ c \Rightarrow L_3\ a\ b \,|\, L_0\ c = A \,|\, B$$

Then it is not necessary to recognize concrete sub-concept belonging to $a(ab)^*a$ by generation of DFA for $a(ab)^*a$, but it is sufficient to derive the applicative DFA for regular expression $A|B$, where terminal symbol $A$ represents the set of final states of applicative DFA for ($L_3\ a\ b$) and terminal symbol $B$ represents the set of final states of applicative DFA for application ($L_0\ c$).

Considering (15), the number of applications commonly highly exceeds the number of elementary languages. That is why we can formulate the hypothesis on saturation of the machine mind, which can be realized as slowing-down expansion of set the $L$ with each new concept on input. Multiple occurrences of terminal symbols in arguments in (16) are of less importance, since they physically do not exist, because they represent just interconnections to reality records.

## X. Conclusion

The main advantage of internal machines supercombinator form is addition of automatic conceptualization criterion. It is the minimal count of elementary languages, which themselves are supercombinators as well. Internal language of a mind does not expand with ongoing stream of symbols on input. It is common knowledge that almost everything is new for a little child but an adult hardly finds something new that he hasn't heard or seen. In order for learnable machine to communicate with human, it needs to work on similar thought principles. This thinking is language oriented. If this principle is present, it can then absorb reality, symbolize it and based on abstraction it can create concepts in form of internal languages of a mind.

Our position isn't that supercombinator form is the only form able to represent internal language of mind. It is but an algorithmic realization of a possible way not to store anything multiplicity inside mind but to remember everything. Our supercombinator form has future applications possibilities despite the fact that each of cognition steps could look differently, if someone else performed it. Experiment with higher order expressions shows us that our future work may be involved in other forms of grammars.

We do not think the machine mind evolution is based just on regular expressions, as presented in this paper. But using this simplest case we were able to introduce the principle of applicative automata for output communication. Clearly, machines should be active in communication, i.e. able to formulate the questions.

Derived language of the machine mind consists of elementary languages, such that each of them can be fetched associatively by matching. An interesting structural similarity between the machine mind and neural brain network can be noticed. Both mind meta-operations and brain neurons are the nodes and both mind applications and brain synapses are arcs of a graph. However, in our opinion, no bidirectional relation between brain and mind can be deduced from mentioned structural similarity.

***Abstract*—Automatic processing of requirements (e.g. to generate code) remains a challenge in contemporary software development. Requirements are still treated as secondary artifacts by software developers, as they are written in natural languages which causes ambiguity. In this paper, we present an approach to generate working code from requirements through applying precisely formulated domain models. As the source, we use the Requirements Specification Language (RSL) which is a precise constrained language, based on a central domain model composed of domain notions. These notions are linked from use case scenarios and create a form of a 'wiki'. Notions are graphically visualized in RSL, and resemble UML classes with attributes. Notions can be used in phrases that can represent various operations used within use case scenarios. In our approach we introduce model transformation algorithms that allow to generate database access code associated with operations to persist (store, retrieve) data in a database system. To focus our work, we present code generated for Hibernate which is an object relational mapping framework.**

***Index Terms*—model-driven requirements engineering, model transformations, database access, metamodelling**

## I. Introduction and Background

TYPICAL requirements specifications in contemporary software projects use natural language, possibly with some elements of modelling. This poses a significant challenge for approaches to automate the process of turning requirements into working code. A prominent field of research that aims at changing this situation is Model-Driven Requirements Engineering (MDRE) [1]. In MDRE, requirements are expressed as models, often by using the Unified Modelling Language (UML) [2]. Such models are intended to be comprehensible to both software developers and end-users. This comprehension is most often assured by introducing a comprehensive vocabulary of the problem domain in the form of a domain model. This allows to use the techniques of domain engineering [3]. Most often, UML class diagrams are used. Classes represent domain objects (noun phrases) with associated atomic attributes (also nouns) and operations (verb phrases). What is more, class models can define relationships between domain objects (notions), thus allowing to build a certain semantic network of related notions.

Still, UML does not offer any means to associate domain models with the remaining models and it has no precise syntax for textual elements like scenarios. Thus, in this paper we will use a language dedicated to formulating precise requirements models, called the the Requirements Specification Language (RSL) [4], [5]. The syntax of RSL is defined through a meta-model using the Meta-Object Facility (MOF) meta-language [6]. An important feature of RSL is that it introduces precise (hyper-)linking of domain models within textually expressed requirements units.

To link textual requirements with domain models, we need to represent requirements by using notions from the domain model in a consistent way [7]. This means – for instance – that use case [8] scenarios should be composed of links to domain model elements – noun phrases and verb phrases, contained in a central domain model. In RSL, this is done very consistently: all the scenario sentences are in fact links to phrases contained in the domain model. This makes the whole RSL-based specification resemble a 'wiki' system (see Fig. 8 for an illustration) with consistent use of hyperlinks to specific vocabulary notions.

This consistency of RSL allowed Śmiałek et al. [9], [10], [11] to formulate formal translational rules for generating code from requirements models (use cases and their scenarios) down to UML design models and Java code. The resulting code follows the Model-View-Presenter (MVP) [12] architectural pattern. The rules focus on generating full code for the View and the Presenter layers, and method stubs for the Model layer. They also permit to generate Data Transfer Objects, that facilitate control flow between the three layers. Unlike for other approaches in MDRE, these rules allow for a fully automatic translation from high-level requirements models (use cases, scenarios, domain vocabularies) down to fully operational code.

The above approach with RSL still lacks rules for generating code associated with persistence operations at the Model layer. Thus, in the current work, we concentrate on defining and implementing rules for generating database access code that is responsible for processing and persisting data. We want this code to be consistent with that for the View and Presenter layers as introduced in the previous paragraph. For this, we will use the Hibernate framework [13] which is an Object Relational Mapping (ORM) that allows for mapping Java Classes (DTOs) to database tables, and for managing data with the Data Access Object (DAO) design pattern [14]. We give rules to generate general Create/Read/Update/Delete (CRUD) operations for persisting Java objects in database tables.

In the following sections we introduce our approach which

978-83-60810-66-8/$25.00©2015, IEEE

is consistent with typical model transformation approaches of Model-Driven Software Development [15], [16]. In Section II we briefly present the domain vocabulary part of RSL which is the source language for our transformations. In Section III we present the transformation itself: selected rules and algorithms that implement them. The rules define the translation from RSL to UML with inserted operational Java code. The algorithms are expressed in a graphical transformation language called MOLA (MOdel Transformation LAnguage) [17], [18]. The last section presents conclusions stemming from implementing the presented algorithms within the RSL environment called ReDSeeDS [19] and using a UML tool (Enterprise Architect - EA, from Sparx Systems, sparxsystems.eu) to visualise the generated UML models and to generate the final Java code.

## II. Requirements Specification Language: Overview of the Domain Notions Part

Requirements Specification Language (RSL) is a semi-formal language for specifying precise requirements [5], [20]. The fundamental idea behind RSL is separation of concerns: separating description of the system's application behavior and the description of the system's problem domain. The behavior of the system is described with ***use cases*** and their ***textual scenarios*** written in constrained natural language. The domain specification is defined using ***notions*** (words). Phrases in scenario sentences constitute the **application logic**, and are linked to notions that constitute the **domain logic**. Notions can be composed of both "nouns" and "verbs".

The RSL's grammar is defined formally through a metamodel written in MOF which is standardized by the Object Management Group (OMG, www.omg.org) [6]. The primary goal of MOF is to allow metamodels to be defined using basic class model syntax (classes with attributes and relationships). The full description of RSL consists of the abstract syntax (i.e. the metamodel), the concrete syntax (definitions of visual language elements), and informally specified semantics (natural language descriptions similar to those in the UML specification [21]). It can be found in a comprehensive report from the ReDSeeDS project [4] which uses the 'Complete' (CMOF) dialect of MOF. A variant that uses the 'Essential' dialect of MOF (EMOF) is presented in the book by Śmiałek and Nowakowski [11]. The book also presents a comprehensive approach to defining RSL's semantics in a formal, translational way.

Figure 1 presents a small excerpt from the RSL metamodel pertaining to notions and their relationships. As we can notice, in contrast to UML, **Notions** contain *notionAttribute*s that are also **Notions**. Attributes can be distinguished from regular notions by their possession of an **AttributeDataType**. The possible data types include:

- "text": string-like textual description;
- "number": an integer number;
- "floating number": a number with a possible decimal;
- "truefalse": a boolean value;
- "date": a value containing date or time;

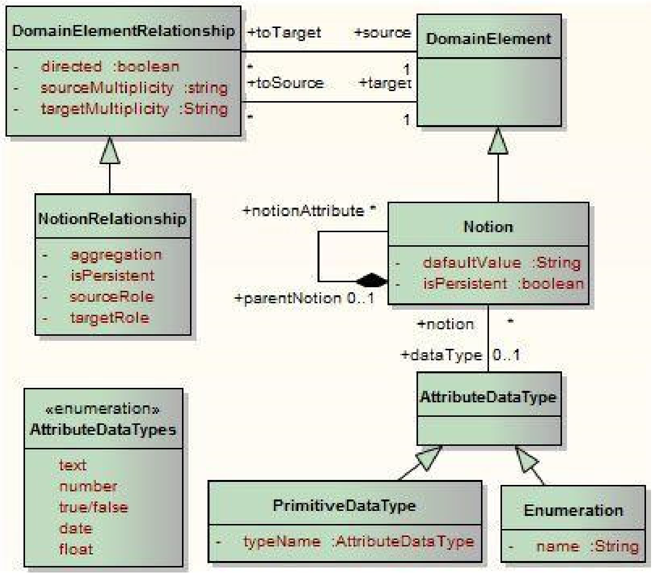

Fig. 1. Part of the RSL's metamodel for notions and their relationships

It can be noted that to represent requirements for software we need to define domain elements in two areas: 1) the problem (business) domain, and 2) the application domain. The problem domain is the actual reality that the software supports. It is stable and quite independent from the application to be built and changes when the reality changes. The application domain changes when the application changes and contains various parameters and user interface elements.

Here we will concentrate on the the problem domain that consists of domain notions (e.g. "book", "publisher", "author"...etc), and their attributes (e.g. "title", "name", "address" ..etc.). The concrete notation for domain notions in RSL is similar to that found in UML class models. An example is shown in Figure 2. The basic type of **Notion** in RSL is the *"Concept"*. Graphically, it resembles a UML class. The second type of **Notion** is the *"Attribute"*. We can notice that unlike in UML, attributes are not contained graphically in the *"Concepts"*. This is a feature of RSL that facilitates sharing attributes between various notions, especially of the 'view' type (see below).

*Concepts* and *attributes* are presented as rectangles adorned with appropriate tags. *Attribute* elements additionally contain information about the data type included in brackets. We should note that the data types are not limited and can be easily extended in the metamodel, depending on the problem domain (e.g. with sound, graphics, etc.), but should be defined in advance prior to developing a transformation.

Other notion types in RSL are called "**Data views**" and are divided into two kinds: "Simple data view", and "List data view". Data views point to sets of attributes. "Simple data views" serve to present single instances of combined attributes. "List data views", are used to present lists, containing many instances. "Data views" and other RSL elements are not treated in detail in this paper, for more details please refer to the book by Śmiałek an Nowakowski [11].

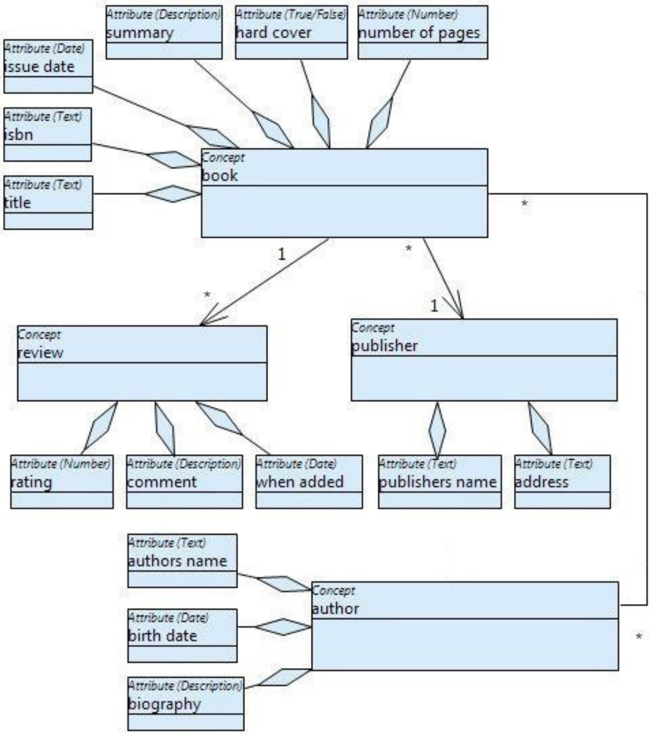

Fig. 2. Example of notions and their relationships in RSL's concrete notation

The different types of domain elements are connected by "relationships". The first kind of relationship is denoted similarly to associations in UML. It relates two concepts, and can have multiplicities. The second type of relationship is containment of attributes within concepts, where the diamond is placed on the concept side. The notation of containment relationship is also taken from UML and resembles aggregations.

In RSL, we can define all kinds of problem domains (e.g. Physics, Aeronautic, Finance, etc.). Figure 2 illustrates an example of RSL model for the "Library Management" problem domain. In this domain we have four elementary **concepts**: book, author, publisher and reviewers. Each concept can hold a number of attributes (shown via the containment relationship). For example, the "book" concept has attributes like: ISBN, title, number of pages, issue date, etc. The four concepts are connected via associations, that have appropriate multiplicities (one-to-many, many-to-one, many-to-many, ... etc.).

## III. Generating Database Access Code From RSL

This section consists of two parts. In the first part we introduce selected transformation rules that constitute translational semantics for RSL's domain vocabulary constructs, where the target languages are UML and Java. In the second part we present algorithms expressed in MOLA that implement these transformation rules.

### A. *Transformation Rules*

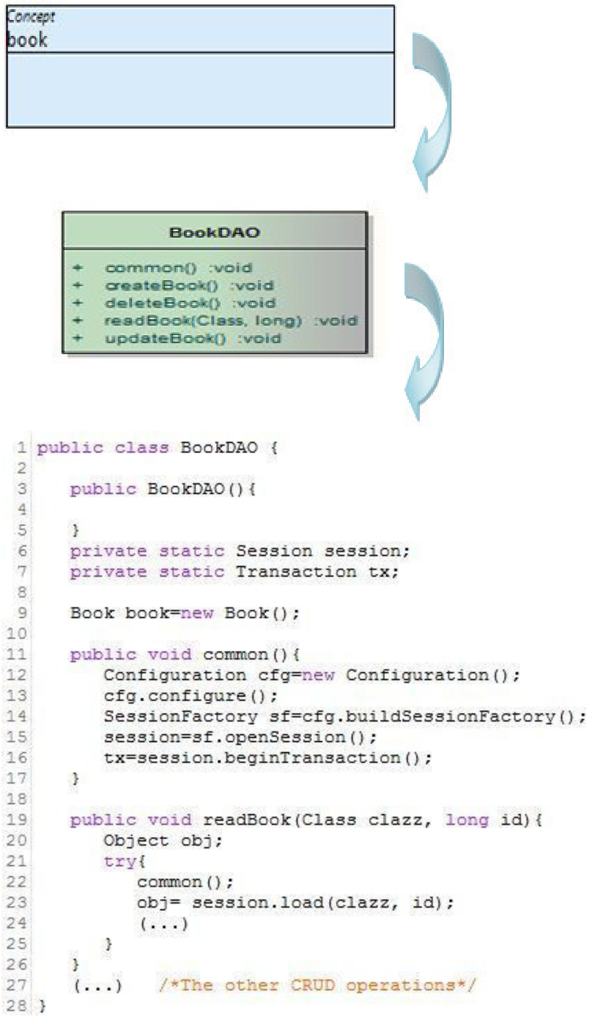
In order to generate database access code from RSL we need to explain its semantics concerning this aspect. For this, we will use a pragmatic translational approach [22], which is based on translating a "Source language" to a "Target language" which has already well-defined semantics [23], [24]. In our case, the source language is "RSL", and the target languages are "UML" and "Java". The reason behind choosing Java and UML as target languages, is that they are widely used and understood by a large community of software developers.

We will define a set of translation rules to generate data base access code from RSL domain models. For this, we will use the Data Access Object (DAO) design pattern [14], that implements the access mechanism required to work with the data source (e.g. Relational Database Management Systems like: MySQL, Oracle, PostgreSQL, etc.). We will apply this pattern in the context of the Hibernate framework, which is an open source Object-Relational-Mapping (ORM) that allows for persisting and storing data in a database [13], via CRUD (Create/Read/Update/Delete) operations within the DAO classes.

Hibernate maps Java persistent classes to database tables, and from Java data types to SQL data types, and provides data query and retrieval facilities. The Java persistent classes are Data Transfer Objects (DTOs) [25] or POJOs (Plain Old Java Objects). Hibernate uses XML files for mapping Java classes into tables, which are: Hibernate Configuration file, and Hibernate Mapping files. The Hibernate Configuration file contains all the required information related to the database, and other related parameters. The Hibernate Mapping files should be generated for each DTO class, and should contain information related to associations between database tables.

In the following, we will present two translation rules that defines semantics of RSL domain models in terms of DAO classes, and Hibernate classes. Other rules, that allow to generate Data Transfer objects and configuration files are out of scope of this work.

- **Rule R1:** Every "Concept" in the RSL domain model is translated into a DAO class. The name of the class is derived from the Concept's name and concatened with the "DAO" string. Each class contains four operations: "Create", "Read", "Update", and "Delete", plus the "common" operation. The operations' names are derived from the name of one the CRUD operations, concatenated with the name of the "Concept". Figure 3 provides a description of Rule R1. In this example we can see that the "book" concept in RSL, is first translated into a UML class named "BookDAO" with four CRUD operations (createBook, readBook, updateBook, and deleteBook), plus the "common" operation. The UML class is then translated into a "BookDAO" Java class. The "common" operation (lines 11-17) initialises various variables required by Hibernate. In lines 19-26, we show a fragment of code for the "readBook" operation, which takes two parameters as input: the Class (i.e. the DTO class) and the identifier (ID), and reads the proper object using the "load" method of the 'session' object.



```
public class BookDAO {

   public BookDAO(){

   }
   private static Session session;
   private static Transaction tx;

   Book book=new Book();

   public void common(){
      Configuration cfg=new Configuration();
      cfg.configure();
      SessionFactory sf=cfg.buildSessionFactory();
      session=sf.openSession();
      tx=session.beginTransaction();
   }

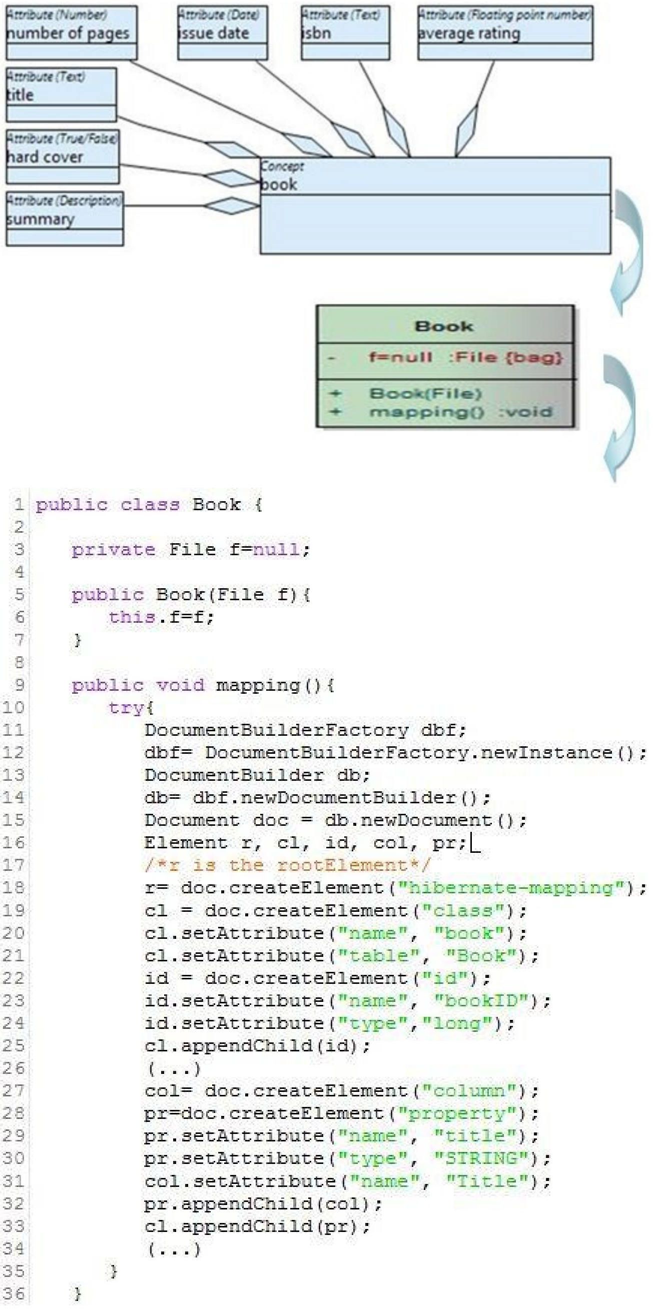
   public void readBook(Class clazz, long id){
      Object obj;
      try{
         common();
         obj= session.load(clazz, id);
         (...)
      }
   }
   (...)   /*The other CRUD operations*/
}
```

Fig. 3. Generation of the “BookDAO” class with CRUD operations

- **Rule R2:** Every “Concept” with its attributes in the RSL domain model is translated into a mapping class. The class’ name is derived from the concept’s name. Each mapping class contains a constructor with a parameter, and the “mapping” operation. Rule R2 is illustrated in Figure 4. The example shows a fragment of the code for the “mapping” operation. This operation is responsible for mapping of the Book class into the book table which exists already in a database, this table of course has a unique identifier (ID). Each attribute is mapped into a column in a database table (see lines 27-31).

### B. Transformation Algorithm

The presented rules define the expected outcome of a transformation from RSL’s domain models to database access code. To implement these rules, we have developed appropriate transformation algorithms. Here we introduce them by using MOLA, a language dedicated to model transformations, developed at the University of Latvia [17], [18]. The MOLA notation is graphical, as illustrated in Figures 5-7 and is based on graph-grammar rules that are defined in the context of UML activity diagrams.



```
 1 public class Book {
 2
 3    private File f=null;
 4
 5    public Book(File f){
 6       this.f=f;
 7    }
 8
 9    public void mapping(){
10       try{
11          DocumentBuilderFactory dbf;
12          dbf= DocumentBuilderFactory.newInstance();
13          DocumentBuilder db;
14          db= dbf.newDocumentBuilder();
15          Document doc = db.newDocument();
16          Element r, cl, id, col, pr;
17          /*r is the rootElement*/
18          r= doc.createElement("hibernate-mapping");
19          cl = doc.createElement("class");
20          cl.setAttribute("name", "book");
21          cl.setAttribute("table", "Book");
22          id = doc.createElement("id");
23          id.setAttribute("name", "bookID");
24          id.setAttribute("type","long");
25          cl.appendChild(id);
26          (...)
27          col= doc.createElement("column");
28          pr=doc.createElement("property");
29          pr.setAttribute("name", "title");
30          pr.setAttribute("type", "STRING");
31          col.setAttribute("name", "Title");
32          pr.appendChild(col);
33          cl.appendChild(pr);
34          (...)
35       }
36    }
```

Fig. 4. Generation of Hibernate mapping code for the ”Book” concept

MOLA is a procedural language, and Figure 5 shows a sequence of 6 procedure calls. This forms the main procedure of our algorithm. After cleaning-up the target model, the procedure creates a general package structure. Then, it creates appropriate Data Transfer Objects and Data Access Objects. Finally, it generates Hibernate mappings and configuration files.

In this current short introduction to the transformation algorithm we will concentrate on creating the DAOs (cf. Rule 1 in the previous section). The appropriate procedure for

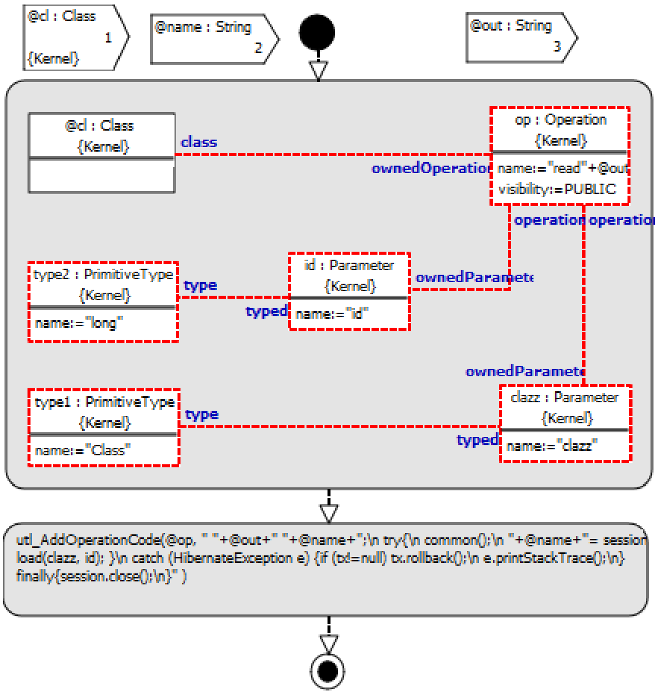

Fig. 7. MOLA rule for “SpecificRead” operation

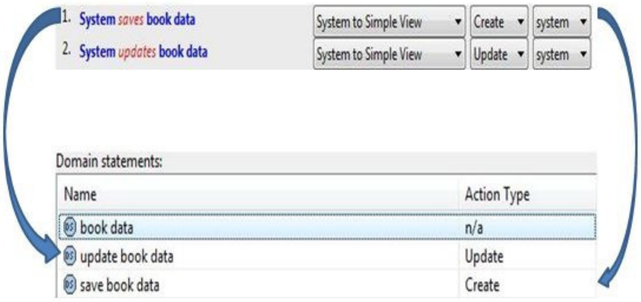
implementing this is presented in Figure 6. The procedure iterates over all the **Notion** objects (refer to Figure 1) found in the source model (see the object ‘n:Notion’ in the top-left of the figure). Note that in MOLA, loops are represented by rectangles with thick borders which encompass all the actions to be performed within them. For each notion, the loop determines the notion’s type, and if it is of type ‘concept’ it creates a new **Class** type object (see ‘cl: Class’). This object is placed inside an existing **Package** (see ‘p:Package’) named ‘DAO’. Additionally, the newly created class is related through a realisation relationship to a DAO interface object and through a mapping relationship (see ‘isalloc:IsAllocatedTo’) – to the original notion object. It is also completed by generating some relations to other elements that allow for importing certain elements specific to the Hibernate framework.

The main loop concludes by generating four CRUD operations within the new class. One of these procedures is illustrated in Figure 7. This procedure takes two parameters as input – the class and its name. In the class it creates an operation (see ‘op:Operation’ with two parameters (see ‘id:Parameter’ and ‘clazz:Parameter’). As we can see, the main MOLA rule presented in Figure 7 shows a configuration of 5 objects to be created (one operation, two parameters and two primitive types). This configuration is consistent with the UML’s metamodel which can be found in its official specification [21].

Note that the generated operation matches code illustrated in line 19 in Figure 3. In addition, by using a simple text processing statement (see ‘utl_AddOperationCode’), the procedure appends the method of the operation with the code like in lines 20-24 in the same figure.



1. System saves book data | System to Simple View ▾ | Create ▾ | system ▾
2. System updates book data | System to Simple View ▾ | Update ▾ | system ▾

Domain statements:

| Name | Action Type |
|---|---|
| book data | n/a |
| update book data | Update |
| save book data | Create |

Fig. 8. Linking domain elements from scenarios

## IV. Conclusion and Future Work

To validate the presented approach we have implemented the above introduced algorithm within the framework of the the ReDSeeDS (Requirements-Driven Software Development System) tool suite [19] (see: www.redseeds.eu). The tool offers a full Model-Driven Software Development (MDSD) life cycle: i.e. from requirements to UML models down to Java code. In our application, the source RSL domain model with its notions were specified using the ReDseeDS editor (see Fig. 2). After writing and testing the transformation rules using the MOLA environment (see: mola.mii.lu.lv) we have integrated them into the ReDSeeDS tool. The MOLA transformation has been compiled and made available within the ReDSeeDS transformation menu. More details about this integration process can be found in the book by Śmiałek and Nowakowski [11]. The transformations generate UML classes with embedded method code. These UML classes are then handled by the UML tool (Enterprise Architect) and its standard code generator, to produce Java code.

The resulting transformation from RSL to Hibernate ORM produced good quality, consistent code that could be used directly to implement the data access layer. In current work we did not approach at generating the database tables, but it can be noted that our solution shows that a complete persistence layer could be generated automatically from domain models in RSL. This is an interesting research direction and we treat this as future work.

Moreover, our future work will also include integration of the persistence layer within the Model-View-Presenter (MVP) [12] architectural pattern. The upper layers (View and Presenter) of a complete software system can be fully generated from RSL models as shown by Śmiałek et al. [10], [11], [26]. This approach does not generate any contents of the Model layer. However, we can approach at generating meaningful code for the CRUD operations. Such operations are used frequently in RSL scenarios, as illustrated in Figure 8. Links between scenario sentences (e.g. 'System saves book data') and domain statements (e.g. 'save book data') can be transformed into calls from the Presenter layer to the Model layer. The RSL environment allows for determining the type of operation (e.g. Create or Update) and thus appropriate database access code can be provided in proper places.

Technical University of Košice
Letná 9, 042 00 Košice, Slovakia
Email: matus.sulir@tuke.sk, milan.nosal@gmail.com

***Abstract*—*Context:* Developers possess mental models containing information far beyond what is explicitly captured in the source code. *Objectives:* We investigate the possibility to use source code annotations to capture parts of the developers' mental models and later reuse them by other programmers during program comprehension and maintenance. *Method:* We performed two studies and a controlled experiment. *Results:* Developers' mental models overlap and thus can be shared. Possible use cases of shared annotations are hypotheses confirmation, feature location, obtaining new knowledge, finding relationships and maintenance notes. In the experiment, the presence of annotations reduced program comprehension and maintenance time by 34%. *Conclusion:* Annotations are a viable way to share programmers' thoughts.**

## I. Introduction

When programmers develop a new program, they continuously create a mental model, which is a representation of the program in their mind. They try to express the mental model in the programming language constructions. However, not all parts of the mental model are transferred into the source code and some details are lost.

### A. Motivation

For example, in small parts of a large information system, we can be forced to deal with a character encoding different than in the rest of the system because of the legacy library limitations.

Later, during the program maintenance phase, developers make a tremendous effort to recover such types of information from the source code [2]. However, they rarely persist their findings [3] and the situation occurs again and again.

We could record the information about the encoding from the aforementioned example in a form of a Java annotation `@Encoding("win-1250", reason="myOldLib 2.4")` above all affected classes or methods. It would be later possible to use the IDE (integrated development environment) searching capabilities on the given annotation to find all methods where this encoding is used if an encoding-related bug is reported or refactoring is planned to replace the legacy library.

### B. Aim

The purpose of this paper is to investigate the viability of annotations as a medium to share parts of developers' mental models.

**Hypothesis**: Annotations created by one group of developers are useful for comprehension and maintenance tasks performed by other developers.

We formulate the research questions as follows:

- **RQ1**: Do programmers' mental models overlap?
- **RQ2**: How do developers use shared annotations when they are available?
- **RQ3**: Does using annotations created by others improve program comprehension and maintenance correctness, time and confidence?

To answer each of the questions, we used an appropriate empirical research methodology [4].

## II. Concern Annotations

Before describing the studies, we briefly introduce the notion of concerns and their kinds.

### A. Basic Concepts

A *concern* can be characterized as a developer's intent of a particular piece of code: What should this code accomplish? How would I tersely characterize it? Is there something special about it? Some concerns can be obvious by looking at the code itself (chiefly from names of the identifiers), but many concerns are hidden.

A concern is similar to an aspect in aspect-oriented programming. In contrast to aspects, concerns can overlap – one piece of code can belong to multiple concerns [5]. This complicates the situation: We cannot simply name all classes and methods according to their concerns since one identifier can have only one name. Thus, we can also look at concerns as alternative names for identifiers.

It is possible for a class or method in Java to have more than one annotation. Therefore, source code annotations (attributes in C# terminology) are an ideal candidate to implement concerns.

This work was supported by VEGA Grant No. 1/0341/13 Principles and methods of automated abstraction of computer languages and software development based on the semantic enrichment caused by communication. The first two research questions are also elaborated in the second author's PhD thesis [1].

978-83-60810-66-8/$25.00©2015, IEEE

For each distinct concern, we recommend to create one Java *annotation type*. For example, we can create an annotation type `@Persistence` which tells us the code marked with it fulfills the task of persistent storage of objects.

Subsequently, in our imaginary program, we could mark the methods like `FileDialog.open()`, `Note.load()`, `Note.save()` and a class `FileFormat` with it. We will call them *annotation occurrences*.

At the same time, the first of the mentioned methods could be also annotated with the `@GUI` concern, as it presents a GUI (graphical user interface) dialog to a user.

Compared to traditional source code comments, concern annotations are more formal. We can use standard IDE features like navigating to the declaration, usages searching, refactoring [6] and other on them.

Concern annotations can have parameters to further specify their properties. They may be also commented by natural language comments if needed.

### B. Kinds of Concern Annotations

*Domain annotations* document concepts and features of the application (problem) domain. For example, all source code elements representing the feature of filtering a list of items can be marked with an annotation `@Filtering`. Similarly, all code related to bibliographic citations could be annotated by `@Citing`.

*Design annotations* document design and implementation decisions like design patterns, e.g., `@Observer`.

*Maintenance annotations* are intended to replace the traditional TODO and related comments. An example is the `@Unused` annotation for parts of code not used in a project at all.

## III. Mental Model Overlapping

Our first goal is to find out whether at least some of the concerns recognized by one programmer can be recognized by other developers. If so, then the mental model of one developer at least partially overlaps with the other persons' mental model. This is a necessary condition for concern annotation sharing to be useful.

### A. Method

We asked multiple programmers to independently annotate the source code of an existing program. Then we measured to what extent their annotations overlap.

*1) Materials:* For this and subsequent studies, we used EasyNotes[1] – a desktop application for bibliographic note-taking. It is a small-scale Java project consisting of around 2500 lines of code located in 33 classes. Except for scarce source code comments, it has no documentation available.

TABLE I
The number of recognized concerns and annotation occurrences per individual subjects

| Subject | Concerns | Occurrences |
|---|---|---|
| A | 11 | 70 |
| B | 12 | 56 |
| C | 24 | 108 |
| D | 20 | 79 |
| E | 12 | 56 |
| F | 14 | 89 |
| G | 17 | 140 |
| **Total (distinct)** | **46** | **464** |

*2) Participants:* This study had 7 participants:

| | |
|---|---|
| A | a researcher and lecturer with PhD in Computer Science, |
| B | an industrial Java programmer, |
| C | a postdoc and Java programmer, |
| D | an associate professor with extensive Java experience, |
| E, F | first-year PhD students, |
| G | the author of EasyNotes. |

None of the subjects, except for the author, had a previous experience with EasyNotes. The activity was individual and the participants were not allowed to interact during the experiment.

*3) Procedure:* First, the participants were given the original source code of EasyNotes without any annotations (commit `a299e64`). They had an arbitrary amount of time available to become familiar with the application both from an end-user and programmer perspective.

Next, they were asked to create a custom annotation type for each concern they recognized in the application and to mark classes, member variables and methods with the annotations they just created whenever they thought it was appropriate.

*4) Analysis:* Finally, we collected the modified projects and analyzed them semi-automatically for an overlap in annotation types and the use of the annotations on specific elements. A manual intervention was necessary because some participants used a slightly different name for the same concern – e.g., `@Tags` and `@Tagging` both represent the "tagging" concern.

### B. Results

For each participant, a set of created concerns (annotation types) was constructed. The number of concerns created by individual participants ranged from 11 to 24 and the number of annotation occurrences from 56 to 140 (see Table I).

*1) Concern Sharing:* We constructed a set of distinct concerns, i.e., an union of all sets of the concerns recognized by the participants. The size of this set, i.e., a number of distinct concerns, is 46 (the Total row in Table I). More than a half of them (26) was shared by at least two participants. We will call them *shared concerns*. A list of all shared concerns is in Table II.

[1] http://github.com/MilanNosal/easy-notes

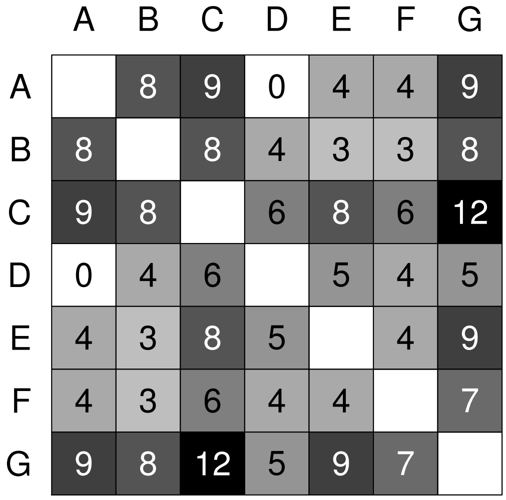
TABLE II
A LIST OF ALL SHARED CONCERNS IN EASYNOTES

| | Concern | Shared by *n* participants | Effective agreement |
|---|---|---|---|
| 1 | Searching | 6 | 61% |
| 2 | Note editing | 5 | 60% |
| 3 | Note change observing | 5 | 50% |
| 4 | Note presenting | 5 | 21% |
| 5 | Unused code | 4 | 67% |
| 6 | Tagging | 4 | 64% |
| 7 | Persistence | 4 | 41% |
| 8 | Links | 4 | 39% |
| 9 | Note adding | 4 | 38% |
| 10 | Data model | 4 | 36% |
| 11 | Loading notes | 4 | 35% |
| 12 | Saving notes | 4 | 31% |
| 13 | GUI | 4 | 26% |
| 14 | Note deleting | 4 | 18% |
| 15 | UI-model mapping | 4 | 4% |
| 16 | Filter implementation | 3 | 18% |
| 17 | TODO | 3 | 8% |
| 18 | Exceptions | 2 | 100% |
| 19 | Utilities | 2 | 50% |
| 20 | Model change watching | 2 | 17% |
| 21 | Filters management | 2 | 12% |
| 22 | Notes manipulation | 2 | 8% |
| 23 | Questions about code | 2 | 0% |
| 24 | Coding by convention | 2 | 0% |
| 25 | BibTeX | 2 | 0% |
| 26 | Domain entity | 2 | 0% |

*2) Occurrence Sharing:* Similarly, we constructed a set of all distinct annotation occurrences with a total size of 464 (as noted in Table I). 128 of them were so-called *shared annotation occurrences* which means they were shared by at least two participants.

We define an *effective agreement* as the number of shared annotation occurrences divided by the total number of annotation occurrences. For our EasyNotes study, the overall effective agreement was 27.59%. It is possible to see the values of effective agreement for individual concerns in Table II. We can consider the effective agreement of a specific concern its quality indicator – to what extent multiple developers agree about the mapping of this concern to source code elements.

*3) Agreement between Participants:* Fig. 1 shows the number of shared concerns between each pair of participants. We can obtain interesting insights from this matrix. The subjects A and D did not create any common annotation type in our study – this could be an indication of a huge difference in the mental models of these two people. In fact, D is a former or current supervisor of all other participants except A. On the other hand, G (the author of EasyNotes) shares the most concerns with all other people. This could mean that the source code author is the best annotator.



| | A | B | C | D | E | F | G |
|---|---|---|---|---|---|---|---|
| A | | 8 | 9 | 0 | 4 | 4 | 9 |
| B | 8 | | 8 | 4 | 3 | 3 | 8 |
| C | 9 | 8 | | 6 | 8 | 6 | 12 |
| D | 0 | 4 | 6 | | 5 | 4 | 5 |
| E | 4 | 3 | 8 | 5 | | 4 | 9 |
| F | 4 | 3 | 6 | 4 | 4 | | 7 |
| G | 9 | 8 | 12 | 5 | 9 | 7 | |

Fig. 1. The number of shared concerns between individual subjects

A similar matrix was constructed for concern occurrences. Qualitatively, it resembled the annotation type matrix.

### C. Threats to Validity

*1) Internal Validity:* While some hypotheses were outlined in this section, being an exploratory study [7], there is a need to properly quantify and statistically confirm or reject them. This suggest interesting future research directions.

*2) External Validity:* We performed the study only on a small-scale Java project. The participants were all from the same department which could affect their mental models. A more extensive study should be conducted in the future.

### D. Conclusion

We studied mental model overlapping, where parts of the mental model were represented by source code annotations. In our study, about

- 57% of all concerns
- and 28% of concern occurrences

were shared by at least two participants. This means there is a potential in recording and subsequent reuse of these data.

## IV. CONCERN ANNOTATIONS USE CASES

The goal of the second study is find out how third-party developers (i.e., not the annotation authors) use the annotations in the source code if they are available.

### A. Method

We conducted an observational study.

*1) Materials:* We copied all annotation types shared by at least two subjects (from the first study, see Table II for a list) into the EasyNotes project. For each of these annotation types, we merged all its occurrences (recognized by at least one developer) into the project. The resulting source code was manually edited for consistency by the EasyNotes author. It is published as the commit `f52872b`.

*2) Participants:* There were three participants:

K a first-year Computer Science PhD student,

L a masters degree student with a minor industrial experience,

M a professional developer with 2 years of industrial experience.

None of them had a previous knowledge of EasyNotes.

*3) Procedure:* First, all annotations were briefly introduced by the EasyNotes author. The subjects were reminded about common feature location possibilities of the NetBeans IDE.

Each participants was given the same task: To add a "note rating" (one to five stars) feature to EasyNotes. The fulfillment of this task required a modification of multiple application layers – from the model to the user interface.

We used a think-aloud method [7], i.e., the participants were kindly requested to comment their thoughts when comprehending the code.

### B. Results

We will now look at typical use cases of concern annotations during our study.

*1) Confirming Hypotheses:* The most common use of concern annotations was to confirm hypotheses about the code. For example, the participant K used the `@NotesSaving` annotation to confirm that a particular piece of stream-writing code actually saves notes.

*2) Feature Location:* In contrast to traditional comments, it is possible to use the Find Usages feature on an annotation type to find all concern occurrences. Our participants were finding the occurrences of the "filtering", "note adding", "note saving" concerns and others. This was considered helpful especially to find if they did not forget to implement the necessary methods for a particular aspect of the note rating feature.

*3) Non-Obvious Concerns:* The developers also used annotations to obtain new knowledge about the source code. For instance, a UI (user interface) code contained a method used both when adding a new note and when editing an existing one. However, just a note editing concern was obvious from a brief source code inspection. Only thanks to the concern annotation `@NoteAdding`, the participant M noticed the code is used for note adding, too.

*4) Elements Relationship:* The subjects noticed that if two or more elements are marked with the same annotation type, there is an implicit relationship between them. For instance, when using the MVC (Model-View-Controller) design pattern, the code in the model marked with a specific annotation is linked with the UI code with the same annotation.

*5) Maintenance Notes:* The annotation `@Unused` marks methods not used in the rest of the code. This helped the participants to skip them when scanning the code and thus save time.

### C. Conclusion

*1) Advantages:* The participants stated that compared to traditional natural language comments, annotations are much shorter and thus easier to spot. They are also better structured and usually less ambiguous. The ability to find all usages of a particular concern through standard features present in contemporary IDEs was also appreciated.

*2) Disadvantages:* The participant with an industrial experience (M) remarked there is a possible scaling problem. Even in a small project like EasyNotes, 26 shared concerns were identified. In large projects, where this number is expected to grow, some sort of concern categorization would definitely be needed. As Java annotations do not support inheritance, marking them with meta-annotations or sorting them to packages are possible solutions.

## V. The Effect of Annotations on Program Maintenance

We performed a controlled experiment to study the effect of the annotated source code on program comprehension and maintenance.

The guidelines to perform software engineering experiments on human subjects [8] were used. To present our findings, the experiment reporting guidelines [9] were followed. We customized them to the specific needs of this experiment.

### A. Hypothesis

Similar to Barišić et al. [10], we were interested in correctness, time and confidence.

We hypothesize that the presence of concern annotations in the source code improves program comprehension and maintenance correctness, time and confidence. Thus we formulate the null and alternative hypotheses:

**$\mathbf{H1_{null}}$**: The correctness of the results of program comprehension and maintenance tasks on an annotated project = the correctness on the same project without concern annotations.

**$\mathbf{H1_{alt}}$**: The correctness of the results of program comprehension and maintenance tasks on an annotated project > the correctness on the same project without concern annotations.

**$\mathbf{H2_{null}}$**: Time to complete program comprehension and maintenance tasks on an annotated project = time to complete them on the same project without concern annotations.

**$\mathbf{H2_{alt}}$**: Time to complete program comprehension and maintenance tasks on an annotated project < time to complete them the same project without concern annotations.

**$\mathbf{H3_{null}}$**: Participants' confidence of their answers to program comprehension questions on an annotated project = their confidence on the same project without concern annotations.

**$\mathbf{H3_{alt}}$**: Participants' confidence of their answers to program comprehension questions on an annotated project > their confidence on the same project without concern annotations.

We will statistically test the hypotheses with a confidence interval of 95% ($\alpha = 5\%$).

### B. Variables

Now we will define independent variables, i.e., the factors we control, and dependent variables – the outcomes we measure.

*1) Independent Variables:* There is only one independent variable – the presence of concern annotations in the project. It has a nominal scale which means there is a finite number of possible values without any meaningful ordering [4]. The levels (possible values) of this variable are: yes ("annotated") and no ("unannotated").

*2) Dependent Variables:* The correctness was measured as a number of correct answers (or correctly performed tasks) divided by the total number of tasks (5). The tasks are not weighted, each of them is worth one point. The assessment is subjective – by a researcher.

The second dependent variable is the time to finish the tasks. Its scale is of a ratio type since the ratio between two values is meaningful [4]. Although it was technically measured with millisecond precision, we will use the unit "minutes" rounded to two decimal places in subsequent analysis. We are interested mainly in the total time, i.e., a sum of times for all tasks.

Instead of measuring just time alone, it is possible to define efficiency as a number of correct tasks and questions divided by time. On one hand, efficiency depends on correctness, which already is a dependent variable. On the other hand, efficiency can deal with participants who fill the answers randomly to finish quickly [11]. We decided to use efficiency only as an auxiliary metric to make sure that time differences are still significant even if the correctness is considered.

For each comprehension question, we also asked a subject how confident (s)he was on a 3-point Likert scale: from Not at all (1) to Absolutely (3). Since we asked a subject about the confidence equally for each task, we consider it meaningful to calculate the mean confidence, which is the third dependent variable.

### C. Experiment Design

*1) Materials:* Again, the EasyNotes project was used. This time, we prepared two different versions:

- with shared concern annotations (as in the second study)
- and without annotations.

As the project was only scarcely commented, we deleted all traditional source code comments from both versions to remove a potential confounding factor. Only comments for the annotation types themselves were left intact, as we regard them as their integral part.

During this experiment, we used the NetBeans IDE.

*2) Participants:* We used 18 first-year master's degree Computer Science students as participants. Carver et al. [12] recommend to integrate software engineering experiments performed on students with teaching goals. We decided to execute the experiment as a part of the Modeling and Generation of Software Architectures course, which contained Java annotations in its curricula.

The course was attended by students focused not only on software engineering, but also on other computer science subfields. Inclusion criteria were set to select mainly students with a prospective future career as professional programmers. Additionally, as EasyNotes is a Java project, a sufficient Java language knowledge was required.

The experiment was performed during three lessons in the same week – the first time with four students, then 9 and finally with the remaining 5 students. Each session lasted approximately 1.5 hours. The study was executed in a separate room, so the participants were not disturbed.

*3) Design:* When assigning the subjects to groups, we applied a completely randomized design [4]. This means that each group received only one treatment – either an annotated or an unannotated program – and the assignment was random. Each participant drew a piece of paper with a number on it. Subjects with an odd number were assigned to the "annotated" group, participants with an even number to the "unannotated" one. Our design was thus balanced, with n=9 per group.

*4) Instruments:* To both guide the subjects and collect the data, we designed an interactive web form[2]. All fields in the form were mandatory, so the participants could not skip any task.

We asked the subjects to install a NetBeans plugin, SSCE[3]. Although it is not its primary feature, it provides an option to record programming sessions – time elapsed, a list of open files and NetBeans windows gaining the focus. Just before the start of each task, a subject clicked the button to start a new session, named after the task (e.g., "Filter"). Immediately after the task was finished, (s)he clicked the button again to end the session. The collected data were written to an XML file which the participants uploaded to the web form at the end of the experiment.

### D. Procedure

*1) Training:* At the beginning of the experiment, the users were given 5 minutes to familiarize themselves with EasyNotes from an end-user perspective, without looking at the source code. This provided them an overview of the application domain and helped them to better understand their subsequent tasks. Then, the session monitoring plugin was briefly introduced.

A short presentation about concern annotations usage in the NetBeans IDE followed. A researcher presented how to show a list of all available concerns, how to use the Find Usages feature on an annotation type and how to navigate from the annotation occurrence to an annotation type.

Just before each of the two maintenance tasks, the researcher presented the participants a running application with the required feature already implemented. This had two positive effects:

- It significantly lowered the task ambiguity. While a natural-language description was available in the web form during the tasks, seeing the finished application gave the participants greater confidence, so almost nobody asked unnecessary questions.
- We consider this a replacement for unit tests. As GUI code is notoriously difficult to test [13], we decided not implement the test code. At the same time, the

[2] http://www.jotformeu.com/sulir/sharing-annotations

[3] http://github.com/MilanNosal/sieve-source-code-editor

researcher's discretion about the task correctness was not indispensable during the experiment. Students just knew they finished the task when their application did the same thing as we had showed them.

In addition, the participants later uploaded their modified version of the source code to the web form. This way, potential disputes could be resolved without time stress.

*2) Tasks:* The experiment comprised of:

- one additive maintenance task (we will name it *Filter*),
- three program comprehension questions (*Test*),
- one corrective maintenance task (*Cite*),

in that order.

The tasks were formulated as follows:

Filter In a running EasyNotes application, load the sample notes and look at the searching feature (the down-right part of the window). Try how searching in the note text works (the option "Search in": "text"). Your task will be to add a filter to the EasyNotes application, which will search in the notes title (the option "title").

Cite In the EasyNotes application, there is a field "Cite as:" (the down-right window part). Currently, it displays information in the form: *somePubID* where somePubID is the value of the "PubID:" field. Your task is to modify the program so the "Cite as:" field will display information in the form: *\cite{somePubID}*.

Both tasks were simple, although the *Filter* task was slightly more complex than the latter. It required the creation of a new class with approximately 15 lines of code, whereas the *Cite* task could be accomplished by modifying just one source code line.

The questions asked in the *Test* about program comprehension were:

Q1 What does the `runDirMenuItemActionPerformed` in the class `easynotes.swingui.EasyNotesFrame` do?

Q2 How is the class `easynotes.model.abstractModel.UTFStringComparator` used in the EasyNotes project?

Q3 What method/s (and in which class) do perform note deleting?

*3) Demographic Data Collection:* At the end of the experiment, the form contained three demographic questions about the subjects' abilities:

- a general programming experience,
- their experience with Java, annotations and NetBeans
- and their English level.

Each question had possible answers on a 5-point Likert scale: from Beginner to Expert. We did not perform any specialized tests to measure programming experience, as a subjective opinion is good enough [14].

*4) Debriefing:* We also included a question asking to what extent did the subjects use annotations when comprehending the code. Possible answers ranged from Never to Always on a 5-point Likert scale. Finally, the form also contained a free-form question where the participants could describe how the annotations helped them in their own words.

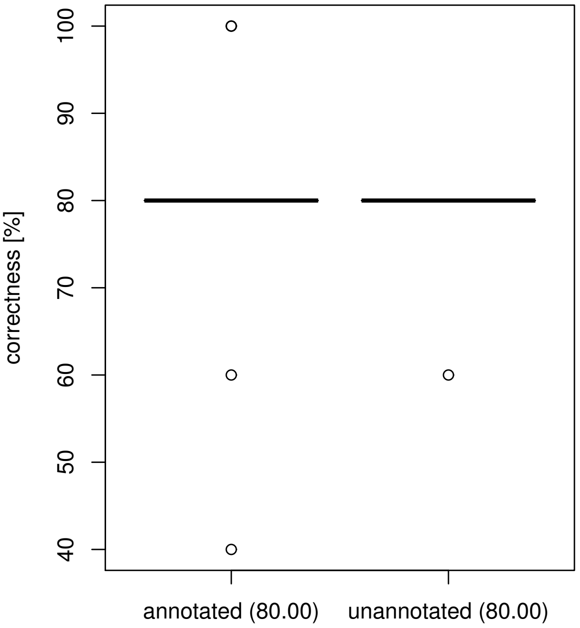


Fig. 2. The ratio of correct answers for each group.

### *E. Results*

The measured values and their summary is presented in Table III. To analyze the results, we used the R scripting language, auxiliary Ruby scripts and spreadsheets.

Each specific hypothesis considers one independent variable on a nominal scale with two levels (annotated, unannotated) and one dependent variable (either correctness, time or confidence). For each dependent variable, we displayed the values on a histogram and a normal Q-Q plot. None of the variables looked normally distributed, so we used the Mann-Whitney U test as a statistical test for our hypotheses.

*1) Correctness:* The median of correctness for both the "annotated" and "unannotated" group was 80%. Except for a few outliers, all subjects answered exactly 4 out of 5 questions correctly. See Fig. 2 for a plot.

The computed p-value (roughly speaking, the probability that we obtained the data by chance) is 0.3898, which is more than 0.05 (our significance level). This means we accept $\mathbf{H1_{null}}$. We did not prove that the presence of annotations has a positive effect on program comprehension and maintenance correctness.

As we can see in Table III (column Correctness), the most difficult question was Q2. Only two participants answered it correctly – both from the "annotated" group. The class of interest was not used in EasyNotes at all. This fact was noticeable by looking at the `@Unused` annotation.

TABLE III
THE EXPERIMENT RESULTS FOR INDIVIDUAL SUBJECTS

| The "annotated" group | | | | | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| ID | Correctness [true/false] | | | | | | Time [min] | | | | Efficiency [tasks/min] | Confidence [1-3] | | | | Files | Annotations useful? [1-5] |

| 18 | 1 | 1 | 1 | 0 | 1 | 80% | 25.54 | 9.59 | 12.94 | 48.07 | 0.08 | 3 | 2 | 3 | 2.67 | 16 | NA |
| **Median** | **1** | **1** | **1** | **0** | **1** | **80%** | **11.11** | **7.19** | **11.23** | **31.96** | **0.13** | **3** | **2** | **3** | **2.67** | **14** | **NA** |
| **Std.dev.** | **-** | **-** | **-** | **-** | **-** | **6.67%** | **9.56** | **6.98** | **4.18** | **11.06** | **0.05** | **-** | **-** | **-** | **0.30** | **4.22** | **-** |

*2) Time:* The differences in the total time for all tasks between two groups are graphically depicted in the box plot in Fig. 3. The median time changed from 31.96 minutes for the "unannotated" group to 21.07 minutes for the "annotated" one, which is a decrease by 34.07%.

The p-value of time is 0.0252, that is less than 0.05. The difference is statistically significant, therefore we reject $\mathbf{H2_{null}}$ and accept $\mathbf{H2_{alt}}$. The presence of concern annotations improves the program comprehension and maintenance time.

It is possible to see from Table III (column Time) that the median time for each individual task was better for the "annotated" group. The most prominent difference was for the task *Cite*. This can be due to the fact that the project contained the concern annotation `@Citing` which helped the participants find the relevant code quickly.

The median of efficiency, which we defined as the number of correctly performed tasks (and answers) divided by total time, raised by 42.32% (p=0.0385). This means the time improvement is significant even if we take correctness into account.

*3) Confidence:* The median of mean confidence is the same for both groups (2.67), as obvious from Table III, column Confidence / Mean and Fig.4. The p-value is 0.1710 (>

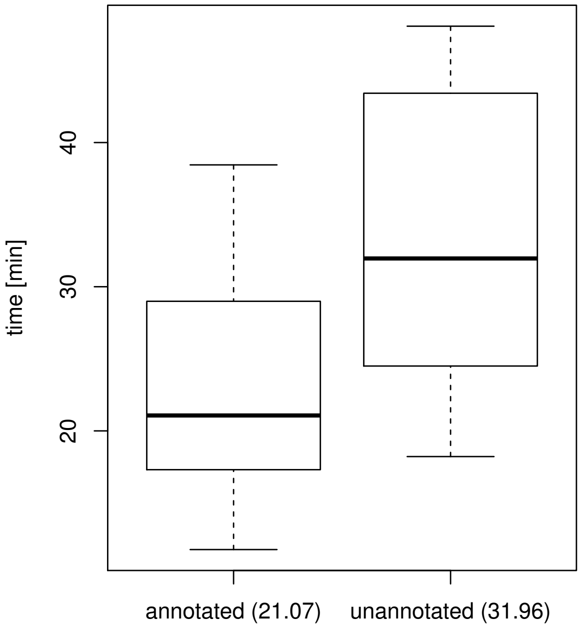

Fig. 3. Time to complete comprehension and maintenance tasks on an annotated vs. unannotated project

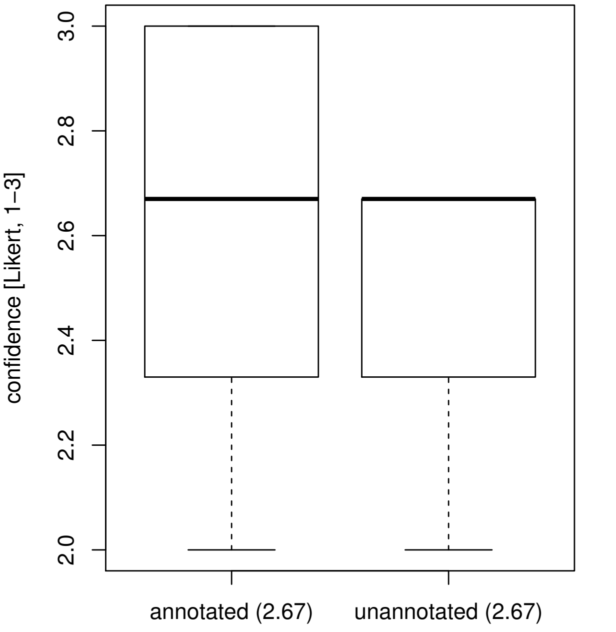

Fig. 4. The mean confidence for the "annotated" and "unannotated" group

0.05) and therefore we accept $\mathbf{H1_{null}}$. The effect of concern annotations on confidence was not demonstrated.

Looking at individual questions, Q2 was clearly perceived the most difficult. This corresponds with our previous finding about the correctness. An interesting fact is that no participant in the "unannotated" group was confident enough to select the level 3 (Absolutely), while in the "annotated" group, there were 4 such subjects and two of them really answered correctly.

*4) Other Findings:* Although not included in our hypotheses, we also measured how many unique Java source files did the subjects open in the IDE during the whole experiment. We excluded the annotation type files in these numbers. The results are in Table III, column Files. There was only a marginal and statistically insignificant improvement in medians (from 14 to 13).

As seen from Table III, column "Annotations useful?", concern annotations were perceived relatively helpful by the participants (median 3 from 5-point Likert scale).

Answers to a free-form question asking how specifically were the annotations useful included:

- faster orientation in a new project,
- faster searching (mainly through Find Usages on annotations),
- less scrolling,
- "they helped me to understand some methods",
- "annotations could be perfect, but I would have to get used to them".

### *F. Threats to Validity*

To analyze threats to validity of this experiment, we used [15] as guidelines.

*1) Construct Validity:* Similar to Kosar et al. [11], we compensated the students with points for the participation in the experiment, which increased their enthusiasm. Unlike them, we did not reward the participants with bonus points for good results because our experiment spanned several days with the same tasks and this would motivate the students to discuss the task details with classmates, which could negatively affect the construct validity (interaction between subjects). Furthermore, the participants were explicitly told not to share experiment details with anyone. Therefore, we do not consider executing the experiment in three separate sessions an important validity threat.

To measure confidence, we used only a 3-point Likert scale. This decision was not optimal. Because subjects rarely select the value of 1 (which can be interpreted as guessing an answer), there were only two values left. This could be one of the reasons we did not found a statistically significant difference in confidence.

*2) Internal Validity:* There could be a selection bias in the experiment because we selected the participants using subjective criteria. As we already mentioned, we concentrated on subjects with a potential future career as developers.

We divided the subjects into groups randomly. Another possibility was a quasi-experiment (nonrandom assignment), i.e., to divide the subjects evenly according to the most important co-factor affecting the results, like their programming experience. However, random assignments tend to have larger effect sizes than quasi-experiments [16].

We did not perform a full pilot testing with third-party participants, only tested the comprehension questions on one of the researchers. We rejected 3 out of the 6 prepared questions because we considered them too difficult and ambiguous. Despite this, all tasks were either completed by almost all participants (Filter, Q1, Q3, Cite) or by almost none (Q2) during the experiment. This negatively affected the results for the "correctness" variable.

During the actual experiment, we used a native language (Slovak) version of the web form to eliminate the effect of English knowledge on the results. While the source code was in English, this did not present a validity threat since all participants had at least a medium level (3 on a 5-point Likert scale) of English knowledge.

*3) External Validity:* We invited only students to our experiment, no professional developers. We can take this fact positively – concern annotation consumers are expected to be mainly junior developers, whereas potential annotation creators are mostly senior developers. Furthermore, some students may already work in companies during their study.

EasyNotes is a small-scale Java project – around 3 KLOC (thousands of lines of code), including annotations. The effect of concern annotations on larger programs should be investigated.

*4) Reliability:* The concern annotations training (tutorial) was presented manually by a researcher. However, there were two independent researchers which took turns.

The experiment is replicable, as we published the data collection form (`http://www.jotformeu.com/sulir/sharing-annotations`) which contains both the guidelines and links to the materials (two versions of the EasyNotes project).

*5) Conclusion Validity:* A small number of subjects (n=9 per group) is the most important conclusion validity threat. If we used a paired design (to assign both treatments to every subject), we could easily reach n=18. However, the participants would quickly become familiar with EasyNotes and the second set of tasks would be affected by their knowledge.

### G. Conclusion

We successfully confirmed the hypothesis that concern annotations have a positive effect on program comprehension and maintenance time. The group which had concern annotations available in their project reached a time more than 34% shorter than the group without them ($p < 0.05$).

On the other hand, we did not discover a significant change in correctness and confidence. The difference was neither negative (which could mean the annotations are confusing because of their "visual noise") nor positive and it was probably a result of the discussed validity threats.

## VI. Related Work

### A. Concerns

Reinikainen et al. [17] present concern-base queries to reason about the program. However, their approach is based on UML (Unified Modeling Language) models, while we use the source code of a system.

Niu et al. [18] propose the application of HFC (hierarchical faceted categories) on source code. Their approach requires specialized tools whereas we use source code annotations which have a standard IDE support.

### B. Source Code Projections

In [5], we used concern annotations as one of the ways to perform source code projections. Projections allow to look at one source code from multiple different perspectives. For example, an IDE plugin can filter all code marked with a specific annotation type and display it in an editable window – even if it is spread across multiple files.

In this work, we take a more pragmatic approach. We investigate the possibility to use concern annotations in contemporary IDEs, using the features already available, like Find Usages. Above all, we perform three empirical studies to assess the viability and find possible use cases of concern annotations in everyday developer's life.

### C. Annotations

Today, one of the most common applications of annotations is configuration. A programmer marks selected source code elements with appropriate annotations. Later, they are processed either by an annotation processor (during compilation) or by reflection (at runtime). For example, annotations can be used to define concrete syntax in parser generators [19] and to declare references between elements in a domain-specific language [20]. This way, annotations can indirectly modify the annotated program semantics. In contrast, our approach utilizes annotations just as clues for a programmer which are processed by an IDE when needed.

Sabo and Porubän [21] use source code annotations to preserve design patterns. Therefore, their approach does not include recording and sharing domain and maintenance annotations.

In Java, annotations can be only applied to packages, classes, member variables, methods and parameters. @Java [22], an extension to the standard Java language, brings annotations below the method level. It allows to mark individual source code statements like assignments, method calls, conditions and loops with annotations. This could be useful to capture e.g., algorithmic design decisions with concern annotations.

### D. Mental Model Overlapping

Revelle et al. [23] also studied concern overlapping. However, their study included only two concern sets (compared to our 7). Their results are positive, too. This further confirms our hypothesis that it is possible to share mental models.

### E. Code Bookmarks

Source code bookmarks are one of the standard features present in today IDEs. They allow a developer to mark specific source code lines with notes and later list the bookmarks and jump to each of them.

Collective code bookmarks [24] provide a way to share parts of developers' mental models. The plugin allows to share code bookmarks between developers in a team. However, this approach is IDE-dependent and the bookmarks are not saved to the original source code files which complicates standard procedures like versioning and merging.

### F. Maintenance Notes

Developers often write "TODO comments" like `// TODO: fix this` to mark parts of source code which need their attention [25]. IDEs can then try to parse and display these notes in a task list window.

Our approach is more formal, as annotations are a part of the standard Java grammar and can be parsed unambiguously. Furthermore, it is possible to distinguish between multiple maintenance note types through individual annotation types.

## VII. Conclusion and Future Work

In this paper, we presented an idea to use Java source code annotations to capture parts of developers' mental model, namely their concerns (intents), thus the name "concern annotations". Each concern (e.g., "searching", "editing", "GUI code", "unused code") is implemented as an annotation type. Subsequently, all classes and methods relevant to that concern are marked with the given annotation. Two studies and one experiment were conducted to assess the practical implications of this approach.

It is possible to share these annotations because the developers' mental models overlap: More than a half of the concerns created by one of 7 developers in our study was recognized by at least two of them. More than 1/4 of concern occurrences (locations in source code where a particular annotation is used) were shared by at least two participants.

An interesting future research question is to what extent the source code itself, when the same program is created separately by multiple people, overlaps.

In the second study, we discovered that concern annotations are particularly useful to confirm hypotheses about the code, locate the features, find out non-obvious concerns which a method fulfills, discover hidden relationships between elements. Concern annotations can be also used as a replacement of traditional TODO comments.

In the controlled experiment, we showed there is a statistically significant improvement of development time when performing program comprehension and maintenance tasks on a small-scale Java project. The group which had an annotated version of the same program available, consumed 1/3 less time than the group which did not have concern annotations present in the source code.

In our studies, the source code was commented scarcely or not at all. An interesting future comparison would consider an annotated program vs. a program without annotations, but with high-quality traditional source code comments instead.

Currently, the source code is annotated manually by a programmer, which is a time-consuming task. An interesting future work would be a method of (semi-)automatic annotation.

***Abstract*—The objective of feature modeling is to foster software reuse by enabling to explicitly and abstractly express commonality and variability in the domain. Feature modeling alone is not sufficient to express all the aspects of the software being developed. Other models and, eventually, code is necessary. These software assets are being configured by the feature model based on the selection of variable features. However, selecting a feature is far from a naive component based approach where feature inclusion would simply mean including the corresponding component. More often than not, feature inclusion affects several places in models or code to be configured requiring their nontrivial adaptation. Feature inclusion recalls *transformation* and this is at heart of the approach to feature model driven generation of software artifacts proposed in this paper. Features are viewed as solution space transformations that may be executed during the generative process conducted by the feature model configuration.**

***Index Terms*—feature modeling; transformation; metatransformation; generative process; reuse**

## I. Introduction

FEATURE modeling is an approach used in software development proposed in 1990's [1] with the growing popularity of software product lines. The objective of this approach to modeling is to foster software reuse by enabling to explicitly and abstractly express commonality and variability in the domain. Based on commonality and variability, appropriate implementation mechanisms can be selected [2].

Feature modeling alone is not sufficient to express all the aspects of the software being developed. Other models and, eventually, code is necessary. These software assets are being configured by the feature model based on the selection of variable features. However, selecting a feature is far from a naive component based approach where feature inclusion would simply mean including the corresponding component. More often than not, feature inclusion affects several places in models or code to be configured requiring their nontrivial adaptation. Feature inclusion recalls *transformation* and this is at heart of the approach to feature model driven generation of software artifacts proposed in this paper.

The rest of the paper is organized as follows. Section II discusses the possibilities of representing software artifacts in feature modeling. Section III identifies specifics of feature modeling necessary for the employment of this technique in the generative process. Section IV explains how features can be perceived as transformations, which is the essence of the approach proposed in this paper. Section V presents the overall process of feature model driven generation of software artifacts. Section VI reports the implementation of the approach. Section VII presents the evaluation. Section VIII discusses related work. Section IX concludes the paper.

## II. Representing Software Artifacts in Feature Modeling

Feature modeling can be used to configure software assets—models and code—in order to create software instances that exhibit desired features. One way to achieve this is by employing so-called superimposed variants [3] where the software models or code contain all the variants that are being reduced based on the features selected—or not selected—in the corresponding feature model [4], [5]. The FeatureHouse project [6] implements an approach that uses these models and allows language independent source code generation.

The pure::variants software tool [7] uses a specialized family model to represent a feature to architecture mapping. In this model, it is necessary to specify the type of the impact on the software instance. There are several possible impact specifications that allow for a wide scope of software artifact to be created, such as files, file fragments, XSLT transformations, conditional XML or text, C/C++ flag files, makefiles, class alias files, or symbolic links to folders or files.

These types of interaction can be effectively used to describe various architectural parts of elements, but provide no way of direct implementation of quality attributes [8]. Extra-functional[1] features can be mapped to specific modules/components or software artifacts in general by implying rules the software artifacts have to comply with, such as specific testing procedures or documentation requirements, or by specifying a human interaction task to be performed, such as evaluating a managerial decision or performing human assessment of a feature instance in a finalized product (e.g., evaluating user experience or GUI usability) [10].

In automatic software composition, software artifacts represent the reusable and generated parts of software. By putting together these parts and rules expressed by extra-functional

[1] We use term *extra-functional*—as proposed by Mary Shaw [9]—to refer to requirements and features that go beyond software system functionality instead of more widely used, but potentially confusing term non-functional.

978-83-60810-66-8/$25.00©2015, IEEE

features, it is possible to automatically compose large parts of software.

## III. Feature Modeling for the Generative Process

To drive the generative programming by a feature model, it is necessary to represent the software assets in a configurable manner. Also, the feature model must be capable of expressing different transformations of the software assets to produce the software artifacts that correspond to the features that have been selected.

### A. Feature Types

As has been explained in Section II, features can be functional or extra-functional. Some functional features exhibit a crosscutting nature, i.e., they affect several distinct and often unrelated parts of the system. Extra-functional features commonly correspond to the quality requirements (e.g., security or performance) or to the impact of the software being created to its environment.

Furthermore, internal and external features can be distinguished. Internal features are contained within the software being created and they can be changed during the development process. External features represent environment functionality and quality implications and these are part of the deployment environment and thus are not affected by the development process. An example of an internal feature is a configuration file for a web server to which the product is going to be deployed. The web server and its running environment is an example of an external feature.

### B. Feature Implications

The inclusion or exclusion of specific features in a particular feature model configuration has an impact on the final software product being created. Apart from the features that serve purely organizational purpose, which is mostly to group other features, the features in a feature model can be viewed as abstract elements having some impact on the final software product. This idea is crucial to automated software generation and configuration because a feature can be viewed as prescribing a change to the configuration or generative process. This means that the whole generative process consists of a set of events that are implied by the inclusion or exclusion of the features in a specific configuration.

The set of features that are included in the generative process is a result of a feature model configuration process. This process resolves variability in the feature model and a fully-specified feature model configuration can be used as an input to the generative process.

A feature inclusion can have various kinds of impact on a final software product: file or folder operations, deployment rules to provide documentation, realizing the testing requirements, etc. It is necessary to distinguish between a fully autonomous feature impact that requires no human interaction to deliver a final software asset (e.g., source code generation) and an impact that requires human interaction (e.g., designing a splash screen). With respect to the fully automated generative programming approach, the latter is not applicable. One way of integrating human interaction into the generative process is to create task placeholders that notify developers their input is needed for the process to continue.

Autonomous actions can be described by a set of events that perform a particular computer operation. This leads to the concept of extending the feature model by including the information of these events that are implied by the specific features in the model. By this, we get the description of the generative process event chain that has to be executed when processing a particular configuration of a feature model.

### C. Generative Process

A generative process based on a feature model is driven by its configuration, i.e., by selecting the features. This process represents the transformation of the input models or code into resulting software artifacts according to the feature selection. The process can be restricted to only a single solution space transformation or it can represent a complex multi-tier set of intermediate actions where each of these can be perceived as a stand-alone process with its own inputs and outputs. In any case, the key issue is how to realize the impact of the feature inclusion on the underlying software assets. This is different for functional and extra-functional features.

*1) Functional Feature Inclusion:* Functional features can be directly mapped to software artifacts such as source code or resource files. The relationships between functional features can be quite complex and the problem of feature interaction can aries.

A simple example of a functional feature is the choice of the data provider for some other feature. The corresponding feature diagram is displayed in Figure 1. In this paper, a simple FODA-style feature diagram notation [1] is used. A feature diagram is a tree whose nodes represent features that can be selected or not for the resulting configuration. For a feature to be selected, its parent feature has to be selected. Empty circle ended edges connect parent features with their optional features. An arc over a group of edges means the corresponding features are mutually exclusive (alternative). Non-decorated edges connect mandatory features. We do not elaborate on textually expressed constraints and default dependency rules that are necessary to overcome the limitations of the tree structure of feature diagrams [11], [12], as for the purposes of the approach proposed here, these can be considered as any other feature relationships to be applied in feature model configuration.

A configurable piece of code corresponding to this model could in C# look like this:[2]

```
DataProvider provider = new DataProvider();
provider.DataSource = new <Template Field>();
Page.GridView.DataSource = provider;
Page.Databind();
```

Choosing the *XML Data source* changes the second line of the code sample to the following one:

[2] The further examples in this paper are in C#, too, if not stated otherwise.

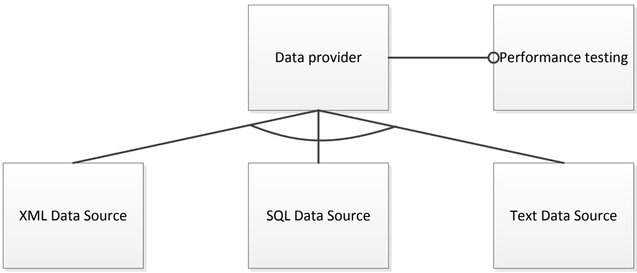

Fig. 1. The choice of the data provider as a functional feature and performance testing as an extra-functional feature.

```
provider.DataSource = new XMLDataSource(params []);
```

Another example would be an inclusion of the logging feature. This example is a little bit more complex as the points in source code to which the feature has to be bound are changing with as the code base grows. Aspect-oriented programming can be applied here to express so-called join points declaratively and address them without having to actually modify their source code representation.

*2) Extra-Functional Feature Inclusion:* Extra-functional features are a more difficult problem than functional features as it is rarely possible to map them to functional software artifacts. However, it is possible to implement the tests of the corresponding software artifacts against the conditions stated by extra-functional features. Consider the performance testing requirement as an example. The corresponding optional performance testing feature (see Figure 1) represents the fact that the software product has to conform to performance criterion and therefore needs to be tested against this criterion. This type of a feature can be directly represented in source code:

```
class XMLDataSource {
}
```

Having the *XMLDataSource* class to represent a functional feature when the extra-functional feature *Performance testing* is included, the source code can be transformed as follows:

```
class XMLDataSource {
    private TestContext testContextInstance;
    ///<summary>
    ///Gets or sets the test context which provides
    ///information about and functionality for the current test run.
    ///</summary>
    public TestContext TestContext {
        get {
            return testContextInstance;
        }
        set {
            testContextInstance = value;
        }
    }
    [TestMethod]
    public void PerformanceTesting() {
        throw new NotImplementedException();
    }
}
```

The *XMLDataSource* class has been enriched by methods and properties that support the performance testing. Among these is the *PerformanceTesting()* method, which has a placeholder that states it must be implemented manually.

## IV. Features as Transformations

Fully configured feature model provides a list of all features that are affecting the generative process. Each of these features that are included provides a partial information on what actions shall be taken during the automated software creation. A transformation is an entity that represents these actions to be taken for a particular feature. Consequently, the generative process becomes a composition of all transformations included in the particular configuration that was the input for generative process. A problem with this approach is that it is necessary to define the order in which the transformations will be executed. There are several possible solutions:

- Explicitly adding the ordering information in the input feature model configuration
- Traversing the feature model configuration structure in a predefined way
- Providing a priority property to transformations

An explicitly stated order in the feature model depends on the knowledge of priority in which the transformations have to be executed. This means that if we add a new feature into the model, the whole model needs to be examined to accommodate the changes in priority. Traversing the feature model in a predefined way is based on an idea that a feature model is a tree, so it can be scanned breadth-first or depth-first. In both cases, a priority parameter has to be introduced into features.

Many actions are common to different features. Consider creating a file, creating a folder, or making a text input text into a file. These transformations are actually generic, but rely on specific parameters in achieving their result. Therefore, a transformation is in fact a transformation template that uses the information provided to create a specific transformation instance. Consequently, a transformation in our approach is an entity consisting of the following elements:

- List of events, i.e., actions to be performed
- List of requirements that are imposed on the feature model
- List of metatransformations that are included in this transformation

Transformations are bound one-to-one to features in the feature model. This means that every feature that is included in the feature model and is relevant to the generative process of the final solution has its a transformation assigned to it. The feature node in the feature model also carries all the additional information that is bound to the transformation assigned to it.

### A. Transformation Reusability

The process of the transformation design requires an interaction on part of a domain engineer to provide the necessary domain information specific to the project and a software engineer to design the transformations in such a way that they implement the information provided by the domain engineer and the requirement analysis of the corresponding features. For an effective cooperation between the domain and software engineer, it is useful to distinguish different levels of transformations with respect to reuse:

- Specialized transformations that can be used only for the specific features in the specific configuration of the feature model
- Specialized transformations that can be used only for the specific features, but in any configuration of the feature model
- Domain dependent generic transformations, which can be used across multiple software product lines in the same domain
- Domain independent generic transformations, which are the most reusable transformations as they can be included in different software product lines across multiple domains

Distinguishing these transformation types helps designing transformations that are as generic as possible at their level.

### B. Transformation Hierarchy

An atomic transformation is a transformation impossible or unwanted to be decomposed into smaller transformations. Thus, even though such a transformation may consist of differentiable actions, the transformation is conceptually perceived as a one. Complex transformations are transformations that can be decomposed into a set of transformations where each of these lower level transformations represent an atomic transformation or a complex one (see Figure 2). Complex transformations themselves can have their own event chain besides the event chains of atomic transformations they embrace.

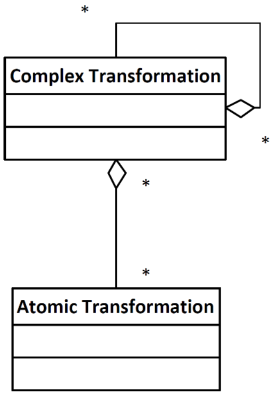

Fig. 2. Atomic and complex transformations (UML).

### C. Transformation Inheritance

The inheritance relationship known from object-oriented programming can be applied to transformations, too (see Figure 3). It is possible to use inheritance as a way of combining ancestor and descendant event chains. There are several possible approaches to inheriting event chains:

- The ancestor event chain remains the same
- Items are added or removed to the event chain
- The event chain is completely overridden in the descendant transformation

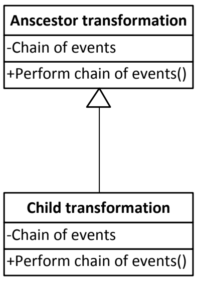

Fig. 3. Inheritance between transformations (UML).

The inheritance model can also be perceived as a way of organizing transformations into logical groups or packages. With respect to this, the inheritance is purely a tool of categorization and it is not necessary to maintain the typical parent–child class relationship, i.e., if transformations are represented as classes, it is not necessary to support inheritance mechanism at the level of methods and attributes.

### D. Metatransformations

There are some features that have a global effect that spans throughout the whole software product (or its significant part). Quality features, such as logging requirement or performance and security constraints, represent a typical example. Including such a feature with the corresponding transformation into the configuration leads to the necessity of modifying other transformations in one of the following ways:

- Modifying the event chain of a transformation
- Modifying the requirements of a transformation
- Providing information that is defined by the transformation requirements

The modification of the event chain means that some actions are added or removed to or from the transformation being modified, or some properties of these actions are changed. This leads to the connection with the other two types of modification that can be defined on their own or are a result of this first type of modification.

### E. Transformation Requirements

Seeing a transformation as a transformation template that instantiates a specific transformation based on external information, such as the file name in the create file transformation, constitutes the need for the external information required to perform this transformation. Therefore, it is necessary to include the information in the feature model or the associated feature model configuration to allow for this. However, having two features represented by the same type of transformation, the information provided can vary (see Figure 4).

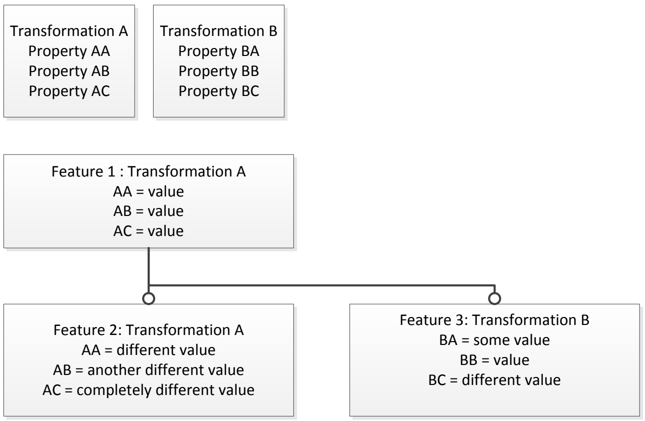

Fig. 4. Mapping transformations and properties to features.

Each transformation defines these requirements as a list of items that contain the particular facts about the requirements. This means that upon including a transformation in the feature model, it is necessary to specify its requirements.

## *F. Transformation Granularity*

There are two extreme approaches with respect to extending feature models with transformations. One approach is to target the separation of concerns with a large number of small transformations. This allows us to isolate the implications of transformations on the final software product into many small groups independent of each other (see Figure 5). The advantage of this approach is that the transformation model is easily changed without the need to analyze the impact on the whole transformation/feature model tree.

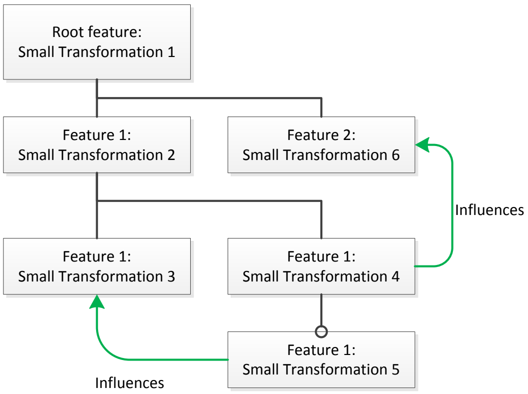

Fig. 5. Relationships between small independent transformations.

The other approach is to describe most actions in one global transformation that can be assigned to the root feature in the feature model. This global transformation is afterwards modified by the metatransformations that are assigned to the rest of the feature model nodes and their execution is based on the inclusion or exclusion of these features in a specific configuration (see Figure 6).

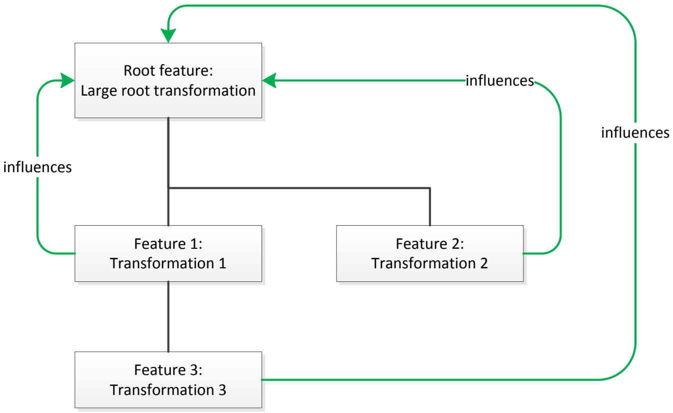

Fig. 6. The transformations influencing a large root transformation.

With respect to the transformation granularity, it is also important to consider the number of complex transformations in the model. Again, there are several approaches that can be used. One approach is to define only the simplest actions as atomic transformations and then to compose other transformations out of these atomic transformations. Another approach is to provide fairly large transformations that perform a substantial part of the tasks connected to a particular feature. It is also possible to employ an approach that lies somewhere inbetween of these extreme viewpoints. This is possible for the high or low granularity extremes and also for the complexity aspect of transformations. For example, metatransformations can be avoided by providing specific transformations for each feature.

## *G. Including Transformations in the Feature Model*

Since one transformation corresponds to one feature, their inclusion into the feature model means simply assigning the corresponding information to each feature (see Figure 7).

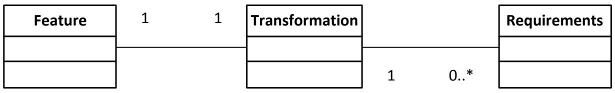

Fig. 7. Transformations are associated with features (UML).

One way of connecting the feature model with transformations is to include it directly in the feature model (an XML representation in used in this example):

```
<feature>
    <feature>
        <transformation>
            <!–– Transformation information including
            the event chain, metatransformation
            information, requirements, etc. ––>
        </transformation>
    </feature>
</feature>
```

There are two main problems connected with this approach: the degree of the transformation reuse between different models is reduced and it is necessary to parse the transformation information separately for every feature, even though the type of the transformation they use can be the same (e.g., create a file).

Another approach is to store the transformation definitions outside the feature model. A sample structure of this can be a feature model represented in XML and the transformations defined as C# classes that are used by the generator:

```
<feature transformationClassName=”CreateFile”
   fileName=”Samplefile.cs”>
</feature>

public class CreateFile : Transformation {
   public override void ExecuteTransformation() {
      ... // Create a file
   }
}
```

With this approach, it is necessary only to specify the transformation type and requirements of this transformation. The information about the metatransformations is not included in the feature model as it is internal to the transformation system and including this information in the feature model would be redundant.

## V. The Overall Process

The overall process of employing the feature model driven generation of software artifacts is as follows:

1) The input to the process is a feature model
2) Transformations are assigned to the feature model
3) Transformation requirements are provided where possible
4) A specific configuration of the feature model is created
5) Configuration specific requirements of the transformations are provided
6) The metatransformations are executed
7) The requirements and changes to the configuration model are incorporated or provided
8) The generator processes the fully specified configuration of the feature model and performs the event chain of the transformations included in it
9) The output of this process is a generated instance of the software system based on the input feature model, its configuration, and the transformations specified in the feature model

Transformation requirements are being fulfilled at three levels:

1) Feature model level
2) Feature model configuration level
3) Feature model configuration level after the execution of metatransformations

One may wonder whether it is not possible to merge the latter two levels into one. This is not possible because the metatransformations depend on the information provided at level 2 and therefore it is necessary to provide this information before executing level 3.

Often, the impact of a feature inclusion is not easy to analyze. Therefore, a stepwise approach to the transformation defining the impact of a feature design can help to analyze the impact of each atomic operation that a transformation consists of and also it can help to decide the order in which the transformations are applied. This is important because in many cases the final impact of a transformation depends on the order of the transformation in the sequence in which transformations are executed.

In the manual transformation application, it is not necessary to have this order predefined, but when a software asset generator employs an extended feature model as an input to perform the execution sequence, it must be deterministic and specified before the generative process starts as the generator is not aware of the final implications during the generative process: it merely executes the transformations that result from the input feature model configuration.

In summary, the main objectives of the stepwise transformation design are:

- Create complex transformation by a stepwise application of low-level transformations
- Assess the solution space after each low-level transformation in a stepwise manner
- Analyze the whole generative process by exploring it by this stepwise approach

When applying this approach, it is necessary to record the steps taken in the manual application of transformations. This recording can be further specified to create a complex transformation that can be used in the generative process. It also allows to analyze the impact of transformations that perform mass file renaming or other large-scale operations. The last important information contained in this recording is the transformation order, which allows to analyze and prioritize transformations in the generative process.

## VI. Implementing the Transformation Approach

The proposed approach of the feature model driven generation of software artifacts has been implemented in the .NET framework. A study of implementing the family of simple web sites has been performed.

### A. Applying the Transformation

It takes three steps to apply a transformation:

- Process all metatransformations in the model
- Check for requirements
- Execute the transformation

Consider the transformation called *CreateStaticHTMLPage* as an example. This transformation utilizes its parameters to fill a predefined HTML template string that is processed with the *String.Replace()* method. The template defines the HTML file and contains placeholders that are replaced with the values of the transformation parameters:

```
#region html text template
protected string htmlContent =
      ”<!DOCTYPE html PUBLIC \”−//W3C//DTD XHTML 1.0
            Strict//EN\”
      \”http://www.w3.org/TR/xhtml1/DTD/xhtml1−strict.dtd\”>” +
      ”<html xmlns=\”http://www.w3.org/1999/xhtml\”
```

```
        xml:lang=\”en\”> <head> ” +
    ”<meta http−equiv=\”content−language\”
        content=\”en\” />” +
    ”” +
    ”<title>Title placeholder</title>” +
    ”</head>” +
    ”” +
    ”<body>” +
    ”Content placeholder” +
    ”</body>” +
    ”</html>”;
#endregion
```

This transformation has four parameters:

- *PageName*: the file name that is used when creating the HTML file
- *htmlTemplate*: the template that is set up can be customized with this parameter
- *htmlTitle*: the text that replaces the *Title* placeholder
- *htmlContent*: the text that replaces the *Content* placeholder

If the transformation is included in the feature model, the configuration with these parameters:

```
<feature name=”StaticContent−History” ID=”2”
    Transformation=”org.crd.dp.CaseStudy.SimpleWebFinal,
        org.crd.dp.CaseStudy.
    SimpleWebFinal.Transformations.CreateStaticHTMLPage”
    htmlContent=”&lt;h1&gt;History&lt;/h1&gt;&lt;p&gt;
        Lorem Ipsum&lt;/p&gt;”
    htmlTitle=”StaticPage− History”
        PageName=”Site\\History.html” />
```

creates the following HTML file:

```
<!DOCTYPE html PUBLIC ”−//W3C//DTD XHTML 1.0
    Strict//EN”
    ”http://www.w3.org/TR/xhtml1/DTD/xhtml1−strict.dtd”>
<html xmlns=”http://www.w3.org/1999/xhtml” xml:lang=”en”>
    <head>
        <meta http−equiv=”Content−Type”
            content=”text/html; charset=utf−8” />
        <meta http−equiv=”content−language” content=”en” />
        <title>StaticPage− History
        </title>
    </head>
    <body><h1>History</h1>
        <p>Lorem Ipsum
        </p>
    </body>
</html>
```

### B. Feature Model Configuration

In this sample implementation, the feature model configuration is represented by an XML file. The structure of this file follows the tree structure of the feature diagram:

```
<?xml version=”1.0” encoding=”utf−8” ?>
<featuremodel>
<feature>
    <feature>
        <feature />
        <feature />
    </feature>
    <feature />
< /feature>
</featuremodel>
```

Each XML feature node has three compulsory attributes:

- name
- ID
- Transformation

Accordingly, the simplest feature node looks like this:

```
<feature name=”DynamicContentProvider” ID=”7”
    Transformation=”Transformations.Empty” />
```

The *name* and *ID* attributes have solely the purpose of identifying the node when the node is processed. The *Transformation* attribute specifies the transformation that will be used with this feature.

The transformation attribute consists of two parts delimited by a comma. The first part represents the dynamic link library that contains the transformation, and the second part the full class name of the transformation. The dynamic link library has to be a .NET managed library. Therefore, a filled transformation attribute looks like this:

```
Transformation=”org.crd.dp.CaseStudy.SimpleWebFinal, ...
    Transformations.Empty”
```

This model is afterwards transformed into an object model contained within the *TransformationStore* object.

### C. Transformations

The transformations in this implementation are based on a single class called *Transformation*. This class implements the *ITransformation* interface. This interface provides the basic methods needed by the generator to process the transformation:

```
public interface ITransformation {
    CheckPrerequisites();
    ExecuteTransformation();
    GetParameterNames();
    GetMetaTransformations();
    ...
}
```

The *CheckPrerequisites()* method does basic requirement checking before a transformation is processed. In this implementation, only a basic verification whether the transformation requirements are fulfilled is performed. However, it is possible to write a model aware method at the level of a metatransformation that can check the transformation dependencies. A sample of a model aware transformation is provided with the dynamic access log page.

The *ExecuteTransformation()* method represents the action which is contained within the transformation. This method is called in the final step of model processing.

The *GetParameterNames()* method is used in the XML file parsing, when it provides the parameter names to be retrieved from the feature node attributes.

The *GetMetaTransformations()* method provides a way how to retrieve the metatransformations that are connected with this transformation. This allows to connect a metatransformation list with a transformation and by this provide it with model awareness, which means that it can influence other transformations in the model within the possibilities provided by the connected metatransformations.

Two lists are initialized in the transformation class constructor:

```
protected Transformation() {
    metaTransformations = new List<MetaTransformation>();
    parameters = new Dictionary<string, object>();
}
```

These two lists contain the metatransformation list and key–value pairs of parameters. As the metatransformation list is of type *List <MetaTransformation>* and the interface requires *List <IMetaTransformation>*, it has to be casted:

```
public virtual List<IMetaTransformation>
    GetMetaTransformations() {
    return metaTransformations.ConvertAll(
        mt => (mt as IMetaTransformation));
}
```

The implementation of the transformation class provides two other important methods, *SetParameter()* and *GetParameter()*, which are the basis for parameter provisioning:

```
public object GetParameter(string name) {
    return parameters[name];
}
public void SetParameter(string name, object value) {
    if(parameters.ContainsKey(name))
        parameters[name] = value;
    else
        parameters.Add(name,value);
}
```

### D. Composite transformations

To cope with complex transformations, composite transformations, i.e., transformations that contain other transformations can be used. In the following implementation sample, the composition is based on overridden methods in a descendant class:

```
public class CompositeTransformation : Transformation {
    private TransformationStore transformations;
    protected CompositeTransformation(): base() {
        transformations = new TransformationStore();
    }
    public override string CheckPrerequisites() {
        foreach(ITransformation transformation
            in transformations.Store)
        { transformation.CheckPrerequisites();
        }
        ...
    }
    public override void ExecuteTransformation() {
        foreach(ITransformation transformation
            in transformations.Store)
        { transformation.ExecuteTransformation();
        }
    }
    ...
}
```

As it is observable form the sample code, the composite transformation contains *TransformationStore*, which is basically an ordered list of transformations. The *ExecuteTransformation()* and *CheckPrerequisites()* methods operate on this list. In the case this list contains another composite transformation, the transformations are processed in a depth-first recursive way.

The problem that arose with implementing this list was that at the point of creating an instance of a composite transformation, the child transformations could not access the parent transformation parameters as these were not yet extracted from the XML file and often these child transformations rely on the information provided in the model. Therefore, a new method called *InstantiateChain()* was introduced to the composite transformation. This method is called after the transformation requirements are extracted to the parent transformation. The name of this method suggests that this child transformation list represents a list of events as described in Section IV, which can be modified by metatransformations as suggested in Section IV-D.

### E. Metatransformations

The metatransformations are implemented by the *MetaTransformation* class. The difference between this class and the *Transformation* class is that the *MetaTransformation* class is model aware. This means that it can traverse the feature model and make changes to it. The specific changes are shown with transformation implementation samples. The difference is in the *ExecuteTransformation method()*:

```
ExecuteTransformation(object model, TransformationStore store);
```

In this method, the *TransformationStore* object is passed, representing the feature model. To allow for the modification of composite transformations, this method is implemented in a recursive way:

```
ExecuteTransformation(objectmodel, TransformationStorestore) {
    ...
    foreach(var trans in store.Store) {
        if(IsSubclassOfClass(typeof(
            CompositeTransformation),trans.GetType())) {
            ExecuteTransformation(model,
                ((CompositeTransformation)trans).Store);
        }
    }
}
```

### F. Generator

The generative process consists of these steps:

- Parse the feature model configuration from the XML file

- Parse and execute the metatransformations contained within the transformation from the XML file
- Check the requirements of the parsed transformations
- Execute the transformation

The step of checking the requirements before parsing the metatransformation is omitted as it is contained within the metatransformation parsing step. To support these steps, a parser object is introduced. This object is represented by the *IFeatureModelParser* interface:

```
public interface IFeatureModelParser {
    ParseFeatureModel(...);
    ExecuteTransformationChain(...);
    ParseMetaTransformations(...);
    CheckPrerequisites();
}
```

This object contains the methods that provide the functionality required to perform these steps. The *XMLModelParser* class is used to represent this object. This class provides the functionality required based on an XML feature model representation. The steps will be described in separate sections.

*1) Parse the Feature Model Configuration File:* The first step that is necessary is to translate the transformations from the XML feature model configuration into an object model. The transformations are parsed in a top-down order. It is possible to override this behavior using the *Priority* attribute at transformation nodes. First, the assembly and class name are parsed from the XML node and basic reflection is performed to create an instance of the transformation:

```
var assembly = Assembly.Load(assemblyName);
var ttype = assembly.GetType(typeName);
var transformationInstance = ttype.GetConstructor(
    Type.EmptyTypes).Invoke(null) as ITransformation;
transformationInstance.SetID(Convert.ToInt32((string)
    node.Attributes[”ID”].Value));
```

After creating an instance of the specified transformation, the *GetParameterNames()* method is used to obtain the list of parameters that this transformation uses. Afterwards, the XML node attributes that correspond to this list are copied into the dictionary containing the parameter key–value pairs:

```
foreach (var parameter in parameterNames) {
    if (node.Attributes[parameter] != null)
    transformationInstance.SetParameter(
        parameter, parameter != null ?
        node.Attributes[parameter].Value : null);
}
if (node.Attributes[”Priority”] != null)
    transformationInstance.SetPriority(
        node.Attributes[”Priority”].Value);
```

The last step to be done is to add the transformation to the *TransformationStore* object. This object serves as an advanced list for storing transformations. The enhancements against a standard list lie in the *AddTransformation()* methods that allow priority based insertion of transformations into the list. Another change is that simple and composite transformations are added in a different way as with composite transformations it is necessary to call the *InstantiateChain()* method to create instances of child transformations:

```
if (IsSubclassOfClass(typeof(CompositeTransformation),
    transformationInstance.GetType())) {
    if (node.Attributes[”Priority”] == null)
        store.AddTransformation(((CompositeTransformation)
            transformationInstance));
    else
    store.AddTransformation(((CompositeTransformation)
        transformationInstance),
        transformationInstance.GetPriority());
}
else {
    if (node.Attributes[”Priority”] == null)
        store.AddTransformation((Transformation)
            transformationInstance);
    else
        store.AddTransformation((Transformation)
            transformationInstance,
            transformationInstance.GetPriority());
}
```

The *IsSubclassOfClass()* method uses .NET reflection to recursively check for a match in all ancestor classes up to the *Object* class. Reaching the *Object* class signals that we are at the top of inheritance chain as in .NET the *Object* class is the topmost class from which all classes implicitly inherit. This step ends by adding all the transformation objects to the store, by which they become a part of the object model making the XML model unnecessary.

*2) Parse and Execute the Metatransformations:* After adding the transformations into *TransformationStore*, it is possible to perform metatransformations over this object model. The metatransformations are extracted from all transformations preserving their order as in the store:

```
foreach (Transformation trans in store.Store) {
    foreach (var a in trans.GetMetaTransformations()) {
        string[] parameterNames =
            a.GetParameterNames().ToArray();
        foreach (var parameter in parameterNames) {
            if (trans.GetParameter(parameter) != null)
            a.SetParameter(parameter, parameter != null ?
                trans.GetParameter(parameter) : null );
        }
        if (trans.GetPriority() != null)
            a.SetPriority(trans.GetPriority());
        ...
        // Add the metatransformation to the temporary store
        ...
}
```

The code for adding metatransformation to the temporary metatransformation store is similar to the code regarding common transformations. As a metatransformation can also be a composite transformation, it is again necessary to call the *InstantiateChain()* method. After obtaining a complete metatransformation store, it is possible to proceed with checking the prerequisites and perform the execution of metatransformations:

```
foreach (IMetaTransformation trans in metaStore.Store) {
    trans.CheckPrequisites();
}
foreach (IMetaTransformation trans in metaStore.Store) {
    trans.ExecuteTransformation(model,store);
}
```

After performing this last step, the changes to the transformations contained in the processed metatransformations have been applied to the transformation object model and therefore it is possible to perform the final prerequisite check over the model and proceed with executing the transformations.

*3) Check the Requirements of Parsed Transformations:* The requirement checking is simple. The only thing that is necessary is to call the *CheckPrerequisites()* method over all the transformations in the *TransformationStore* object. The current implementation uses a simple fault detection mechanism that is based on raising an exception when a problem occurs. One of the signals used is the *TransformationParameterNullException* exception. This signal means that a parameter expected at the XML model level was not provided:

```
public class TransformationParameterNullException : Exception {
    public TransformationParameterNullException( string transID,
        string parameter): base(”Transformation” + transID +
            ”:Parameter ” + parameter + ” was not defined.”){}
}
```

This exception can be raised afterwards in the *CheckPrerequisites()* transformation method:

```
public override string CheckPrerequisites() {
    if (GetParameter(”PageName”) == null)
        throw new TransformationParameterNullException(
            this.GetID().ToString(), ”PageName”);
}
```

With metatransformations it is possible also to check for transformation dependencies using the enhanced model aware method with the necessary parameters: *CheckPrerequisites(**object** model, TransformationStore store).*

*4) Execute the Transformations:* The precondition for this step is that the *TransformationStore* object contains a list of transformations that is prepared in a way that the metatransformations have been applied and the prerequisites checked. Afterwards, the *ExecuteTransformation()* method is called in a loop for each of the transformations contained in the list:

```
public void ExecuteTransformationChain(
    TransformationStore store) {
    foreach (var transformation in store.Store) {
        transformation.ExecuteTransformation();
    }
}
```

The order in which the transformations are executed is defined by their order in the *TransformationStore* object. After this step, the software artifacts specified in the transformations are created.

## VII. Evaluation

To evaluate the approach of feature model driven generation of software artifacts, we developed a study of the family of simple web sites comprising all the possibilities that may arise with features and transformations described in the previous section. Figure 8 shows the corresponding feature diagram.

The page features (ID 2, 3, and 4) embrace two ways of creating the text content: statically, by an HTML document (ID 2 and 3) or dynamically, by a script that generates the HTML document (ID 4).

A model aware transformation is introduced with the dynamic page feature (ID 4), with the utilization of a metatransformation providing the model traversal. Variability is introduced with the data provider (ID 5) providing an XML or Microsoft SQL database backend.

Optional features connected to the root feature (ID 10, 11, and 12) represent crosscutting features that require either metatransformations to change the actual features (ID 10 and 11) or they represent a parameter influencing the generative process (ID 12) to show an implementation of the development or generative environment property.

## VIII. Related Work

The pure::variants approach [8], mentioned in Section II, embraces a large set of predefined transformations that are assigned to particular features in the family model. The difference lies in the implementation where pure::variants is relying on XML transformation definitions and the solution proposed here uses C# classes, which is more flexible, allowing for custom programmed transformations.

Edicts [13] is another approach that aims at the mapping of features to source code parts. In addition, Edicts supports different binding times. The concept of binding time [14] should be taken into account when creating feature binding points in the suggested superimposed architectural framework.

XANA [15] strives for bringing closer the development process to end users using feature modeling. It decouples software product line design and implementation, which is to be performed by more technically knowledgeable users or professional developers, from application derivation, which is intended to be manageable by non-technical end users. Application derivation assumes not merely feature selection, but also providing parameters for parameterized features. A similar kind of decoupling can be applied to the approach proposed here. Generic transformations could be provided as a framework. Accompanied by an appropriate development environment extension, these generic transformations could be accessible to end users.

The superimposed variants approach [16] provides a way of mapping features to variabilities in external models, which can be used to activate or deactivate particular parts of the superimposed architectural framework. The transformation based approach proposed here is related to the idea of superimposed variants with respect to the external system of transformations used as the superimposed architecture or model. Differently than in our approach, the superimposed variants approach utilizes external models that are configured [16]. It is also possible to create such transformations that would prepare

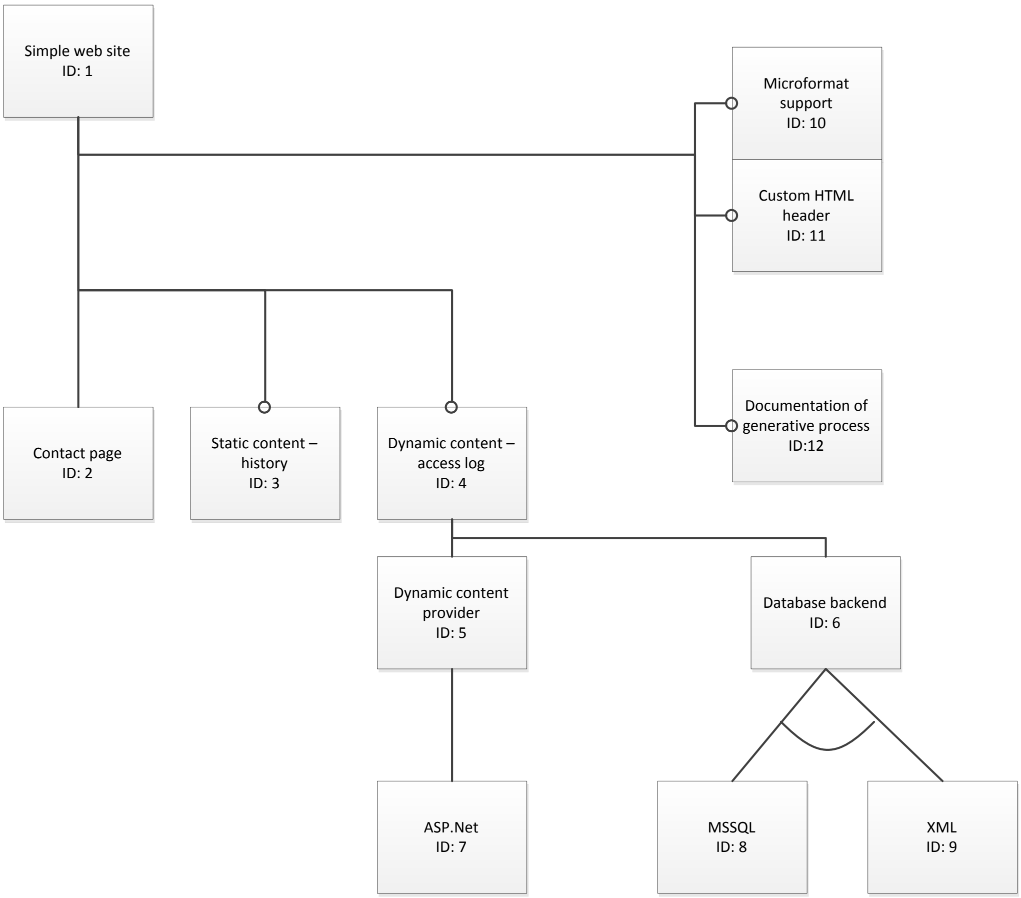

Fig. 8. The feature diagram of the family of simple web sites.

and configure additional models effectively emulating the superimposed variants approach.

One of the actions that is realized by metatransformations in the approach proposed here is the parameter replacement. This is similar to the template text replacement based on generic methods in generative programming for C and C++ [17]. However, the approach proposed here is different in the way that there are no restrictions on what is a transformation template parameter. Another difference is that in a template system, template fields are replaced and then the code is built, but in the approach proposed here, a transformation can represent a complex event chain, and not just a simple text replacement.

Dynamic code structuring [18], [19], [20] is based on explicit representation of possibly overlapping concerns in code for providing different perspectives. In the approach proposed here, dynamic code structuring can be applied to the code that defines transformations. However, dynamic structuring is potentially applicable to feature models themselves. In its essence, featural software decomposition is a decomposition by concerns with features representing the concerns, including the crosscutting ones [12]. Feature models with different organization of features in the feature diagrams can be equivalent [17]. Moreover, a feature can have alternative decompositions into subfeatures, including not being decomposed at all. The different representations of the same feature model may suit different stakeholders or situations and the transformation code attached to it can be presented in different ways accordingly. For large feature model presentation, design pattern detection techniques [21] may be of interest. Feature models can be represented as grammars [22], in which case grammar refactoring could be applied [23] to obtain different views.

## IX. Conclusions and Further Work

This paper proposes an approach of feature model driven generation of software artifacts, in which features are viewed as solution space transformations that may be executed during the generative process conducted by the feature model configuration. The approach has been evaluated on a study of the family of simple web sites comprising all the possibilities that may arise with features and transformations.

The main advantages of this approach are is that the system of transformations is basically self-contained and does not require additional modeling techniques except for the enhanced feature model. The code within the transformations is not limited with respect to its effects on the resulting software system behavior, i.e., anything that can be achieved by manual code writing can be achieved by appropriate transformations. In large part, the flexibility of the proposed approach lies in the concept of metatransformation. Metatransformations are the transformations that represent the impact of crosscutting features by modifying the common transformations before they are executed by changing their input parameters or by modifying their event chains.

A practical adoption of the approach proposed in this paper could be significantly supported by providing directly reusable transformations, transformation templates (i.e., parameterized transformations), or even just transformation schemes or examples to be adapted manually to the application context.

Actual feature models are huge and therefore are more effectively presented by individual concepts [12]. In general, a concept is an understanding of a class or category of elements in a domain [11]. Syntactically, in feature modeling, the root node of a feature diagram represents a concept [17]. Thus, raising a feature to the level of a concept is a matter of choice. Of course, this has to reflect the needs and objectives of the particular case of modeling. Having a feature model decomposed into a set of feature diagrams, rather than a single tree, involves having references between the trees (i.e., concept references [11]). Exploring how this affects feature model driven generation of software artifacts represents a research challenge.

## Acknowledgments

The work reported here was supported by the Scientific Grant Agency of Slovak Republic (VEGA) under the grant No. VG 1/1221/12.

This contribution/publication is also a partial result of the Research & Development Operational Programme for the project Research of Methods for Acquisition, Analysis and Personalized Conveying of Information and Knowledge, ITMS 26240220039, co-funded by the ERDF.

# Education, Curricula & Research Methods

ECRM is a FedCSIS conference area aiming at interchange of information, ideas, new viewpoints and research undertakings related to university education and curricula as well as recommended methods of doing research in all computing disciplines, i.e. computer science, computer engineering, software engineering, information technology, and information systems. This area spans typical FedCSIS events (conferences, workshops, etc.) with rigorous paper submissions and review processes as well as panels, PhD and research consortia, summer schools, etc. Events that constitute ECRM are:

- DS-RAIT'15 – 2$^{nd}$ Doctoral Symposium on Recent Advances in Information Technology

# 2$^{nd}$ Doctoral Symposium on Recent Advances in Information Technology

THE second international Doctoral Symposium on Recent Advances in Information Technology (DS-RAIT 2015) will be held in Lodz (Poland) on September 13-16, 2015 as a satellite event of the *Federated Conference on Computer Science and Information Systems* (FedCSIS 2015) and *Education, Curricula & Research Methods* (ECRM 2015) conference.

The aim of this meeting is to provide a platform for exchange of ideas between early-stage researchers, in Computer Science, PhD students in particular. Furthermore, the symposium will provide all participants an opportunity to get feedback on their studies from experienced members of the IT research community invited to chair all DS-RAIT thematic sessions. Therefore, submission of research proposals with limited preliminary results is strongly encouraged.

Besides receiving specific advice for their contributions all participants will be invited to attend plenary lectures on conducting high-quality research studies, excellence in scientific writing and issues related to intellectual property in IT research. Authors of the two most outstanding submissions will have a possibility to present their papers in a form of short plenary lecture.

## Topics

DS-RAIT 2015 invites the submission of papers on all aspects of Information Technology including, but not limited to:

- Automatic Control and Robotics
- Bioinformatics
- Cloud, GPU and Parallel Computing
- Cognitive Science
- Computer Networks
- Computational Intelligence
- Cryptography
- Data Mining and Data Visualization
- Database Management Systems
- Expert Systems
- Image Processing and Computer Animation
- Information Theory
- Machine Learning
- Natural Language Processing
- Numerical Analysis
- Operating Systems
- Pattern Recognition
- Scientific Computing
- Software Engineering

# Research Proposal: Barriers to new user and new domain adoption of the XSEDE Cyberinfrastructure

Richard Knepper
School of Informatics and Computing / Pervasive Technology Institute
Indiana University
2709 E. 10th St, Bloomington, Indiana, USA
Email: rich@iu.edu

***Abstract*—This research proposal proposes the examination of user attitudes about the Extreme Science and Engineering Discovery Environment (XSEDE). The XSEDE project supports basic research with a common system for making use of national cyberinfrastructure. The systems and infrastructure that make XSEDE useful for researchers are part of an actor network: these systems are socially constructed and they play their own part in the work of XSEDE, and in turn have an effect on the progress of basic research. I have completed previous work on the user relationships in the predecessor to XSEDE, the TeraGrid, and currently carry out participant observation with the management groups of the XSEDE project. By understanding the barriers to adoption of XSEDE by new researchers and new scientific domains, I hope to explore the linkage between resources (in this case computational resources) and scientific outputs.**

## I. Introduction

STARTING in 2001, the United States National Science Foundation (NSF) funded a distributed, high-performance computing project known as the TeraGrid, with the goal of supporting scientific research at the frontiers of current research. With over $430M invested in the TeraGrid grants to date and more projects open for solicitation, the TeraGrid has created an ecosystem of interacting researchers, technologists, and administrators [1]. The TeraGrid was superseded in 2011 by XSEDE, which continues the implementation of the architecture started in the TeraGrid project with additional work towards making these large scale systems more flexible, usable, and open to a broader range of research agendas [2]. XSEDE has been awarded over $64M to date for its management structure, with sites deploying resources based on NSF awards of as much as $77M for the National Institute for Computational Science's Kraken system, and $55M for the Texas Advanced Computing Center's Stampede system, to name the largest investments. The creation of national cyberinfrastructure in support of basic research is a resource-intensive effort: not only do the initiatives involved in XSEDE require substantial material investment, the centers that support these systems employ large numbers of staff to manage the systems, provide user support, adapt code to ever-larger systems and broader architectures, and reach out to the scientific community in order to bring in new researchers.

### A. XSEDE and outreach to new domains and users

The NSF mandates that the XSEDE project reach out to new disciplines and new institutions, including Minority Serving Institutions and Historically Black Colleges and Universities. Despite efforts to broaden the number of disciplines and institutions served in XSEDE, surveys of researchers indicate that only 30% of respondents feel that there are sufficient cyberinfrastructure resources available to meet their research needs. XSEDE's quarterly resource allocations process is oversubscribed by roughly 3 times. In order for XSEDE to meet NSF's recommendations to broaden its user-base, XSEDE needs to change the strategies used to recruit and develop users. Despite this charge from the NSF, non-traditional users of XSEDE still experience difficulties adapting and transitioning to the XSEDE project.

It is critical in the estimation of the NSF to provide a broad-use cyberinfrastructure framework for the support of basic science, and this has been emphasized in reports from the XSEDE project[3], as well as prominent researchers such as Richard Tapia and others. XSEDE includes in its management structure units for reaching out to new communities and has an emphasis on highlighting novel uses of XSEDE, but the current user base and user profile remains quite narrow. New systems on XSEDE advertise "Computing for the 99%", but this paradigm has yet to be fleshed out, not to mention actual usage information.

### B. Motivation and research goals

This investment in infrastructure for research represents considerable outlay for the government in real terms. While not large compared to other government expenditures, these services provide the long-term innovative capacity for the country, and they influence the nation's competitiveness and future technological development. XSEDE represents a system in which researchers have access to considerable resources, but only by adopting technologies as provided, and with access to resources governed by a peer-reviewed allocations process. In some ways this is like other resource-distribution mechanisms in science such as publications and grants, but the technological requirements to use and specificity of available

978-83-60810-66-8/$25.00©2015, IEEE

analyses on XSEDE resources means that different groups are more able to take advantage of resources.

The basic research questions in this study surround the impact that resources make on scientific work. XSEDE is a project intended to provide computational resources to scientists, no matter what their local resources may be. This research project is intended to reveal what these barriers to utilization of XSEDE resources are from the users' point of view, and to examine what these potential users of XSEDE say about their experiences, but also to analyze and understand the training and documentation materials provided for potential users, as well as observe some of the activities and NSF strategies for user recruitment. These findings will be examined along with the NSF's initiatives to generate user participation, with the goal of creating requirements for the next phase of the XSEDE project that can be incorporated into XSEDE's architectural processes: use cases and quality attributes. The products of architectural processes will include programmatic interfaces, training and documentation materials, and broader educational materials.

By understanding how researchers use resources, and how they compete for them, I intend to get more information about appropriate cyberinfrastructure and allocations methods to best serve the needs of the nation for basic research. By better understanding the users of XSEDE and their needs and relationships within XSEDE, successor infrastructures to this project can be built in order to do a better job supporting scientific research. My own previous research has focused on the management of XSEDE and relationships between supercomputing centers, and to understand the functioning of the project it is imperative to also see the project from the perspective of its client-constituents. By understanding linkages between resources and scientific outputs, it is possible to understand what kind of information is needed to drive science policy decisions as governments attempt to manage limited resources and still remain competitive.

## II. Literature on resources and performance

In order to explore the connection between resources available to scientists and their productivity, it is important to understand the more general background of resources for scientific activities. Most commonly these are competitively awarded grants that provide scientists with the financial means to accomplish research goals.

While it may be argued that funding for cyberinfrastructure for research is qualitatively different from research practices, I draw upon the stream of research that examines performance management for research, noting a few major correspondences between research infrastructure and research itself. First and foremost, the large scale cyberinfrastructure that characterizes the TeraGrid and XSEDE projects is in itself treated as a computer science research project. Creating software that makes use of large scale systems efficiently and effectively, providing services that allow users to make use of cyberinfrastructure with ease, and creating links between large scale systems that allow them to be used in concert with each other easily constitutes as significant challenge for computer science researchers. Secondly, the practice of providing research cyberinfrastructure for research is largely modeled after the process for obtaining grants for research itself. Proposals are created with broader impacts and scientific merits in mind, subjected to peer review, and projects are evaluated based upon the publications and reports they generate, as well services provided. Finally, there is limited evidence to suggest that infrastructure in support of research behaves and can be treated similarly to other infrastructure provided by other government agencies, thus our understanding of research funding is the closest analogue to assist in our understanding of dynamics driving cyberinfrastructure funding.

Performance management for grants is perhaps the most important difference between grant funded work and contracting work, and monitoring of scientific progress has singular difficulties. Partha and David [4] catalog the difficulties of economic evaluation of research: economic returns may come quickly or may take decades to realize, rights to intellectual properties are difficult to extract economic rents from (in fact restricting access to research may hamper further returns on initial investments), fundamental research progress may have dramatic and far-reaching impacts that are difficult to capture, and it is especially hard to forecast the success of any one particular research project. Hanson's [5] appraisal of focusing on effort as opposed to results has marked the transition from measuring research outputs towards measuring research processes. The standard operating procedure for evaluating both inputs (proposals) and outputs (scientific work) of grant-funded projects remains the peer review process. Garcia and Sanz-Menendez [6] discuss the context of peer review as metric of scientific research quite fully in their evaluation of competition in research initiatives. The authors begin tracing the path of peer review with the assertion that individual reputation and credit are central to the creation of the social structure of science, and that recognition by ones' peers is the foundation of legitimacy and leadership in a given field. Garcia and Sanz-Menendez note that the measurement of scientific production has long been based in volume and quality of scientific publications, but that these metrics cannot be separated from peer review. Peer review, despite some of its flaws outlined below, is not only the basic mechanism for ensuring quality of research, but also a critical factor in monitoring the efficiency of government investment in science. Peer review provides legitimacy to governmental bodies, and scientific work which has passed peer review has greater esteem in its scientific surroundings [6]. However, with the advent of new initiatives in government for assessing and monitoring of performance, peer review has had mixed fortunes as an evaluative tool for officials in charge of awarding research grants.

Shapira and Kulhman [7] describe the growth in requirements evaluation of research projects as governments attempt to control costs and derive better benefits from programs, noting that there are significant issues to measuring performance in this area. Impacts of these programs tend to be diffuse, as do costs, leading to difficulties in capturing all of the inputs and outputs. As research programs grow in complexity, including more disciplines and addressing broader problems, the evaluation of these programs must similarly become more complex. Government demands for continuous monitoring and program learning initiatives for research have led toward inclusion of subsidiarity, socioeconomic effects, and broader impacts into research evaluations. The increasing frequency of public-private partnerships for research also increases the complexity of program evaluation [7]. Partha and David [4] describe the the new attitudes towards measurement of research projects as a new economics of science, in which the previous free-market scientific workplace, characterized by scientists competing in the peer review process in order to gain funds and recognition is supplanted by a more interventionist government hand that is in the process of turning science toward more applied tasks. Government demands for better program evaluation both in the US and in Europe, as well as budgetary constraints from the recent economic crisis, have resulted in a call for more scrupulous examination of research performance.

The response to this call for increased evaluation and measurement of performance, has been variable at best. Cozzens [8], providing the context of evaluation in US research funding, describes the clash between the traditional evaluation tools for research, peer review and the journal selection process, and the new requirements based on the Government Performance and Results Act (GPRA) and increased requirements for management performance from the OMB. Peer review as the status quo for evaluation of science works in what Cozzens describes as an "autonomy-for-prosperity" model. Agencies support research activities in order to solve specific problems in an indeterminate amount of time, with limited oversight from Congress or agencies. Emphasis in evaluation is placed on the input end of the process, based on the quality and relevance of research proposals, and most importantly the accountability of this evaluation is placed on the research community, who is responsible for fairly making decisions, rather than on the researchers themselves to produce results to the general public. Guston [9] notes that peer review makes up a substantial amount of the selection process for research: \$37.7 billion or 86% of the reported total funding for research is merit reviewed. Applied research agencies, in contrast, have review processes based in personnel evaluation and budgeting that determine quality, although Cozzens, Bozeman, and Brown [10] note that there is a shift towards the competitive model of peer review even for these agencies. Peer reviewed grants are a feature of new federal research funding programs in the Department of Agriculture, the Environmental Protection Agency, and the Advanced Technology Program [9]. Peer review for research projects can happen both prospectively in the proposal selection process as well as retrospectively in evaluation [11], and have also been used as inputs in evaluating information for drafting regulation, creating state policies, and in evaluating courtroom decisions [9].

The peer review process conflicts directly with GPRA requirements for monitoring outputs of research, which explicitly focus on planning and achieving strategic objectives, rather than a culture of fairness in evaluation of proposals. As Cozzens [8] states, this "clashes with the traditional notion that the benefits that flow from research cannot be predicted in timing or content, but rather are visible only retrospectively". Response to the new evaluation requirements has been met by providing measures that are generic and qualitative: outcomes such as "advances in knowledge" or "ideas, peoples, and tools", or the NSF's frequently sought-after "science nugget", used to provide Congress with information about program success in a brief, easily-digestible package. As a result, such weak measures of evaluation lead to reinforcement of existing political forces, especially when coupled with another popular new metric of stakeholder input, which gives greater voice to those parties already engaged in the selection process [8]. Another approach to evaluation is to provide broad indicators of research progress: publications, funded research, and patents. Campbell [12] directly contrasts the peer review and indicator approaches finding that peer review results in complex but subjective evaluations of research work, while indicators are objective and easily quantified, but tend to be superficial in nature. Hagstrom [13] notes that peer reviewers frequently are able to identify the authors they are reviewing, or at least make educated guesses based on prior research and citation patterns. There is some evidence that researchers understand the peer review process and anticipate elements of it when drafting proposals. Knorr-Cetina [14] found in comparing proposals submitted for peer review to those without peer review that the style of the proposals changed rather than the content of the science inside. Furthermore, peer review is frequently conducted by established researchers, which leads to a problem in the assessment of new and innovative research directions, and relationships of mutual dependency that create self-reinforcing factions within scientific communities [12]. The world of the peer- reviewed scientist may be viewed as one mired in competition with other researchers first to get research proposals approved in order to get funding, and then to get the results of that research published.

Competition is in many ways the coordinating feature of scientific progress just as it is in economic activities. Hagstrom [13] describes the competition that takes place between scientists as specifically occurring when a scientist finds that her research in a particular area, on a problem not previously published, has been beaten to publication by another researcher. This form of competition may be extended to include being passed over in favor of another researcher in the grant selection process. Latour and Woolgar [15] established research funding as a vital part of researchers' credibility and reputation with other scientists. Garcia and Sanz-Menendez [6] sum the idea of competition up well: "Thus, competition for funds is an essential mechanism in the cognitive functioning of research, articulated in the credibility cycle, and a vehicle for relationships between science and government". Competition between researchers has a number of valuable features that aid scientific development. Competitive publication practices mean that additional researchers may be working on the same problems, which ensures an abundant supply of possible investigatory techniques and results. Competition drives hard work on the part of the competitors to outdo each other. Finally, competition reduces the risk of dilatory publication, and it encourages differentiation and innovation as scientists attempt to identify new problems to explore [13]. While competition should promote the best quality research, issues have been identified with competitive processes for publication and funding that may slow the progress of science. Competition thus has a complex relationship with peer review. Laudel [16] notes that the competitive process may have impacts to the course of science as scientist averse to risk select other research topics in order to avoid competition and increase favor in peer review, promote mainstream or existing research techniques in order to be more competitive with particular review boards. Reports from leaders in grant-funded research centers find that competitive resubmissions for funding has a disruptive effect on getting the work of the center done [17].

With the understanding that research is driven by competitive processes, as scientists attempt to establish a track record that allows them to build capital to drive further research, and reputation that allows them to secure that research, a number of questions arise prompting further investigation into the workings of grant funded science. Firstly, what role does scale play in the competitive process? A number of authors have investigated the shift from individually-centered projects to larger labs and research centers. If scientists are engaged in competition for resources and prestige on the individual level, what forces do these interactions exert on the organizations that they work within? Does individual competition influence the structure and performance of these organizations? Secondly, what is the interplay between competition and collaboration in scientific projects? Federal agencies in the US and abroad have invested in funding projects to take on "Grand Challenge" projects such as the Large Hadron Collider, the caBIG project for cancer research, and the Laser Interferometer Gravitational-Wave Observatory (LIGO), which incorporate researchers from multiple institutions and are multidisciplinary investigations of research questions. Collaboration is an essential element of these large-scale scientific projects. However, Edwards notes that collaborative work is frequently hindered by "friction" of various types, categorizing "data friction" as issues that keep researchers from being able to easily exchange and manipulate data and "computational" friction which keeps scientists from easily making use of supercomputers or transferring work between different supercomputing sites [18], and later positing a "collaboration friction" which is the effort required for scientists in multiple disciplines and or differing backgrounds to work together in order to achieve collaborative success [19].

Finally, how can government agencies structure their programs and investments to take advantage of these factors? The NSF and to some lesser extent, the NIH, are under considerable pressure to reduce funding outlays and to provide rigorous performance management indicators for the scientific research done under their auspices. Are there features of collaborative and competitive research that allow the grantors to get better results and better science faster?

## III. Previous research efforts

As a student of social informatics and of public management, with an interest in science policy, I have followed the development of the Supercomputing Centers program through the TeraGrid project and the XSEDE project. As an administrative manager in Indiana University's Pervasive Technology Institute, my duties include a management role within the XSEDE project, and this combination of theoretical, empirical research and access to the internal workings of the organization represent an opportunity for participatory research that is an extremely compelling case. In my efforts to get a better understanding of the TeraGrid user community, I conducted a social network analysis of the TeraGrid users and project allocations [20], noting the prevalence of traditional "hard science" disciplines, but also finding evidence of collaborations that span multiple fields of science. Since the end of the TeraGrid project and the advent of the XSEDE project, I have engaged in a case study [21], which characterizes the XSEDE project and similar advanced cyberinfrastructures as "living infrastructure" with qualitatively different attributes to traditional scientific instruments. These cyberinfrastructures have their own intents and goals that may or may not be aligned with their users' and the relationship between large cyberinfrastructure organizations and users becomes a collaborative arrangement in its own right.

Currently I am also working on a project with Katy Börner in the Department of Library and Information Sciences at Indiana University to characterize resource utilization on the XSEDE project as it relates to publication, in an effort to understand a general utilization-to-publication ratio, but also to examine whether different supercomputing centers and systems represent different research output profiles as well as the possibility of different fields of science having different resource/output functions.

## IV. Hypotheses

I hypothesize that there will be a number of barriers that are already well-described in documents such as the NSF's Advisory Committee on Cyberinfrastructure's Campus Bridging Task Force report, such as: difficulties in moving large amounts of data from its place of collection to computational systems for analysis difficulties in getting analyses to run on different resources unfamiliarity with national cyberinfrastructure frameworks and utilities I also hypothesize that in discussion with users, it will become evident that there is a lack of fit between the resources available via XSEDE and the new domains of interest. The XSEDE project and its predecessor, the TeraGrid, are rooted in the highly computational "hard science" disciplines such as high-energy physics, astronomy, and molecular dynamics. The new domains of interest to the NSF are slowly building computational emphases, but these techniques are often reliant on significantly large amounts of data, and analysis tools are developed on personal computers, rather than the codes developed in the era of centralized computing facilities. These analyses include ”Big Data” techniques–computational social sciences, for example–but also a significant number of life science analyses.

## V. Methods of analysis

A number of methods appear to make sense for investigating user benefits and difficulties taking advantage of XSEDE. XSEDE management already commits significant effort to improving practices within the project, from an in-depth architectural process to external evaluators who conduct general surveys of users and employees, as well as interviews in order to get more in-depth understanding, and case studies of individual initiatives within XSEDE. Leveraging the work of the external evaluation team can provide a considerable amount of information and indicate areas that require further inquiry.

### A. Document Analysis

In order to understand the current underlying body of knowledge, I propose to examine existing reports carried out by the external evaluation team, which has produced from 12-20 reports each project year [3]. This document analysis will be focused on user-centered evaluations (items such as the staff climate report will be excluded). Specific areas of interest will be the identification of mechanisms that support successful research activities as well as resource allocation schemes that have either facilitated projects or made them more difficult to carry out.

### B. Survey and Interview Activities

With some initial understanding of the existing data collected on XSEDE user activities, making use of the materials already present, I intend to conduct a survey of users with specific focus on sharing and utilization of resources, in order to understand how resources are obtained and allocated within projects. In order to understand the issues of new domains and new user populations–which may not easily conform to XSEDE’s practices for obtaining access to and using resources, I will elicit proposals from the XSEDE allocations committee which were not approved, looking for proposals which were not turned down for lack of preparation or scientific merit, but for lack of fit to the project or for other issues. I will interview these researchers in order to understand how they planned to make use of XSEDE and what issues they felt kept their proposal from receiving an allocation of resources. These interviews will be conducted by teleconference or videoconference by one to one arrangement.

I also plan to conduct close interviews with members of the XSEDE “Campus Champion” program, who are local users who volunteer to assist others in making use of XSEDE by training and facilitating research activities. These individuals frequently help new users address problems getting started conducting analyses on XSEDE, and they often have some research component of their own to pursue.

### C. Participant Observation

In concert with the survey and interview activities described above, I intend to participate in training activities for new users, webinars and targeted outreach events that address user needs, and to engage in other activities, in hopes of observing users in action as they learn, examine, test, and adapt to the XSEDE environment. Events for participant observation of users will include the upcoming Linux Clusters Institute Workshop[1], the XSEDE annual conference meeting, and online training and webinar events held by XSEDE, Ohio Supercomputing Center’s HPC University, and Cornell University’s Virtual Workshop program.

## VI. Potential Benefits of Research

The current climate for science policy in the United States, but also in other countries is a problematic one. Support for basic research is being eroded: not long ago it was common to hear the phrase “flat is the new doubling” when speaking to research center leadership, this has changed to “minus five percent is the new flat”. If the US and other nations are to ensure competitiveness and continued innovation, judicious use of resources and a strong understanding of the relationship between resources supporting research and scientific outputs is required. Scientific productivity is a problematic area to measure and there will be many different pieces of research that inform a larger stream, these will include studies of scientometrics and bibliometrics, but there is also significant work on large technical systems [22], [23] and the social element of technological systems [24], [25] that will contribute to our understanding of the social elements of scientific research.

This study will benefit our understanding of the linkage between access to resources and scientific outputs. In order for organizations such as the NSF to successfully support basic research, a better understanding of the effect of resources on research outcomes is required, especially in the case of shared resources such as the XSEDE project, which provides a long-lived scientific cyberinfrastructure service. XSEDE and its service provider units represent significant investment on the part of the National Science Foundation and making sure that the most effective distribution of resources can be made is critical to the longevity of the NSF and its mission. In a broader sense, understanding how centralized resources for research are best implemented in a general sense will provide better strategies for makers of science policy to present effective and equitable distribution of resources that ensures scientific progress and competitiveness in general.

# Promoting the understanding of electronic components and circuit parameters by using didactic dynamic pictures - qualitative analysis of research results

Krzysztof Krupa
University of Rzeszow, 35-959
Rzeszow, al. Rejtana 16C, Poland
Email: kkrupa@ur.edu.pl

*Abstract* — **This article describes the qualitative analysis of the research results of the effectiveness of promoting an understanding of the parameters of electronic components and circuits by using dynamic circuit and block diagrams as well as the dynamic characteristics integrated with them. The introduction highlights the characteristic way of understanding the parameters of electronic components and systems and an outline of my research conducted in this area. The second chapter presents a typology of the dynamic pictures used and a description of sample animations. The third chapter contains the explication of the concepts of understanding electronic components and circuits. The fourth chapter presents the description of the research, while in chapter five the qualitative analysis of the research results is shown, from which the conclusions are contained in chapter six.**

## I. Introduction

IN MOST mechanical structures, moving parts play a major role. They are integral to sensory cognition. The phenomena taking place inside electronic structures are not available to sensory cognition, which is why images play a leading role in the teaching of electronics. Since these phenomena exhibit variations in time, the didactic dynamic picture, visualizing the time dependence, may affect the effectiveness of teaching electronics. Part of my research on the effectiveness of using dynamic pictures was spent teaching the meanings of the parameters of electronic components and circuits. They represent a part of the test results on the effectiveness of teaching using didactic dynamic pictures that were included in the dissertation [2].

## II. Didactic Dynamic Pictures In Shaping The Understanding Of Electronic Components And Circuit Parameters

Didactic dynamic pictures used in the teaching-learning of electronics were divided into four groups. They perform the following didactic functions: illustrating the operation of electronic components, functioning of electronic components in basic work systems and illustrate the construction and operation of electronic circuits. In order to visualize the electronic components, dynamic area models are utilized. The operations of electronic components in basic systems, can be presented by the analogy of hydro-mechanical and dynamic schematics. The functioning of electronic circuits can be presented by using dynamic circuit diagrams and composite structures using dynamic flowcharts. Dynamic characteristics may be used for a detailed visualization of the parameters [4].

In order to shape the understanding of electronic components and systems parameters, the most appropriate images are those under which direct visualization of parameters occurs. These include dynamic circuit diagrams and dynamic flowcharts and corresponding dynamic characteristics.

Figure 1 shows an application, visualizing the operation of a basic amplifying circuit, constructed using a bipolar transistor. The application consists of two modules. On the left is a dynamic scheme, on the right the dynamic characteristic, which was operably linked to the diagram. The value of the input voltage to the system can be changed by using a slider. According to the characteristics of the bipolar transistor, the input voltage's $U_{BE}$ changes are reflected in the value of the current flowing through the base of the transistor - $I_B$. According to the characteristics of transition, changes in the intensity of the base current of the transistor causes proportional changes in the current of the collector - $I_C$. Changes in the collector's current, which is also the current of the resistor R, causes changes in voltage across the resistor, working together with the transistor in the voltage divider, whereby it also changes the output voltage of the system.

The scheme uses a series of dynamic elements. For example, numeric values of parameters such as base-emitter voltage ($U_{BE}$), the base current ($I_B$), the collector current ($I_C$) and the voltage at the collector's resistor ($U_R$) and the output voltage ($U_{CE}$). The magnitudes of these parameters are further displayed, in graphic form, with the help of dynamic

978-83-60810-66-8/$25.00©2015, IEEE

arrows whose size varies depending on the value visualized by the arrow’s signal.

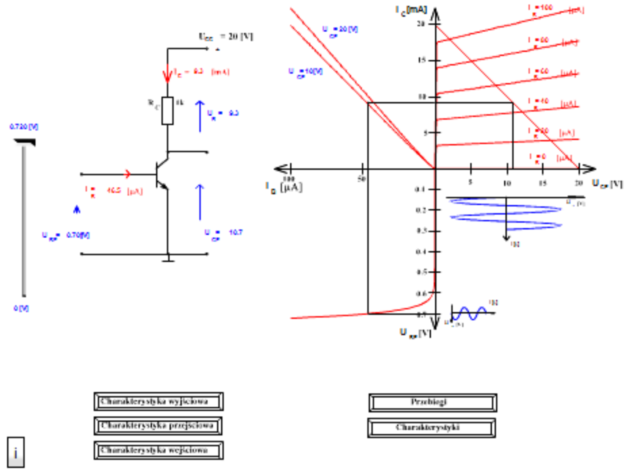

Figure 1. Didactic dynamic scheme with dynamic characteristics. The application shows the OE transistor amplifier [4].

Placed next to the schema, is a collection of dynamic characteristics of the static characteristics of the bipolar transistor in a common emitter’s circuit. Includes the input characteristics $I_B = f(U_{BE})$, transient characteristics $I_C = f(I_B)$ and the output characteristics $I_C = f(U_{CE})$. The output’s characteristics also draws the static characteristics of the resistor R. The main element in the dynamic characteristics are the lines indicating the individual parameters of the static characteristics. Furthermore, applied were dynamics, plotted out on the screen of timeline charts, of sinusoidal signals present at the input and the output of the system. All elements of the dynamic characteristics can be freely switched on and off using the appropriate buttons.

Figure 2 shows a different kind of teaching dynamic picture - a dynamic block diagram of an AC adapter for continuous operation. Despite the fact that all the blocks and timing diagrams of the system were presented, the application allows for their stepwise actuation by pointing the cursor over their names and blocks.

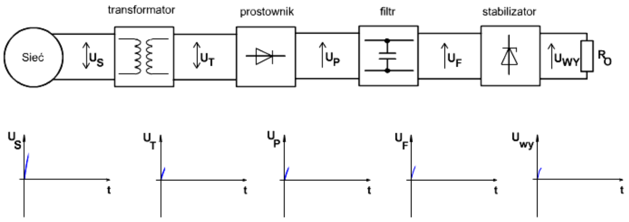

Figure 2 is a block diagram showing the dynamic power supply for continuous operation [4].

The application makes it feasible to present the essence of the shaping signals in particular functional blocks of the system. It is the basis from which to present, to the students, the construction and operation of consecutive blocks, such as the transformer, rectifying circuit, filter and stabilizing system.

The article shows only two examples of the teaching dynamic pictures. For empirical research purposes, much more of these aids were developed. These encompassed ten issues of analog electronics. The effectiveness of the application presented in the article has been confirmed [3]. Also undertaken were a series of works, aimed at creating a didactic dynamic picture visualization of digital systems. They have been applied in teaching materials used for teaching electronics over the Internet. These are applications that act as simulators of basic digital electronic systems.

## III. UNDERSTANDING THE PARAMETERS OF ELECTRONIC COMPONENTS AND CIRCUITS

This article assumes that understanding is the discovery of such content in objects, as their significance, meaning, structure, function, role, origin, durability, usefulness, look, what it does, how it arises, what it interacts with, the category to which it belongs and what specific characteristics does it possess [1]. One of the areas of understanding electronic engineering is to understand the parameters of electronic components and systems [3], which the student exhibits by their behavior relative to the described, in any way (image, symbol, text), element or electronic system [3]: assigns characteristic parameters to the element, describes the main characteristics of electronic components and systems, determines the unit of a given parameter, estimates the value of the given parameter, assigns characteristics to the stated element or electronic circuit, outlines the characteristic parameters of electronic components and systems, identifies, explains, indicates the essential points of the characteristics of electronic components and devices, explains the essence of the parameters of electronic components and devices, solves problems (including computing) using the parameters of electronic components and systems and selects a parameter or characteristic element or system to solve the design problem.

The set of these manifestations of understanding was used to construct the test tasks for the purpose of measuring the effectiveness of dynamic pictures in the development of understanding the parameters of electronic components and systems [3].

## IV. DESCRIPTION OF THE COURSE OF RESEARCH

Research of the efficiency of shaping the understanding of the parameters of electronic components and systems was carried out as part of a study involving the effectiveness of teaching electronics using didactic dynamic pictures on the example of the education process of students of technical and information technology. A didactic experiment, as the research method, was adapted and ran based on the parallel group technique. The study included students of technical-informatics education, educated under the three-year undergraduate studies and the five-year study mode.

The research used 120 didactic dynamic pictures presented to students of the experimental group consisting of ten lectures on analog electronics. The control group was given only static pictures were. After each lecture, students in both groups were subjected to a 20 task test. Four weeks after the last lecture, a test was given containing sixty tasks from ten sections of analog electronics.

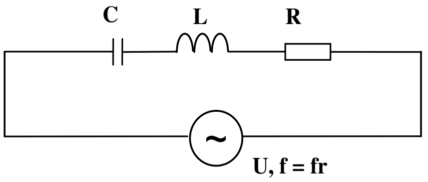
Quantitative analysis allowed for the confirmation of the hypothesis, in which it was assumed that the use of didactic dynamic pictures contributes to the efficiency of promoting the understanding of parameters of electronic components and systems. In order to fully present the results of the test, qualitative analysis was used [3].

## V.QUALITY ANALYSIS OF TEST RESULTS

Qualitative analysis allows for the identification of the kinds of difficulties faced by students in the experimental and the control groups while solving the tasks of understanding the parameters of electronic components and systems.

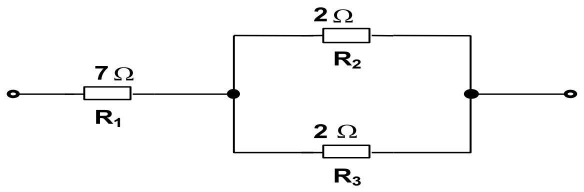
The first task was to indicate whether the impedance is at its lowest when the frequency of the current flowing through the serial RLC circuit is equal to the resonant frequency.

1. When the frequency of the current flowing through the system of equations is analyzed, resonant frequency of the circuit impedance is the lowest. true / false - underline the right answer.



RLC circuits in serial configurations, parallel and mixed are widely used in electronics, especially in the input circuit of the radio. In the case of this task, the experimental group received 83% correct responses relative to the control group that received a score of 41%.

2. Please calculate the equivalent resistance of the circuit. - Select the correct answer with a cross in the table.



| | | |
|---|---|---|
| 1 | 8 Ω | |
| 2 | 5 Ω | |
| 3 | 4 Ω | |
| 4 | 16 Ω | |

The solution to the 2nd task was to calculate the supplementary resistance of a circuit consisting of resistors connected in series and in parallel.

The experimental group received a score of 78% correct responses, and control group 48%. In the experimental group, 24% of students made the wrong choice as a result of not doing any calculations on the test sheet. In the control group, however, this situation occurred in 41%.

In view of the fact that didactic dynamic pictures do not support directly the skills of solving mathematical equations, it may indicate that there is another, deeper reason for the significant difference in the results of the groups at the expense of the control group. The didactic work with students, in the experimental group, noted that they often rely on lectures where dynamic hydraulic analogies are used. Facilitating the understanding of the presented phenomena, thus making it possible to avoid erroneous algorithms during problem solving, which were observed among those students who never dealt with analogies.

In a further, third task, a time constant of an RC circuit with specified parameters had to be calculated.

3. Calculate the time constant of the RC circuit with parameters: R = 100kΩ, C = 10ΩF.

The solution to this task depended on the reproduction of the correct mathematical expression, substitution of the given values into the formula, appropriate transformation of data prefixes and the performing of calculations. The experimental group received a score of 17% correct answers, while the control group 34%. The grading of the solution to the problem was based on the proper conversion of units.

In the experimental group, 73% of students did not attempted to solve this task, whereas in the control group, 62% reported omissions. This shows a complete inability to solve the task. A similar conclusion can be drawn on the basis of an incorrect formula, which was reported in 7% of the responses of the experimental group and in 3% of the responses of the control group of students.

The ability to apply the message in typical situations with regard to the understanding of the electronic parameters was measured with the use of task 4, in which the current-voltage characteristics of a semi-conductive diode should be drawn. On this characteristic, the forward voltage should also have been marked.

4. Please draw a semi-conductive diode's characteristics and highlight the forward voltage.

This task was solved correctly by 54% of the students in the experimental group and 34% of the control group. In the experimental group, a reported 12% had partial responses containing omissions in the description of the axis on the graph, and 17% had incorrect charts. In the control group, 31% of such completely incorrect responses were reported. In 21% of the tasks, of the control group, students did not attempt to find a solution. In the control group, in 31% of cases, the answer was completely random, for example, a student drew a sinusoidal waveform. In the experimental group, this phenomenon occurred in 17% of the cases. These experimental lectures exposed the dynamic characteristics of diodes, which illustrated the relevant parameters of their application in electronic circuits.

Obtaining a solution to task no. 5, it was crucial to indicate which of the expressions describes the amplification of current of a bipolar transistor.

5. Which of the expressions describes bipolar transistor current amplification of the OE circuit?................. – **check the right answer**

$A: \frac{I_C}{I_B};$ $B: \frac{U_{BE}}{I_B};$ $C: \frac{U_{BE}}{U_{CE}};$ $D: \frac{I_E}{I_B};$

The experimental group, for this task, received a score of 22% correct answers, while 48% was attained by the control group. Bipolar transistor current gain was mistakenly identified, by specifying the ratio of the emitter current to base current, 7% of the students in the experimental group and 31% of the control group. This demonstrates a better understanding of this parameter by persons participating in lectures, in which no didactic dynamic pictures were used. 46% of the responses in the experimental group and 17% in the control group indicated that the current gain is calculated by using the expression containing the voltage ratio value UBE to UCE. In this case, a separate dynamic picture was not applied, from which, in a direct manner, the issue of the current gain can be assimilated.

In task no. 6 it was necessary to describe the "minimum holding current". In the control group there was no single correct answer, while in the experimental group, the number of correct responses was 37% of the total number of results. This data suggest a beneficial impact of the experimental agent on the effectiveness of understanding the parameters.

6. Please describe the concept of "minimum holding current".

Majority of the students (69%) in the control group did not specify the electrodes of the thyristor, in which the parameter, included in the job, is expected to be. One student from the control group mistook the holding current with the conduction current (4%). The experimental group reported a 15% omissions of tasks, while 14% of the respondents in the control group did not attempt to solve the task.

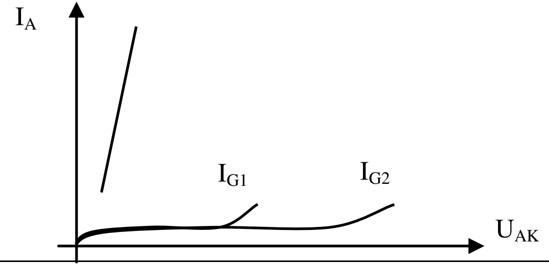
Further, task no. 7 referred to the skills used in typical situations in terms of understanding the parameters of semi-conductive switching elements. Solving this task required plotting out the current-voltage characteristics of the triac. 66% of the students in the experimental group and 38% of students in the control group solved the task correctly.

7. Please draw the characteristics of the triac. Pay attention to the description of the axis.

Basic mistakes committed during problem solving consisted of drawing unidirectional triode thyristor (9% in both groups) or bidirectional diode thyristor. Such errors were committed by 15% of the students in the experimental group and 24% in the control group. In the experimental and control group, there were no omissions of the task. A significant difference in both groups' output results can testify to the high efficacy of the use of didactic dynamic pictures in shaping the understanding of parameters.

Similarly, high results were obtained in the task 8, in which the person being tested needed to indicate a relationship between the parameters of $I_{G1}$ and $I_{G2}$ on the current-voltage characteristics of the thyristor (IA = f ($U_{AK}$)).

8. What is the relationship of the size of the current of the switching device's gate with characteristic as shown in the figure? IG1 ................... IG2- between these parameters,correctly enter the sign of the majority, minority or equality.



In this case, the experimental group received a score of 88% correct responses, while the control group 59%. The ability of answering this task indicates skills in identification, assessment and understanding of the parameters affecting the operation of the switching elements.

The task of no. 9 was to draw a phototransistor's output characteristics.

9. Please draw a phototransistor's output characteristics. Pay attention to the description of the axes and constant parameters.

The ability to draw the characteristics showed 27% of the students in the experimental group and 14% of students in the control group. The experimental group reported 58% omissions of the job or a completely wrong realization of it, while in the control group these solutions were 72%. In the experimental group, 24% of the tasks were incompletely resolved. Characteristics properly drawn, from a graphical point of view, were not described with proper parameters nor have the axis' signatures drawn into (IC = f (UCE), E = const).

The level of understanding a photoresistor's parameters was measured with the help of task 10. 39% of the students in the experimental group correctly answered the question, while the control group attained 62% correct answers. In this case, there was no positive impact of the didactic dynamic pictures on the level of to understanding the parameters.

10. Please describe the parameter of "dark resistance"

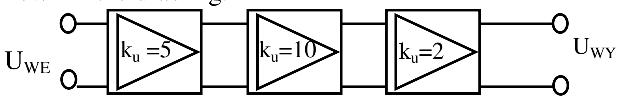
22% of students in the experimental group turned the process around by switching the cause of the phenomenon with its effect, for example, one of the responses reads: "it is a small light caused by high resistance". In the didactic dynamic picture, it was shown how a photoresistor works under conditions of complete darkness, however, the name of its resistance was not specified.

Task no.11 was dedicated to the understanding of the parameters, in which the essence of the squareness ratio needed to be explain. Here the experimental group received a result of 5%, while the control group got 10% correct answers.

11. Please explain the nature of the parameter: squareness ratio. In the explanation please use an appropriate figure and expression.

None of the dynamic pictures used in the study directly referred to this parameter, however, the issue of the steepness of the frequency characteristics of filtration systems and a tuned generator was presented with the help of the didactic dynamic pictures. However, this proved insufficient.

12. Please calculate the total voltage gain of the circuit shown in the drawing.



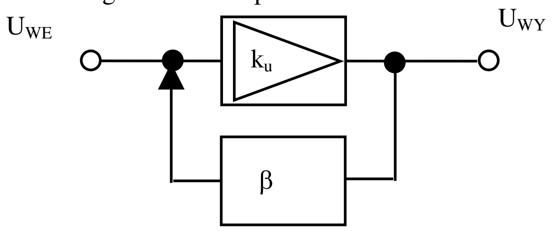
The voltage gain is:

The next task (12), relating to the understanding of the electronic circuit parameters, concerned the calculation of the voltage gain of a triple set of amplifying blocks, connected in series, with a given intensification.

In this task the experimental group received 49%, while the control group received 83% of correct answers. As is apparent from the number of correct answers, this task was relatively simple, however, in this case, no positive effect of the experimental agent was noted. Among the errors in solving this task, the most frequent were attempts the summation of individual gain values. This phenomenon occurred in 36% of the answers given by the students in the experimental group and 6% of students in the control group. The other students did not attempt to solve the task.

The next task (13) related to the ability of using the messages in problematic situations referring to the understanding of the electronic circuit parameters. In this task, the input voltage of the amplifying circuit, with feedback, had to be calculated, using the data contained in the problem.

13. Please calculate what the input voltage is given to the system if there is voltage at the output of 10V. The β value is -0.1 and the gain of the amplifier k = 100.



The experimental group received a score of 12%, while the control group achieved 3% of correct answers. The experimental as well as the control group reported the same number (24%), which acknowledges that the basic pattern of amplification of a circuit, with feedback, is well known to students and the result of this study is caused by the control group's student's inability to exploit it.

In task 14 the characteristic of a secured progressive AC adapter had to be draw. The experimental group reported 32%, while only 3% of correct answers in the control group.

14. Please draw the load carrying characteristics of a power supply with progressive protection.

In the experimental group's answers, the correct shape of characteristics were included, but did not adequately describe its axis. There were 9% of such responses. In the control group, 6% of the responses contained the mistake of shifting the graph's y-axis for the x-axis. This demonstrates the misconception of the nature of dependency on the phenomena presented with the help of the overload characteristics. It should be noted that the didactic dynamic picture was not used directly in illustrating the activities of progressive security. A higher percentage of accurate answers, in the experimental group, demonstrates the indirect effects of the didactic dynamic pictures.

The next task (15) related to the measurement of the ability to use the message in typical situations, within the meaning of the parameters of electronic systems.

15 Graph showing the following equation such as f=f($U_{CC}$) illustrates:

| | | |
|---|---|---|
| 1 | frequency response of the output signal when changing the amplitude | |
| 2 | frequency of the amplitude of the output signal when changing the supply voltage | |
| 3 | frequency response of the output signal when changing the supply voltage | |

It was necessary to explain the essence of the characteristics described for each model. The results obtained in this work are the following: the experimental group - 78% correct answers; control group - 90%. Distractor 2 was chosen by 12% of students in the experimental group and 10% of the students in the control group. Three people in the experimental group showed distractor 3 [3].

## III. Conclusion

Experimental studies have shown that the use of the didactic dynamic pictures has an important influence on the understanding of the parameters of electronic components and systems. Qualitative analysis of the results allow the following conclusions:

- students of the control group more often than the students of the experimental group did not attempt to solve the task,
- control group students more frequently than in the experimental group gave accidental or absurd answers,
- mistakes made by the students in the control group are more important than the mistakes made by the students in the experimental group.

Qualitative and quantitative analysis of the results of the studies on the effectiveness of using didactic dynamic images in the development of understanding the parameters of electronic components and systems confirm the hypothesis, in which the expected positive effect of the experimental factor.

***Abstract*—This paper describes the basic components of a research project aimed at the application of natural computing metaheuristics to optimize the horizontal scaling of databases. Column oriented databases were selected for the project because of their unique properties. A mathematical model has been created in order to align the problem of horizontal scalability to the general optimization methods, such as natural computing algorithms.**

## I. Introduction

THIS article is an overview of research on column oriented databases (DB) partitioning optimization with the use of the natural computing algorithms. Column-oriented databases are believed to qualify for this purpose nicely thanks to their physical storage structure. Sometimes they are used as a NoSQL equivalent for relational database management systems because of their flexibility and partial similarity to relational model. In the class of the natural computation algorithms there are metaheuristic procedures that suite well to the problems of optimization with multiple constraints and multi-modal objective functions.

There are three main pillars of the research, described in the following subsections. Subsection I-B contains a general description of the column-oriented databases along with the most important relevant details. From the scalability options for databases, horizontal scalability gained some noticeable attention and major implementations, especially in a modern so-called “web 2.0” services. Subsection I-A describes basic features along with pros and cons of a database horizontal scaling. The natural computing algorithms described in the section I-C are an important branch of the research on computation models and methods. Their main goal is to implement heuristics inspired by the natural environment’s behaviors and processes, to solve optimization problems.

The next sections describe current state and results of the aforementioned research. They consists of the prototype implementation of a column-oriented DBMS along with its mathematical model. Selected natural computing algorithms were also implemented in order to discover and describe their features on the basis of the typical benchmarking optimization problems. Section III contains the description of the application of the algorithms to the optimization problem using a created mathematical model. Current short- and long-term plans for further research are described in order to familiarize the reader with the expectations of the research.

### A. Database partitioning

In general, two main classes of scalability solutions can be distinguished: vertical scaling and horizontal scaling. These approaches are slightly different. Vertical scalability is based on the assumption that, in order to increase system capacity, its resources should be enforced, e.g. by swapping the CPU to a faster one. In this approach, a unit of work remains assigned to only one processing unit and is therefore limited by the unit’s capabilities. Additionally, hardware capabilities are finite and it is possible to reach to the point in which it will not be possible or reasonable to deploy a more powerful hardware. Instead, this approach is easy to implement, because it preserves previously used computation model and processing methods. Especially, it does not involve any work division, which means no additional synchronisation issues are introduced. In the horizontal scalability (scaling out) approach, it is assumed the unit of work to be done exceeds the capacity of any single unit and needs to be divided. That slightly changes the processing model and introduces concurrency- and synchronisation-related issues, but in return, offers virtually infinite theoretical capacity.

Within the database domain, horizontal scalability can be split into the three classes: replication, sharding (also referred

978-83-60810-66-8/$25.00©2015, IEEE

to as a horizontal partitioning) and partitioning (also known as the vertical partitioning). Please note that the terms "vertical" and "horizontal" regarding partitioning and sharding are absolutely not related to the general scalability terms. Both are parts of the horizontal scalability class. That is, both involve some division of a data in a database into more than one database management system (DBMS) instance. Replication is out of the research scope, so it will not be described here. It has been covered widely, along with the remaining solutions in the master thesis [1].

Horizontal and vertical partitioning differ by a division plane. Horizontal partitioning duplicates database (or just single table) schema on many instances but splits the data between them. Please note that specific partitions can be distinctive (that is, every records belongs to one and only instance) as well as redundant. Partitioning function can take into consideration record's identifier, single other field or a set of fields. A value which is used to perform partitioning is so-called "partitioning key". Typical partitioning schemas include:

- by range (e.g. clients with last name starting with letters A, B, ..., I, J go to the instance#1, K, L, ..., Y, Z - #2);
- by modulo function (e.g. if record have natural numeric key they go to instance number (key % n) where n = number of instances);
- by list (if record has a field constrained by a finite set of values, instances can be assigned with its subsets; e.g. clients born on monday, tuesday and friday go to the first instance, others to the second one);
- by hash function (hash function result set must reflect instance set).

More sophisticated methods include combinations of previously enumerated ones and consistent hashing. Consistent hashing is a technique which optimizes a division for frequent remapping, reducing number of data to be migrated after every change.

Very useful concept here is the abstraction of hash function results from the physical arrangement of database engine instances. That requires additional mapping between these two tiers, but brings some significant advantages of a direct linkage. Primarily, changes in the arrangement of database servers does not involve modifications of the hash function. In other words, it satisfies well-known "single responsibility principle" coming from the software engineering domain.

Sharding can then be considered as a data division between duplicated schema instances. Vertical partitioning, in turn, can be thought as a schema division. It requires a deep analysis of the data usage and implicitly assumes that structure of every records is common if not exactly the same. Then rarely used parts of data are extracted and moved to a different instance(s) than the frequently used parts. That is not the only possible analysis schema though. It is also possible to highlight data parts which are frequently used together and divide a database by that. Obviously, in real world application both techniques can be joined and applied together in any arrangement, which leads to virtually infinite number of possible variants.

### B. Column-oriented databases

Column-oriented databases (sometimes referred to as a column-family databases, columnar databases or column stores) is a non-relational database data model. Although not strictly defined, this model brings some significant features increasing its horizontal scalability. The current section describes the model as it is understood within the conducted research. For the ease of understanding, analogies to the well known relational database model are highlighted. Nevertheless, it needs to be stated explicitly that both models are not related. Modern column-oriented data stores have been covered in [2]. Implementation details of the Apache Cassandra column-family store have been described in [3].

Fundamental terms and concepts are common to every column-oriented DBMS implementation. Keyspace is the basic storage and logical entity. It acts as a container for lower level entities and could be compared to database or schema in terms of relational databases. A column family is a named collection of records with similar or the same column set. Column families belong to the keyspaces.

The most important feature coming from the described concepts is so-called schemalessness, which means that column family's data structure is flexible. A column set for specific records within the same column family is variable. In real world solutions it is usually "defined" only by an established convention, not by a strict constraints stated during the database creation process. As opposed to the relational database tables, if a given record does not have (in a logical sense) value in given column, it does not store actual NULL value (in a storage sense). That feature brings a significant impact on the storage structure and application logic. Also, it allows to implement some use cases which are not effective or even possible in relational databases. A common use case is the time-series data store, which contains actually only one row of data, but with dozens of columns created every time a new value is saved. In that case, the value timestamp becomes a column name. Another typical appliance is a data store for a recommendation system. Such systems rely on huge matrices correlating all users with all items.

### C. Natural computing algorithms

Natural computing algorithms are a significant class of the heuristic procedures, which takes its inspiration in processes and behaviors taken from nature. According to [4], natural computing algorithms can be divided into three main categories:

- evolutionary algorithms;
- swarm intelligence algorithms;
- bacterial foraging algorithms.

They are all based on an observation, that many processes in nature are in fact non-linear, multi-modal and multi-objective optimization processes. The whole evolution process leads to survival of the fittest specimens and species. Within that process there are many constraints, most of which are not well-defined or even not well-known, in some cases they could be fuzzy. Obviously, individuals do not use any numeric, analytical methods to fit, because it is not possible. That conclusion leads to arise of metaheuristic algorithms, which follow the nature patterns and can be used to perform optimization under similar conditions. For the sake of correct understanding the algorithm's abstraction, it is very important to emphasize analogies between the biological domain and optimization domain. Evolution's goal (in nature it is simply survival and reproduction of given individual's genes) is reflected by the objective function, which is minimized or maximized during the computation. As the algorithms are iterative, iteration loop reflects the lapse of time and generations succession. Candidate solutions are equivalents of the real population members and they pass from generation to generation using rules which differ between the algorithms and applications. In contrast to nature, algorithms are initialized (that is populated with an initial population) with random solutions to provide some reasonable starting point for the algorithm execution. It is very important to note that natural computation algorithms, as they are metaheuristics, do not guarantee finding optimal solution. Although, given enough population size and generation number, they usually lead to the suboptimal solutions which are suitable enough for the most of applications.

Two algorithms for the evaluation and application were chosen in the described research: the Flower Pollination Algorithm (FPA) and the Krill Herd Algorithm (KHA).

*1) Flower Pollination Algorithm:* The first one has been proposed by Xin-She Yang of Department of Engineering, University of Cambridge in the paper [5] with further description in the paper [6]. It belongs to the class of evolutionary algorithms and it reflects the process of reproduction of flowering plants by the pollination. It is performed by pollinators, such as insects, birds or bats (biotic pollination) or by the wind or water (abiotic pollination). Pollination can take the form of a cross-pollination, in which a flower is pollinated with pollens coming from flowers of different plant, or a self-pollination, in which flowers on the same plant pollinate each other. Some pollinators stick to some species and specialize in pollinating them. This phenomenon is called flower constancy. Author highlighted four abstractions which make up the basis of the FPA:

- global pollination is an abstraction of biotic cross-pollination, pollinators move by performing Lévy flights;
- local pollination is an abstraction of abiotic self-pollination;
- flower constancy is expressed by the fact that reproduction probability increases appropriately to similarity of the two involved flowers;
- probability of occurrence of local and global pollination is defined by the switch probability p, which abstracts external factors, such as wind, physical proximity of different plants and so on.

There are some additional assumptions and rules as well:

- the best solution from the generation $g_i$ passes directly to the next generation $g_{i+1}$;

**Algorithm 1** FPA pseudocode

```
Objective min or max $f(X), X = (X_1, X_2, ..., X_d)$
Initialize a population of $n$ flowers/pollen gametes with random values
Find the best solution $g_*$ in the initial population
Define a switch probability $p \in [0, 1]$
while $t < MaxGeneration$ do
  for $i = 1..n$ do
    if $rand < p$ then
      Draw a ($d$-dimensional) step vector $L$ which obeys a Lévy distribution
      Global pollination via $X_i^{t+1} = X_i^t + L(X_i^t - g_*)$
    else
      Draw $\epsilon$ from an uniform distribution in $[0, 1]$
      Randomly choose $j$ and $k$ among all the solutions
      Local pollination via $X_i^{t+1} = X_i^t + \epsilon(X_j^t - X_k^t)$
    end if
    Evaluate new solution
    If the new solution is better, update it in population
  end for
  Find the current best solution $g_*$
end while
```

- with global pollination, candidate solutions tend to the current most fit individual;
- a random value determining pollination type is obtained for every flower in every iteration;
- newly generated solution passes to the next generation if, and only if, it is better fitted than its predecessor.

Assuming that the current best solution is represented by $g_*$, generating solution $x_i$ in step $t + 1$ in global pollination is performed by the following formula:

$$X_i^{t+1} = X_i^t + L(X_i^t - g_*) \tag{1}$$

where $L > 0$ is acquired from the Lévy distribution. A local pollination version is in turn expressed by the formula:

$$X_i^{t+1} = X_i^t + \epsilon(X_j^t - X_k^t) \tag{2}$$

where $\epsilon$ is a value obtained from the regular uniform distribution.

The FPA has been benchmarked with some typical two dimensional functions enumerated in the original FPA article, as well as custom function created especially for the sake of research. Tests were performed on the implementation created in the SciPy environment using a small custom test framework. Tunable parameters of the algorithm were changed between specific test runs, which led to the following conclusions:

- finding a solution for the unimodal problem requires much less effort (in terms of generation number and population size) than for the multimodal problem;
- probability switch parameter p does not matter significantly in unimodal problems;
- given enough iterations, every other parameter also does not really matter in unimodal problem solving;

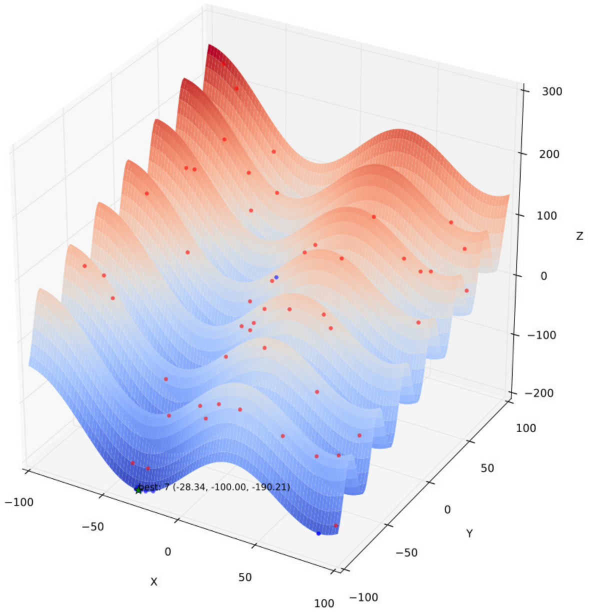

Fig. 1. Results of the application of FPA to the custom benchmark two-dimensional function.

- for multimodal problems, increasing population size gave significantly less improvement than increasing iteration number;
- in extreme cases, during the few first generations there was no improvement in comparison to the initial random population (!);
- high values of the pollination switch parameter p decreased effectiveness by sticking the computation to local minimum values in a multimodal problems.

Figure 1 presents a plot of the custom two dimensional benchmark function. Its objective function is the minimum in the domain of $[-100, 100]$ in both dimensions.

$$\begin{aligned} f(x) \quad &= \quad \left(\left(\frac{x_i}{20}\right)^2 - 2\right)\left(\frac{x_i}{20}+2\right) - \ 2 \\ &+ 50\sin\left(\frac{x_i}{40}\right) + 10\sin\left(\frac{\left(\frac{x_i}{20}\right)^2}{2}\right) \qquad (3) \end{aligned}$$

Red dots are individuals of the initial flower population, while blue dots are individuals of the population in the last generation. Green stars mark the most fit flower in the last generation along with its coordinates.

*2) Krill Herd Algorithm:* The Krill Herd Algorithm represents a slightly different category of metaheuristic nature-inspired algorithms from the FPA. It is a swarm intelligence algorithm. Originally proposed by Amir Hossein Gandomi and Amir Hossein Alavi in the paper [4], it mimics the behaviour of the individual krill specimens moving together as a herd. Such herds, or swarms, move accordingly to environmental factors, but every krill moves separately. An individual's movement is determined by three factors:

- the movement vector of the whole swarm (neighbours within the swarm);
- food foraging;
- additional random bias (diffusion).

After removal of an individual krill (caused by predator attack) from a herd, krills tend to “fix” the low-density gap while still being oriented on finding food. From this emerges a multiobjective optimization problem. Overall, generalized n-dimensional formula for difference of krill position in subsequent time units goes as follows:

$$\frac{dX_i}{dt} \quad = \quad N_i + F_i + D_i \qquad (4)$$

Enumerated aspects of individual krill moves can be described by a set of equations:

- $N_i$ - motion induced by neighbours:

$$N_i^{new} \quad = \quad N^{max}\alpha_i + \omega_n N_i^{old} \qquad (5)$$

where $N^{max}$ is the maximum possible speed that can be induced, $\omega_n$ in the range $[0, 1]$ is the inertia weight of an individual krill. $N_i^{old}$ is the motion induced in the previous turn and

$$\alpha_i \quad = \quad \alpha_i^{local} + \alpha_i^{target} \qquad (6)$$

$\alpha_i^{local}$ is the local influence of the neighbours on an individual krill, while $\alpha_i^{target}$ is the target direction. Target is determined by the position and movement of the best individual in a swarm.

$$\alpha_i^{local} \quad = \quad \sum_{j=1}^{NN} \hat{K}_{ij}\hat{X}_{ij} \qquad (7)$$

$$\hat{X}_{ij} \quad = \quad \frac{X_j - X_i}{\|X_j - X_i\| + \epsilon} \qquad (8)$$

$$\hat{K}_{ij} \quad = \quad \frac{K_i - K_j}{K^{worst} - K^{best}} \qquad (9)$$

where $K$ in general is a fitness value of a given krill, so $K^{worst}$ and $K^{best}$ are the worst and the best fitness degrees achieved so far by any individuals. $NN$ is a number of reachable krill neighbours and $\epsilon$ is an immaterial positive number introduced to avoid singularities in the formula.

The $NN$ value depends on a stated sensing scope of krill individuals. It can be defined in a static way, e.g. individuals always take into consideration a constant number of closest krills, regardless of their distance. The other way is to determine neighbour sets using the heuristic in every iteration:

$$d_{s,i} \quad = \quad \frac{1}{5N}\sum_{j=1}^{N} \|X_i - X_j\| \qquad (10)$$

Every krill individual has its target vector defined as follows:

$$\alpha_i^{target} \quad = \quad C^{best}\hat{K}_{i,best}\hat{X}_{i,best} \qquad (11)$$

where

$$C^{best} = 2\Big(rand + \frac{I}{I_{max}}\Big) \tag{12}$$

$I$, $I_{max}$ is the current iteration number and a maximum number of iterations. $rand$ is a random value between 0 and 1.

- $F_i$ - food foraging:

$$F_i = V_f \beta_i + \omega_f F_i^{old} \tag{13}$$

where $V_f$ is the food foraging speed and $\omega_f$, as previously, is the inertia of the movement. Food fitness of the individual is defined as follows:

$$\beta_i = \beta_i^{food} + \beta_i^{best} \tag{14}$$

And food attraction for the krill individual is:

$$\beta_i^{food} = C^{food} \hat{K}_{i,food} \hat{X}_{i,food} \tag{15}$$

The food coefficient, expressing global attraction of the food center, is:

$$C^{food} = 2\Big(1 - \frac{I}{I_{max}}\Big) \tag{16}$$

$$\beta_i^{best} = \hat{K}_{i,best} \hat{X}_{i,best} \tag{17}$$

where $K_{i,best}$ is the best fit achieved by given krill individual so far.

- $D_i$ - random physical diffusion. In the simplest case it can be fully random. A general rule concerning the diffusion states that the better the krill's position is, the less its random motion diffusion is. The following formula defines a diffusion on the basis of that rule and the assumption that krills' positions improve by the time:

$$D_i = D^{max}\Big(1 - \frac{I}{I_{max}}\Big)\delta \tag{18}$$

where $D^{max}$ is the maximum possible diffusion, $\delta$ is the random directional vector.

The distinctive feature of the KH algorithm is a implementation of two basic evolutionary operators, crossover and mutation, despite it is not really an evolutionary algorithm. The crossover operator is inspired by the genetic algorithms. Its result is an individual with some features of both "parents". Mutation, in turn, is a random change in an individual's features. Paper [7] contains a description of the process of incorporating mutation scheme into the KH algorithm. A stop condition for the algorithm could be a time limit, reaching a desired fitness level or the combination of these two. High level pseudocode of the KHA is presented as the Algorithm 2. Applications and studies on parameters tuning of the KHA have been described in publications: [8], [9], [10] and [11]. Papers [12] and [13] contain other proposed modification of the algorithm.

**Algorithm 2** High-level KHA pseudocode

```
Define and populate algorithm's data structures
Initialize random initial population
while stop condition is reached do
    Evaluate fitness of each krill individual on the basis of its position
    Calculate motion of each krill individual
    Perform genetic operations
    Update each krill position in the search space according to calculated motion and eventual genetic operations results
end while
```

## II. CODB - PROTOTYPE IMPLEMENTATION OF A COLUMN-ORIENTED DB

One of the main goals of the research is the implementation of a column-oriented database management system (the term CODB will be used). A typical contemporary Java SE development stack has been chosen as an implementation environment. It consists of the standard Java Development Kit 8 along with supplementary libraries Google Guava (general purpose library), Logback (logging facility), jUnit (unit testing framework) and Mockito (mocking facility for unit tests). This implementation is used as a foundation for the further research.

Implementation objectives were stated as follows:

- possibility to be used as embedded database in Java and other JVM-based programming languages, but enabling future use with custom connectivity protocol and drivers for other languages, as well as a REST service;
- usage of the memory-mapped data files, thus requiring 64-bit OS for sufficient performance;
- UUID v1 as an objects' identifiers;
- custom binary storage file structure (please see the description below);
- all values stored as an UTF-8 encoded strings;
- full in-memory indexing;
- static storage garbage collection;
- full unit test coverage of logic and storage code (except so called boilerplate code, such as field accessor methods);
- lack of any access rights/database user management facility;
- object-oriented API;
- partitioning and/or sharding support.

### A. Storage structure

The CODB supports one keyspace in one running instance, i.e. one instance serves for only one keyspace. Keyspace is simply a directory in the operating system's file system tree. It does not have any metadata except a name. The keyspace directory contains subdirectories representing column families.

The column family directory contains binary column datafiles, one file per one column. Binary data files contain a sequence of value entries. Every value entry consists of the actual UTF-8 encoded value, a set of UUIDs of records which contains a given value and length values necessary to calculate offsets. UUIDs are stored as a pair of long (64-bit) values. Every length value is just a long 64-bit value. Please note that every specific value is stored only once, notwithstanding the number of records which contain it. Table I shows a structure of a single entry in the column datafile.

The current implementation offers full in-memory indexing. A full datafiles scan is performed during startup in order to build the indices. Planned materialized indices or eventual column metadata would be stored in the same directory as the data. The indexing facility in the CODB engine has two aspects:

- indexing physical location (offset) of column values in the datafile;
- indexing offset of spare space fragments in the datafile (see description below).

Because of performance reasons record entries (that is pairs (value, UUID)) are not actually updated, but removed and created again with new values. When a value which belongs to a given record is changed, the record's identifier is removed from the UUID set assigned to the previous value and will be added into UUID set of a new value. If there is no entry of a new value, it is appended at the end of the datafile. If the identifier set of the new value does not have enough space to be extended directly in its place, it is removed from its current place and appended at the end of the datafile. When a value is removed from the last record which possessed it, the record's identifier is removed from the set but the value remains in the datafile. That feature raises a need of some garbage collecting mechanism. A prototype implementation offers a static garbage collection facility, that is a separate application which is intended to be run when the actual DBMS engine is not running. The garbage collector performs a full data scan to build the full index and then squashes the datafile by placing values one directly after another and throwing out the values without any corresponding records. That way, spacings introduced while updating values, as well as unused value entries, are removed from the datafiles.

## III. Mathematical model of a column-oriented DB and application

In order to apply selected natural computation algorithms to the CODB project, one needs to translate fundamental concepts of the domain into the mathematical model which reflects the nature domain. Correct translation between these three fundamentally different worlds is the key to obtaining satisfying results. Natural computation algorithms are a general heuristic mean of optimization problem solving. They are not tailored to any particular problem domain, but the problem itself should provide a mathematical model instead. Such models consist of a few basic components:

- objective function;
- input as a scalar or vector value or n-dimensional matrix;
- output as a scalar or vector value or n-dimensional matrix.

The objective function for the considered problem must take several criteria into consideration when calculating the score for the candidate partitioning solution, these include:

- partitioning scheme application cost, that is cost of moving data back and forth between database engine instances;
- estimated cost of the data division introduced by the selected partitioning scheme.

Input for the objective function is a candidate solution. Its output is the fitness degree, a value which determines a given candidate's quality. Enumerated objectives can be formulated on the basis of a query log and other data usage statistics, which must be analysed for mutual co-appearance of different data parts. The superior goal here is placing data which often occur together in the same instance.

The input of the algorithm should consider at least the following aspects:

- relationship between different data parts;
- current state of the database;
- cost of moving the data item between instances (usually size).

For every application, such a list can differ fundamentally, but probably always it will be an n-dimensional matrix, in which one of the dimensions will represent all records currently stored in the considered database.

The output of the algorithm is the most fit model of partitioning the database. In the simplest, non-optimized case, it will be at least a 2-dimensional matrix, in which one dimension covers all the records.

## IV. Summary

This paper summarises the overall perspective on the research about horizontal scalability of column-oriented databases with use of natural computing algorithms. The research has already brought some encouraging results. Currently, the biggest challenge is the creation of an appropriate objective function reflecting all the necessary aspects of distributed database operation. Correct mapping of the problem from the database domain to the mathematical model also is crucial for the effectiveness of the proposed solution. The primary goal at the current stage is careful creation of the model and elaboration of the database usage log analysis methods. Another important objective is inspection of the FPA and KHA algorithms' features and properties in details. Creation of the fully featured column oriented database management system in Java, intended as a foundation of solution application is yet another goal, although it goes beyond the scope of the research.

***Abstract*— The paper deals with the problem of improving speech recognition by combining outputs of several different recognizers. We are presenting our results obtained by experimenting with different classification methods which are suitable to combine outputs of different speech recognizers. Methods which were evaluated are: k-Nearest neighbors (KNN), Linear Discriminant Analysis (LDA), Quadratic Discriminant Analysis (QDA), Logistic Regression (LR) and maximum likelihood (ML). Results showed, that highest accuracy (98.16 %) was obtained when k-Nearest neighbors method was used with 15 nearest neighbors. In this case accuracy was increased by 7.78 % compared with best single recognizer result. In our experiments we tried to combine one native (Lithuanian language) and few foreign speech recognizers: Russian, English and two German recognizers. For the adaptation of foreign language speech recognizers we used text transcribing method which is based on formal rules. Our experiments proved, that recognition accuracy improves when few speech recognizers are combined.**

## I. Introduction

Speech recognition applications could be subdivided into two broad classes: the applications using large vocabulary continuous speech recognition and applications using the recognition of voice commands from a predefined set of voice commands. It may seem that the first type of applications has the wider area of possible applications. But it is more complicated task to ensure the necessary recognition accuracy when using large vocabulary continuous speech recognition. At the same time there are a lot of potential applications when high accuracy of voice commands from a predefined set of allowable voice commands (may be even very big set of voice commands) is enough to achieve users satisfaction. The area of similar applications is big and such applications could be developed more rapidly than applications based on continuous speech recognition. The areas of voice commands based applications could be transport, logistic, medical and other information systems, various personal assistants, etc. It should be noted that for widely used languages (English, Spanish, German, etc.) voice recognition based applications became everyday reality and could be found in a various situations and areas. Among the well known examples we can mention set of tools distributed by Google or Nuance.

The development of large vocabulary speech recognition systems requires enormous resources: both material and human resources. It is difficult to find such resources in the countries where relatively not widely spoken languages are used as a primary mean of communication. This could be illustrated by the fact, that companies such as Microsoft, Apple, Nuance aren't particularly interested in developing Lithuanian speech recognition systems, because Lithuanian language is not so widely used as some others and don't have significant market potential. Among the possible solutions for the problem might be to try to create own speech recognition engine, or to adapt the ones created for other languages. The proprietary recognizer has bigger potential and is more flexible solution, but this is also the more costly solution. At the same time it has been shown that proper adaptation of existing foreign language acoustic models could speed up the development of recognizer and lead to the acceptable recognition level in that language [1]–[4], [6], [7]. Some previous studies have shown that speech recognition systems of languages such as English, Spanish or Russian can be quite well adapted for Lithuanian speech recognition [1], [3], [4]. However, the recognition results are not always as good as necessary and depend on many factors. So, it is natural to try to create hybrid systems, which are based on combination of different speech recognition systems and consequently try to achieve better recognition accuracy. The essence of hybrid recognition is a parallel use of several different recognizers with the hope, that at least one of the recognizers will give the correct result and it will be possible to detect the correct answer [4]. Hybrid approach is one of the ways to achieve higher recognition accuracy in speech recognition systems. This implies combination of hypotheses provided by different recognition engines in order to get higher recognition accuracy.

The idea of creating hybrid speech recognizer and adapting other languages acoustic models is not new. These kinds of researches are especially important for all under resourced languages. There were successful attempts to estimate acoustic models for new target language using speech data from varied source languages, but only limited data from the target language [10]. Also, Google researchers show very promising results in transformation of English to other languages such as Lithuanian, French and so on. What is more, researchers are experimenting with different acoustic models adaptation methods in order to maximize the recognition performance with small amount of non-native data available [11]. Statistical algorithms for combining different acoustic models are used quite often and produces promising results [1], [3], [4], [6], [11], [12]. These researches shows, that in many cases it is possible to achieve high enough recognition accuracy by using hybrid systems with adapted acoustic models.

The paper presents our activities to adapt several foreign

978-83-60810-66-8/$25.00©2015, IEEE

language (English, German, Russian) speech recognizers for the recognition of limited Lithuanian vocabulary and evaluate some methods (k-Nearest neighbors, Linear Discriminant Analysis, Quadratic discriminant Analysis, Logistic Regression, and maximum likelihood), used for different speech recognizers combination.

Further paper is organized as follows. In Chapters I and III we are presenting method and tools used for adaptation of foreign language recognizers. In Chapter IV there is presented prototype system used in experimental evaluation experiments. Chapter V briefly summarizes the speech corpus used in recognition experiments. Finally in Chapter VI there are presented and discussed the results of experiments. In Chapter VII several conclusions are presented and discussed.

## II. Foreign Language Recognizers Adaptation

For the evaluation purposes we decided to use one native[1] (Lithuanian) and several foreign language recognizers. Among foreign language recognizers we used Russian[2], English[3] and two German[4] language open source speech recognizers. The adaptation procedure will be described as follows. First of all foreign speech recognizers were adapted to recognize Lithuanian commands. Adaptation was done by using formal rules method [5]. All Lithuanian commands, that were collected in this corpus, where transcribed by using foreign language phonemes. By using formal rules method a set of transcription rules were created. The structure of rules was as follows: left context; current letter; right context and list of phonetic units. This list represents foreign language sound that best matches current letter with left and right contexts. If left or right context of the rule can be any, then symbol '*' was used. In this way the new written form of Lithuanian voice command was obtained. Some of the transcribing rules are listed in Table I.

Table I.
Some examples of transcribing rules

## III. Methods Used For Evaluation

We proposed a method to combine different speech recognition engines by using neural networks algorithms [4]. Results in earlier studies showed, that this method increased speech recognition accuracy by almost 5% compared with the best results of single recognizer. As the next step we decided to evaluate other methods and to see how efficient they could be for combining different speech recognizers. We selected five methods which we think are quite good for this task: k-Nearest neighbors (KNN), Linear Discriminant Analysis (LDA), Quadratic Discriminant Analysis (QDA), Logistic Regression (LR) and maximum likelihood (ML). These methods were selected because of their efficiency and well studied properties.

## IV. Hybrid Speech Recognition Prototype

For evaluation of the selected methods hybrid speech recognition system prototype was developed. Python programming language was used for its development. Block diagram of such system is showed in Fig. 1.

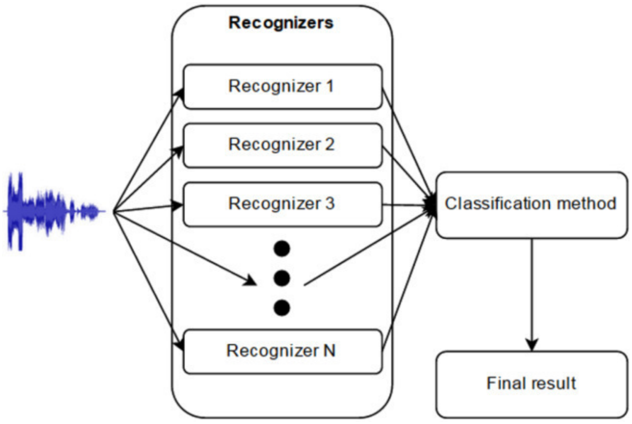

Fig. 1. Block diagram of hybrid speech recognition system.

As could be seen in the prototype, voice command is passed to all speech recognizers in parallel. After that, all recognizers produces output. Output of the recognizer is the hypothesis: score of how well audio signal matches the acoustic model [8]. This hypothesis score is passed to classification algorithm and it makes final decision.

To develop speech recognizers, PocketSphinx toolkit was used. PocketSphinx is a lightweight speech recognition engine, specifically tuned for handheld and mobile devices, though it works equally well on the desktop computers and notebooks. It is distributed under the same permissive license as Sphinx toolkit itself. Algorithmically this is hidden Markov model based speech recognition framework, which provides simple way for creating custom speech recognition systems [8].

For the quicker classification methods realization, we used scikit-learn library [9]. Scikit-learn is an open source machine learning library for the Python programming language. It realizes various classifications, regression and clustering algorithms including support vector machines, logistic regression, naive Bayes, random forests, gradient boosting, k-means and is designed to interoperate with the Python numerical and scientific libraries NumPy and SciPy [9].

## V. Speech Corpus

A speech corpus of 25 drug names and 25 names of dis-

| PREDUKTALIS | ANTRINĖ GLAUKOMA | DANTŲ VYSTYMOSI SUTRIKIMAI |
| PROPODEZAS | APELSINO ŽIEVELĖ | |

Speech corpus, used in the experiments, was gathered by recording speech of 12 people (5 female and 7 male). Each of these speakers pronounced each command name 20 times at sampling rate 16 kHz in a single session. So, every command was pronounced for 240 times. Vocabulary of all commands used in this experiment is listed in Table II.

It should be noted, that the corpus, used in these experiments, is the part of the bigger medical terms Lithuanian speech corpus. The selection of this particular set of voice commands was based on the fact, that 25 commands were those voice commands, which resulted in the highest number of recognition errors using proprietary Lithuanian speech recognizer, while the additional 25 commands were selected randomly.

## VI. EXPERIMENTAL EVALUATION OF DIFFERENT SPEECH RECOGNIZERS COMBINATION METHODS

For the evaluation of methods, we used the developed prototype and described speech corpus. All acoustic models used in the recognition experiments were derived without the use of the speech corpus presented in Chapter V. So the recognition experiments were performed in speaker independent mode. Default PocketSphinx configuration was used for evaluation.

First of all, single recognizers were tested using obtained recordings. Recognition results are shown in Table III.

TABLE III.
SINGLE RECOGNIZERS ACCURACY

| Recognizers | Accuracy, % |
|---|---|
| Lithuanian | 89.26 |
| Russian | 81.32 |
| English (voxforge) | 88.30 |
| German | 81.38 |
| German (voxforge) | 90.38 |

Best results were obtained using German recognizer from voxforge repository. Other recognizers, such as Lithuanian and English (voxforge), showed similar recognition accuracy too. Accuracy of other recognizers was above 80 %, but lower than above mentioned recognizers.

Before the experiments, we thought that Russian recognizer will be one of the best, because Russian language and Lithuanian language have a lot similar sounds, but as results shows, our guess failed.

Later all the selected speech recognizers combination methods were trained using obtained recordings. 168 recordings were used for training and 72 recordings for testing. After training, selected methods accuracy was evaluated. The obtained results are presented in the Table IV.

TABLE IV.
ACCURACY OF COMBINED SPEECH RECOGNIZERS

| Combination method | Accuracy, % |
|---|---|
| k-Nearest neighbors (11) | 89.70 |
| k-Nearest neighbors (15) | 98.16 |
| k-Nearest neighbors (21) | 89.70 |
| Linear Discriminant Analysis | 93.16 |
| Quadratic Discriminant Analysis | 98.05 |
| Logistic Regression | 93.60 |
| Maximum likelihood | 89.70 |

Results shows, that three methods (k-Nearest neighbors (11), k-Nearest neighbors (21) and maximum likelihood) can't be used for speech recognition engine combination, because obtained accuracy is lower than best single recognizer. Other methods are suitable for speech recognizers combination. Best results (98.16 %) were acquired, when k-Nearest neighbors (15) method was used. It is very interesting, that such a simple classifier as k-Nearest neighbors generated the best results. We think that it is because of data used to evaluate selected classification methods. As we know, k-Nearest neighbors classifier requires a small amount of training data to estimate the necessary parameters. We are planning to increase number of data used for classification methods evaluation and repeat experiments to see if our guess is right. Detailed commands recognition accuracy is displayed in Table V (results were rounded to fine integer values).

TABLE V.
RECOGNITION ACCURACY % OF EVERY COMMAND

| Command | k-Nearest neighbors (11) | k-Nearest neighbors (15) | k-Nearest neighbors (21) | Linear Discriminant Analysis | Quadratic Discriminant Analysis | Logistic Regression | Max hypothesis |
|---|---|---|---|---|---|---|---|
| ANALGINAS | 69 | 86 | 69 | 78 | 82 | 79 | 69 |
| BIFOVALIS | 85 | 99 | 85 | 96 | 99 | 96 | 85 |
| CYKLODOLIS | 97 | 100 | 97 | 99 | 100 | 99 | 97 |

We calculated average accuracy of every command and results showed, that almost 58 % of all commands are recognized with 95 – 100 % accuracy, 22 % with 90 – 95 % accuracy, 14 % with 80 – 90 % accuracy and 6 % of all commands are recognized with 40 – 80 % accuracy.

## VII. CONCLUSIONS

The results of our experiments showed, that it could be reasonable to use k-Nearest neighbors (15) or Quadratic Discriminant Analysis methods to combine different speech recognizers using open source PocketSphynx based recognizers. Comparing with the best single recognizer and the best combined speech recognizers, average error was decreased by 7.78 %. In some cases, even bigger increase of recognition accuracy has been observed.

Foreign language speech recognition adaptation shows, that English, German, Russian recognizers could be quite good adapted for Lithuanian voice commands recognition.

One of the interesting areas for further research could be investigation of how different acoustic models from different language could be used to recognize the same Lithuanian voice command.

In the future, we are planning to increase recognition accuracy by finding better transcriptions to recognize Lithuanian commands using foreign languages speech engines. Also, it is necessary to increase size of the vocabulary used in the experiments. Especially important is to increase the variety of the phonetic elements used in the adaptation process.

# Applying fuzzy clustering method to color image segmentation

Omer Sakarya
University of Gdańsk
Institute of Informatics
osakarya@inf.ug.edu.pl

***Abstract*—The goal of this paper was to apply fuzzy clustering algorithm known as Fuzzy C-Means to color image segmentation, which is an important problem in pattern recognition and computer vision. For computational experiments, serial and parallel versions were implemented. Both were tested using various parameters and random number generator seeds. Various distance measures were used: Euclidean, Manhattan metrics and two versions of Gower coefficient similarity measure. The $F$ and $Q$ segmentation evaluation measures and output images were used to assess the result of color segmentation. Serial and parallel run times were compared.**

## I. Introduction

COLOR image segmentation is a method of assigning pixels of given image to segments which share similar color. Pixels from a segment should be similar colorwise and pixels from different segments should be distinct. The problem of color image segmentation is one of the most difficult problems in computer vision. There exist many algorithms for this particular problem, however none of them work well for all kinds of images. Photos of real world are very different in colors, shapes and noise. Usually before choosing an algorithm for color image segmentation, domain knowledge is used to assess the type of algorithm needed for particular set of photos. The goal of color image segmentation research is to find an universal algorithm that would not require domain knowledge prior use and would provide good results for all kinds of photos. Color image segmentation is an important part of various computer vision problems, including pattern recognition. It is a step performed before pattern recognition, so if the color segmentation is poor, the pattern recognition step may fail. The aim of this paper was to apply fuzzy clustering algorithm known as Fuzzy C-Means to color image segmentation with intention of developing a general method for various types of images.

The paper is organized as follows. Section II introduces color image segmentation problem. In section III distance measures and fuzzy clustering method are described. In section IV the implementation details are presented. Section V presents a possible way of source code parallelization for speed-up. Section VI overviews the computational experiments and achieved results. The last section contains conclusions and plans for further research.

## II. Color image segmentation

Formally image segmentation can be defined as follows [1]: If $P()$ is a homogeneity predicate defined on groups of connected pixels, then segmentation is a partition of the set $F$ into connected subsets or regions $(S_1, S_2, \ldots, S_n)$ such that:

$$\bigcup_{i=1}^{n} S_i = F \wedge \forall_{i \neq j} S_i \cap S_j = \phi \wedge \forall_i P(S_i) = true \wedge \forall_{i \neq j} P(S_i \cup S_j) = false \tag{1}$$

The two most important problems in color image segmentation is choosing the proper algorithm for given type of images and choosing the right colorspace. There are various color representations used in color image segmentation, however none of them is perfect for all kinds of images [1]. In computational experiments the RGB color space was used (see section IV).

## III. Fuzzy clustering

In data clustering, elements from data set are divided into clusters where elements in the same cluster are similar and elements from different clusters are not. There are many similarity and distance measures $dist(x, y)$ that can be used in combination with a clustering algorithm. Example distance measures are Euclidean (2) and Manhattan (3) metrics:

$$d_e(x, y) = \sqrt{(y_1 - x_1)^2 + \ldots + (y_n - x_n)^2} \tag{2}$$

$$d_m(x, y) = \sum_{k=1}^{n} |x_k - y_k| \tag{3}$$

Fuzzy clustering is one of the possible approaches to clustering. As opposed to hard clustering where data element $x$ belongs exclusively to one cluster, in fuzzy clustering element $x$ belongs to every cluster to some degree.

Fuzzy C-Means (FCM) is one of the fuzzy clustering algorithms that can be used for color image segmentation. It is an iterative algorithm that can make use of various similarity and distance measures. The FCM algorithm assigns membership values to each data element, which are inversely related to the relative distance of an element to the centroids. In FCM, the closeness of each data $x_k$ to the center of a cluster $v_i$ (centroid) is defined as the membership $(u_{ik})$ of $x_k$ to the $i$-th cluster of data set minimizing the following objective function [2]:

$$J_m(U, V) = \sum_{i=1}^{c} \sum_{k=1}^{n} u_{ik}^{m} dist(x_k, v_i)^2 \tag{4}$$

where $X = \{x_1, \ldots, x_N\}$ a given set of unlabeled $N$ data; $V = \{v_1, \ldots, v_c\}$ are the cluster centers and $m = [1, \infty]$

978-83-60810-66-8/$25.00©2015, IEEE

is the weighting exponent which determines the fuzziness of the resulting clusters, $U = [u_{ik}]$ matrix $c$ x $n$, where $u_{ik}$ is membership of $x_k$ to the $i$-th cluster $\sum_{i=1}^{c} u_{ik} = 1, \forall k = 1, 2, \ldots, n$. The cluster centers and the memberships are computed as:

$$v_i = \frac{\sum_{k=1}^{n} u_{ik}^{m} x_k}{\sum_{k=1}^{n} u_{ik}^{m}} \tag{5}$$

$$u_{ik} = 1/\sum_{j=1}^{c} \left( \frac{dist(x_k, v_i)}{dist(x_k, v_j)} \right)^{2/(m-1)} \tag{6}$$

Algorithm 1 presents the Fuzzy C-Means method. The $initU$ function randomly initializes the membership matrix $U$ and the parameter $maxItNum$ specifies the maximum number of iterations of the algorithm. $U'$ stores the previous values of $U$ and is used in line 8 to check if the solution found so far has converged according to some $\varepsilon$ and the algorithm should stop, $dist()$ is one of the distance measures. As a result of the algorithm membership matrix $U$ and centroids $V$ are computed. In (6) it is possible that the denominator will be equal to 0, such situation should be considered in computer implementation of the algorithm to avoid errors.

**Algorithm 1** Fuzzy C-Means

```
Require: $X$ - data set, $c$ - number of clusters, $dist$ - distance
    measure, $maxItNum$ - maximum number of iterations
Ensure: $U$ - membership matrix, $V$ - centroids
 1: $U \Leftarrow initU$
 2: $i \Leftarrow 0$
 3: while $i < maxItNum$ do
 4:   compute new centroids $V$ using (5)
 5:   $U' \Leftarrow U$
 6:   compute new membership matrix $U$ using (6) and $dist$
 7:   $i \Leftarrow i + 1$
 8:   if $max|U - U'| < \varepsilon$ then
 9:     break
10:   end if
11: end while
```

## IV. Applying FCM to color image segmentation

Images in a computer are stored in various formats, however many of them use the RGB color space. This means that each pixel is represented by three numbers being the red, green and blue components. Such triples can be treated as vectors, which means that it is is possible to use the FCM algorithm to cluster such data. The advantage of using fuzzy clustering for color image segmentation is that as a result we obtain a membership matrix which may be used to generate more than one segmented image. This can be achieved by choosing for each pixel which one of the membership values we want to use as the one defining the final color of a pixel in segmented image.

To perform the computational experiments for this paper the FCM algorithm was implemented in the C programming language on GNU/Linux operating system. The portable pixmap image format was used for simplicity, because it only contains a small header and the following values represent RGB triples. Binary method of randomly initializing the membership matrix $U$ was used, where each column has value $1$ in one of the rows, and the rest contains $0$. The output membership matrix $U$ and centroid values $V$ were used to generate the segmented image file. In $U$, the membership information defines to which segments to what degree given pixel belongs. The centroids $V$ contain colors of the segments. For each column of $U$ the maximum membership value was selected, then the index of this value was used to assign color from the set of centroids $V$ to a pixel. Algorithm 2 presents the segmentation method.

**Algorithm 2** Segmentation

```
Require: $pixels$ - array of RGB triples representing pixels
    of original image, $N$ - number of pixels, $c$ - number of
    clusters, $U$ - membership matrix, $V$ - centroids
Ensure: $pixels$ - segmented image
for $k \Leftarrow 1; k \leq N; k \Leftarrow k + 1$ do
  $m \Leftarrow 0$
  for $i \Leftarrow 1; i \leq c; i \Leftarrow i + 1$ do
    if $u_{ik} > u_{mk}$ then
      $m \Leftarrow i$
    end if
  end for
  $pixels_k \Leftarrow V_m$
end for
```

## V. Parallelizing source code using OpenMP

Serial source code was parallelized using OpenMP. Independent 'for loop' iterations were identified and OpenMP pragmas were used, which resulted in speed-up caused by parallel computation. This solution is automatically scalable, which means that when the same program is executed on a CPU with more computing cores, the program will use all of them automatically and execute faster. The experiments for this paper were performed on a laptop with Intel Core 2 Duo processor.

Although the main loop in FCM algorithm is not independent, it was possible to parallelize centroids vector $V$ and membership matrix $U$ computation in each iteration. Each centroid and membership can be computed independently from others, there is no data race condition. In the implementation, for research purposes, also the computation of $J_m$ objective function and square error criterion were parallelized. It is important to note that there was no need to modify the algorithm, only the source code was parallelized using few OpenMP pragmas.

## VI. Results overview

Two versions of the program were used - serial and parallel. The difference between them was that the parallel version used OpenMP pragmas. Both versions were compiled from the same source code, where the serial version had disabled pragmas. The run time was measured for both programs executed with the same parameters, however it is the wall-clock time of the whole program, which not only computes the FCM function, but also reads, writes files and computes $J_m$, square error criterion and more. The programs would execute even faster if the additional operations and computations were removed. The time measurement is just a very general information of how OpenMP pragmas influenced the run time of a parallel program in comparison to serial program.

The experiment was performed using different parameters on the same image (photo), it was 402 pixels wide and 600 pixels high. Parameters that could be specified for the program were: photo file, number of clusters, maximum iterations number, distance measure and random number generator seed. The available distance measures were Euclidean, Manhattan metrics and two versions of Gower coefficient [3] - regular (7,9) and modified (8,9). The modified version that takes specifics of RGB vector data into account was prepared for experiments in this paper.

$$S_i(x_i, y_i) = \begin{cases} 1, & \text{if } x_i = y_i \\ 0, & \text{if } x_i \neq y_i \end{cases} \tag{7}$$

$$S_i(x_i, y_i) = \begin{cases} 1, & \text{if } x_i \in [y_i - C, y_i + C] \\ 0, & \text{if } x_i \notin [y_i - C, y_i + C] \end{cases} \tag{8}$$

$$S(x, y) = \sum_{i=1}^{n} \frac{\omega_i S_i(x_i, y_i)}{n} \tag{9}$$

Since Gower coefficient is a similarity measure, it was converted to distance measure as follows: $dist(x, y) = 1 - S(x, y)$. $C$ is some constant and $\omega$ is weight applied to similarity of the $i$-th element of data vector. For experiments, the value of $\omega$ was set to 1, which means that each color component of pixel RGB vector was equally important and various values of $C$ were tested. No satisfactory results were achieved with regular and modified Gower coefficient. The final segmented image had only one, sometimes few segments with colors not similar to colors found in original photo (see table VII). Specifying random number generator seed allowed to test both programs with the same pseudo random numbers. For each parameter setting and different seed the programs were executed 10 times.

As suggested in [4] two evaluation measures $F$ and $Q$ were used (10,11) to assess the quality of result color image segmentation. Both measures do not require any parameter or threshold value and can be used for automatic evaluation, however it is important to remember that they should not be treated as definitive evaluation of final segmented image.

$$F(I) = \frac{1}{1000 \times N} \sqrt{r} \sum_{i=1}^{r} \frac{e_i^2}{\sqrt{A_i}} \tag{10}$$

$$Q(I) = \frac{1}{1000 \times N} \sqrt{r} \times \sum_{i=1}^{r} \left[ \frac{e_i^2}{1 + \log A_i} + \left( \frac{r(A_i)}{A_i} \right)^2 \right] \tag{11}$$

$I$ is the segmented image, $N$ the image size (number of pixels), $r$ the number of regions of the segmented image, while $A_i$ and $e_i$ are, respectively, the area and the average color error of the $i$-th region; $e_i$ is defined as the sum of the Euclidean distances between RGB color vectors of the pixels of region $i$ and the color vector attributed to region $i$ in the segmented image. $r(A_i)$ represents the number of regions having an area equal to $A_i$. The smaller the $F$ and $Q$, the better the segmentation result should be. Equation (10) is composed of three terms: the first is a normalization factor that takes into account the size of the image, the second, $\sqrt{r}$, penalizes segmentations that form too many regions, the last term, the sum, penalizes segmentations having non-homogeneous regions. Since the average color error $e_i$ of the region is significantly higher for large regions than for small ones, $e_i$ has been scaled by the factor $\sqrt{A_i}$. In equation (11) the body of the sum is composed of two terms: the first is high only for non-homogeneous regions (typically, large ones), while the second term is high only for regions whose area $A_i$ is equal to the area of many other regions in the segmented image (typically, small ones) [4].

Number of result nonzero clusters was recorded, usually it was smaller than required through parameter $c$ number of clusters. The average, minimum and maximum values of $F$, $Q$, serial and parallel run times were computed. During the experiments, the value of $m$ was set to 2. Computational experiment results are presented in tables I-VI and the images are in tables VII and VIII.

## VII. Conclusions

While performing computational experiments the following observations were made.

- The final number of clusters was always smaller than required $c$
- Using OpenMP caused significant speed-up
- Euclidean and Manhattan metrics were used successfully
- In performed experiments, both regular and modified Gower coefficient similarity measures could not be used efficiently for color image segmentation

Table VIII illustrates the best and worst result color image segmentations according to $Q$ evaluation measure.

Plans for further research include applying various clustering algorithms to color image segmentation for example kernel methods and using different distance measures and color representations. The FCM algorithm may be sensitive to initial membership matrix $U$, so different initialization experiments could be performed. The source code, program output logs, input and output photos are available on-line [5].

***A problem of identification of faulty processors of a multiprocessor system is investigated. A method to reduce a pattern of a global syndrome for multiprocessor system which has a 4-cube topology, for the MM model, is presented. Results of the method for some topologies are also presented.***

## I. Introduction

In the paper a problem of identification of faulty processors of multiprocessor system is investigated. Identification of faulty processors is a problem which is analysed in many publications ([2]-[8],[12]-[15]). The process of identifying faulty processors in a system by analysing the outcomes of available inter-processor tests is the system level diagnosis. Faulty processors, beside fault-free processors, are involved in testing process. The basis of the system level diagnosis and original diagnostic model, namely the PMC model, were proposed by Preperata, Metze and Chien in [9]. An example of another diagnostic model is the MM model (comparison-base diagnosis model) [3], [2], [8]. PMC model and MM model assume that communication links between the processors are reliable (useable). In PMC model all tests are performed between two adjacent processors, and it was assumed that a test result is reliable (respectively, unreliable) if the processor that initiates the test is fault-free (respectively, faulty). In the MM model, the same job is assigned to a pair of processors of the network and their outputs are compared by a central observer. This central observer performs diagnosis using the outcomes of these comparisons. The comparison-based diagnosis model was extended [2] to allow comparisons carried out by processors themselves. In [7] authors proposed that comparisons have no central observer involved. The diagnosability of hypercube under the comparison-based diagnosis model were presented (i.a.) in [9].

A multiprocessor network (system), presented in the paper, belongs to class of the fault-tolerant system ([1]) and is mounted onto objects which are difficult to access. The network belongs to the class of self-diagnosable systems [7] as well. The multiprocessor system, in general, has a regular logical structure (e.g.: torus, hypercube) and is homogenous. A faulty processor in the system is not interchanged nor repaired. The faulty processor is removed from the logical structure of the network and access to it is blocked. If certain conditions are met the system with degraded structure continues to operate, and tasks of faulted processors are taken over by fault-free processors of the system (network) with degraded structure. The diagnosability of the network (system) is defined as the maximum number $t$ such that the network is self-diagnosable as long as the number of the faulty processors is not greater than $t$.

This paper focuses on selected issues connected with identifying of faulty processors of the 4-dimensional hypercube network and its node induced subgraphs ($H^4$ class for short) based on MM model and comparison diagnosis for such $t$-diagnosable system, where $1 \leq t \leq 2$. The rest of this paper is organised as follow. Section 2 gives some preliminaries; Section 3 focuses on a method of reduction of number of comparative trials. Section 4 concludes the paper.

## II. Preliminaries

The processors network topology is represented by an undirected graph $G = \langle V, E\rangle$, where each node $u \in V$ denotes a processor and each edge $(u, v) \in E$ denotes a two-way link between nodes $u$ and $v$. In the paper graph $G$ is a 4-dimensional hypercube (4-cube for short) or nodes-included subgraph of 4-cube. A 4-cube ($H^4$) is such undirected graph $G = \langle V, E\rangle$, $|V| = 2^4$, $|E| = 4{\cdot}2^{4-1}$. Each node $u \in V$ is assigned an unique 4-bit binary vector (a coordinate) and each edge $(u, v) \in E$ links only those nodes whose coordinates differ in exactly one bit position (the Hamming distance between coordinates of linked nodes is equal 1).

Comparison diagnosis is based on inference of a network state on the basis of a set of results of comparative trials. Three processors are involved in the comparative trial: comparator $c \in V$, and comparative pair: $\{p_1, p_2\} \in V$: $\{p_1, p_2\} \subset V(c)$ ($V(c)$ is a set of nodes adjacent to $c$). A comparator $c$ instructs adjacent nodes $p_1, p_2$ to perform the same task and then checks to see if test results are the same. A $\psi = (c; p_1, p_2)$ is named a comparative trial.

Fig. 1 A pattern of the global syndrome (b) for $H^2$ network (a)

Let $\Psi(H^4)$, $E(\psi)$, $K(\psi)$ and $P(\psi)$ denote respectively: a set of all possible comparative trials of $H^4$, a set of processors participating in the comparative trail $\psi$, a comparator of $\psi$, and a comparative pair of $\psi$.

A set $\Psi' \subseteq \Psi(H^4)$ is a comparative trial cover of set of processors if $P(\Psi') = V$. In other words a set $\Psi' \subseteq \Psi\ (H^4)$ is a comparative trial cover of set of processors if $\forall(e \in V)\ \exists(\psi \in \Psi')\ e \in P(\psi)$.

A diagnostic structure of $H^4$ based on comparative trails is such an ordered pair $\langle H^4, \Psi'\rangle$ $(\Psi' \subseteq \Psi(H^4))$, that a set $\Psi'$ is a comparative trials cover of set of processors of $H^4$.

Let $V^1$, $V^0$ and $d(\psi, V^1)$ denote respectively the set of faulty processors of the network, the set of fault-free processors of the network, and the result of comparative trial $\psi$ for set $V^1$, wherein $d(\psi, V^1) = 0$ denotes that test results of comparative trail for both processors are identical, and $d(\psi, V^1) = 1$ denotes that test results of comparative trail for both processors are different

The following rule of inference based on comparative trials is valid [2], [3].

$$[(K(\psi) \in V^0) \wedge (P(\psi) \cap V^1 = \emptyset)] \Rightarrow [d(\psi,V^1) = 0];$$
$$[(K(\psi) \in V^0) \wedge (P(\psi) \cap V^1 \neq \emptyset)] \Rightarrow [d(\psi,V^1) = 1]; \quad (1)$$
$$[(K(\psi) \in V^1)] \Rightarrow [d(\psi,V^1) = x;\ x \in \{0,1\}].$$

From formula 1 and Fig. 1 follows that if the network has faulty processors, then there exist several syndromes which faulty processors could produce. Let $\sigma(V^1)$ represents the set of syndromes which could be produced. Two distinct sets $V'$, $V'' \subset V$ are said to be indistinguishable if and only if $\sigma(V') \cap \sigma(V'') \neq \emptyset$; otherwise, $V'$, $V''$ are said to be distinguishable. Let $\sigma^*$ denotes a set of patterns of syndromes which faulty processors could produce, then from Fig.1 follows that i.e. $\sigma^*(\{1\}) \cap \sigma^*(\{2\}) \neq \emptyset$ which implies that there is no possibility to point out a faulty processor (for $t \geq 1$ ).

A processors network is one-step $t$-diagnosable by a set of comparative trials $\Psi' \subseteq \Psi(H^4)$ if each pair such sets $V'$, $V''$ $(|V'| \leq t, |V''| \leq t)$ of faulty nodes is distinguishable by at least one comparative trail $\psi \in \Psi'$.

*Theorem 1*[7]: For any $V'$, $V''$ where $V'$, $V'' \subset V$ and $V' \neq V''$ is a distinguishable pair if and only if at least one of following conditions is satisfied:

1) $(\exists(i,\ k \in V \setminus \{V' \cup V''\}) \wedge \exists\ (j \in \{(V' \setminus V'') \cup (V'' \setminus V')\})) \Rightarrow (\psi = (k;\ i, j) \wedge \psi \in \Psi')$,
2) $(\exists(i, j \in V' \setminus V'') \wedge \exists(k \in V \setminus \{V' \cup V''\})) \Rightarrow (\psi = (k\ ;\ i, j) \wedge \psi \in \Psi')$, (2)
3) $(\exists(i, j \in V'' \setminus V') \wedge \exists(k \in V \setminus \{V' \cup V''\})) \Rightarrow (\psi = (k\ ;\ i, j) \wedge \psi \in \Psi')$.

*Theorem 2*[7]: A system, is $t$-diagnosable if and only if each node has order of at least $t$ and for each distinct pair of sets $V'$, $V'' \subset V$ such that $|V'| = |V''| = t$, at least one of the conditions of theorem 1 is satisfied.

Let us note, for example, that, for sets $V' = \{0\}$, $V'' = \{3\}$ (graph Fig. 1a) and diagnosability $t = 1$ none of conditions of theorem 1 is satisfied.

For a processors network given by $H^4$ and $\langle H^4, \Psi'\rangle$ and for a set of nodes $X \subset V$, $T(X)$ denotes the set of those nodes in $V \setminus X$ which are compared to some nodes of $X$ by some nodes of $X$:

$$T(X) = \{j \in V \setminus X : \exists(\psi \in \Psi')\ \ \psi = (k\ ;\ i, j) \wedge i, k \in X\}.$$

*Theorem 3*[7]: A system with $n$ nodes is $t$-diagnosable if and only if

1) $n \geq 2t + 1$,
2) each node has order of at least $t$,
3) $\forall(0 \leq p \leq t - 1)\ \forall(X \subset V : |X| = |V| - 2t + p) : |T(X)| > p$.

Let us note, for example, that for the graph on Fig. 1a for set $X = \{0,3\}$ and $t = 1$ theorem 3 is not satisfied.

On the basis of the above definitions and notation the problem of measurement of the multiprocessors system integrity is addressed in the next section.

## III. Reducing the number of comparative trails

The system diagnosability of $H^4$ class depends on orders of nodes and the number of nodes. It is known (*Theorem 3*) that diagnosability is not greater than the minimum order of the network node. Note that, for a processors networks having n nodes, maximum number of comparative trials is $\sum_{i=0}^{n-1}\binom{\mu(i) : \mu(i) > 1}{2}$, where $i$ is a node label and $\mu(i)$ is an order of $i$ node.

| {7} | 0 | 0 | 0 | 0 | 0 | 0 | 1 | 1 | 1 | x |

Fig. 2. A pattern of global syndrome (b) computed for multiprocessor system (a)

*Corollary 1:* Path graph[11] of graph $G = \langle V,E\rangle$ which has at least 6 nodes ($|V| \geq 6$) describes an 1-diagnosable system under MM model.

Proof: We must show that $\forall(X \subset V : |X| = |V|\text{-}2) : |T(X)| > 0$ (*Theorem 3* point 3). If $(|V| \geq 6$ then $|X| \geq 4$, $|V \setminus X| = 2$ and $\exists(k; i, j) : k, i \in X \wedge j \in \mathrm{V} \setminus \mathrm{X} \wedge (k, i) \in E \wedge (k, j) \in E$.

If a processors network of $H^4$ class is described by graph $G = \langle V, E\rangle$: $|V| \geq 6$ which has a Hamiltonian path[10] then the number of comparative trails for diagnosability of 1 is $|V| - 2$.

*Example 1:* Given cube $G' = \langle \mathrm{V}',E'\rangle$: $V' = \{0,1,2,3,6,7\}$, we want to find a pattern for global syndrome under MM model for diagnosability of 1. On Fig.2 is presented the entire pattern of global syndrome. Red edges (Fig. 2a.) and cells of table filled with red colour (Fig. 2b) presents the global pattern for Hamiltonian path of graph *G'* (after reduction).

*Corollary 2:* Hamiltonian graph[11] of graph $G = \langle V,E\rangle$ which has at least 10 nodes ($|V| \geq 10$) describes 2-diagnosable system under MM model.

Proof: We must show that that $(\forall(X \subset V : |X| = |V| - 4) : |T(X)| > 0) \wedge (\forall(X \subset V : |X| = |V| - 3) : |T(X)| > 1)$ (*Theorem 3* point 3). If $(p = 0$ and $|V| \geq 10$ then $|X| \geq 6$, $|V \setminus X| = 4$ and $\exists(k; i, j) : k, i \in X \wedge j \in \mathrm{V} \setminus \mathrm{X} \wedge (k, i) \in E \wedge (k, j) \in E$. If $p = 1$ and $|V| \geq 10$ then $|X| \geq 7$, $|V \setminus X| = 3$ and $\exists\Psi'':|\Psi''| >1$

Fig. 4 A reduced pattern of global syndrome (b) computed for multiprocessor system (a) which has not Hamiltonian cycle or a Hamiltonian path

$\Rightarrow(\forall(k;\, i,\, j)\in\Psi'' : k, i \in X \wedge j \in \mathrm{V} \setminus \mathrm{X} \wedge (k, i) \in E \wedge\ (k, j) \in E)$.

If a processors network of H4 class is described by graph $G = \langle V, E\rangle$: $|V| \geq 10$ is a Hamiltonian graph then number of comparative trails for diagnosability of 2 is $|V|$.

Example 2: Given cube $G' = \langle V', E'\rangle$: $V' = \{0,1,2,3,6,7,8,9\}$, we want to find a reduced pattern for global syndrome under MM model for diagnosability of 2. Fig.3b presentes the reduced pattern of global syndrome. Red edges (Fig. 3a.) present the Hamiltonian cycle of graph $G'$.

If a multiprocessor system $G'$ has no Hamiltonian path or is not a Hamiltonian graph then you should find longest path or longest graph cycle and add the missing nodes.

Example 2: Given cube $G' = \langle V', E'\rangle$: $V' = \{0,1,2,3,5,7,8\}$, we want to find a reduced pattern for global syndrome under MM model for diagnosability of 1. On Fig.4b is presented the reduced pattern of global syndrome. Red edges (Fig. 4a.) presents the longest path of graph G' and green edges present links to missing nodes.

## IV. Conclusion

The problem of reduction of number of comparative trials for MM model is complex. The paper only addresses the problem of generating a pattern of global syndrome for multiprocessor system of $H^4$ class under MM model and reduce the global pattern. Corollaries and examples presented in the paper shown the benefits of reducing a pattern of global syndrome. Other issues that should be considered are: the development of diagnostic procedures and the development of a test for a single processor system.

*Abstract* — **Nowadays, Wireless Sensors Networks (WSN) are the most important components in the booming Internet of Things (IoT). Given the use of WSN in systems that are part of the critical infrastructure of a country, the primary task is continuous authentication of WSN nodes. This paper describes how to use the Trusted Platform Module (TPM) to authenticate sensors which create a sensors' domain in WSN. A model of wireless sensor network as well as operations associated with authentication in the sensors domain are presented. Additionally, an implementation of selected operations in the sensors domain is described; this includes: the master node initialization, slave nodes registration, and data transfer between them. Testing environment including the construction of nodes equipped with the TPM is described. The solution developed by the authors of the paper is only a partial realization of a broader concept of authentication in WSNs supported by the TPM.**

## I. Introduction

In the age of common electronic communications security plays an increasingly important role. This applies to a wide range of aspects of everyday life starting from household to complex control systems. Mainly results used for communication generally available network in order to minimize costs, increase the efficiency of data processing, as well as reducing access time to data. In this issue also part of Wireless Sensor Networks WSNs networks that have a wide application.

A WSN can be defined as a group of independent nodes, communicating wirelessly over limited frequency and bandwidth [1]. Execution of the tasks by the WSNs compared to typical sensor networks depends on dense deployment and coordination of sensors. Only the level of technology and human imagination are a limitation in applying of WSNs in any field of life. In a certain implementations of WSNs (e.g. in military areas) an ensuring of adequate level of security is required. In various implementations of WSNs confidentiality and reliability play an important role. A suitable level of confidentiality and reliability of data as well as security level against attacks can be achieved by applying a data encryption and an authentication of the nodes.

An attempt to design a secure WSN requires that the security components should be included into each node in the system. Any component of a network implemented without any security could easily become a point of attack. This means that security must permeate every aspect of design applications of wireless sensor networks that collect or disseminate sensitive information. Such solutions require a high level of safety.

Considering the military, police, emergency services or others, secrecy is part of their nature, so the data (sensed/disseminated/stored) are required to remain confidential. This is critical to the successful operation of a military, police, emergency applications. Enemy/threat tracking and targeting are among the most useful applications of wireless sensor networking.

Usually, the wireless sensor networks (WSNs) consist of large number of ultra-small, low-power and inexpensive wireless sensor nodes with sensing, computing and communication capabilities [2], [3]. It is assumed that such sensors must operate unattended for long periods of time such as several months or even years. In military applications, where the most important element is the safety, the times of maintenance-free operation are not most important, more that, often the life of the sensor will be limited to, for example, a few hours or days. In consequence, the power consumption may not be a critical parameter.

Security mechanisms deployed in WSNs should involve collaborations among the nodes due to the decentralized nature of the networks and absence of any infrastructure. The situation becomes critical when the nodes are equipped with cryptographic materials such as keys and other important data in the sensor nodes. Moreover, enemies/ adversaries can introduce fake nodes similar to the nodes available in the network which further leave the sensor nodes as un-trusted entities.

A characteristic property of WSN are limited resources of nodes creating the network. Attempting to implement an additional functions in such network is always a big challenge for designers of such a network. Introduction to WSN of any security mechanism is also the subject to this rule. Therefore, scientists have tried to offer various network security solutions tailored to the limited resources WSN. These proposals includes: secure and efficient routing protocols [1], [4], secure data aggregation protocols [5], [6],

978-83-60810-66-8/$25.00©2015, IEEE

[7], [8] and additional security mechanisms supported by Trusted Platform Module (TPM) [9], [10], [11], [12], [13], [14], [15]

A characteristic property of WSN are limited resources of nodes creating the network. Attempting to implement an additional functions in such network is always a big challenge for designers of such a network. Introduction to WSN of any security mechanism is also the subject to this rule. Therefore, scientists have tried to offer various network security solutions tailored to the limited resources WSN. These proposals includes: secure and efficient routing protocols [4], [1], secure data aggregation protocols [5], [6], [7], [8] and additional security mechanisms supported by Trusted Platform Module (TPM) [9], [10], [11], [12], [13], [14], [15].

Usually, the sensors used in military applications should be capable of being used for a relatively short period of time (e.g. several hours or days rather than months or years).The time is limited to the execution of a single task. In such situations typically, there is no restriction on energy consumption by sensor. Examples of such applications are shown in Fig. 1.

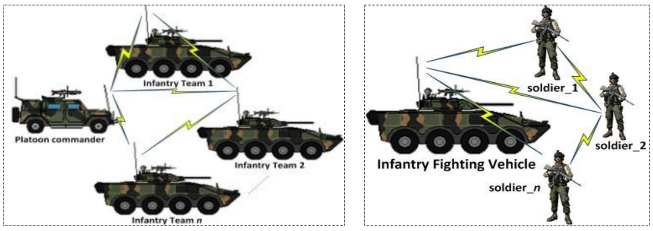

Fig. 1 WSN in military applications

Considering the above, the secure method of transmitting and storing data in WSNs is proposed in the paper. The Trusted Platform Module (TPM) is the basis of the presented method. A TPM is used for secure storing the necessary data to authenticate the nodes, and generate symmetric keys, and asymmetric keys (private/public). The solution presented in the paper uses the concept of authentication in WSNs using TPM developed by the authors of the paper and described in detail in [13].

In the second section proposed architecture of WSNs, and basic definitions are presented. The basic data of each node are stored in every nodes (type and scope of stored data depends on the role they played in the network e.g. domain master (node M), and slave (node S)). In the section the basic data structures used in the nodes are also defined. The third section shortly describes procedures to ensure proper authentication of sensors in domain and correct data transfer between sensors and in detail describes a certain operations in sensors' domain. In the fourth section a few experiments with selected operations in sensors domain and obtained results are presented. Finally, a few concluding remarks are presented.

## II. The model of Wireless sensor network with authentication[1]

In the domain of sensors there are two authorities. The first is the node (Data Collector) which is the recipient of the data emitted by the domain sensors. The node which manages the Root of trust is the second authority. The Root of trust is to be used to authenticate all sensors involved in the exchange of data between elements of the domain of sensors. The second authority is to act as a master of domain and will be called the node M. The presented concept assumes that both the role of the recipient of data from the sensors (i.e. Data Collector) and the role of the master of domain plays the same node.

In the sensors' domain is exactly the one node that acts as the domain master (node M). To this domain belong sensors of type slave (nodes S), which are registered by the node M. Nodes S are the source of data. Node S is initiated and authenticated by node M of domain. Node M stores the root trust of sensors' domain. The sensors' domain structure is shown in Fig. 2.

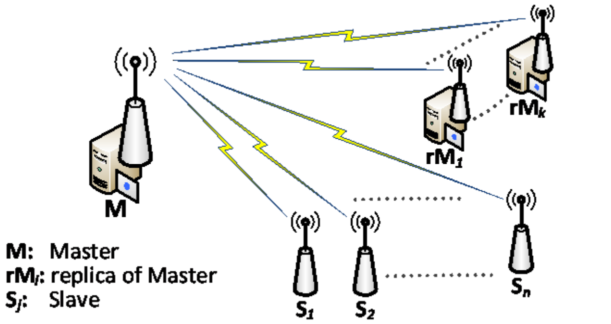

Fig. 2 The structure of sensors' domain

In the domain may be designated nodes acting as backups masters (replicas of master - rM). Such a node may be a S node after the establishment the role rM for him, on condition that its hardware and software resources provide this capability. In the domain may be no node type rM (this is not recommended), but there may be a few such nodes. The task of node rM is to store a copy of the root of trust from the node M of domain.

From the viewpoint of authentication procedures nodes M and rM for nodes S are the same. Node rM can become a new node M of domain after changing its role, due to proven inactivity of old node M. In this case the node, which has so far acted as a node M, becomes a node rM, or node S, or is removed.

When the sensor does not function, is turned off or damaged, it is assumed that this node is in a *non-active* state, and when the sensor is functioning, then the node is in the *active* state.

Sensor, which acts as a node M receives data from S nodes.

[1] The model of WSN with authentication and concept of authentication in such WSN was presented on Federated Conference on Computer Science and Information Systems, 2014 [13].

Minimum requirements for a sensor type S are as follows:

- sensor must be equipped with a TPM (see the next section);
- sensor must have an interface that allows direct connection to the node M (e.g. via USB or Serial) in the registration procedure of the node in the domain;
- the ability to send sensor data (i.e. measurement data) to M node using only wireless connection.

In order to enable automatic authentication procedure of the node and regeneration procedure for S node credentials, S node should be able to receive data transmitted by node M via a wireless connection. Otherwise, the node authentication procedure is not possible and change of credentials of this node will be possible only after the re-registration of the node. Nodes that are designed to play the role of M or rM must be able to bi-directional communication with other nodes, and should also have adequate resources in terms of power, processing capability and storage capacity.

### A. *Trusted Platform Module*

In the presented model for authentication sensors are used mechanisms offered by the Trusted Platform Module (TPM). It is assumed that each element of the domain of sensors is equipped with TPM.

TPM is an implementation of a standard developed by the Trusted Computing Group [16]. This module is designed to support the cryptographic procedures and protocols that can be used for securing data [17]. Trusted Platform Module provides the following functions:

- generating an asymmetric key pair,
- secure storage of keys,
- generating an electronic signatures,
- encryption and decryption,
- implementation of an operation defined by the standard PKCS #11.

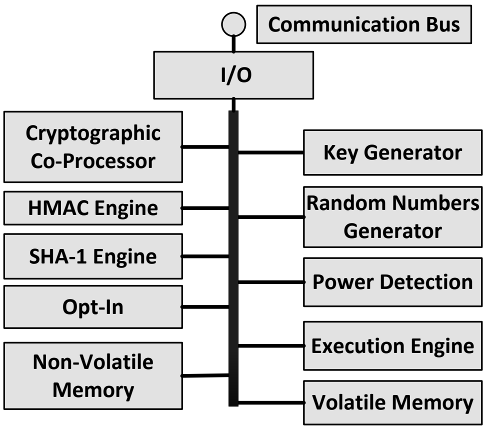

Fig. 3 TPM Component Architecture (based on [16])

The following algorithms are typically implemented in TPM [18]: RSA, SHA-1, HMAC and AES[2] [19]. In addition, each TPM chip stores a unique serial number and its RSA private key that is never available to read. TPM components are shown in Fig. 3. In laboratory stand was used TPM (AT97SC3205) developed by Atmel, which was designed in accordance with the security requirements for cryptographic modules (FIPS 140-2) Level 1 [20]. Used module additionally meets the requirements described in Security Policy for Atmel TPM [21], which says that authentication mechanisms meet the strength requirements of FIPS 140-2, Level 2.

### B. *Resources of sensors*

Each sensor is equipped with a TPM. The necessary data to authenticate the node in domain are stored in non-volatile memory of TPM. Access to the memory is protected by Endorsment Key of the module. The data structure of the node acting as the S is shown on Fig. 4[3]. Sensors, which are to play the role of M or rM must be equipped with additional memory, which is intended to store the description of the domain and descriptions of remaining domain nodes.

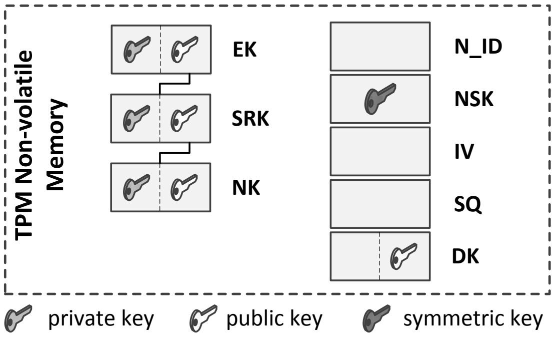

Fig. 4 The data stored on S node

Content of credentials stored in non-volatile memory of the TPM, which are used by a node S (Slave data):

- EK (*Endorsment Key*) - key pair (private/public) generated in the development phase of the TPM – the private part of the key never leaves the module and it is not possible to read this part of the key;
- SRK (*Storage Root Key*) - key pair (private/public) generated during the process of initiating the TPM in the procedure for registering a S node in the domain of sensors; private part of the key is wrapped by public part of EK, and access to the key is protected by secret of module owner;
- NK (*Node Key*) - key pair (private/public) of node; generated during the procedure for registering a S node in the domain of sensors; private part of the key is bound by public part of SRK;
- N_ID (*Node ID*) – ID of the sensor;
- NSK (*Node Symmetric Key*) – symmetric key to encrypt the data sent from this node to M node and to decrypt the data received from M node; obtained during the procedure for registering the node

[2] TPM uses a symmetric algorithm AES to protect the confidentiality of the session in which it participates. However, symmetric encryption functions are not normally accessible outside the TPM.

[3] The data shown on Fig. 5, Fig. 6 and further have been partially modified during the implementation of the method to those described in [13].

in the domain and renovated in the regeneration procedure of S node credentials;

- IV – initiating vector for encryption using NSK key in Cipher Block Chaining mode;
- SQ - the sequence number of the last sent frame (modified after each message);
- DK (*Domain Key*) – public part of the key of sensors' domain to which the node belongs; obtained during the procedure for registering the node in the domain.

Access to keys stored in non-volatile RAM is protected by the secret of the TPM module owner.

Credentials stored by the node M (the structure of the data is shown on Fig. 5) consist of three resources: Node description, Domain description and Description of domain nodes. The content of these resources is as the following:

- **Node description** - it is similar to the description of the node S but, instead the public part of the key DK, are stored both parts (i.e. public and private) of the DK key in Root of trust of M node and additionally the DK key is bound by NK key of M node;

  DK (*Domain Key*) – key pair (private/public) of sensors' domain; generated in the process of creating the domain of sensors and establishing the role of the "master" in the domain for the first node;

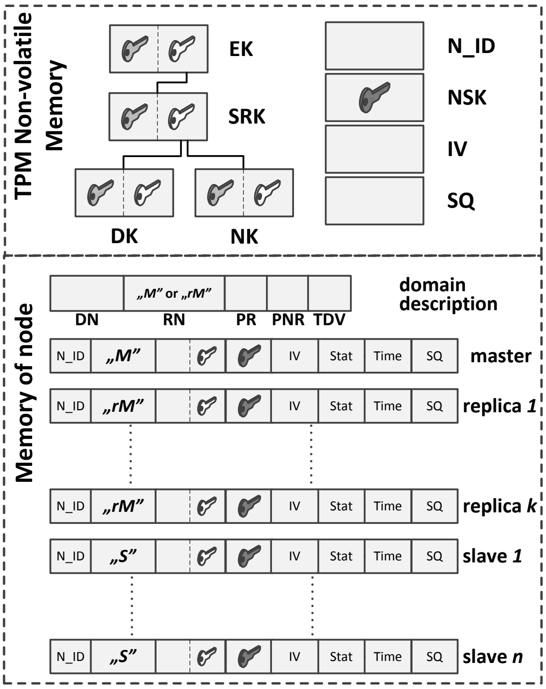

Fig. 5 The data stored on M node or rM node

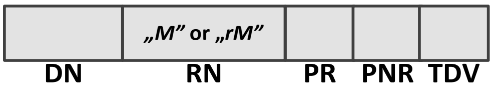

Fig. 6 The data structure describing a domain

- **Domain description** (the structure of the data is showed on Fig. 6):
  - DN (*Domain Name*) – the name of domain (up to 20 chars length);
  - RN (*Role of Node*) – determine whether below data are the resource of master node or the resource of replica of master; it is synonymous with the role it plays in the domain; may have one of values: M or rM;
  - PR (*Period of Replication*) – the time (in *msec*) after which the rM node is required to establish communication with the node M and refresh the domain data;
  - PNR (*Period of Non-success Replication*) - the time (in *msec*) after which the node rM is obliged to repeat the attempt to establish communication with the M node if the previous attempt refreshing the domain data was not successful;
  - TDV (*Time of data validity*) – after this time (in *msec*) and the inability to refresh, the domain data are invalid and node becomes a node S.

  All the data of domain description are encrypted using the NSK key and IV vector of M node.

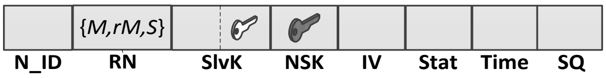

Fig. 7 The data structure describing a node

- **Description of domain nodes**. Description of each node contains the following data (the structure of the data is showed on Fig. 7):
  - N_ID (*Node ID*) – ID of the node (4 bytes length);
  - RN (*Role of Node*) – the role filled by the node in the domain; it can take values from the set {M, rM, S};
  - SlvK - public part of an asymmetric key N_ID node of sensors' domain;
  - NSK - symmetric key to encrypt the data sent from this node to M node and to decrypt the data received from M node; obtained during the procedure for registering the node in the domain and renovated in the procedure for the regeneration of S node credentials;
  - IV – initiating vector for encryption using NSK key in Cipher Block Chaining mode;
  - Stat - status of the node; it can take one of the values: *non-active(-1)*, *active(0)*, *active non-confirmed (n)*, where *n* is the number of consecutive unsuccessful attempts to establish communication with the node
  - Time (in *msec*) - moment of the last and the effective transmission [4];

[4] It was assumed that *Time* field is modified each time the field SQ is modified. In order not to complicate the understanding of the procedures outlined in the following sections, this field has not been included in these procedures.

- SQ - the sequence number of the last sent frame (modified after each message).

All node description data except N_ID field are encrypted using the NSK key and IV vector of M node.

Key EK, SRK, NK and DK form a root of trust node M. Access to keys from a root of trust and access to other data in the non-volatile memory is protected by the secret of the TPM module owner.

Because the description of the domain and descriptions of nodes are encrypted, they can be stored outside the TPM module non-volatile memory, for example in SD memory.

## III. Operations in the wireless sensor network with authentication

In [19] was presented the concept of authentication in WSNs using TPM. Ensuring proper authentication of sensors in domain and correct data transfer between sensors were taken into account in the concept. The concept consist the following procedures:

1. Procedure for initiating M node.
2. Procedure for registering the S node in the domain of sensors.
3. Procedure for removing rM or S node from the sensors' domain.
4. Authentication procedure of the node.
5. Integration test of nodes in sensors' domain.
6. Procedure for the regeneration of S node credentials.
7. Procedure of sending data from S node to M node.
8. Procedure of reading data on M node which were received from S node.
9. Procedure for giving role rM in the domain for S node.
10. Procedure for updating resources of rM node based on resources of M node.
11. Procedure for changing the node role from rM role to role M;
12. Procedure for determining the "new" node M after the failure of the "old" node M.
13. Integration test of resources of M and rM nodes.

In this study in the following sections the procedures listed in paragraphs 1, 2, 7 and 8 are comprehensively described. The procedures implementation details are described in the next section.

### A. *The procedure for initiating M node*

This procedure is intended to create the domain of sensors and to initiate the node that will play the master of the domain role.

Input data:

- M node owner secret;
- NK usage secret;
- DN - sensors' domain name;
- N_ID - node identifier;
- time periods (i.e. PR, PNR and TDV) associated with the operation of nodes rM..

The procedure for initiating M node comprises the following steps:

1. Take ownership of the TPM and SRK key generation.
2. Generate asymmetric key NK (NK attributes: Binding, Non-Migratable, Authority_always), SRK is a parent of NK);
3. Put NK into the root of trust stored in the TPM of "M" node.
4. Generate the data for M node:
   - generate asymmetric key DK for sensors' domain and put it into the root of trust stored in the TPM of "M" node (DK attributes: Storage, Migratable, Authority_always), SRK is a parent of DK; later public part of DK will be used by "S" node to bind the data which will be sent from "S" node to "M" node);
   - generate symmetric key (NSK – size 32 bytes) and initialization vector (IV – size 16 bytes) for AES cryptography;
   - generate sequential number SQ for M node;
   - put M node data into non-volatile memory of the TPM of S node.
5. Prepare of the domain description, which includes the fields DN, RN, PR, PNR, TDV and then encrypt this description using the NSK key and IV vector. The RN field should have a content of "M".
6. Prepare of the M node description and then encrypt this description using the NSK key, and IV. The fields of the description should have the following values:
   - N_ID = input data N_ID (the field is not encrypted);
   - RN = „M";
   - SlvK = public part of the node NK key;
   - NSK = the node NSK key;
   - IV = initiating vector for NSK key;
   - Stat = 0;
   - Time = current time;
   - SQ = random number from the range <0; 65535>.
7. Save the M node description in M node resources.

### B. *The procedure for registering the S node in the domain of sensors*

In the procedure of registration S node in the domain is assumed that during this procedure S node is connected to the node M via the Serial interface[5].

Input data:

- N_ID - node identifier;
- public part of the DK key.

After installing S node in serial port of M node the procedure for registering S node in the domain comprises the following steps:

1. On S node take ownership of the TPM and SRK key generation.

[5] If it was not possible to use the USB interface, in order to ensure the safety of the registration procedure, is required to develop additional ways of mutual authentication of both parties involved in the registration.

2. Generate asymmetric key NK of S node (NK attributes: Binding, Non-Migratable, Authority_always); SRK is a parent of NK).
3. Put NK to TPM resources of S node.
4. Generate the data for S node:
   - obtain the public part of the DK key from non-volatile memory of the TPM of M node; send a *dom_pub_key_req* packet from S node to M node through the serial line:

     ***dom_pub_key_req***

     | **code** | |
     |---|---|

     where:
     **code** = 101 for *dom_pub_key_req* packet;
     and get from M node a dom_pub_key_ans packet:

     ***dom_pub_key_ans***

     | **code** | **DK** |
     |---|---|

     where:
     **code** = 102 for *dom_pub_key_ans* packet;
     **DK** public part of Domain Key of sensors' domain;
   - generate symmetric key (NSK – size 32 bytes), initialization vector (IV – size 16 bytes) for AES cryptography;
   - put S node data into TPM non-volatile memory of S node.
5. Prepare S *node_description_req* packet

   ***node_description_req***

   | **code** | **N_ID** | **NSK** | **IV** | **NK** |
   |---|---|---|---|---|

   where:
   **code** = 103 for *node_description_req* packet;
   N_ID, NSK, IV and public part of NK key (the first three fields are bound using public part of DK key).
6. Transfer the blob to M node and then unbind it using the private part of DK key.
7. On M node prepare the S node description and then encrypt this description using NSK key and IV vector of M node. The fields of the S node description should have the following values:
   - N_ID = input data N_ID (the field is not encrypted)
   - RN = „S";
   - SlvK = public part of the S node NK key which be registered;
   - NSK = the NSK key of node which be registered;
   - IV = initiating vector for NSK key;
   - Stat = 0;
   - Time = current time;
   - SQ = random number from the range <0; 65535>.

   Save the S node description in M node resources.
8. Send a confirmation of registration to the node S. The confirmation should contain N_ID, Time and SQ and be encrypted using NSK key and IV vector of node S.

   ***node_description_ans***

   | **code** | **N_ID** | **Time** | **SQ** |
   |---|---|---|---|

   where:
   **code** = 104 for *node_description_ans* packet;
   N_ID, Time and SQ (the fields are encrypted using NSK key of S node).
9. Put SQ into TPM non-volatile memory of S node.
10. Uninstall the S node from serial port of M node

### C. *The procedure of sending data from S node to M node*

Input data:

- N_ID – identifier of node;
- SD – sensor's data;
- NSK – symmetric key of S node;
- IV = initiating vector for NSK key;
- DK – public part of domain key.

***sensor packet***

| **code** | **N_ID** | **SD** | **SQ** | **Hash** |
|---|---|---|---|---|

The structure of the frame containing the sensor data is showed above. It includes the following fields:

- code = 7 for sensor packet;
- N_ID = input data N_ID;
- SD = Sensor's Data encrypted using the NSK key and IV vector;
- SQ = current SQ incremented by 1;
- Hash = the value of the hash function determined on the basis of fields N_ID, SD and SQ.

The procedure of sending data from S node to M node comprises the following steps:

1. Preparing *sensor packet* containing the sensor data, as shown above
2. Binding the frame using the public part of DK.
3. Sending the frame to M node by XBee link.
4. Incrementing SQ field in resources of S node.

### D. *The procedure of reading data on M node which were received from S node.*

Input data:

- Received frame from S node;
- Resources of M node.

The procedure of receiving data on M node from S node comprises the following steps:

1. Receiving of the frame, as shown on Fig. 8.
2. Unbinding of the frame using the private part of DK.
3. Searching the description of N_ID node in description of domain nodes stored in protected resources of M node. If not a success, the N_ID node is unrecognized.
4. Comparing SQ field from received frame and SQ field from node description. If not equal, the SQ is incorrect.
5. Updating the description of N_ID node:
   - **stat** = 0;
   - **Time** = current time;
   - **SQ** = **SQ**+1.

6. Decrypting of the SD field using the NSK and IV acquired from description of domain nodes of “slave 1” node.

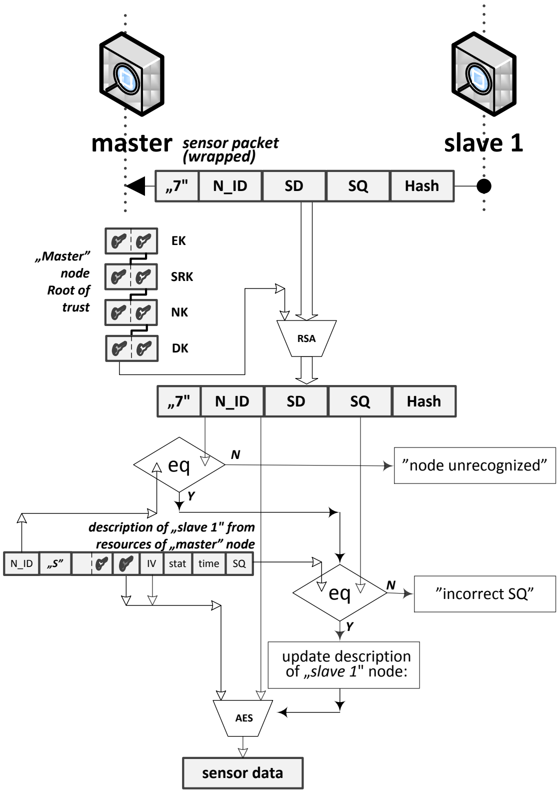

Fig. 8 The procedure of reading data on “master” node which were received from “slave 1” node

## IV. THE TESTBED TO EXAMINE AUTHENTICATION PROCEDURES IN WSN

The laboratory stand to examine the authentication procedures in WSN utilizing TPM was developed. The laboratory stand includes a few sensors equipped with TPM and several workstations to perform research. Block diagram of the sensor is showed on Fig. 9 and view of an exemplary sensor used in the experiments is showed on Fig. 10.

Fig. 9 Block diagram of the sensor

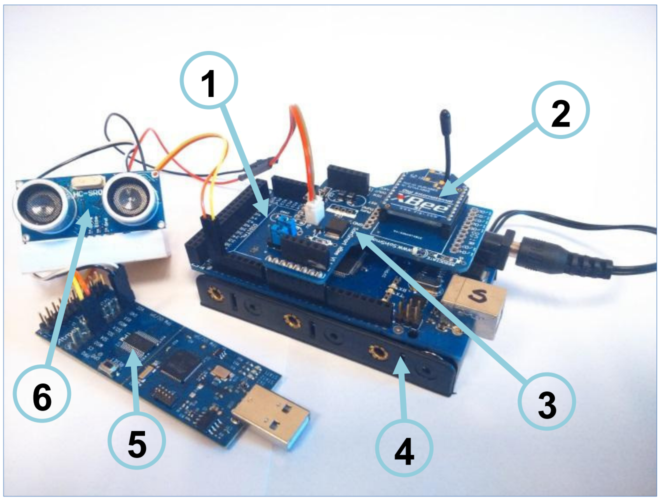

Fig. 10 View of an exemplary sensor

Sensor (showed in Fig. 10) used in the experiments was built with the following components:

- Arduino Mega2560R3 (in Fig. 10, indicated by 1) – based on microcontroller ATmega2560 (clock speed 16 MHz, 256 KB of flash memory for storing code (of which 8 KB is used for the bootloader), 8 KB of SRAM and 4 KB of EEPROM). The board has: 54 digital input/output pins (of which 15 can be used as PWM outputs), 16 analog inputs, 4 UARTs (hardware serial ports).
- XBee 1mW Wire Antenna Series 1 (indicated by 2) – wireless communication module with other wireless modules (compatible with the 802.15.4 standard). The module is connected to the Arduino Mega by adapter XBee Shield (indicated by 3) and communicates with Arduino by Serial 0.
- Ultrasonic distance sensor (indicated by 6) includes ultrasonic transmitters, receiver and control circuit. Provides 2cm - 400cm non-contact measurement function, the ranging accuracy can reach to 3mm.
- TPM (indicated by 5) – detachable part of hardware component of Atmel I$^2$C/SPI Demonstration Kit connected to Arduino through the I$^2$C Interface.
- Power bank (indicated by 4) – 9V power supply.

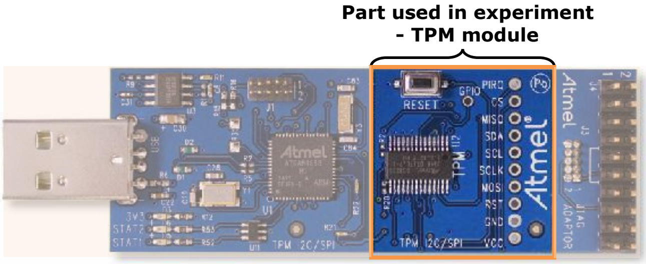

Fig. 11 Atmel I2C/SPI Demonstration Kit

In this laboratory stand was realized an experiment consisting of the following stages:

1. Initiating M node.
2. Registering the S node in the domain of sensors.
3. Transferring data from S node to M node:

a) sending a first frame (its structure is shown in subsection III.C) from node S to M as a plain text i.e. without encryption field SD and without binding frame with the public part of DK.
b) sending a second frame (its structure is the same) from S to M node containing encrypted SD field with NSK, but without binding the frame with the public part of DK;
c) sending a third bound frame with the public part of DK from S to M node containing encrypted SD field with NSK.

**STAGE 1.** The entire first stage is initiated and implemented autonomously on the node that will act as the Master. After this step this step the TPM is initiated and node ownership is acquired. The description of M node is written in non-volatile memory of TPM. Moreover, encrypted[6] description of sensors domain, in which is registered one node (i.e. Master), is created. Exemplary, encrypted description of sensors domain which was created as a result of this step for M node (node ID is 0xCC CC CC CC) is shown in Fig. 12.

Fig. 14 Description of sensors domain after S node registering procedure

In the first three steps of the stage TPM of S node is initiated, node ownership is acquired and the root of trust on S node is created. Then direct connection to M by Serial interface node is needed to transfer public part of the DK. DK is transferred as a plain text. In next step NSK and IV is randomly generated and put into non-volatile memory of S node. Then N_ID, NSK, IV and public part of NK key are bound using public part of DK key and transferred to M node through the Serial interface. On the basis of these data M node prepares a description of the node S and attach it

[6] In description of sensors domain all fields are encrypted with the exception of node IDs

to the sensors' domain description. Now domain description. After it the domain description might look like on the Fig. 14.

In the last step confirmation of S node registering (encrypted using NSK key of S node) is sent to S node. In this moment S node is registered and should be disconnected from Serial interface connecting it with M node.

### STAGE 3.

The S node is ready to transfer its sensor data by XBee interface – Serial line used in stage 2 is disconnected. In experiment takes part, in addition to S and M node, Observer station equipped with Xbee interface as shown on Fig. 15 and Fig. 16.This node is designed to interception the data transmission between nodes S and M.

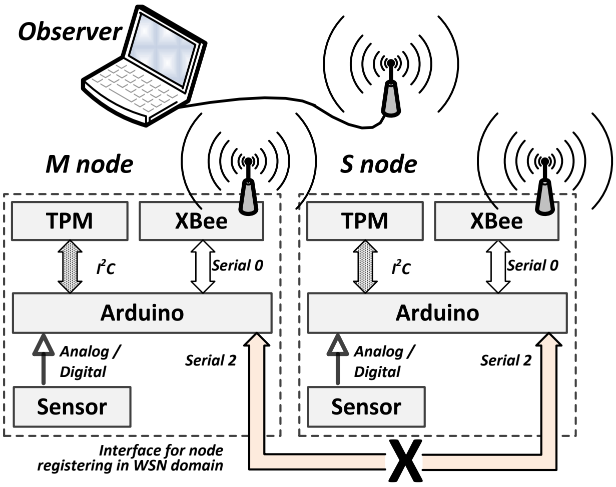

Fig. 15 Block diagram of M node, S node and observer during transferring data between S node and M node

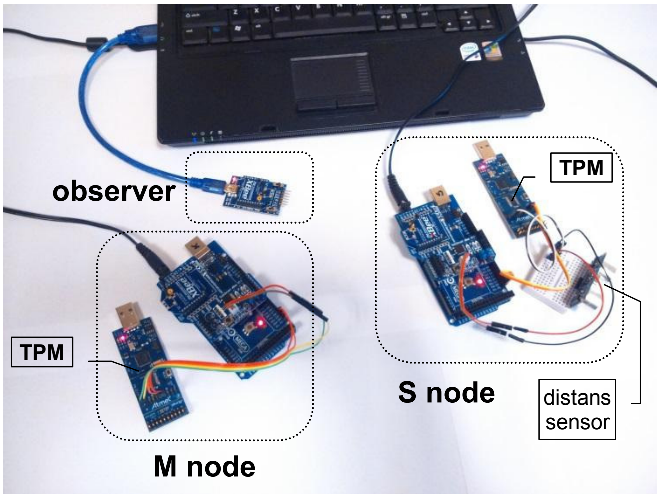

Fig. 16 View of the testbed during transferring data between S node and M node

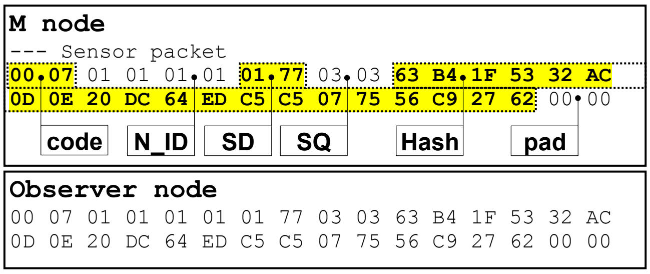
Data received in step a) by nodes M and Observer should be the same - an example is shown in Fig. 17.



```

```

Fig. 19 Data after step c).

The experiment shows that the data transferred between nodes S and M are secured. Unauthorized nodes that are not registered in the domain of sensors, even if they are able to receive the data, they are not able to use them.

## V.CONCLUSION

This paper presents the model, concept of authentication in sensors' domain and implementation of securing transmissions between nodes of WSN. For this purpose, the mechanisms provided by the TPM are used. In paper was presented only the most important operations in sensors domain: nodes initiating and transfer data between the nodes. Particular attention was paid to secure the transmission and to secure the nodes of network. In all procedures hardware support provided by the TPM was used. If you apply all the requirements specified in the security Requirements for cryptographic modules (FIPS 140-2), the securing data is very strong. The effect is, however, come at a price relatively high power consumption and requires the use of modules that have more computing power and more resources of RAM. The biggest problem during the implementation was the shortage of sufficient RAM in used Arduino modules. For this reason, in further work we anticipate to use the EEPROM and/or SDRAM memory.

***Abstract*—The widespread use of the HTTP and hypertext makes it possible to freely publish new information and expose it in the context of its description. Unfortunately, this is a human-centric environment that cannot easily be adapted to an application-centric approach, which is required to provide distributed enterprise management and real-time process control. In this article new architecture is presented that can provide a generic solution for publishing and updating information in the context that can be used to describe and discover it. It is proposed to distribute the publisher (server) tasks to three classes: (a) information context management using the object oriented programming paradigm, (b) a predefined fixed set of services to access data and meta-data, and (c) a pluggable custom process data binding mechanism. It is also proposed to implement this architecture using the OPC Unified Architecture - a new emerging industrial integration standard.**

## I. Introduction

BEFORE commencing discussion about how to use the Internet the question “What is it?” must be addressed. Usually we can hear a definition like that: “the public worldwide computer network system that carries a vast array of information resources and services”. It seems to be too broad for further discussion. From the definition, it is networking technology providing access to information resources and services. “To get access”, the information transfer must be carried out between the Internet users, i.e. a resource or service provider and its consumers. To enable this, the following assertions must be made:

- Communicating parties must use the Internet protocol (IP) [1];
- All access points to the Internet communication infrastructure must have globally unique addresses;
- Users must be attached to those access points.

As long as the above rules are obeyed the communicating parties use Internet communication – colloquially, they are connected to the Internet. Reversing this sentence, we can say that the Internet is an infrastructure connecting any entities following the above principles. From the user point of view that is all, but to traverse information over the network the Internet infrastructure must be smart enough to locate the access points.

From any ICT solution we would expect information processing rather than having only interconnection between the Internet access points. To meet this requirement the Internet users must be processing engines rather than hosting applications responsible for this work. Application to application connectivity is, therefore, required that can be provided by an additional transport protocol. Examples of such protocols are TCP (connection oriented) and UDP (connectionless). It is worth stressing that we can use a variety of protocols as the transport protocol and the above assertions still hold true.

On the other hand, any user expecting information processing from the communicating party is interested in selecting appropriate functionality, but not a particular application instance. Therefore, we can distinguish three meanings of the transport protocol address, called a port:

- Functionality selector – for a consumer interested in utilizing a particulate information resource or service;
- Functionality publication end point – for servers offering resources or services;
- Address to identify sending and receiving application end-points – for the protocol stack.

The TCP and UDP protocols share the same address space with a capacity of 64k end points. Even today, having so many applications hosted on any network node is impractical and hard to manage. Unfortunately, mapping between functionalities and their identifiers is static, which means that the majority of available port numbers are globally unique functionality identifiers governed by the Internet Assigned Numbers Authority (IANA). The others called dynamic/private ones are not assigned and used to identify sending and receiving application end-points only.

Using a global dictionary instead of a description, discovery and integration mechanism results in a fully exhaustion of transport protocol address space and the registration of new functionality becomes very difficult. Therefore, to communicate over the Internet, users need to select one from the 49152 existing options.

The selection should be based on well-defined requirements, but how to define the requirements having only the general assumption that we expect access to the

978-83-60810-66-8/$25.00©2015, IEEE

information resources or services. Many aspects may be taken into consideration. For the above assumptions a solution that allows server to freely publish new resources and services is needed. A globally acceptable discovery and integration mechanism is a possible option. Alternatively, another protocol must be selected on the following assumptions:

- The publishing server is responsible for managing the address space;
- The protocol provides an infinite address space capacity;
- The protocol is transparent for the payload transported.

The above assumption make the Internet a publication platform containing countless resources, but, to be useful, consumers must be allowed to find the appropriate ones using a description and discovery mechanism. It requires that publisher must provide additional information (meta-data), which describes the resources to allow the selection. Additionally, the descriptions must be coupled with addresses to selectively access them. For human-centric solutions a graphical interface is an appropriate mechanism. HTTP [1] as a protocol and HTML [2] (more general a hypertext) as a description language are the big winners selected by millions of people and they have led to the establishment of the World Wide Web.

Unfortunately, for application to application connectivity a programming interface (API) is required. Because community acceptance and reuse of the existing solutions is so important for the Internet evolution, a new solution – called web services - atop HTTP has been developed by the World Wide Web Consortium (W3C) [2]. This specifications suit is commonly referred to as WS-* and contains:

- Simple Object Access Protocol (SOAP) to use the services;
- Web Services Description Language (WSDL) to describe the services;
- Universal Description, Discovery and Integration (UDDI) to get access to the services description.

To obtain applications interoperability all clients consuming services provided by a server offering them must conform to a WSDL specification prepared in advance that defines a contract between them. Hence, this process requires software development and, because WSDL cannot provide complete semantics of the service, the process is usually manual and requires conformance testing. There are no good global scope solutions of this issue. Today solution is for the server publisher organization to provide complimentary compliant client applications. In this approach, typical problems like operating system dependence, software updating and versioning must be solved. Finally, it leads to a static solution where functionality is exposed as a fixed set of services.

It seems that the next level of abstraction is needed to meet the above mentioned goal and allow the server to freely publish resources and services. Generally speaking, all ICT systems are expected to provide information processing capabilities. Information is an abstract knowledge; it cannot, therefore, be directly processed by physical machines. To make information capable of being processed, it must be represented as computer-centric binary data. To propose a solution that meets those requirements two questions should be addressed:

- How to get access to (transport) the process data?
- How to represent (model) the information?

To answer the first question we need a globally accepted, platform-neutral (assuring that the above stated assertions hold true) communication standard that allows also addressing the second question, i.e. designing of an appropriate Information Model.

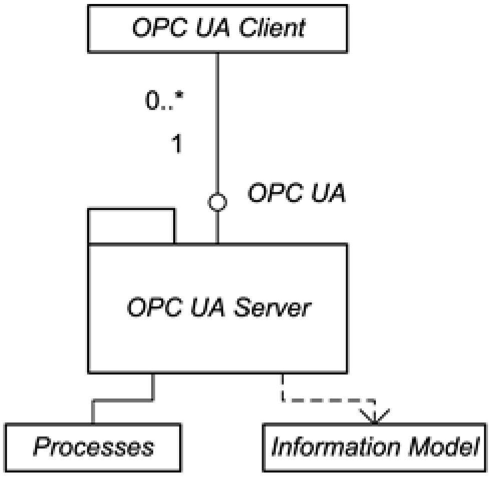

Fig. 1 OPC Unified Architecture archetype

The OPC Unified Architecture (UA) (Fig. 1) technology [3], [4], [5], [6] meets all the requirements, because:

- It is Internet based technology;
- It is a platform neutral standard allowing easy implementation on any system including embedded systems;
- It is designed to support complex data types and object models;
- It is designed to achieve high speed data transfers using efficient binary protocols;
- It is scalable from embedded applications up to the process control and enterprise management/operation systems;
- It has broad industry support and is being used in support of other industry standards such as ISA S95, ISA S88, EDDL, MIMOSA, OAGiS, etc. [7].

It is a broad class of application domains where business IT and control systems are converged in a global scope to make a large whole with the aim to improve performance as the result of the macro optimization and synergy effect. One of the main requirements of the Industrial ICT is to provide a consistent mechanism for the integration of the vast varieties of systems. This requirement can be met as the result of employing the OPC Unified Architecture (UA) as the mechanism for the integration. It is assumed that it should be robust and the implementation should be platform independent. Fig. 1 illustrates the architecture of the proposed solution. In this approach three elements are distinguishable from the typical client server archetype:

- *OPC UA*: an interface representing invariable Service Model [8] responsible for providing client/server connectivity;
- *Information Model*: application domain unique description of a context the process data is made accessible in to the clients.
- *Processes*: source of exposed information resources and services hereinafter referred to as process data.

To make systems interoperable, the data transfer mechanism must be associated with a consistent information representation model. OPC UA uses an object as a fundamental notion to represent data and activity of underlying processes (see Sec. II.B). The objects are placeholders of variables, properties, events and methods and are interconnected by references. This concept is similar to well-known object oriented programming (OOP) that is a programming paradigm using "objects" – data structures consisting of fields, events and methods – and their interactions to design computer programs [9]. The OPC UA Information Model [10], [11] provides features such as data abstraction, encapsulation, polymorphism, and inheritance.

The OPC UA object model allows servers to provide type definitions for objects and their components. Having defined types in advance, clients may provide dedicated functionality, for example: displaying the information in the context of specific graphics.

The OPC UA information modeling concept (Sect. III) is based on layers, which step by step expand the basic model provided by the OPC UA Specification [19]. The Information Model is abstract and hence, in a real environment, it must be implemented in terms of bit streams (to make information transferable) and addresses (to make the data selectively available). To meet this requirement, OPC UA introduces a node notion as an atomic addressable entity that consists of attributes (value-holders) and references (address-holders of coupled nodes). The set of nodes that an OPC UA server makes available to clients is referred to as its Address Space [4], [5], [12], which enables representation of both underlying processes environment and its behavior. The Address Space exposed by the server makes up a context the process data is made available in to the clients (Fig. 1). Creation of this context (Sec. IV) depends on an application domain unique Information Model.

*Processes* in Fig. 1 represents a class of functions responsible for getting access to business or industrial processes source of exposed information resources and services hereinafter referred to as process data.

Basing on the defined typical enterprise systems structure and requirements [25], a new architecture is proposed (Sect. IV) where an intermediate component called Process Observer is proposed. The model allows for significant reduction of the solution complexity, but the implementation of this model proves that the architecture additionally could increase robustness by adding redundancy. The example (sect. V.B), where the presented model has been used, shows that the approach can be a platform for multi-enterprise collaboration to benefit from synergy effect and macro optimization.

Sect. III, III.C and IV describe novel architectural proposal and corresponding communication algorithms allowing building robust real time distributed systems. A case study where the presented solutions have successfully been implemented is in Sect. V.

## II. OPC Unified Architecture Key Features

### *A. Service Oriented Architecture*

At the very beginning of a new solution development the question about its fundamental paradigms and architecture must be addressed. Observing continuous evolution of the ICT domain, it seems that finding a solution that will guarantee an unlimited lifetime is a real challenge. However, decoupling the solution from any base technology increases the chance of its surviving the disappearance of the base technology from the market. Fortunately, as mentioned above, there are many options on how to get applications interconnected over the Internet. Developing services and deploying them using Service Oriented Architecture (SOA) is the best way to utilize ICT systems to meet this challenge. A service differs from an object or a procedure because it is defined by messages that it exchanges with other services. SOA defines the way in which services are deployed and managed. Adopting of the SOA approach increases reuse, lowers overall cost, and improves the ability to rapidly change and evolve systems, whether old or new.

To make systems interoperable, any even brilliant idea is not enough - a data transfer technology is needed, however – when defining data exchange in context of messages – we do not need to bother about different technologies used by the participants as long as they can absorb the messages.

Today, an ideal platform for the SOA concept implementation is Web Service technologies. Web Services are a set of standards based on XML (eXtensible Markup Language) and developed by W3C (World Wide Web Consortium) [2] marked with a WS-* symbol. Because the WS-* standards are developed without any initial assumption concerning the underlying system platform they are implemented on, they therefore must precisely define what must be on the "wire".

The WS-* standards are the basic foundation for OPC UA but, using them alone, would not be enough to reach the expected data throughput performance in industrial applications. To promote scalability, the OPC UA suite of protocols, therefore, expands the WS-* standards by defining a few proprietary ones that can be used alternatively. OPC

UA messages may be encoded as an XML text or in binary format for efficiency purposes.

### *B. Object Oriented Information Model*

OPC UA uses an object as a fundamental notion to represent data and activity of an underlying processes system. The objects are placeholders of variables, events and methods and are interconnected by references. This concept is similar to well-known object oriented programming (OOP) paradigm [9]. The OPC UA Information Model [4], [5], [10], [11] provides features such as data abstraction, encapsulation, polymorphism, and inheritance.

The OPC UA object model allows servers to provide type definitions for objects and their components. Type definitions may be abstract, and may be inherited by new types to reflect polymorphism. They may also be common or they may be system-specific. Object types may be defined by standardization organizations, vendors or end users. Each type must have a globally unique identifier that can be used to provide description of the information meaning, i.e. semantics from the defining body or organization. Using the type definitions to describe the information exposed by the server allows:

- Development against type definition;
- Unambiguous assignment of the semantics to the data expected by the client.

### *C.Abstraction and Mapping*

Interoperability of applications can be achieved if communicating parties are able to interchange streams of bits and assign to these streams the same meaning without any ambiguity. Unfortunately, the representation of information on the wire, and communication protocols are subject to continuous evolution, if not revolution nowadays. This could be dangerous for any long term initiatives. Because it is impossible to stop the progress of technology changes, some other precautions must be taken to keep the specification alive within a long term horizon. It is achieved by clear separation of definitions provided by the specification from their actual implementation. It makes OPC UA seamlessly portable from one technology to another. Mappings defined in the specification [13] set forth how to implement an OPC UA feature using a specific technology.

### *D.Security*

Security is the fundamental aspect of computer systems, in particular those dedicated to enterprise and process management. Especially in this kind of applications, security must be robust and effective. Security infrastructure should also be flexible enough to support a variety of security policies required by different organizations. OPC UA may be deployed in diverse environments; from clients and servers residing on the same hosts, throughout hosts located on the same operation network protected by the security boundary protections that separate the operation network from external connections, up to applications running in global environments using public network infrastructure. Depending on the environment and application requirements, the communication services must provide different protections to make the solution secure [14].

OPC UA Security is concerned with the authentication of clients and servers, the authorization of users, the integrity and confidentiality of their communications and the auditing of client server interactions. To meet this goal, security is integrated into all aspects of the design and implementation of OPC UA servers and clients.

OPC UA relies upon the site cyber security management system to protect confidentiality on the network and system infrastructure, and utilizes the public key infrastructure to manage keys used for symmetric and asymmetric encryption [15]. OPC UA uses symmetric and asymmetric encryption to protect confidentiality as a security objective, as well symmetric and asymmetric signatures to address integrity as a security objective.

### *E. Profiles*

OPC UA is designed to support integration of wide range of servers, from plant-floor control devices to enterprise management and operation systems. All of them are characterized by a variety of performances, execution platforms and functional capabilities. Therefore, OPC UA defines a comprehensive set of capabilities servers may implement a subset of. These subsets are referred to as *Profiles*, and servers may claim conformance to them.

### *F. Robustness*

Because it is to be used in the production environment including real-time process control applications, OPC UA is designed especially to provide robustness of the remote access to the underlying process data. OPC UA provides mechanisms for clients to quickly detect and recover from communication failures associated with transfers without having to wait for long timeouts provided by the underlying protocols [16].

## III. Information Model

### *A. Concept*

The primary objective of the OPC UA server is to expose information resources and services, which then can be used by clients to manage an underlying real-time process or the entire enterprise as a large whole with the main challenge of integrating systems and management resources into one homogenous environment. Information describes the state and behavior of the processes and the server must be able to transfer it in both directions. The main challenge of the OPC UA Information Model is to support this transfer by a unique and transparent means in spite of the process complexity and roles of clients in the enterprise management hierarchy.

Information is an abstract knowledge; therefore it cannot be directly processed by physical machines. To make information capable of being processed, it must be represented as the binary data. To define the relationship between information and binary data on the one-to-one basis, syntax and semantics are needed. Syntax defines rules of the vocabulary usage, and semantics maps valid bits pattern to the associated piece of information.

An Information Model for OPC Unified Architecture is such a collection of vocabulary, syntax and semantics. This collection plays a role similar to high level programming languages that describe data structures and an algorithm to be executed by the processor.

Information exposed by the OPC UA server may be complex. Clients may, therefore, want to obtain the information definition. Generally speaking, to select a particular target piece of information we have two options: random access or browsing. Random access requires that the target entity must have been assigned a globally unique address and the clients must know it in advance. We call them well-known addresses. The browsing approach means that the clients walk down available paths that build up the structure of information. For example hypertext document containing URL's locating recursively hypertext documents and other resources.

It seems that, in spite of the access method, we have to assign an address to all of the accessible items in the representation of the information structure. Therefore we call the collection of these items the Address Space [4], [5], [12]. This atomic addressable item is called a node. Each node is a collection of predefined set of attributes that have values accessible locally in context of the node. To represent information about the internal structure, nodes are interconnected by references.

Accessing information by clients is the first aspect of controlling the data stream between the clients and the underlying process environment of the server. Another one is creating and maintaining the Address Space in real-time.

To create the Address Space, we need to instantiate nodes and interconnect them by references. Instantiating nodes operation requires assigning appropriate values to attributes and adding references. To make information internally consistent as a large whole, we need rules governing the creation and modification processes. The Information Model implies these rules using the following two concepts:

- ***NodeClass*** – as a formal description of the node defining the allowed attributes and references;
- ***Type*** – as a formal description of the node defining the allowed attributes and references values.

For the client to understand the Information Model, it must be predefined or exposed.

Available NodeClasses are predefined, i.e. the specification provides a strictly defined non-extensible set of NodeClasses. Each one is assigned a dedicated function, e.g. *Variable* NodeClass defines nodes that provide a value, and *Method* NodeClass represents a function.

Like the NodeClass concept, the specification provides a set of predefined types, which is extensible. According to the above rule, all not predefined types must be exposed in the Address Space. To expose predefined and proprietary type definitions in the Address Space, there are dedicated NodeClasses, namely *ObjectType*, *VariableType* and *ReferenceType*. For example, nodes of the *VariableType* NodeClass provide clients with definitions of types derived from the *BaseVariableType* that is a base type for all variables. The main role of the types represented by the above NodeClasses is to provide a description of the Address Space structure and to allow clients to use this knowledge to navigate to desired information resources (represented by the *Variable* nodes) and services (represented by the *Method* nodes) in the Address Space exposed by the OPC UA server.

DataType NodeClass is also dedicated to describe types. In this case, the represented types have a special mission, because they describe underlying process data that client has access to using a connection to the OPC UA server. For example, a node of the DataType can provide information to clients that the data has a numeric value and the clients reading it can use this knowledge to interpret and process the obtained value.

Types are called metadata since they describe the data structure (context) not the actual data values.

Even though the OPC UA specification contains a rich set of predefined types, the type concept allows designers to freely define types according to the application needs. New types are derived from the existing ones. The derived types inherit all features of the base types but can include modifications to make the new types more appropriate for information that is to be represented.

The Address Space concept based on types can be a foundation for exposing any information that is required. Clients understand the Address Space concept and have a browse service to navigate through the Address Space. Since browsing is based on the incremental and relative passage among nodes it is apparent that each path must have a defined entry point, so the question as to "where to start" must be addressed. To meet this requirement, the Address Space must have a predefined template containing well defined nodes that can be used as anchors from which a client can start browsing the Address Space content. Thus to design an Address Space and define new types, they must be derived from the existing ones. At the very beginning the only existing types are the standard ones defined by the specification. The available standard types are briefly described in the Section III.B.

### *B. Standard Information Model*

The primary objective of the OPC UA Address Space is to provide a standard way for servers to represent objects to the clients. The Object NodeClass is used to define objects. Each object in the Address Space has an assigned *ObjectType*. The specification has provided a

*BaseObjectType* from which all other *ObjectTypes* shall either directly or indirectly inherit.

*Variable* NodeClass is dedicated to provide a value to the clients. To define a *Variable* two types must be provided:

- *VariableType*: describes the type of a variable. Each Variable node has the *HasTypeDefinition* reference to its type definition.
- *DataType*: describes the type of the value of the variable. It is assigned to the *DataType* attribute.

The type of data provided by the *Variable* Value attribute is defined by the associated *DataType*. *DataType* is pointed out by the *DataType* attribute of the *Variable* and *VariableType* nodes. In many cases, the value of the *DataType* attribute will be well-known to clients and servers. Well-known data types allow clients to use random addressing and interpret values without having to read the type description from the server.

To some standard data types – called built-in types - special rules apply. Built-in data types are a fixed set that should be known to all OPC UA products. Examples of built-in data types are *Int32* and *Double*. Most of the built-in data types are similar to those in programming languages.

Process data could be complex. *Structure* is an abstract data type defined as the base for all structured types. All complex data, if not defined in the specification explicitly as primitive, are created by defining of new types derived from the *Structure*.

Reference types are used to create interconnections between nodes. They are not instantiated, i.e. a NodeClass representing a reference is not defined. Instead of instantiating the references, they are added to a collection associated with each node. NodeClass of the node and its type decide what references are allowed to be added to this collection.

The base of all references is an abstract *References* type. There is no semantics associated with it. There are two disjoint sets of standard references:

- *HierarchicalReferences*
- *NonHierarchicalReferences*

This distinction reflects two fundamental relationship categories that can be generally distinguished: the association and the dependency. Associations are used to build information architecture – nodes hierarchy - that can be discovered by the clients using the browsing mechanism. An example of the association is the “parent/child” relationship. In this case it can be said that the target belongs to the source. A dependency of a source element (called the client) on a target element (called the supplier) indicates that the source element uses or depends on the target element. An example of dependency is the variable and the variable type relationship. In this case the target describes the source.

### C. Extending OPC UA Information Model

The standard OPC UA Information Model is expandable. For example, in 2008 the OPC Foundation announced support for Analyzer Devices Integration into the OPC Unified Architecture and created a working group composed of end users and vendors with its main goal to develop a common method for data exchange and an analyzer data model for process and laboratory analyzers. In 2009 the OPC Unified Architecture Companion Specification for Analyzer Devices was released [17]. To prove the concept a reference implementation has been developed containing ADI compliant server and simple client using the Software Development Kid released by the OPC Foundation [17].

It is an example of how OPC UA standard Information Model can be expanded by a selected domain application. Standardized expandability of the metadata used to provide a context of underling process data is key requirements of the presented Object Oriented Internet concept.

In this example, the model described in the specification is intended to provide a unified view of analyzers irrespective of the underlying device. This Information Model is also referred to as the ADI Information Model. As it was mentioned, analyzers can be further refined into various groups, but the specification defines an Information Model that can be applied to all the groups of analyzers.

The ADI Information Model is located above the DI Information Model [18] [19]. It means that the ADI model refers to definitions provided by the DI model, but the reverse is not true. To expand the ADI Information Model, the additional layers shall be provided.

## IV. Information Model Deployment

The OPC UA is a standard that allows clients to get access to the server underling processes. To meet this objective, each server instantiates and maintains an Address Space that is a collection of data to be exposed to clients. The OPC UA Address Space consists of nodes and references. The main role of the nodes is to expose the underlying processes state and behavior as a selectable, well-defined piece of information.

To create the Address Space the OPC UA servers must instantiate all nodes and interconnect them by means of references.

As it was stated previously, typical implementation architecture consists of OPC UA Clients, which are connected to an OPC UA server (Fig. 1). To get access to underlying *Processes* data a generic client does not need to have any awareness of the Information Model used to create the Address Space exposed by the sever in advance. However, in the production environment, the Information Model (types) knowledge may be useful to offer additional functions, like dedicated data processing, customized control panels or predefined structure of the database tables. Types knowledge also simplifies configuration of the clients, because all of the items composing the complex process information can be accessed simultaneously – they can have one single address – identifier.

To implement the Address Space two questions must be addressed [20]:

- How to couple the nodes bi-directionally with the underling process data sources?
- How to create and maintain it?

Using the instantiated nodes by means of a well-defined set of services [8] (*OPC UA interface*), clients get access to data representing a selected part of the underlying processes environment. Nodes are divided into classes. The *Variable* class is used to represent the values – has the Value attribute. To be used as the process state representation, the value of the Value attribute must be bound with a real data source, e.g. an analog signal or a database item. The *Method* class represents a function that can be called by the clients connected to the server. In this case the real-time process bindings are responsible for conveying the parameter values, invoking the represented series of operations and returning the execution result. In Fig. 1 both classes are the main building blocks of the architecture that allow the server to couple the exposed Address Space with the current state and behavior of the underlying *Processes*.

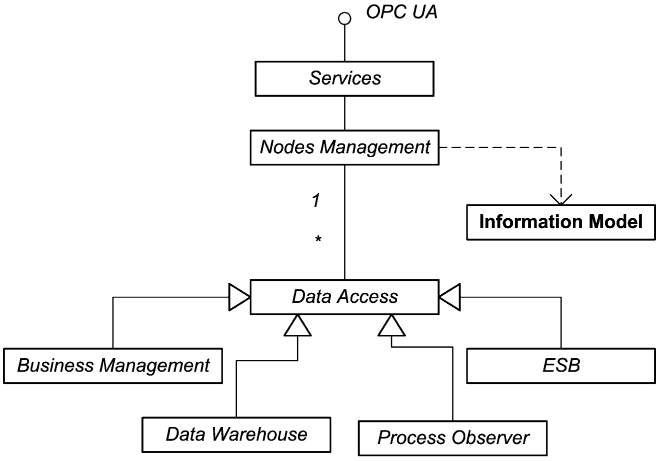

Fig. 2 Process Observer archetype diagram

The technique of binding the nodes with process data is vendor specific, but it must be transparent to the *Clients*. Nodes management functionality on the *Client* part is standardized by the OPC UA Service Model [8] (*OPC UA* interface - as a set of services depicted in Fig. 2). Access to the values representing the current process state is provided by the Read/Write functions. The client can also be informed about changes of the process state using "data change" notifications. Invoke and event notification functionalities allow clients to use the *Methods*.

In Fig. 2 the proposed internal diagram of the *OPC UA Server* package is shown. To implement the functionality presented above, three coupled function classes shall be distinguished:

- *Services*
- *Nodes Management*
- *Data Access*

The diagram in Figure 2 shows the associations between the above function classes. In this architecture the *Data Access* is responsible for transferring process data up and down. The *Nodes Management* function class couples the *Processes* data with appropriate nodes instances representing underling process metadata and provides a homogenous picture to *Services* that finally exposes it to all connected clients.

Real-time process data can be obtained from any underling process, i.e. file system, database, device or even large scale highly distributed automation system. For embedded applications it may directly use internal controller registers of the device. The *Data Access* function class is able to obtain data using the random access or underlying communication infrastructure and vendor-specific protocols.

To create the Address Space - i.e. to instantiate all nodes and interconnect them by means of references - the *Nodes Management* function class uses a predesigned static *Information Context* (dependent on the *Information Model* – not shown in Fig. 2) providing a detailed description of all the nodes, including their attributes and references. Static means that the model is predefined for the selected environment, but it does not mean that the exposed Address Space is static. In this approach, nodes can be instantiated and linked dynamically, however this operations must conform to the model definition. Dynamic behavior of the Address Space can be controlled by the connected clients using services or by the current state of the process.

Before nodes making up the Address Space can be instantiated by the server, this Address Space must be designed first. Model designing is a process aimed at designing Information Model as a set of nodes and their associations and, next, creating the *Information Context* as its representation in a format appropriate for the implementation of the *Nodes Management* function class. Depending on the OPC UA server implementation, the Information Model representation and support for the modeling process varies. The main challenge that must be faced up is how to prepare *Information Context* seamlessly without programming. The designing process can be supported by the Address Space Model Designer tool [19], [21], [22] that is intended to help architects, engineers and developers accomplish *Information Context* preparation. Using the tool it could be similar to preparation of a hypertext document.

The tool developed by a team leaded by the author is very useful to make the publication of the process data in the context of metadata straightforward and without programming, but it is only proof of the solution concept. To promote the Object Oriented Internet concept in a wider scope more research is required with the goal to define a formal, widely accepted representation of Information Model, semantic validation methods, generation of the Address Space and custom complex data serialization to leverage the deliverables to the designers, developers, end user, etc. and to integrate them into other applications. It is proposed to carry on this research work as a common effort using an open source project [23] as the research workspace, which offers basic work framework and very convenient project management utilities available on the well-known GitHub platform. In other words, applications interoperability is yet granted by the OPC UA standard, the next step is to work out unification of the designing/deploying methods and supporting tools to make people cooperation possible and finally the Object Oriented Internet a real option.

## V. Accessing Information Resources

### A. Architecture

According to the definition the Internet is expected to provide access to information resources and services hereinafter referred to as data sources. For the architecture proposed in Fig. 2 the *Data Access* functional class is responsible for fulfilling this job. Because the underling information resources and services are to be exposed in the context of the Address Space the functional class *Nodes Management* is responsible for binding the underlining data sources with appropriate variable and method nodes embedded in the Address Space. These variables and methods are accessible by the remote clients using the standard *OPC UA* interface provided by the *Services* functional class

In the proposed approach there are no limits regarding possible data sources that can be coupled by the *Data Access* with *Nodes Management*. Generally, three classes of data sources can be distinguished:

- Data representing the current state and behavior of the underling real-time industrial processes;
- Archival data representing the behavior of the underling processes in time;
- Current processed data obtained from business supporting applications and other connectivity standards.

A typical example of the real-time physical processes is the industrial automation process control system. The process control contains digital plant floor devices responsible for measurements, controlling and condition monitoring of the real-time process locally. Usually, the predominant function in this case is accomplished using PLC (Programmable Logic Controller) or DCS (Distributed Control System) class products. In a distributed process, one can distinguish autonomous islands of automation, whose cooperation has to be harmonized by a supervisory system that is responsible for controlling the process as a larger whole.

To get access to the plant floor devices and couple them to the *Nodes Management* functional class underlying proprietary communication links must be instantiated. Although from the design point of view this communication can be considered transparent, its availability and reliability is crucial for the final result. Assuming transparency, it simplifies the problem to a great extent, provided that the assumption is valid.

To instantiate a link we need a medium. To transfer data over the medium, we have to use selected protocols controlling access to the medium and responsible for robust data transfer. Additionally, the protocol and medium often limit the bandwidth and medium access. Any of these requirements can cause that the above assumption and, in consequence, this approach becomes unreal. Therefore, we need to look for a compromise between an unacceptable complexity and unreal assumption.

To make the plant floor device interoperable with the *Data Access* functional class, both have to use the same vendor-specific or standard-compliant protocol. Relying on vendor-specific solutions limits future solution expandability. Generally, it is, therefore, not recommended and vendors usually offer a standard protocol for plant floor devices. Unfortunately, there are hundreds of “open standards” defined in the automation marketplace.

For the highly distributed process control systems (like smart grid, smart heat distribution networks, etc.) assuming that the whole system uses one common communication medium is not feasible [24].

Lack of common medium coverage of the whole area that the controlled process is dispersed over requires engaging simultaneously many communication infrastructures, and dealing with a multidimensional communication network. The main advantage of using many infrastructures is the possibility of improving robustness of the system by providing communication redundancy [24] in overlapping areas provided that it is possible to utilize them alternatively.

To transfer the data, we need a medium, but to use the medium, we need to engage an infrastructure: a technology (Internet, GSM, satellite, ISDN, etc.) governed by technical standards and an organization governed by regulations, procedures, practice, etc. A platform optimal today may be useless for future because technology is progressing rapidly and economical standing of organizations may fluctuate.

To address all issues described above the *Data Access* functional class has to be expanded to employ appropriate communication functionality. It is proposed to implement Process Observer architecture presented in next section as an extension to manage the underling communication infrastructure and transfer process data in real-time in a systematic manner.

The next example of the underlying data source is a repository containing manufacturing process information, like data base or even a data warehouse. Data warehouses are designed to facilitate reporting and analysis. This kind of application focuses on data retrieving and analysis, to extract, transform and load data.

To interconnect with an archival processes data repository the *Data Warehouse* extension of the *Data Access* functional class has been added to the proposed architecture in Fig. 2.

Data without context has no meaning, hence metadata is critical to a data strategy. Designing a data binding mechanism both data and metadata must be considered. The *Data Warehouse* extension is responsible for providing an appropriate translation (according to the OPC UA Information Model) between metadata of the underling process data and the context of the server Address Space where the data is made available to the clients. Simplicity of this relationship is crucial to the business, because metadata exposed by the OPC UA server and metadata describing the underling repository content must be designed on the basis of the same semantics rules. In the design process, where the metadata originates and how to synchronize it should be addressed first.

Usually, apart from the historical data access mechanism OPC UA clients use real-time data access subscribing to current data changes. Therefore, the *Data Warehouse* must be smart enough to provide updates by following the repository modifications.

Business Intelligent (BI) applications are a keystone for macro optimization at the enterprise level because they provide an insight into data, which allows analysts and executives to easily uncover patterns and abnormalities in the business [26]. In the late 90s organizations also implemented enterprise resource planning (ERP) and customer relationship management (CRM) software that can be candidates for the next data source. There are many other business level applications (BLA) processing information and providing results that can be published by the OPC UA server in the Internet using the Object Oriented approach.

Usually a data warehouse (DW) is a central part of today's BLA and real-time process control deployment and hence the archival data may be available also indirectly via the *Business Management* or *Process Observer* data bindings.

The cornerstone of a successful BI application is its capability to provide business users fast and easy access to data for analysis. Online analytical processing (OLAP) tools are a foundation of BI application. In the discussed architecture, another option is to distribute BI application over the Internet and couple the OPC server exposing OLAP functionality to the remote applications.

The implementation of the above described functional classes requires a dedicated link used to manage data transfer. Data transfer for the most popular database management systems are governed using Structured Query Language [27]. It is a language rather than connectivity, but can be used together with widely used vendor services to standardize the data access and simplify the *Data Warehouse* implementation.

To make the enterprise more and more beneficial, the applications supporting automation and business processes have to be integrated. From integration, we should expect additional performance improvement as a result of synergy and real-time macro optimization effects. Enterprise Service Bus (ESB) [28] is a standard-based concept and hence it is well suited for integration projects. The ESB provides a highly distributed, event-driven Service Oriented Architecture (SOA) that combines Message Oriented Middleware (MOM), web services, XML data transformation and intelligent routing based on content.

Using ESB as a foundation for the applications integration allows for implementation of the OPC UA server data bindings by interconnecting of the *Data Access* with this bus. In the architecture presented in Figure 2 this role is fulfilled by the ESB extension of the *Data Access*.

### B. *Process Observer Architecture*

*The Process Observer* architecture described in [24], [25] is proposed to be used as a consistent sole representation of a distributed real-time process (Fig. 3). It is an extension of the *Data Access* class (Fig. 2).

In the presented architecture the following classes are distinguished:

- *Cache* is a collection of the latest values of the process data.
- *Controller* holds the plant-floor device data description.
- *Channel* is used to represent independent communication threads conducted simultaneously to each other.
- *Segment* represents a single communication path and is responsible for managing communication resources and data transfer from a group of devices that is to be accessed using the same transport connection.
- *DataProvider* is responsible for providing a stream of data to the *Segment*.
- The *Pipe* is a collection of *Ports*, where only one of them is active at any time.
- The *Port* represents a bidirectional device data streaming functionality.

The description represented by the *Controller* is used to schedule in time all read operations to update the data in the *Cache*.

Usually, lower layer communication requires multidimensional networks. The *Channel* class allows creation as many simultaneous communication paths as it is necessary. To assure mutually exclusive access to common resources, the *Channel* activates only one *Segment* at any time.

To provide a consistent process data from multidimensional network environment and using custom protocols the proposed solution enables to create many *DataProviders* instances by a *Channel* and use them by a data transfer algorithm realized by the *Segment*. Each *Segment* can use only one *DataProvider*, but one *DataProvider* can be used by many *Segments* associated with the same channel.

To provide polymorphism for the environment specific needs, the *DataProvider* is located outside the main software package and inherits an interface ensuring flexible management of the communication medium and transfer of the process data. This solution makes it possible to keep the core software unchanged and adapt a Software Development Kit to the specific needs. In this scenario, the late binding approach is supported. Late binding is useful if it is required to replace a part of software package without recompiling of the code base. In this case, a variety of protocols might be supported with a separate module for each protocol specification. A declarative configuration can be used to tell the application to use a specific module at runtime. Another scenario where late binding can be useful is to enable users of the system to provide their own customization through a plug-in. Again, the system can be instructed to use a specific customization by using a configuration setting.

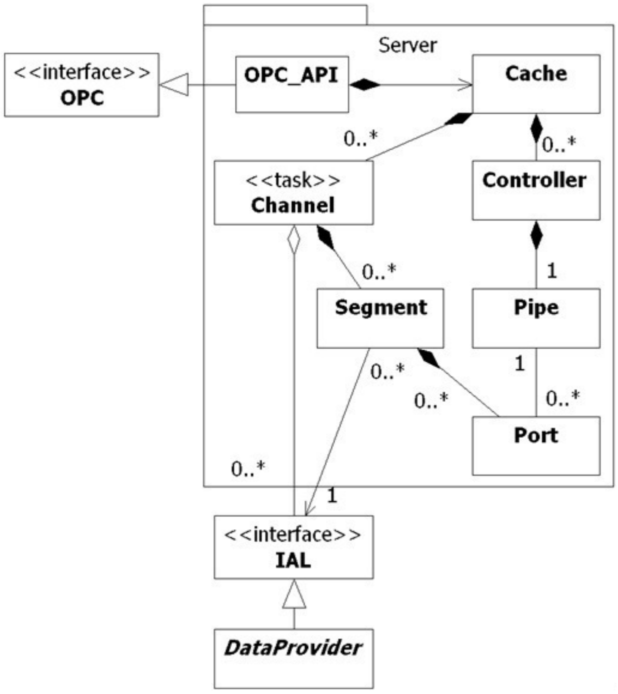

Fig. 3 Process Observer Architecture

In a real environment, apart from accessing underlying process data, monitoring and management of the recourses and communication infrastructure are often of the same importance. Monitor class (Fig. 4) represent this functionality. To commence factory tests or provide a state observer a simulation environment is required. Simulator class is responsible to provide the simulated data and can be used in place of the Protocol class for testing purpose. This concept makes it possible to publish all of the mentioned types of information in the same way using the defined interface and late binding approach.

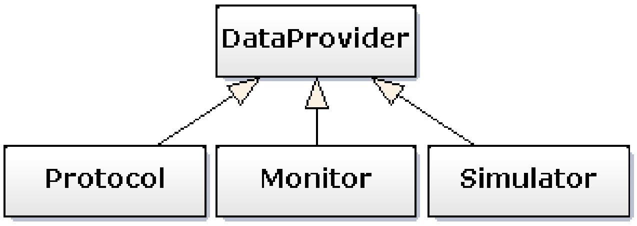

Fig. 4 DataProvider functions

In the proposed model (Fig. 3), the *Pipe* concept is used to assure redundancy. After detecting a failure of the active path, another *Port* belonging to the same pipe is activated immediately. *Segment* uses only active *Ports* and, therefore, the data is transferred over the network once only. The *Pipe* checks availability of non-active paths periodically. Using paths redundancy additional spare plant-floor devices can be used seamlessly as the next level of redundancy.

The main job of the communication software is to make `best effort' to keep the process data fresh and allow clients to access the data randomly. From the communication point of view, two independent communication environments can be distinguished (Fig. 1):

- *Processes* connecting plant-floor devices to an intermediate component (server);
- OPC UA Interface connecting the intermediate component (server) to *OPC UA Clients*.

Because both are used to transfer the process data, it is vital how these data transfer processes are related to one another. To finally design an appropriate sampling scheduling mechanism on the process side, we need to take into consideration:

- Needs of the *OPC UA Clients*.
- Current real-time process state;
- Current communication path load and its throughput;

All of them can change in time and, therefore, it is proposed to implement the following two unique closely coupled costs saving algorithms providing process data just in time and preserving communication bottlenecks:

- *Adaptive Sampling Algorithm* (ASA): responsible for adjusting the plant-floor devices sampling rate according to the current process state.
- *Optimal Transfer Algorithm* (OTA): responsible for minimizing the difference between requirements of client individual process data update rate and current sampling rate of a process control devices;

To minimize the data transfer costs, the sampling rate is adapted to the current process needs.

The Process Observer architecture is widely used as a communication engine in highly distributed systems. The supervisory control of a metropolitan heating system located in the city of Lodz – Poland [24],[25] is an example. The heat distribution network of Lodz (750k citizens) is supplied from heat and power plants with total thermal output of 2.5GW. It consists of:

- 3 heat and power plants,
- 2 backbone pumping stations,
- Hundreds of backbone heat chambers
- Thousands of local distribution points.

Their optimal utilization requires a control system to allow working on common supplying areas. As the system is distributed geographically (about 800km of pipes), safe communication between nodes (automation islands) is very important. An implementation [25] of Process Observer

Architecture proves the concept in highly distributed application.

The architecture presented in this section has been already integrated with the OPC UA services, but further research is required to integrate it with Information Model designing methodology consistently. The main challenge is how to support custom complex data. The complex data must:

- be factored using components gathered from the underling process,
- follow the DataType declarations in the Information Model,
- be transparently serialized over the wire.

## VI. Conclusion

Nowadays, in such a fiercely competitive environment, modern manufacturing and transportation automation systems have to be involved. Such systems usually consist of numerous different ICT systems located at business and process management levels. They are frequently dispersed geographically in multi-division organizations.

The Internet is a globally available communication infrastructure that makes it the first and practically the only candidate to be used as a platform to build a universal solution for the above objectives and even to integrate systems belonging to cooperating organization groups to benefit from the synergy effect and global optimization.

The freely expandable Object Oriented archetype and its practical implementation presented in the article prove that the above goal can be achieved and the final solution offers the following features:

- It provides application to application robust interoperability over the Internet;
- On the server side, it makes it possible to freely publish and update information and services in a contextual (semantics aware) environment;
- On the client side, it makes it possible to get a description, discover and finally get access to the requested information and services;
- Information resources and services exposed by the server that represent the state and behavior of the underlying processes allow clients to manage and control them over the Internet/Intranet;
- Client and server software can be offered by independent vendors as generic off-the-shelf products;
- The products can be tested for interoperability independently of each other.

To accomplish this it is proposed to distribute publisher (server) main tasks to three functional classes:

- A predefined fixed set of services based on the SOA concept conforming to the OPC Unified Architecture specification;
- Information context management using the object oriented programming paradigm;
- A pluggable proprietary data binding mechanism.

Development of generic communication software that can be interoperable requires specification compliance testing. It is proposed that OPC Unified Architecture, a new emerging industrial standard that fulfils requirements derived from this architecture should be used because it provides a definition of an appropriate: set of services and Information Model concept dedicated to formally describe the Address Space – context for the exposed information resources and services. It has wide industrial support and a well defined compliance test procedure governed by the OPC Foundation.

Available reference applications and commercial products pointed out in the article prove that the data binding concept can be successfully implemented as dedicated application-dependent pluggable components. The components must be able to couple the proprietary underling data access mechanism with the server mechanism managing the context where the data is embedded and made available to connected clients.

The approach to represent the underlying data processing environment as presented in the paper can be used for countless applications, from exposing the representation of measurement devices to building multi-enterprise management and remote process control systems. Smart networks, i.e. smart grid, smart district heat distribution networks, utility distribution, oil distribution, railways, etc. are an example of applications like that.

It is worth nothing that to promote the Object Oriented Internet concept in a wider scope more research is required with the goal to define a formal, widely accepted representation of Information Model, semantic validation methods, generation of the Address Space and custom complex data serialization to leverage the deliverables to the designers, developers, end user, etc. and to integrate them into other applications. In other words, applications interoperability is yet granted by the OPC UA standard, the next step is to work out unification of the designing/deploying methods and supporting tools to make people cooperation in this respect possible and finally the Object Oriented Interned a real option.

It is proposed to carry on this research work as a community effort using the open source project [23] as the research workspace on the well-known GitHub platform.

***Abstract*—In this paper, we describe the RobinHeart surgery robot development related project in which entire robot operation is supposedly done remotely, using wide area network connection. In such environment, any vision and telemanipulation data packets are subject to delay, limitations, issues and failures, as any network connections do. It has become necessary to create an internetwork emulation for the purposes of robot-related trials. The INSeRT platform has been developed to fulfill that role. INSeRT platform design is presented and discussed and first results of validation with real-life example are shown. Network channel manipulation techniques can be implemented at data-link OSI layer level, or it may be induced at network layer level – this approach relies on network layer packet manipulation and poses a promising start, as well as raises questions about whether implementing different distributions for delay or reordering is going to have significant impact on channel emulation and traffic parameters.**

***Index Terms*—Network performance, simulation, emulator, WAN, internetwork, telemanipulation, remote operation**

## I. Introduction

THE research and development presented in this paper is driven by the development of a surgical robot for long distance operation. The family of Robin Heart [1] tele-manipulators was founded in the Foundation for Development of Cardiac Surgery of Prof. Zbigniew Religa (FRK) in Zabrze, in collaboration with specialists from several academic centres (Lodz, Gliwice and Warsaw Technical Universities). According to project preliminary assumptions, the robot would have a segment-like structure allowing different configurations set up for various types of soft-tissue surgery. In particular, it should have an independent arm of the endoscopic video track with a wide range of application. The project has evolved together with the increase of experience gathered by the construction team.

In the first phase of the Polish Robin Heart Project, three robot models: Robin Heart 0, 1 & Robin Heart 2 (Fig.1) were created [2], differing from one another by the concept of control system and mounting. Between 2007 and 2008, the Robin Heart Vision, a robot for tracking video endoscopic channel, was constructed and tested. In 2010, after only one year of work, a new model, the Robin Heart mc2 appeared in the laboratory and in the Animal Experimental Medicine Centre for in vitro and in vivo tests. The robot fulfils the role of three operators: the first & second surgeon as well as the assistant holding the vision channel. In the same year, after completing a 2-year project, novel mechatronic tools, the Robin Heart Uni System were created. These innovative tools allowed to put into practice the idea of using the same surgery tools both on the robotic arm, tele-controlled by the operator, and in given cases in the other way: similar to traditional laparoscopic tools - manually but driven by means of a special handle with micro-motors mechanisms.

At the same time, effective systems of Man-Machine interface including ergonomic Surgeon (Master) environment with comfortable operating position of the Surgeon, high quality vision system and intuitive contact with Master tool of tele-manipulator (including force feedback, which is still optional, in research phase) are being developed [3].

In this paper, we describe the part of the project in which entire robot operation is supposedly done remotely, using wide area network connection. In such environment, any vision and telemanipulation data packets are subject to delay, limitations, issues and failures, as any network connections do. It has become necessary to create an emulation of internetwork for the purposes of robot-related trials. The INSeRT platform has been developed to fulfill that role.

This paper is organized as follows: the questions and problems with remote long distance operations in RobinHeart are presented, then the short review on network channel simulation state-of the-art and related issues are mentioned. INSeRT platform design is presented and discussed and first results of validation with real-life example are shown. Conclusions are drawn and the most important fields of further study are pointed out and summary is described at the end.

## II. Telemanipulation Control System for Long Distance Operation by Means of Robin Heart Family of Surgery Robotic Manipulators

Telemanipulator invented for less, minimally invasive cardiac surgery is a computer-controlled device, located between surgeon's hands and the tip of a surgical instrument or endoscopic vision channel. Basic requirements for this device are stable operative field of view, direct surgeon control and high level of precision. Main advantages, motivating the introduction of tele-manipulators to minimal invasive surgery field are also:

- Scaling of movement between Master console and Slave arm
- Filtering and tremor removing

- Comfort of surgeon work improvement with high quality HD (stereoscopic) imaging from operation field with zooming and filtering

General structure of Master-Slave (Operator-Robot arm) teleoperation system with video and manipulation data channel is presented on Fig. 2. Optional force-feedback track is presented, that is used to transfer tool-tissue interaction to Surgeon/Operator.

In this type of robotic arm navigation the slave manipulator mimics movements of master controller, driven by Surgeon/Operator (Fig. 3). A brushless DC motors working in connection with the robust local CAN bus with dedicated low level controllers were used as a driven units for every arm with four degree of freedom. Control system exchange data between master and slave part of control system, which process and transfer data by means of *network shared variables*. Both video transmission as well as manipulation transmission channels performances are closely related to outcome performance of an operator. In case of setting up any of these channels (and practically that would mean both of them) using internetwork, the network channel performance characteristic becomes critical to the system.

## III. Selected Issues of the Network Channel Emulation

The need for analysis and simulation of network traffic is constantly increasing. A large number of studies in this field derives from the need to improve the quality of services (QoS), complete the  service level agreement (SLA) or ensure proper network security level. As a first example, authors in [4] discuss the characteristics of actual Internet traffic in the context of flows and investigates the cause for the high fluctuation in the number of flows. They defined and analyze measurement metrics (such as link utilization, packet arrival rate, and the number of flows) and also test it by the use of university network with over 6000 end hosts and servers.

It is worth mentioning that types and patterns of actual network traffic flows changed dramatically.  As the authors show in [5] the proportion of traditional traffic (determined by well-known port based flows) is decreasing for p2p (peer-to-peer) traffic or other media as streaming or network gaming therefore a better method is to classify the traffic according to application layer programs. The authors indicates that it has become difficult to detect newly developed Internet applications which use random port numbers rather than static and registered ports.

Many aspects of traffic characterization and the dynamics and patterns of network usage was discussed by the authors in [6]. Authors proposed characterization of the traffic by linking the flow measurement architecture with the estimation algorithm. Developed framework was used to estimate the distribution and sample space of the underlying traffic by the use of nonparametric Parzen window (which is an information theory technique, possible to use for classification with various types of data sets [7]). Köandgel in [8] shows how important is characteristic of networks by the use of one-way delay measured, or taken, between any two points in the network. At his work author highlights that precision of one-way delay calculation for flow data depends on the capturing devices, especially on theirs timestamp resolution. Also, [9] presents distributions of flow length, packet size, throughput, for the popular and bandwidth consuming applications as stochastic phenomenon. Flow duration, flow bytes, packet size for popular network applications in the probability density function was presented for the flows collected at several locations on a corporate Intranet.

The classification of network traffic may be performed using machine learning approaches [10]. Network traffic classification can be used for network management (automated problems detection) or automated intrusion detection systems. The authors compare the research in this area. Very interesting subject is the collation of features, used by various researchers, to describe the Internet traffic dataset.

## IV. System design and technical implementation

Taking into account presented works, the most important distinguished features included:

- the necessity of control over the basic parameters of the network connection, in compliance with [11] and just like previously discussed in [12] and [13]: delay (latency), data transmission rate (throughput), lost packets ratio (packet loss) and delay variation (jitter) - this requirements form and review phases were conducted with methods described by one of authors in [14];
- as the requirements elicitation process has proven, specific system functionality has been necessary, which are pre-defined sets of network parameters and their variability trends over time (more on this subject below);
- the system should be able to gather information about the network parameters induced into channel in specific moment in time – the availability of such data will help to identify the correlation between the parameters of telemanipulation channel and assumed measure factors of remote controller operation.

Due to specific project stakeholders demands, the requirement of solution simplicity and capability of operation on available common hardware and software infrastructure has also been considered a ‘must-have’ (entire system had to be mobile and easily transferred, as well as we want to maintain the positive effect on system integration with other components).

The research and business enquiries allowed to distinguish two groups of solutions. Network channel manipulation techniques can be implemented at data-link OSI layer level, or it may be induced at network layer level, with most important examples of:

- Linux operating system kernel providing couple of built-in and patched capabilities, such as *tc* and *netem* package, *Iptables statistics* and/or *random* module, *Iproute2* packet capabilities exploiting *mark* in *iptables* software;
- FreeBSD operating system’s packet *dummynet*, providing similar capabilities;

Both concepts – bridge (Layer 2) or router (Layer 3) based, provide desired functionality in different manners, which will be the subject of another authors’ study. Taken into account the requirement of easy implementation in virtualized environment and the API functionality, the layer 3 approach has been chosen. There are a couple of entire similar systems as well, such as NIST’s project NISTNet (no longer maintained), or Tata’s Performance Engineering Research Centre *WANem* (The Wide Area Network emulator) which was actively taken into consideration, but the decision was made to create own solution, with API dedicated for Robin surgical robot environment and capable of data collection for channel testing purposes. Due to Linux popularity and for stability, CentOS OS 6.6 has been recommended for implementation.

The logical network infrastructure is presented on Figure 4.

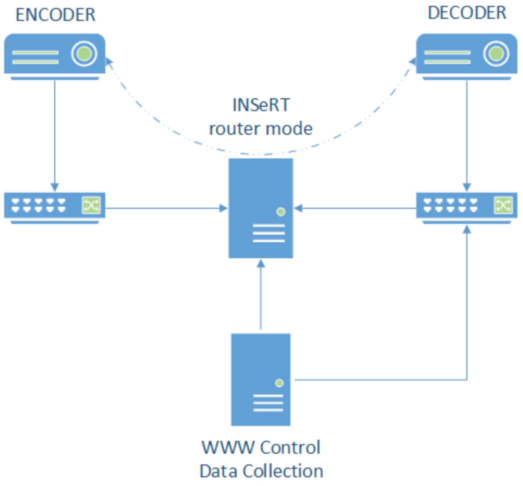

Fig 4. . INsERT system topology

Due to the need for the reduce of the interaction of the transmission line emulator with additional services such as HTTP graphical configuration module or database for connection parameters collection, they have been implemented on a separate server. Communication between a web application that offers GUI functions and module responsible for traffic manipulation takes place on a separate, dedicated channel. Commands are transferred with SSH2 protocol, which allows the use of a wide range of solutions, including certificates, so storing passwords in configuration files is avoided completely. Remote connection using SSH2 library enables standards console stream input and thus the introduction of any previously prepared user commands responses to an event related to changes in network parameters.

## V. Validation of Network Channel Emulation with INsERT

Two network interfaces are used to manipulate outgoing traffic, thus enabling asymmetrical network connection emulation (by varying parameters for both directions). Example of basic manipulation is presented in Table 1.

Table 1.
Basic testbed set example

| Parameter | Values set | Values measured |
|---|---|---|
| **Latency** | 100.0ms | 104.120ms |
| **Packet loss** | 10% | 9% |
| **Jitter** | 50ms | 46.541ms |

Currently, after test trials, three basic sets, or link categories, were defined, illustrating typical internetwork connections that might be used for telemanipulation and/or vision channels:

- Good quality connection – corresponding to leased WAN line;
- Limited quality connection – corresponding to channel realized using Internet;
- Problematic connection – corresponding to ‘challenged links’, for example cellular or even satellite connection.

Those three categories were implemented as a presets of parameters, using simple statistical models of network traffic. Statistical characteristics are based on traffic recorded during experiments with every channel type, but those simple models do not take into the account the non-standard delay distribution, or correlation for packets delay, jitter or loss (which in turn do not emulate burst losses, for example) yet.

The example of limited quality connection emulation with real-life case study as a comparison is shown on Fig. 5 (TCP time/sequence graph) and Fig.6 (throughput). The simplicity of a model is visible on throughput graph comparison in particular – there is much more variation in real-life scenario, however the transmission characteristic is similar.

## VI. Conclusions and Summary

In presented article, the design and implementation process of internetwork channel emulation for surgical robot telemanipulation experiment was presented, as well as the discussion on various methods, issues and future possible work. The system is functional and provides means for emulating real-life scenarios when using internetwork links for remote operation of equipment using video and telemanipulation channels. System provides functionality for traffic manipulation, allowing to simulate different kinds of network links and situations. Open research question, to be pursued in further work, is whether implementing different distributions for delay, reordering, and/or packet loss is going to have significant impact on channel emulation and traffic parameters.

The INsERT system concept assumes that beside traffic characteristics manipulation, the system is designed for collecting the data on network parameters set when working remotely with surgical robot. The maintenance of ergonomic conditions of surgeon’s work is essential to surgical robot system and proper assessment of the network channel conditions impact on any activity is crucial to any experiments on that matter. The determination of the minimum acceptable channel parameters is necessary to anticipate problems with the telemanipulation track, based on changing network traffic characteristics. Thanks to implemented system, it becomes

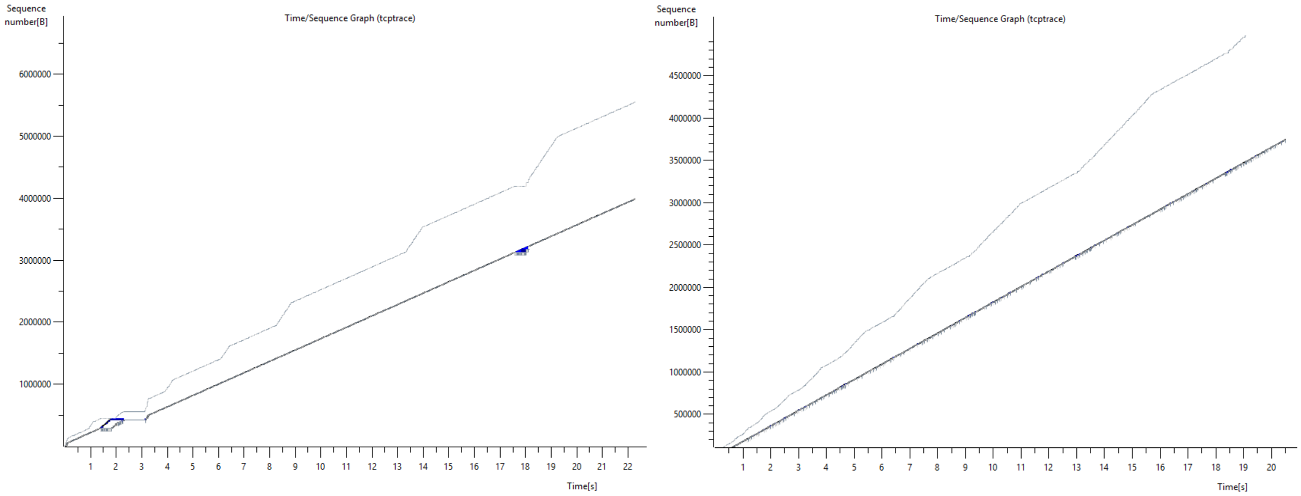

Fig 5. General structure of Operator-Robotic_Arm bidirectional data transfer: video and manipulation channel

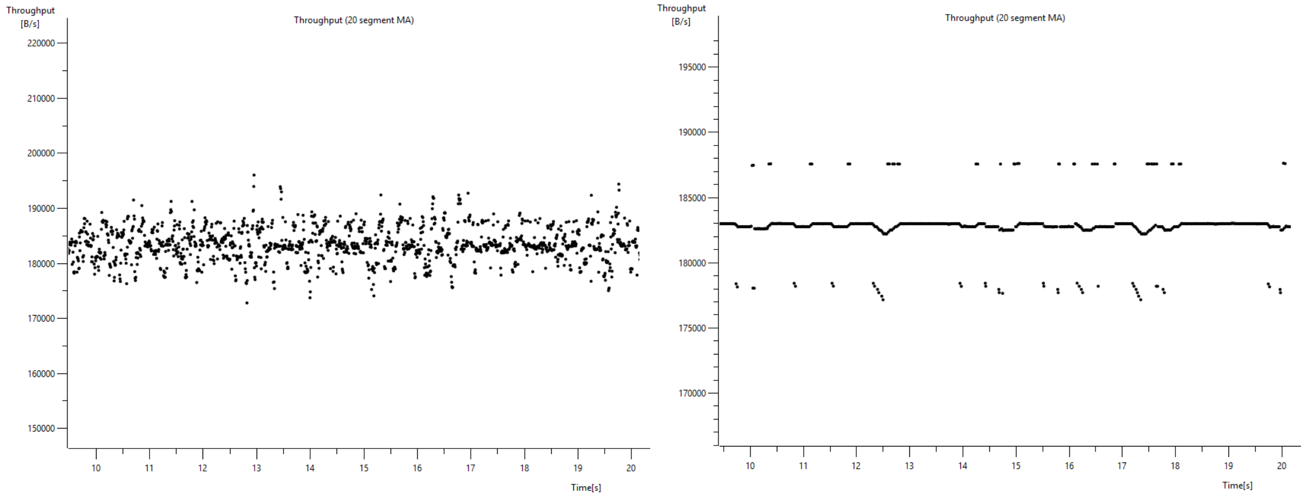

Fig 6. General structure of Operator-Robotic_Arm bidirectional data transfer: video and manipulation channel

possible to designate parameters values in an empirical manner with exercises with real surgeons in controlled training environment. Obtained data will allow for network link validation for surgical robot vision and telemanipulation purposes in real-time. Trial studies with control group of surgeon students were already conducted and will be covered in extensive manner in the future. Current research connected with the studies of influence of network parameters values on telemanipulation performance are tested on new RH Tele ™ arm (Fig. 7).

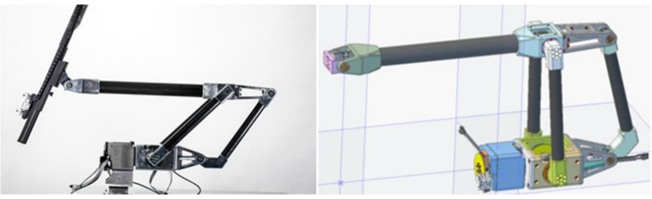

Fig 7. . RH Tele ™ arm, made from carbon base, light materials (final arm and project)

***Abstract*—Mobile self-organizing ad hoc networks (MANETs) can significantly enhance the capability to coordinate the emergency actions as well as monitor contaminated areas, explore unmanned space, inspect and control working environments. The management of networks that can dynamically and freely organize into temporary topologies raises interesting problems, that are particularly challenging for networks formed by mobile devices. Due to the inherent complexity of these systems, the development of applications relying on mobile network nodes and wireless communication protocols would be greatly simplified by the use of specific tools for supporting testing and performance evaluation. Modeling and simulation are widely used in the design and development of wireless ad hoc networks. In this paper we model mobile ad hoc network (MANET) using discrete event systems methodology (DEVS) and describe the functionality and performance of the Java-based simulation tool for the performance evaluation of self-organizing and cooperative networks for emergency situation awareness. The simulator can provide a useful support for the verification of the design of a network system, employed communication protocols, control and coordination algorithms, allowing the user to display a step-by-step evolution of the network in a suitable graphical interface. The practical case studies are provided to illustrate the operation and performance of the presented software.**

## I. Introduction

THE AD hoc networking is a relatively new area of research that has become extremely popular over the last decade and is rapidly increasing its advance into different areas of technology. A mobile, wireless, and ad hoc network (MANET) is formed of wireless mobile devices (network nodes) that can dynamically and freely self-organize into temporary network topologies. The topology of MANET may change rapidly and unpredictably. Moreover, in many application scenarios there is no prearrangement assumption about specific role a given node should perform. Each device makes its decision independently, based on the situation in the domain and its knowledge about the network. Nodes communicate wirelessly and share the same radio channel. The devices located within their transmission range can communicate directly without the need for an established infrastructure and centralized administration. For communicating with devices located beyond the transmission range, the node needs to use intermediate nodes to relay messages hop by hop. Thus, in general, routes between mobile nodes may include multiple hops.

Currently research effort is directed toward the specifics and constraints in ad hoc networks, such as: limited transmission range, limited link bandwidth and quality of transmission, constrained resources, mobility nature of the network and transmission security [1], [2], [6].

To design a self-organizing MANET that can support the monitoring in emergency situations and/or support coordination of emergency actions the following problems have to be solved: (i) how to determine a minimum number of devices to monitor an area, explore an unmanned space or control working environment; (ii) how to determine the optimal positions for all devices and how to manage internode communication to imply connectivity among the working set of devices and a base station, and how to coordinate and control all devices; (iii) how to schedule devices to reach the destination positions, etc.

Design, development and evaluation of MANET is a nontrivial task, especially as it is envisioned to be deployed in a large scale. It is obvious that the complexity and scale of modern ad hoc networks limit the applicability of purely analytic analysis. Therefore, investigation of MANETs is achievable by resorting either to software simulators or to testbed networks. In most applications the lack of flexibility of testbeds and high costs of their development make simulation unavoidable.

In this paper, we model a MANET system using discrete event systems methodology. We describe a flexible interactive simulation environment for the development of self-organizing, cooperative wireless networks formed of static and mobile devices that can be used to monitor contaminated area, inspect a harsh environment, create a communication infrastructure to collect measurements and transmit them to the base station, and support coordination of emergency actions.

## II. Wireless Networks Simulators

Due to the complex nature of MANET, its simulation is a challenging task. It needs models of hardware, wireless propagation, mobility, energy usage, decision making, etc. Hence, simulators are inherently complex and they generally require huge computational resources to execute. In general,

978-83-60810-66-8/$25.00©2015, IEEE

they rely on various techniques for improving their accuracy, usability, scalability, speed, etc.

A variety of software environments simulating wireless networks are available today. Simulators rely on various methods and technologies for improving their accuracy, usability, efficiency and scalability. An overview of state of the art ad hoc network modeling and simulation tools available commercially and from open source is presented in [16], [40] and [14]. Researchers and engineers can choose among publicly available products or alternatively, can develop their own simulator. The commonly used network simulators like Riverbed Modeler (OPNET) [36], ns2 [20], ns3 [21], OMNeT++ [30] or GloMoSim [11], and its commercial version QualNet [31] can simulate ad hoc networks. Moreover, several software tools for mobile robots simulation, like v-rep [39] can be used. These tools provide the facility to simulate the protocols in different layers (MAC protocols, routing protocols, etc.), and some of them simulate movement of nodes (wireless devices). There are a number of possible sets of criteria that could be used for network simulators comparisons, e.g. time of execution, memory requirements, scalability, available functionality, programming interface, etc. Different tools are optimized for different purposes.

Most of available ad hoc networks simulators require costly shared-memory supercomputers to run even medium size network simulation. We are involved to large scale mobile network systems simulation and their practical applications, and our goal was to develop scalable simulator operating in real time. Hence, to provide high performance and scalability we utilized the paradigm of federating disparate simulators [7] and asynchronous distributed simulation technology [22], [40]. This is the main difference between our software and the other tools. Moreover, most existing ad hoc networks simulators focus on the MAC protocols implementation with the lack of the radio management and mobility modeling. Usually only simplified wireless transmission models and obstacles free simple mobility models are provided (ns-2, Castalia project in OMNeT++, v-rep). The other reason for developing a new simulator was the complicated architecture of available tools and limitations in results visualization and user-system interaction. In case of OPNET, OMNeT++ or ns-2 and ns-3 systems a user must read a large number of manuals to learn how to use the tool. The source coding is usually specialized for a given simulator and it is not easy to implement a given example and add modules developed by the user. Many network simulators do not support both the user interactions during the experiments and animation.

The current version of our simulator called MobASim provides implementations of radio propagation models, mobility models handling obstacles and tools for an environment (simulation scene) modeling. All these models are described in the next section. The open design of the architecture of MobASim, and its extensibility to include other open source modules or modules developed by the user, which are specific to a given application, was chosen in the hope that the system will be a useful platform for research and education in ad hoc networks. The federated approach to simulation of networks and provided functionality make different our tool from mentioned popular software systems for simulation.

## III. Ad Hoc Wireless Network Modeling

### A. Network Modelling

The aim is to model an ad hoc network formed by $N$ static and mobile, self-organizing and cooperating wireless devices $D$ (network nodes) equipped with sensors. All nodes can move with the speed $v \in [v_{min}, v_{max}]$ in the workspace $W$ avoiding the existing obstacles and communicate through radio.

In our research we use the discrete event systems methodology (DEVS) to model a mobile network, i.e., the network operation being modeled is understood to advance through events. The considered DEVS system is composed of several components responsible for different functionalities. We distinguish three types of such components: *node* – a mobile or static device that executes the assigned task, *mobility manager* that is responsible for tracking the nodes on the map and collision avoidance and *communication manager* that models the wireless communication between all nodes. Hence, each MANET simulator consists of three groups of logical processes LPs, responsibly Ns, MMs and CMs. The wireless communication and mobility models that are implemented in our simulation software are described below.

### B. Mobile Network Node Modelling

A high quality mobility modeling is a critical aspect that has great influence on the performance characteristics of each network node and the whole ad hoc system simulation. In literature we can find several less and more realistic models, such as a random mobility model with Brownian-like motion, a random waypoint model (RWP) with randomly generated target point and velocity, a random direction model with randomly generated direction of movement. Map-based mobility models are used for applications in which nodes are constrained to move within defined paths. The surveys of mobility models and main directions to mobility modeling of moving wireless devices one can find in [2], [8], [19], [37].

Widely used approach to mobility modeling, is to apply a concept of an artificial potential field that can be viewed as a landscape where the mobile device moves from a high-value state to a low-value state, [5], [37]. The artificial potential function $V$ is a differentiable real valued function, which value can be viewed as energy. The gradient of $V$ results in a force $F$, which points in the direction that locally maximally increases $V$. The potential function can be constructed as a sum of repulsive $V_{-}$ and attractive $V_{+}$ potentials. The obstacle repels the mobile device while the goal attracts it. The sum of $V_{-}$ and $V_{+}$ draws a device to the target while deflecting it from obstacles. The concept of a potential function is used in particle-based mobility schemes [37], where network node considered as a self-driven moving particle is characterized by a sum of forces, describing its desire to move to the target and avoiding collisions with other nodes and obstacles.

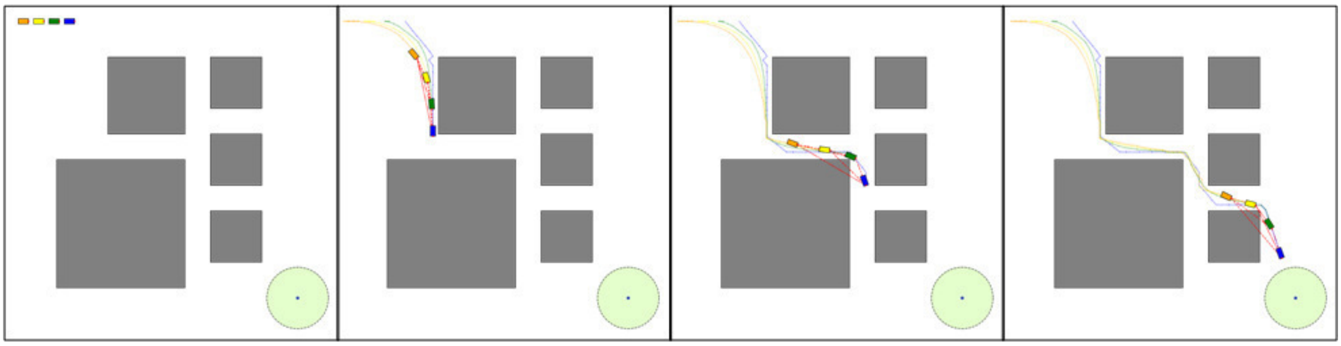

Fig. 1: Convoy formed by the team of mobile devices.

In our research we investigate a group mobility model for calculating of collision-free motion trajectories for $N$ wireless devices that form a cooperative network. Our computing scheme adopts two techniques, the concept of an artificial potential field and the concept of a particle-based mobility. This model can be used to cooperative and fully connected networks design. The detailed description of our model is provided in [24], therefore in this paper we present the summary.

We model each mobile device $D_i$ by a polygon in the workspace. We define its reference point $\mathbf{c}^i = [x^i, y^i]$, which is the location of its antena and a target location – the destination point $\mathbf{c}_g^i = [x_g^i, y_g^i]$. It is obvious that to maintain a constant communication with the base station at least one another device has to be within the transmission range of each $D_i$. Therefore, the motion trajectory of each $D_i$ depends on the potential $U_g^i$ between $D_i$ and its target and the potentials $U_k^i$ between $D_i$ and other devices $D_k$, $k = 1, \ldots, N$, $k \neq i$. Hence, a simple artificial potential function $U^i$ for $i$th device can been calculated

$$U^i(c^i) = U_g^i + \sum_{k=1, k\neq i}^{N} U_k^i(c^i), \tag{1}$$

where

$$U_g^i(c^i) = \epsilon_g^i \Big(\frac{\overline{d}_g^i}{d_g^i} - 1\Big)^2, \qquad d_g^i = ||c^i - c_g^i||, \tag{2}$$

$$U_k^i(c^i) = \epsilon_k^i \left(\frac{\overline{d}_k^i}{d_k^i} - 1\right)^2, \qquad d_k^i = ||c^i - c_k^i||. \tag{3}$$

$\epsilon_g^i \geq 0$ and $\epsilon_k^i \geq 0$ in (2) and (3) denote weighting factors determining the importance of the target point $g$ and the device $D_k$ respectively. $d_g^i$ and $d_k^i$ are real Euclidean distances between $\mathbf{c}^i$ and $\mathbf{c}_g^i$ and $\mathbf{c}_k^i$ after a network transformation, $\overline{d}_g^i$ and $\overline{d}_k^i$ the reference distances calculated due to the current signal strength measurements.

Taking into account the potential function defined in (1) we can formulate the optimization problem (4) and calculate the expected position of the reference point $\mathbf{c}^i$ of $D_i$ after moving the device:

$$\min_{\mathbf{c}^i} U^i(c^i). \tag{4}$$

The Tangent Bug algorithm described in [5] is applied to avoid obstacles in the workspace while moving the devices.

In summary, the following algorithm is used to motion trace calculation of $i$th device at time instants $t_0, t_1, \ldots, t_i, \ldots$:

1) Calculate the reference distance $\overline{d}_g^i$ to the target point $g$ and the reference distances $\overline{d}_k^i$ to all neighbour nodes due to the current maximal radio range and environment characteristics.
2) Calculate the displacement for the device $D_i$ for results of step 1.
3) Move $D_i$ to the new position in $W$.
4) Rotate $D_i$ (if necessary).
5) Calculate and broadcast to the network the new position of the device $D_i$.
6) Return to step 1.

We assume that each network device can calculate its localization in the workspace based on the measurements from GPS or other localization systems ([15], [17], [29], [38]. The algorithm terminates when the minimal the potential function (1) reaches the minimum value, and all the devices don't change their positions. The example results of application of our model to calculate the motion patterns for a group of devices forming a convoy are presented in Fig. 1

### C. Internode Communication and Reference Distance Calculation

A signal strength measurement using the RSSI (*Received Signal Strength Indicator*) are often used to estimate the reference distances $d_g^i$ and $d_k^i$ in real networks. For purposes of the simulation we applied the long-distance path loss model to radio transmission modelling, [35]. It indicates that received signal power decreases with a distance, both in outdoor and indoor environments. We assumed that the radio coverage region of the transceiver of $D_i$th device is a disc centered at $\mathbf{c}^i$. Hence, the signal degradation $PL(d)$ ("path loss") with distance $d$ can be defined as follows $PL(d)[dB] = P_t(d)[dBm] - P_r[dBm]$, where $P_t$ denotes power used by a sender to transmit the signal and $P_r$ power of the signal received by a receiver. In the long-distance path loss model $PL(d)$ is modeled as a random variable with log-normal distribution ([2], [9], [32]).

$$PL(d)[dB] = PL(d_0)[dB] + 10nlog\left(\frac{d}{d_0}\right) + X_\sigma, \qquad (5)$$

where $d_0$ denotes a reference distance ($d_0$=1 m for IEEE 802.15.4) and $X_\sigma$ a zero-mean Gaussian distributed random variable with standard deviation $\sigma$ (all in dB).

To enable the communication the signal strength received by neighboring nodes should exceed a receiver sensitivity $P_s$. The Q-function may be used to determine the probability that the received signal level will exceed $P_s$. It is defined as follows

$$Q(z) = \frac{1}{\sqrt{2\pi}}\int_z^x \exp\left(-\frac{x^2}{2}\right)dx, \qquad Q(z) = 1 - Q(-z). \quad (6)$$

The probability that the received signal level $P_r$ in distance $d$ will exceed a value $P_s$ can be calculated from the cumulative density function as

$$P[P_r(d) > P_s] = Q\left(\frac{P_s - \overline{P_r(d)}}{\sigma}\right). \qquad (7)$$

A tabulation of the Q-function for various values of $z$ is given by Rapaport in [35]. The received signal exceeds the receiver sensitivity with probability of 99% for

$$\frac{P_s - \overline{P_r(d)}}{\sigma} = -2.3, \qquad \overline{P_r(d)} = P_t - PL(d). \qquad (8)$$

From (8) we can calculate $PL(d)$

$$PL(d) = -2.3\sigma - P_s + P_t. \qquad (9)$$

Using (9) and definition of $PL$, (5) we can estimate the reference distance $\hat{d_k^i}$ between $i$-th and $k$-th mobile nodes

$$\hat{d_k^i} = d_0 10^{\frac{-2.3\sigma - P_s^k + P_t^i - PL(d_0)}{10n}}, \qquad (10)$$

where $P_t^i$ denotes a transmission power of a node $i$ and $P_s^k$ the sensitivity of a node $k$.

The value of $X_\sigma$ and $n$ in (10) depend on the workspace conditions, and can be calculated using linear regression such that the difference between the measured and estimated path losses $PL$ is minimized over a wide range of measurement locations. The values of $n$ estimated for various environments are provided in [35].

### D. Environment Modeling

To create a workspace of a network to be simulated a user can define simple objects in the domain as polygons. For more detailed description of a terrain to be considered the MobASim simulator provides the interface to the GeoTools toolkit. The GeoTools [10] is the open source Java coded library containing standard methods for the manipulation of geospatial data, for example to implement GIS (Geographic Information System).

Wireless devices are widely use to establish sensing systems for contaminated areas monitoring. To perform simulations with the MANET system for environmental monitoring it is necessary to model propagation of a pollution. Very dangerous for human beings are clouds created by heavy gases – gases with density greater than that of air. They can move close to the ground for significant time at high level of gas concentration [33].

The models of heavy gas dispersion are divided into categories based on different criteria. Three main groups: empirical, research and engineering models are distinguished [18]. Empirical models are developed based on environmental measurements and laboratory experiments. Research models – formulated by sets of partial differential equations dependent on time and three space coordinates – provide complete and detailed description of the physical process of the heavy gas dispersion. The trade off are engineering models that are widely used in practical applications.

The current version of the MobASim system provides the box model for instantaneous releases to simulate heavy gas dispersion. It belongs to the group of engineering models. It is a simple model that assumes that a gas cloud forms a uniform cylinder. The detailed description is in [23]. Hence, in this section we present the summary of the box model. In general, it is formed by a set of three linear ordinary differential equations:

$$\frac{dc_c}{dt} = v_c, \qquad (11)$$

$$\frac{dr}{dt} = v_f, \qquad (12)$$

$$\frac{dm_a}{dt} = \rho_{air}(\pi r^2)v_t + \rho_{air}(2\pi rh)v_e, \qquad (13)$$

where $c_c = [x_c, y_c]$ denotes the position of the centre of a cloud, $v_c$, $v_f$, $v_e$, $v_t$ denote following velocities: transport, gravitational and entrainment for edge and top of a cloud. $r$ is the radius of a cloud, $h$ its height and $m_a$ is the entrained mass. $\rho_{air}$ denotes the air density.

Equation (11) describes the spreading of the centre of a cloud, (12) the puff horizontal spreading influencing the cloud radius. Mass conservation is described by formula (13).

The gravitational velocity $v_f$ can be calculated for a given standard gravity $g$, the height of a cloud $h$, a cloud $\rho_c$ and an air $\rho_{air}$ densities according to following formula:

$$v_f = C_F\sqrt{\frac{g(\rho_c - \rho_{air})h}{\rho_{air}}}, \qquad (14)$$

where $C_F$ denotes the Froude number of the front. In case of the dense gas models typically assumed $C_F = 1.1$ [23].

The relationship between the edge entrainment velocity $v_e$ and the gravitational velocity is as follows:

$$v_e = \alpha v_f, \qquad (15)$$

where $\alpha \in [0.6, 0.9]$ [18].

Finally, the entrainment velocity for a cloud can be calculated due to the following equation

$$v_t = u_* \left( \frac{\kappa}{1 + \beta \frac{g(\rho_c + \rho_{air})h}{\rho_{air} u_*^2}} \right), \tag{16}$$

where $\kappa = 0,4$ denotes the von Karman constant [18], $u_*$ is the friction velocity [13], $\beta$ denotes the parameter (suggested value $\beta = 0.125$ [3]).

To solve above equations the current cloud density $\rho_c$ and its height $h$ have to be determined. They depend on the concentration $c$ of gas in a cloud. The value of $c$ dynamically changes due to cloud mixing with an ambient air. It can be calculated due to the following formula

$$c = \frac{\frac{m_0}{M}}{\frac{m_0}{M} + \frac{M_a}{M_{air}}}, \tag{17}$$

where $m_0$ denotes a mass of contaminant gas, $M$ and $M_{air}$ the molar weights of the gas and air respectively.

The relation between the gas concentration and its density notable influences a cloud dynamics. This relation is affected by many factors. In our work we assume that mixing of gas with ambient air is the only source of density change. We neglect chemical reactions and occurrence of any aerosol formations in the cloud. Based on these assumptions we can calculate the density of gas

$$\rho_c = \rho_{air} \left( \frac{1 + c\frac{M - M_{air}}{M_{air}}}{1 + \frac{c\Delta H_0}{\left((1-c)M_{air}c_p^{air} + cMc_p\right)T_{air}}} \right), \tag{18}$$

where $\Delta H_0$ denotes the enthalpy difference between the release material at the source and ambient conditions, $c_p$ and $c_p^{air}$ are specific heat capacities of gas and air respectively. $T_{air}$ is the temperature of an ambient air.

Then, the height of a cloud $h$ can be computed

$$h = \frac{V}{\pi r^2}, \qquad V = \frac{m}{\rho_c}, \tag{19}$$

where $V$ is the volume of a cloud.

The Euler method is used to solve the model (11)–(13). It should be pointed that the presented model can be employed to simulate a gas dispersion in a flat area without obstacles. In general, the model is valid until the occurrence of one of two conditions [18]:

- the difference between the density of cloud and air is less than a small assumed value,
- the growth of a cloud radius in single step is small enough.

## IV. Mobile Ad hoc Networks Simulation Platform

MobASim (*Mobile Ad hoc network Simulation*) [25] is a general purpose software framework for wireless, mobile ad hoc networks simulation and a library of Java classes that can be used to build a MANET simulator. Each simulator is designed as federation of disparate simulators of subnetworks that compose the considered MANET or a federation of simulators of independent, geographically dispersed MANETs or WSNs (wireless sensor networks) that cooperate from time to time. The components of such simulators can be easily reused in many computations. MobASim can run on a single or parallel machine or a computer cluster.

Fig. 2: The MobASim application.

The MobASim system is completely based on Java. At the heart of the MobASim technology is the ASimJava library developed by the authors, and described in [26], [28]. MobASim is composed of four main components presented below.

### A. MobASim Modeler

The model of the network considered can be generated using MobASim GUI or can be loaded from the disc file in the XML format. The configuration of the system is saved into the disc file for reuse in other experiments. The following attributes and parameters have to be provided by the user: number of wireless devices that compose a network, wireless transmission model, MAC protocol, radio communication range, type of the mobility model, minimal and maximal velocity, destination, simulation time horizon.

Three libraries are provided to implement a simulator: wireless transmission modeling library (WTML), Mobility Models Library (MML) and Environment Modeling Library (EML). WMTL contains a collection of classes implementing models of wireless transmission and wireless communication standards. The currently available version of MobASim provides the implementation of the long-distance path loss model described in section III-C and three classes of MAC protocols based on the method that they handle the hidden and the exposed terminal problems. Class 1 – protocol assuming random access to the wireless channel (the hidden and exposed node problem is unsolved), class 2 – the protocol solves the hidden node problem but leaves the exposed node problem unsolved, class 3 – the protocol solves both the hidden node and the exposed node problems, but requires the deployment of an additional signaling channel.

MML contains classes implementing three types of mobility models: random mobility model, waypoint model and group mobility model described in section III-B. All models utilize discrete event systems methodology. The state of each mobile node is described by three variables: location within the deployment region, orientation (an angle between X axis and the direction of a node movement) and velocity.

EML contains a collection of classes that allow to model a simulation scene. They provide interfaces to tools used to create a workspace. This library is under development. We plan to implement models for spread of contaminations and various types of gases dispersion. Nowadays, EML provides the heavy gas dispersion model described in section III-D.

*a) MobASim Simulator:* responsible for the simulator implementation and performance. It provides three libraries: basic library – a collection of classes implementing basic elements of a simulator (logical processes, events, etc.), synchronization protocols library – a collection of classes implementing synchronization algorithms and runtime infrastructure (RTI) for parallel and distributed simulation. The functions from these libraries are basic components of a given simulator.

*b) MobASim Database:* stores all geographical information – a map of a workspace, and all network nodes' positions.

*c) MobASim User Interface:* – an integrated GUI that can help a user to define a simulation scenario, create a network topology and provide all attributes of all devices that form a network to be considered. The GUI is organized in a set of nested setting and presentation windows. The setting windows are used to facilitate the configuration phase. The presentation windows are used to display the calculation results – network animation, statistics, etc.

## V. Case Studies

In this paper we demonstrate some of the main capabilities of the MobASim platform by studying the performance of various ad hoc networks application scenarios concerned with an environmental monitoring and coordination of an emergency action. The results of experiments performed on single machine (AMD Sempron 1.67 GHz, 512 MB RAM) were compared with those obtained on parallel machine (Intel Core2 Duo 2.2 GHz, 2038 MB RAM), and computer cluster consisting of three machines (AMD Sempron, Intel Core2 Duo and AMD Athlon-M 1.2 GHz, 512 MB RAM). In parallel and distributed implementations the networks considered were divided into subnetworks simulated in parallel by three processors.

### A. Rescue Action Coordination

The MobASim software can be used to support the design of mobile ad hoc network for the rescue actions – monitoring of the situation after various disasters: earthquake, fire, flood or explosion, etc. In this paper we present the results of hypothetical usage of MANET to support the rescue action in case of real life explosions, which occurred at Buncefield Oil Storage Depot, Hemel Hempstead, Hertfordshire in December 2005. The damages were significant, a large area around the site was evacuated, forty people were injured. The fire burned for several days, destroying most of the site and emitting large clouds of smoke into the atmosphere.

It is obvious that usually the most of the communication infrastructure, i.e., wired phone lines, base stations for cable networks, etc. are devastated after explosions. Hence, mobile, self-configuring and cooperative wireless network can be used to support the rescue action. Let us consider that we plan to send several rescue teams to work on the disaster scene. A coordination action can be achieved only if rescuers are able to communicate, both within their team, the members of the other teams and an emergency action coordination center. Thus, one of the priorities in the disaster management is to reinstall the communication infrastructure as quickly as possible and monitor the situation. It can be done by deploying temporary communication equipment, e.q. vehicles or robots equipped with radio transceivers and sensors, and form an ad hoc network. Computer simulation can be used to support the decision about the number of devices used to create the given network, their destination positions, and finally number of rescue teams [27].

A series of experiments for various network topologies used for reestablishing the communication infrastructure and monitoring were performed. Each network system was built by three types of nodes:

A – mobile devices equipped with transceivers and a set of sensors,
B – static devices equipped with transceivers and a set of sensors; a few of them were mobile (backup devices),
C – base station (emergency action coordination center).

In this paper the results of tests performed for two network configurations are presented:

- Net 1: 23 nodes A, 12 nodes B, 1 node C (36 LPs).
- Net 2: 81 nodes A, 46 nodes B, 1 node C (81 LPs).

In both cases the maximal velocity of all mobile nodes was equal to 10 m/s. Three variants of implementation – sequential, parallel and distributed on three hardware platforms depicted in Table I were compared. The goal of all experiments was to simulate 900 seconds of physical ad hoc network operation. The execution times of each experiment are given in Table II.

TABLE I: Computer systems: sequential, parallel and distributed implementations.

| Variant | AMD Athlon-M<br>1,2 GHz<br>512 MB RAM | AMD Sempron<br>1,67 GHz<br>512 MB RAM | Intel Core2 Duo<br>2,2 GHz<br>2038 MB RAM |
|---|---|---|---|
| Sequential | | X | |
| Parallel | | | X |
| Distributed | X | X | X |

The last two columns collect the speedup for parallel and distributed calculations, defined as $s(p) = T(1)/T(p)$, where

TABLE II: Performance evaluation – comparison of execution times.

| Ex. | Simulation time [s] | | | s(2) | s(4) |
|---|---|---|---|---|---|
| | S | P | D | P | D |
| Net 1 | 64.2 | 49.2 | 49.9 | 1.31 | 1.29 |
| Net 2 | 182.2 | 152.8 | 118.9 | 1.19 | 1.53 |

$T(1)$ denotes execution time in case when all calculations were performed on a single processor and $T(p)$ execution time in case of $p$ processors or machines.

During the experiments the animation of time varying network topologies – all nodes moving from the source to their destination, avoiding the obstacles – was presented in the MobASim display window. The snapshots of initial, temporary and final network topologies are depicted in Figures 3 and 4.

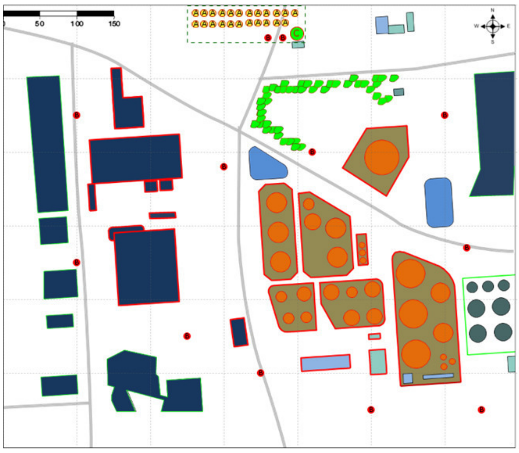

Fig. 3: The snapshot of initial network topology.

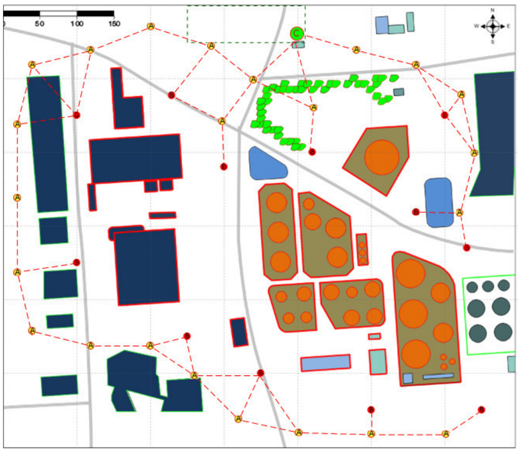

Fig. 4: The snapshot of final network topology.

From the simulation results we see that by using multihop wireless communication and mobile nodes, the communication between the base station and rescuers will be possible without the need for reestablishing the fixed communication infrastructure. We can observe that federated, parallel and distributed simulation developed based upon MobASim software can speedup simulation of MANETs operation w.r.t. sequential implementation. As expected, the calculation speedup depends on the size of network model and assumed degree of parallelism – the speedup factor increases with the problem dimension and complexity. It can be observed that the sequential part of execution concerned with MobASim internal servers and database initializations depends on the size of problem to be considered, and seriously influences the whole computation time. As a final observation, we can point that we obtained the speedup of calculations even in case of small dimension and strongly interconnected network models. We expect much better results for higher dimension networks operating in inherently parallel environments, e.g. cooperating MANETs or sensor networks.

### B. *Gas Cloud Detection and Exploring*

A wireless network formed by mobile devices can reduce lack of situation awareness in area prone to emergencies such as environmental pollution. The MobASim platform was used to simulate various scenarios of application of MANETs for environmental monitoring. The goal of the first series of experiments was to design and develop robot-assisted wireless sensor networks for outdoor and indoor monitoring. The simulation was used to determine the optimal number of sensing devices, calculate collision and obstacle-free motion trajectories for mobile robots carrying the sensor devices and calculate the optimal positions for all sensors (network nodes). Various deployment strategies were considered, i.e., regular and pre-defined grid, self-configuring and hybrid deployments. The results are described and discussed in [27]. The objective of the second series of experiments was to design and develop a MANET for detection, exploration and tracking of a heavy gas cloud. Such cloud may be created as an effect of an instantaneous release of gas heavier than air from a tank [4].

Let us assume that the emergency team has to find, surround and suppress a chlorine gas cloud. The network formed by mobile devices equipped with punctual gas sensors can successfully support the team in detecting and surrounding the cloud. Hence, the set of self-organized mobile devices were deployed in a suspicious area, and formed a coherent network to discover the cloud. After detecting the cloud the devices were divided into two groups. The devices from the first group were responsible for exploring and discovering the shape of the cloud. The task of the remaining devices was to maintain communication between the first group of sensors and the base station.

The results of simulations performed with the example ad hoc network are shown in Fig. 5. The values of all parameters occurring in the equations (18)-(13) are given in Table III [12], [34], [23].

## VI. Summary and Conclusions

The evolution of wireless, mobile ad hoc networks and improved designs will strongly depend on the ability to predict their performance using simulation methods. In this paper we described the application of our software platform MobASim to design mobile ad hoc networks used to detect threats and support decision makers in emergency situations. The presented case studies confirm that the MobASim system can support researches and engineers during the design and implementation of MANETs applications and verification of new MANET's technologies. The tool is especially useful in

# 2nd Workshop on Emerging Aspects in Information Security

ADMITTEDLY,information security works as a backbone for protecting both user data and electronic transactions. Protecting the communication and data infrastructure of an increasingly inter-connected world has become vital nowadays. Security has emerged as an important scientific discipline whose many multifaceted complexities deserve the attention and synergy of the computer science, engineering, and information systems communities. Information security has some well-founded technical research directions which encompass access level (user authentication and authorization), protocol security, software security, and data cryptography. Moreover, some other emerging topics related to organizational security aspects have appeared beyond the long-standing research directions.

The Emerging Aspects in Information Security (EAIS'15) workshop focuses on the diversity of the information security developments and deployments in order to highlight the most recent challenges and report the most recent researches. The workshop is an umbrella for all information security technical aspects. In addition, it goes beyond the technicalities and covers some emerging topics like social and organizational security research directions. EAIS'15 is intended to attract researchers and practitioners from academia and industry, and provides an international discussion forum in order to share their experiences and their ideas concerning emerging aspects in information security met in different application domains. This opens doors for highlighting unknown research directions and tackling modern research challenges. The objectives of the EAIS'15 workshop can be summarized as follows:

- To review and conclude researches in information security and other security domains, focused on the protection of different kinds of assets and processes, and to identify approaches that may be useful in the application domains of information security
- To find synergy between different approaches, allowing to elaborate integrated security solutions, e.g. integrate different risk-based management systems
- To exchange security-related knowledge and experience between experts to improve existing methods and tools and adopt them to new application areas
- To present latest security challenges, especially with respect to EC Horizon 2020

## Topics

Topics of interest include but are not limited to:

-
- Biometric technologies
- Human factor in security
- Cryptography and cryptanalysis
- Critical infrastructure protection
- Hardware-oriented information security
- Social theories in information security
- Organization- related information security
- Pedagogical approaches for information security
- Individual identification and privacy protection
- Information security and business continuity management
- Decision support systems for information security
- Digital right management and data protection
- Cyber and physical security infrastructures
- Risk assessment and risk management in different application domains
- Tools supporting security management and development
- Emerging technologies and applications
- Digital forensics and crime science
- Misuse and intrusion detection
- Security knowledge management
- Data hide and watermarking
- Cloud and big data security
- Computer network security
- Security and safety
- Assurance methods
- Security statistics

# Experimentation tool for critical infrastructures risk management

Andrzej Bialas
Institute of Innovative
Technologies EMAG,
ul. Leopolda 31,
40-189 Katowice, Poland
Email: andrzej.bialas@ibemag.pl

*Abstract*—**The paper concerns a risk assessment and management methodology in critical infrastructures. The research objective is to adapt a ready-made risk manager, supporting information security- and business continuity management systems, to a new domain of application – critical infrastructure protection. First, a review of security issues in critical infrastructures was performed, with special focus on risk management. On this basis the assumptions were discussed how to adapt the OSCAD risk manager designed for the information security/business continuity applications. According to these assumptions, the OSCAD risk manager was adapted to its new domain of application, i.e. critical infrastructures. The aim of this work is to assess the usefulness of such a solution and to elaborate requirements for the advanced critical infrastructure risk manager to be developed from scratch.**

## I. Introduction

CRITICAL infrastructures (CIs) consist of large scale infrastructures whose degradation, disruption or destruction would have a serious impact on health, safety, security or well-being of citizens or effective functioning of governments and/or economies. Typical examples of such infrastructures are energy-, oil-, gas-, finance-, transport-, telecommunications-, and health sectors. CIs provide products and services for the society. In order to function, CIs need many different assets. What is more, they are based on complex processes interrelated with other processes across different sectors. CIs are extremely important for effective functioning of today's societies, especially those of well-developed countries. Critical infrastructures ensure proper relationships between citizens and governments. Each society is very sensitive to any disturbance of a CI. Security and safety issues are very important, but due to the CIs complexity, multi-dimensional interdependencies, large scale and heterogeneity, the problems emerging in these areas are often hard to solve.

A CI can be disturbed by different kinds of threats and hazards. The most important are: natural disasters and catastrophes, technical disasters and failures, espionage, international crime, physical- and cyber terrorism. A new, holistic approach to CI protection is applied by programmes and activities which are understood as critical infrastructure protection (CIP). It is a common effort of the infrastructure owners and operators, manufacturers, users, R&D institutions, governments, international bodies and regulatory authorities. The aim of these efforts is to keep the performance of CIs in case of failures, attacks or accidents and minimize the recovery time and damages.

Well developed countries, including the EU countries, pay more and more attention to the protection of their critical infrastructures. The European Council (EC) Directive [1] specifies the CIP related needs on the EU and member state levels. It precisely defines the rules of the CI identification based on casualties-, economic- and public criteria, risk analysis and management programmes. The EC Directive defines the term ECI (European critical infrastructure). ECI means a critical infrastructure located in member states, whose disruption or destruction would have a significant impact on at least two member states. There are two ECI sectors distinguished:

- energy (electricity, oil, gas),
- transport (road transport, rail transport, air transport, inland waterways transport, ocean and short-sea shipping and ports).

The European Programme for Critical Infrastructure Protection (EPCIP), aimed at both European and national infrastructures, was launched in 2006. The revised and more practical implementation of EPCIP is presented in the EU document [2].

Risk assessment is the basis for critical infrastructures protection programmes. Dozens of EU or worldwide CIP R&D projects which focus on risk methodologies and tools have been completed or are running (FP6, FP7, Horizon 2020, CIPS), which is a proof that the CIP issue is still a challenge.

The researches presented in the paper can be considered preliminary activities of the Ciras[1] project [3]. Ciras was

This work was not supported by any organization

[1] This project has been funded with support from the European Commission. This publication reflects the views only of the author, and the European Commission cannot be held responsible for any use which may be made of the information contained therein (Grant Agreement clause).

978-83-60810-66-8/$25.00©2015, IEEE

launched by the international consortium (ATOS, CESS, EMAG) including the author's organization.

The motivation for researches presented in the paper is to elaborate the experimental OSCAD-Ciras tool to get an input for the Ciras project. Particularly, the following aims are planned to be accomplished:

- to implement the requirements [4] on the OSCAD software platform [5] elaborating the CI risk manager to be used as an experimental platform,
- to assess, using near real data, if the basic requirements of the risk manager can be implemented on the OSCAD software, and
- to summarize the whole experiment, acquiring indispensable knowledge about the usability of this risk manager and to identify directions of the future works.

Apart from the requirements identified during the stakeholders' workshop and the reviewed state of the art of the risk management methodology, the Ciras project will get input from the results of this OSCAD-Ciras feasibility study. This input will be used for the Ciras Toolset development.

The paper includes an introduction to risk management in critical infrastructures (section II), summarizes the preferred features of the risk management tool discussed in the work [4] (section III), presents the functionality of the OSCAD software platform (section IV), gives the specifics of OSCAD's adaptation to be a CI risk manager (section V), and finally draws some conclusions for future works.

## II. Risk management in critical infrastructures protection

Critical infrastructure is a heterogeneous, distributed, adaptive, and, first and foremost, very complex socio-technical system. Such a system encompasses hardware, software, liveware, environmental, management, and organizational elements. The main objective of a CI is to provide products and/or services for the society. This aim can be accomplished when this complex socio-technical system is well harmonized and the disturbances within the system are under control – the system processes its work smoothly and the assets needed to perform this job are well protected. The CI countermeasures, selected on the risk basis, should be properly managed and composed into CIP programmes.

Collaborating critical infrastructures (systems), e.g. electricity, rail transport, gas, oil, telecommunications, constitute a more complex structure, called a system-of-systems (SoS).

Different mutual dependencies (i.e. interdependencies) between particular CIs exist within SoS too. An interdependency [6] is a bidirectional relationship between two infrastructures (systems) through which the state of each infrastructure influences or is correlated to the state of the other [7].

The CIs failures are usually causally linked – the impacts of incidents may pass across the CIs. Certain CI-specific effects are observed. A cascading effect is [8] a sequence of component failures: the first failure shifts its load to one or more nearby components – these components fail and, in turn, shift their loads to other components. This sequence is repeated. An escalating failure is when there is a disruption in one infrastructure which causes an independent disruption in another infrastructure [6]. The effects of hazardous events may escalate outside the area where they occur and exacerbate the consequences of a given event (generally in the form of increasing the severity or the time for recovery of the second failure). Different failures may have a common cause (failures implied by a single shared cause and coupling to other systems mechanisms) and may occur almost concurrently. An important issue is the CI resilience, which is understood as an ability of a system to react to and recover from unanticipated disturbances and events.

The critical infrastructure protection concept comprises preparedness and response to serious incidents which occur within critical infrastructures. To ensure the preparedness and incident response ability, it is necessary to imply the risk source, character and value. In addition, the right countermeasure should be applied and embedded into the risk management framework, sometimes supported by tools.

The comprehensive approach to risk management in critical infrastructures still remains a challenge, due to CIs complexity, interdependencies, specific effects (common cause failures, cascading, escalating effects), different abstract levels applied to manage CIs, and other factors.

The risk management methodology and tools are a subject of current R&D on the national and international levels, including the EU level. Very comprehensive reviews of R&D results can be found in the following knowledge sources:

- the report [9] of the Institute for the Protection and Security of the Citizen, an EC Joint Research Centre (JRC); the report assesses and summarizes 21 existing risk management methodologies/tools on the EU and global level; it identifies their gaps and prepares the ground for R&D in this field, like Ciras project [3];
- the EURACOM report [10]; it presents a study of 11 risk assessment methodologies related to the energy sector;
- the book [7]; in its Appendix C there is a comparison of the features of about 22 commonly used risk analysis methods;
- the ISO 31010 standard [11] characterizes about 30 risk assessment methods for different applications;
- the ENISA website [12] includes an inventory of risk management/assessment methods, mostly ICT-focused.

A very exhaustive review of the state of the art is reported in [13]. To select the most favourable methods/tools features for implementation during the Ciras project, the document summarizes the assessment of: 14 methods (from 46 preselected), 22 tools (from 150 preselected) and considers 19 projects and 8 frameworks.

Usually, methods/tools are focused on the confined domain and they do not address properly the holistic view and resilience. The problem is how to consider CIs interdependencies in the risk management process. This requires to distinguish the internal and external causes of hazardous events as well as the internal and external consequences implied by these events.

The survey on the representative methodologies and tools for the CI risk management was made in [4]. Based on these researches, the most favourable features of the CI risk manager are specified in the next section.

## III. Preferred Features of Risk Management Tools for Critical Infrastructures

The paper [4] discusses the basic requirements of the risk manager to be applied in critical infrastructure protection. This section gives a short overview of these issues.

### A. *Conceptual model of the risk manager*

The implementation of the bow-tie risk concept in the tool is advantageous for CI risk management [4].

The bow-tie conceptual model [8] embraces both multiple and complex causes of the given hazardous event and its diversified and multidirectional consequences (Fig. 1). The triggered hazards or threats, which exploit certain vulnerabilities, can degrade proactive barriers (countermeasures) existing in the system. As a result, an event may occur which is hazardous for assets. The consequences of such an event are usually diversified and multidirectional. To mitigate them, reactive barriers are applied. These barriers can be weakened or even removed by vulnerabilities. Generally, barriers are identified with different kinds of countermeasures. The countermeasures are applied with respect to the risk value and are monitored and maintained – according to the risk management principles. The bow-tie model is focused on risk assessment and can be used to reassess the risk after new/updated barriers are applied.

Consequence
Consequence
Consequence
Consequence
V Vulnerabilities
Engineering/maintenance/operations activities
Barriers (Coutermeasures)

Fig. 1 Bow-tie model

The bow-tie model encompasses the cause analysis and the consequences analysis. These risk analyses can be implemented in less or more complex ways [11], e.g. using FTA (Fault tree analysis) [14] and ETA (Event tree analysis) [15].

There is no analysis of interdependencies in this model, therefore it is necessary to supplement the model in this respect.

### B. *Risk register and risk related data*

The tool should support a CI owner in elaborating and maintaining a risk register as the managed inventory of hazardous events. The listed items (data records) should include at a minimum: related hazards/threats, a possible corresponding hazardous event, probability of the event and its consequences. The risk management process is performed during the CI life cycle, so the risk register can be continuously updated. It is used in CIP programmes. There are some data associated with each item of the risk register, like assets, societal critical functions (SCF) ensuring the basic needs of a society (e.g.: life and health, energy supply, law and order, national security), hazards, threats, vulnerabilities, countermeasures, etc.

### C. *Risk measures and the assessment process*

Risk measures depend on the applied methodology. A common method is to assess the likelihood (probability, frequency) of a hazardous event, e.g.: fairly normal, occasional, possible, remote, improbable, and to assess the consequence severity in different dimensions using the enumerative scales, e.g.: negligible, minor, major, catastrophic damages. The risk is the function of both, usually expressed by a risk matrix, as presented in [4].

### D. *Interdependencies and critical infrastructure specific phenomena*

The risk assessment/management methods/tools (Section II) are focused on the given environment with protected assets and processes, and they do not consider interdependencies between other environments. The interdependencies ought to be considered in the risk management process because they are essential for the CI protection. The risk assessment methodology should be able to take into account the CI specific phenomena mentioned in Section II.

## IV. Functionality of the OSCAD Software Platform

The identified requirements are experimentally implemented on the OSCAD[2] platform [5]. The OSCAD software was originally elaborated to support business continuity management according to BS 25999 (ISO 22301)

[2] developed at the Institute of Innovative Technologies EMAG within a project co-financed by the National Centre for Research and Development (NCBiR).

and information security management according to ISO/IEC 27001. It is used to control factors which disturb business processes or breach information assets in an institution (business, public) leading to negative consequences, to limit losses when an incident occurs, and to help in the recovery process.

The solution is open and flexible and thus, after certain modifications, possible to implement in other application domains, e.g.: flood protection [16], railway safety management systems [17] and coal mining [18].

OSCAD offers the following functions:

- general purpose functions: system management, document and tasks management, reporting, dictionaries, business continuity planning, auditing, etc.;
- functions allowing to assess the system effectiveness: acquiring data, assessing effectiveness, permanent improvement actions;
- external communications functions with ERP, SCADA, GSM.

Additionally, OSCAD offers risk management and incident management functions, which are discussed here in the CI context.

OSCAD is equipped with tools to analyze causes of hazardous events:

- AORA – Asset Oriented Risk Analyzer,
- PORA – Process Oriented Risk Analyzer,

and tools analyzing their multidimensional consequences:

- ABIA – Asset Oriented Business Impact Analyzer,
- PBIA – Process Oriented Business Impact Analyzer.

Countermeasures are selected based on the assessed risk value and their total investment/maintenance costs. Then the risk is reassessed with respect to the acceptance level.

The incident management functions allow for events acquisition. They also enable to assess their severity according to the elaborated criteria. Serious events, which are incidents, are managed according to standards. The incident statistics and corrective actions are prepared too.

## V. Implementation of risk manager requirements on the OSCAD software

The section discusses the author's proposals how to implement the above-listed requirements into the existing OSCAD software platform.

### A. *Bow-tie model implementation in the OSCAD software platform*

The bow-tie model is not directly implemented in the OSCAD software but its existing risk analyzing tools can be used to compose it.

The cause analysis part of the bow-tie model is implemented on the basis of AORA or PORA. AORA analyzes each threat-vulnerability pair which can breach the given asset, while PORA does the same with respect to the given process.

The consequences analysis part of the bow-tie model is implemented on the basis of ABIA or PBIA. For a given asset (process), which is under a hazardous event, multi-dimensional consequences can be assessed with the use of the loss matrix.

Both parts of the bow-tie model are not coupled directly by the hazardous event, but by the threatened asset (or process) related to this event.

Examples of analyses pairs composing the bow-tie model are shown in Fig. 2. The "1-1 RaT AORA (Node)" and "1-2 RaT ABIA (Node)" create one of pairs related to the railway node belonging to the Railway transport (RaT) European critical infrastructure (ECI) [1].

Fig. 2 OSCAD risk analyses composing the bow-tie model

The bow-tie model is rather asset-oriented, similarly to the risk analysis in CIs. For this reason AORA/ABIA may be more convenient for CIs. The given AORA analysis groups the threats related to the given asset. Threats and hazards have the same representation – they are simply the "OSCAD threats". The PORA/PBIA pair represents the process approach. It allows to see a CI from a point of a view of processes, not only assets. Process-oriented risk analyses in CIs need further research.

### B. *Risk register and risk related data – the OSCAD representation*

The basic risk-related data are assets belonging to the critical infrastructures which need protection.

The general CIs taxonomy and assets are implemented in OSCAD. Two groups of CIs are distinguished: ECI (European CI), embraced by the EU Directive [1] and others (non-ECI). Currently only the ECI ones are implemented.

In OSCAD the protected assets dictionary is a simple flat list. For this reason, the assets belonging to the given CI are preceded by a label standing for a CI name: Ele (Electricity), Oil (Oil), Gas (Gas), RoT (Road Transport), RaT (Rail Transport), AiT (Air Transport), IWT (Inland Waterways Transport), Sea (Ocean and short-sea shipping and ports). Figure 3 presents different assets, belonging to the ECI, distinguished according to their labels. Each protected asset can be the central point of any AORA or ABIA. They play a role of primary assets. Please note three attributes CID (CI degradation), IE (Internal escalations), EE (external escalations) which express three types of consequences when the given asset is breached (this will be explained later, when ABIA/PBIA will be discussed).

Fig. 3 Protected assets of ECIs in the OSCAD software

It is possible to create a group of the related secondary assets (technical, personal, immaterial, playing role of countermeasures, etc.) around the given primary asset. This group of assets can be defined in the assets inventory module (Fig. 4). The Railway node asset is represented by a node located in the city of Tarnowskie Góry (Upper Silesia, Poland).

For each of the protected assets, the AORA analysis can be performed. PORA can be done for the processes (not discussed here) in a similar way.

| Identifier | Asset name | Type |
|---|---|---|
| RaT Node 001 | Tarnowskie Góry node | technical |

Fig. 4 Different assets belonging to the given protected assets category

To perform a risk analysis for different barriers, security zones, etc., which play the role of countermeasures, an auxiliary category is defined: A=C (Countermeasures considered as assets), for example A=C:Security zone can be added to the Railway node, and an additional risk analysis for it can be performed when internal escalation effects are analyzed (will be explained further).

The general formula of the threats/hazards scenario is:

[*Threat agent*] exploiting [*vulnerability*] causes [*adverse action*] to [*asset*] or [*process*].

Assuming that a threat agent is identified as the hazard trigger, the common description of threats and hazards is possible in OSCAD. The threat specification includes key terms essential for the risk analysis. Threats specified during the AORA/PORA analyses are considered risk register items. OSCAD is equipped with the incident management functionality (registering, assessment, solving, lessons learnt, statistics). The incidents which have already occurred are assigned to the threat items too. For this reason, the predicted risk scenarios and occurred incidents (materialized risk scenarios) are consistent. OSCAD is able to build statistics of incidents (not discussed here).

Summing up, the risk register is defined in OSCAD as a set of risk scenarios worked out during AORA or PORA, and compatible with the incident inventory.

OSCAD has predefined lists of threats, vulnerabilities and countermeasures. They are flat, but a special grouping mechanism is applied as the hierarchical grouping dictionary. On the upper hierarchy level threats can be ordered according to critical infrastructures, next according to these threats character (Behavioural/Social, Natural/Force majeure, Organizational, Technological). For the given threat (T), relevant vulnerabilities (V) are given, and to the given pair threat-vulnerability, recommended countermeasures (C) can be assigned. These predefined relations speed up the countermeasures selection.

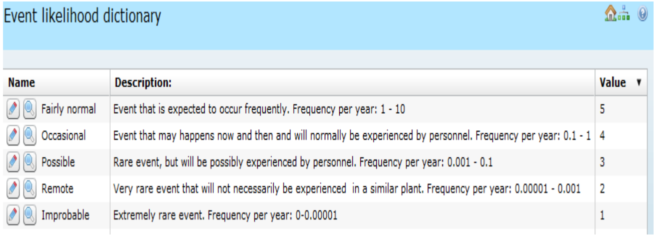
Figure 5 presents the hierarchical structure of the grouping dictionary and some examples concerning railway transport.

### C. *Risk measures and assessment process in the OSCAD software*

For the AORA and PORA analyses two issues should be defined: likelihood of the event (Fig. 6) and its consequences (Fig. 7).

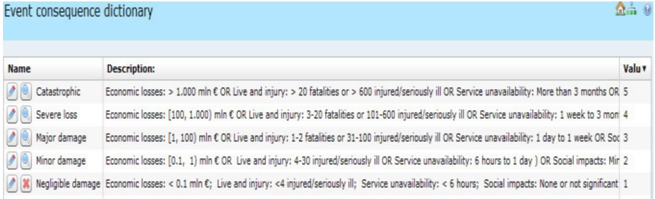
Event likelihood measures with their interpretation are direct implementation of the measures presented in Table 2 included in [4].



| Name | Description: | Value ▾ |
|---|---|---|
| Fairly normal | Event that is expected to occur frequently. Frequency per year: 1 - 10 | 5 |
| Occasional | Event that may happens now and then and will normally be experienced by personnel. Frequency per year: 0.1 - 1 | 4 |
| Possible | Rare event, but will be possibly experienced by personnel. Frequency per year: 0.001 - 0.1 | 3 |
| Remote | Very rare event that will not necessarily be experienced in a similar plant. Frequency per year: 0.00001 - 0.001 | 2 |
| Improbable | Extremely rare event. Frequency per year: 0-0.00001 | 1 |

Fig. 6 Event likelihood measures

The consequences measures are implemented in the same way . They are based on Table 1 from [4].



| Name | Description: | Valu ▾ |
|---|---|---|
| Catastrophic | Economic losses: > 1.000 mln € OR Live and injury: > 20 fatalities or > 600 injured/seriously ill OR Service unavailability: More than 3 months OR | 5 |
| Severe loss | Economic losses: [100, 1.000) mln € OR Live and injury: 3-20 fatalities or 101-600 injured/seriously ill OR Service unavailability: 1 week to 3 mon | 4 |
| Major damage | Economic losses: [1, 100) mln € OR Live and injury: 1-2 fatalities or 31-100 injured/seriously ill OR Service unavailability: 1 day to 1 week OR Soc | 3 |
| Minor damage | Economic losses: [0.1, 1) mln € OR Live and injury: 4-30 injured/seriously ill OR Service unavailability: 6 hours to 1 day ) OR Social impacts: Mir | 2 |
| Negligible damage | Economic losses: < 0.1 mln €; Live and injury: <4 injured/seriously ill; Service unavailability: < 6 hours; Social impacts: None or not significant | 1 |

Fig. 7 Event consequences measures

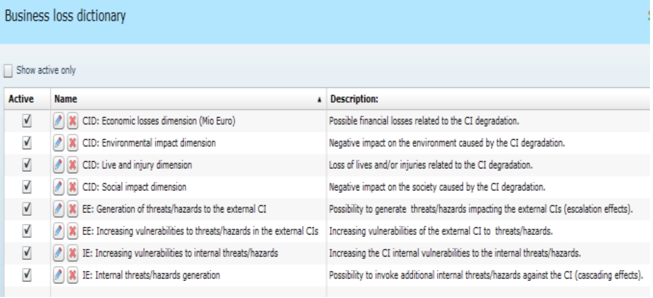
The risk value (AORA/PORA) is calculated with the use of the simple formula:

$$\text{Risk} = \frac{\text{Event likelihood} * \text{Event consequences}}{\text{Countermeasure class} * \text{Countermeasure impl.lev.}}$$

The "Countermeasure class", if used, i.e. when it is > 1, can express countermeasure assurance (basic, advanced). The "Countermeasure implementation level" expresses the stage of the implementation (not implemented, partially, fully implemented). These two additional parameters are used for more advanced applications.

The measures of multidimensional consequences of the hazardous event (Fig. 8) are key issues for the ABIA/PBIA analyses. Three groups of consequences are distinguished. The basic one is the CID (CI degradation) category which expresses different kinds of damages within the given CI. To consider the CI specific effects analyses, two additional categories are introduced:

- IE (Internal escalations), expressing new internally generated threats or new or increased vulnerabilities which influence the considered CI, caused by the hazardous event,
- EE (External escalations), expressing generated threats which impact the external CIs or new or increased vulnerabilities in the external CIs, caused by the hazardous event.



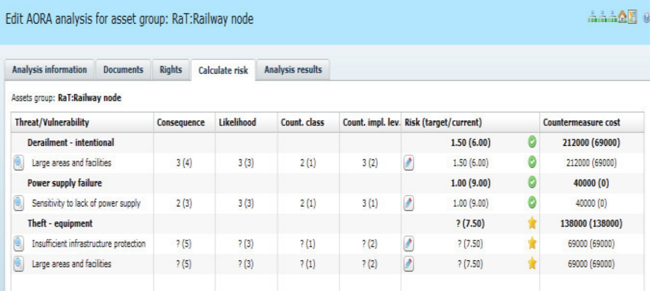
□ Show active only

| Active | Name ▴ | Description: |
|---|---|---|
| ☑ | CID: Economic losses dimension (Mio Euro) | Possible financial losses related to the CI degradation. |
| ☑ | CID: Environmental impact dimension | Negative impact on the environment caused by the CI degradation. |
| ☑ | CID: Live and injury dimension | Loss of lives and/or injuries related to the CI degradation. |
| ☑ | CID: Social impact dimension | Negative impact on the society caused by the CI degradation. |
| ☑ | EE: Generation of threats/hazards to the external CI | Possibility to generate threats/hazards impacting the external CIs (escalation effects). |
| ☑ | EE: Increasing vulnerabilities to threats/hazards in the external CIs | Increasing vulnerabilities of the external CI to threats/hazards. |
| ☑ | IE: Increasing vulnerabilities to internal threats/hazards | Increasing the CI internal vulnerabilities to the internal threats/hazards. |
| ☑ | IE: Internal threats/hazards generation | Possibility to invoke additional internal threats/hazards against the CI (cascading effects). |

Fig. 8 Event impacts measures with CID, IE and EE categories

The implementation of the bow-tie model is presented by the pair AORA-ABIA with respect to the given asset (here: railway node of the RaT infrastructure). The process approach (PORA-PBIA), though possible, is not discussed here.

AORA is shown in Fig. 9.



Assets group: **RaT:Railway node**

| Threat/Vulnerability | Consequence | Likelihood | Count. class | Count. impl. lev. | Risk (target/current) | | Countermeasure cost |
|---|---|---|---|---|---|---|---|
| **Derailment - intentional** | | | | | **1.50 (6.00)** | ✓ | **212000 (69000)** |
| Large areas and facilities | 3 (4) | 3 (3) | 2 (1) | 3 (2) | 1.50 (6.00) | ✓ | 212000 (69000) |
| **Power supply failure** | | | | | **1.00 (9.00)** | ✓ | **40000 (0)** |
| Sensitivity to lack of power supply | 2 (3) | 3 (3) | 2 (1) | 3 (1) | 1.00 (9.00) | ✓ | 40000 (0) |

Fig. 9 Example of the AORA analysis for a railway node

Please note three threats (Derailment – intentional, Power supply failure, Theft – equipment) and vulnerabilities associated with them. For each pair threat-vulnerability, which influences the asset, the risk value can be determined according to the above presented formula. Inherent risk ("risk before") is in parentheses, while the current risk ("after measures applications") – without parentheses. The same rule applies to the cost of countermeasures. Each pair threat-vulnerability is considered a risk register item.

If the risk value is unaccepted, extra (other) countermeasures can be selected (Fig. 10).

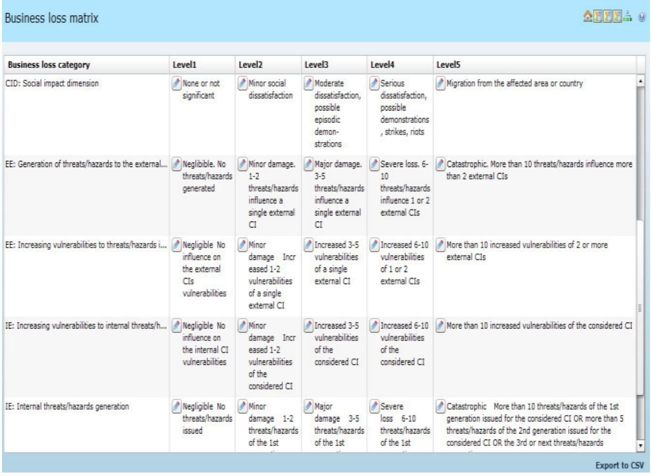
Fig. 10 CI risk management – countermeasures selection

The risk manager can consider up to five variants of decisions with respect to the possible risk reduction and the cost of this reduction.

The next step is the consequences analysis of a given hazardous event embraced by ABIA. It is possible to apply ABIA in the case of each hazardous event, but in most cases it will be more convenient to perform ABIA according to assets.

The basic ABIA tool is the loss matrix (Fig. 11). For each subcategory of CID, IR, EE, losses are assessed with the use of 5 levels. A number of subcategories and levels are configurable. As a result, the CI degradation is assessed.



Business loss matrix

| Business loss category | Level1 | Level2 | Level3 | Level4 | Level5 |
|---|---|---|---|---|---|
| CID: Social impact dimension | None or not significant | Minor social dissatisfaction | Moderate dissatisfaction, possible episodic demon- strations | Serious dissatisfaction, possible demonstrations , strikes, riots | Migration from the affected area or country |
| EE: Generation of threats/hazards to the external... | Neglibible. No threats/hazards generated | Minor damage. 1-2 threats/hazards influence a single external CI | Major damage. 3-5 threats/hazards influence a single external CI | Severe loss. 6-10 threats/hazards influence 1 or 2 external CIs | Catastrophic. More than 10 threats/hazards influence more than 2 external CIs |
| EE: Increasing vulnerabilities to threats/hazards i... | Negligible No influence on the external CIs vulnerabilities | Minor damage Incr eased 1-2 vulnerabilities of a single external CI | Increased 3-5 vulnerabilities of a single external CI | Increased 6-10 vulnerabilities of 1 or 2 external CIs | More than 10 increased vulnerabilities of 2 or more external CIs |
| IE: Increasing vulnerabilities to internal threats/h... | Negligible No influence on the internal CI vulnerabilities | Minor damage Incr eased 1-2 vulnerabilities of the considered CI | Increased 3-5 vulnerabilities of the considered CI | Increased 6-10 vulnerabilities of the considered CI | More than 10 increased vulnerabilities of the considered CI |
| IE: Internal threats/hazards generation | Negligible No threats/hazards issued | Minor damage 1-2 threats/hazards of the 1st | Major damage 3-5 threats/hazards of the 1st | Severe loss 6-10 threats/hazards of the 1st | Catastrophic More than 10 threats/hazards of the 1st generation issued for the considered CI OR more than 5 threats/hazards of the 2nd generation issued for the considered CI OR the 3rd or next threats/hazards |

Fig. 11 Use of the loss matrix during BIA

Additionally, we can identify new threats (or vulnerabilities) caused by a hazardous event. These breaches usually concern assets which are also countermeasures (C=A category). Here AORA-ABIA must be performed with respect to the given asset to identify internal escalation or cascading consequences. Similarly, threats/vulnerabilities which influenced external CIs are identified. This requires extra AORA-ABIA for external CIs with respect to the influenced asset.

Fig. 12 presents an example of a risk assessment scenario driven by CIs phenomena:

1. In CI#n an external event occurs and triggers the hazardous event HE(#n,#m) impacting the primary asset #m which belongs to this infrastructure.
2. AORA(#m) identifies the risk related to this hazardous event, while ABIA(#m) – its multidimensional consequences. The internal degradation caused by the HE(#n,#m) is assessed (CID). ABIA identifies that this event breaches the security zone (#m->#k) which is a secondary asset of #m (IE) and influences the external infrastructure #p (EE).
3. Due to the internal escalation (IE) an extra analysis of the secondary asset (#m->#k), playing the role of a countermeasure, is required: AORA(#m->#k)-ABIA(#m->#k). The related ABIA identifies CI degradation caused by the security zone breaching but does not identify any further IE or EE impacts.
4. Due to the external escalation (EE) an extra analysis of asset #s of the CI#p is performed: AORA(#s)-ABIA(#s). The related ABIA identifies the CI degradation caused by an externally generated threat but does not identify any internal impacts (IE). Moreover, the backward external impacts to the infrastructure #n are identified.
5. Due to the external threat generated by the CI #p for the CI#n on its primary asset #z, an extra pair of analyses is issued: AORA(#z)-ABIA(#z). The CI internal degradation is assessed, and no internal/ external escalations are detected.

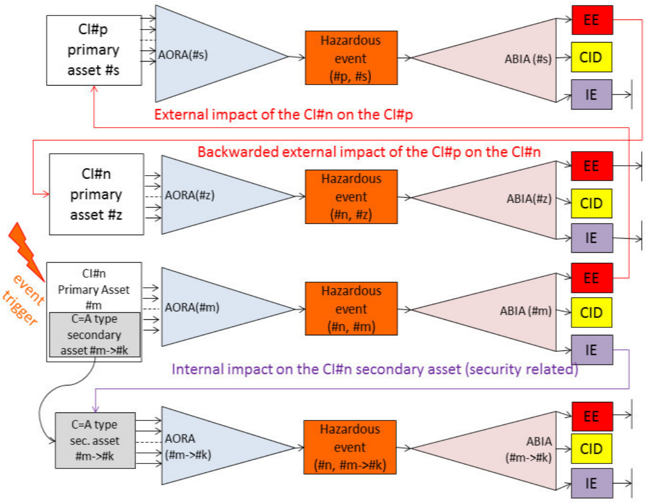


Fig. 12 Risk management in interdependent critical infrastructures

This scenario shows a general plan of analyses driven by the situations occurring in the interdependent CIs.

### D. Interdependencies and critical infrastructure specific phenomena

There is no specific tool in OSCAD to analyze interdependencies, especially the strength of coupling inside CIs. This task should be solved outside the system, e.g. by preparing a map of interdependent CIs. Using this map it is possible to further analyze risk within a set of interdependent infrastructures, which was shown in Section V, subsection C.

There is a mechanism introduced that allows to explicitly distinguish CI internal and external causes of hazardous events, and to distinguish CI internal non-escalating consequences, consequences generating hazards/threats in the same infrastructure, and consequences generating external hazards/threats for other collaborating infrastructures.

## VI. Conclusions

The short feasibility study provided in the paper confirms a possibility to adapt the ready-made OSCAD platform for CI risk management according to the previously [4] identified requirements.

The CI related data were prepared and implemented in the system. Some OSCAD functions and system messages were changed to better express the CI domain. No software changes were needed. Most of the required functionalities of the CI risk manager were successfully implemented. This way the OSCAD-Ciras tool was prepared for further researches.

The key advantage of the presented method, which allows to consider effects implied by interdependencies in risk management, is to distinguish the direct CI degradation (CID) and the internal (IE) and external (EE) escalation/cascading effects.

As far as more complicated CIs relationships are concerned, more iterations of analyses are needed. Here it is required to introduce identifiers of particular analyses, additional managing and reporting. The Ciras-OSCAD tool is currently used to elaborate use cases in the CIRAS project and to design the Ciras Toolset. The OSCAD tool can be integrated into the toolset but should be supported in the range of analyses and interdependencies management. More experiments based on the elaborated use cases are planned.

## Acknowledgment

The author thanks the colleagues from the CIRAS project consortium for reviewing this paper and discussing the presented concept.

***Abstract*—This paper observes different methods for network covert channels constructing and describes the scheme of the packet length covert channel. The countermeasure based on random traffic padding generating is proposed. The capacity of the investigated covert channel is estimated and the relation between parameter of covert channel and counteraction tool is examined. Practical recommendation for using the obtained results are given.**

## I. Introduction

THE IDEA of covert channel was introduced by Lampson in 1973. The covert channel is a communication channel that was not intended for information transfer at all, such as the service program's effect on the system load [1]. It is obvious that covert channel may lead to information leakage and it cannot be eliminated by techniques to detect network anomalies [2], malware activities [3], etc. TCSEC postulates that the covert channel is a communication channel which allows the transfer of data and violation of security policy [4].

Presently, the most popular covert channels are built on packet switching data networks because of some features available in the TCP/IP protocol suite [5]. Moreover, traditional security measures based on traffic encryption also permit the design of different types of covert channels.

Covert channels are divided by the data transfer technique into two classes such as, timing and storage channels [4]. Storage channel allows the direct or indirect storage recording by one process and the direct or indirect reading of it by another. Timing channel allows one process to signal information to another process by modulating of system resources (e. g. CPU time) usage so that the change in response time observed by the second process would provide information.

The first technique to design a storage channel in the IP network is to modulate packet header fields, e. g. TTL [6], IP ID [7], ToS [8]. The second technique is based on the modification of the packet length. Different timing channels in the IP networks use alteration of the inter-packet delays [9], [10], e. g. by JitterBug [11] and packet transfer rate [12]. In addition, the packet reordering could be used to build a timing channel [13]. Timing channel is a channel with noise since a packet timing is a random variable whose distribution depends on the network load [14].

A capacity of undetectable packet size covert channels can be higher than a capacity of timing channels, therefore these channels can lead to a serious security breach. The authors of the paper research this type of covert channels and propose the technique to estimate and limit their capacity which can be useful in different types of information systems, e.g. in data storage system in a cloud [15].

**Our Contribution.** Since a technique to choose the quantitative characteristics of countermeasures in order to keep balance between capacity of covert and communication channels has not yet been proposed, we offer an approach to gain it. This paper describes a technique to estimate and limit the capacity of a packet size covert channel based on random traffic padding generation. The investigation carried out is significant because such type of covert channels could be constructed even if data encryption is used. There are complicated undetectable covert channels which have no noise in contrast to timing channels.

This paper is organized as follows. It gives an analysis of different types of packet size covert channels. The investigated covert channel scheme and the counteracting technique are shown. Then the capacity of the covert channel is estimated and the technique to generate dummy packets is given. The main results and further research guidelines are summed up in the conclusion.

## II. Related Work

For the first time Padlipsky [16] and Girling [17] suggested to modulate the length of data link layer frames in order to accomplish the hidden data transfer. The main idea of the technique is as follows: sender and receiver share the rule used to compose a byte of the covert message depending on the frame length. To describe any byte of the transmitted message, one should use 256 different frame lengths.

Yao constructed a covert channel in which a sender and a receiver shared the periodically updated matrix with elements representing unique unsorted packet lengths in 2008 [18]. The sender using the bits of hidden transmitted message determines the matrix row and randomly chooses a packet length from the row. The receiver finds the gained packet length in the matrix and reconstructs bits of the message according to the row number. Because packet length distribution given by covert channel is not equal to packet length distribution of normal traffic, this type of covert channel is detectable.

978-83-60810-66-8/$25.00©2015, IEEE

Ji suggested a protocol-independent covert channel in 2009 [19]. Before the transmission starts, sender and receiver form the dynamically updated reference of packet lengths by fixing packets lengths in normal traffic. In order to transfer a hidden message the sender transmits a special packet. The length of the special packet is chosen from the reference using the algorithm known to the sender and receiver. The length of the next packet is a sum of lengths of the previous packet and the number corresponding to the message bits. The reference is updated by adding the length of the transmitted packet. The receiver recovers the message bits by evaluating the difference of the packets length gained. The disadvantage of the covert channel is as follows: the lengths of hidden messages are added to the reference, therefore the packet length distribution with the covert channel is not equal to packet length distribution of the normal traffic and this type of covert channels is detectable in case of the large data volume.

Ji worked out another protocol-independent covert channel in 2009 [20]. Before the transmission starts, sender and receiver form a non-updating reference of packet lengths by fixing packets lengths in the normal traffic. The main advantage of the technique is a small space and time complexity of the decoding, since the sender stores the whole reference and receiver saves only the lower and upper bound of each basket. To transmit the hidden data the sender randomly chooses the packet length from the basket, the receiver determines the number of the basket and restores the message bits. The regularity in the distribution of the transmitted message bits could cause a highly probable detection of the channel.

Hussain improved the technique and designed high capacity covert channel based on the alteration of packets lengths and information content in 2011 [20]. Sender and receiver share periodically updated matrix with elements representing unsorted packet lengths in normal traffic. The sender using bits of hidden message determines the matrix row and randomly chooses the packet length from the row. If the chosen length belongs to the stego-column, then the data is transferred in the information content of the packet, otherwise the data is transferred in the number of matrix row. The receiver finds the length of gained message in the matrix, detects the transfer method using the matrix row and recovers bit of the message. The disadvantage of the channel is that information content of the packet has to be used as the hidden container and is more complicated in comparison with the other techniques.

Edekar improved the method in 2013 [22] and realized it using TCP. Packets lengths in the shared matrix are unique. Each matrix element $a$ is associated with the binary vector $(v, y)$, where $v = 1 \Leftrightarrow a$ belongs to the stego-column and $y = 1 \Leftrightarrow a$ belongs to the stego-row. Then if $(v, y) = (1, 1)$ the packet is ignored; if $(v, y) = (1, 0)$ data is transferred in the packet information content; if $(v, y) = (0, 0)$ data is transmitted in the number of the matrix row; if $(v, y) = (0, 1)$ data is transferred in the number of the matrix row and the packet information content.

The way to eliminate covert channels based on length of transferred packets modulation is to equalize packets lengths and send packets with maximum length. However, the technique essentially diminishes the capacity of a communication channel. To limit a covert channel capacity, the random increase of packet lengths and generation of dummy packets can be used. Kiraly suggested the realization of the methods based on IPsec in 2008 in order to make traffic nontraceable [23].

However, a technique to choose the quantitative characteristic of the methods in order to keep balance between capacity of covert and communication channels has not yet been proposed. The authors of this paper offer an approach to gain it.

## III. The Covert Channel Scheme

Let the lengths of transferred packets possess the values from $l_{fix}$ to $l_{fix} + L$. The disjoint sets $L_0$ and $L_1$ are given and

$$\begin{cases} L_0 \cup L_1 = N_{L+l_{fix}} \backslash N_{l_{fix}-1}, \\ \mid L_0 \mid = \mid L_1 \mid \end{cases} \tag{1}$$

where $N_a$ stands for the set of positive integers from 1 to $a$.

Further, we consider a method to build a binary covert channel. In order to transfer «0» the sender communicates a packet with length $l \in L_0$, to transfer «1» the sender communicates a packet with length $l \in L_1$. It is obvious that the capacity of such a channel without counteraction is equal to 1 bit per packet. A large-scale site loses about 26 Gb of data annually if there is a covert channel with such a capacity [24].

If the symbol distribution in a transmitted message simulates a uniformly distributed random sequence (e.g. cryptographic keys sending), a random equiprobable choice of packets lengths from $L_0$ and $L_1$ leads to equally probable random distributed lengths of transmitted packets. Moreover, $L_0$ and $L_1$ could be periodically changed multisets so that a random choice of packets lengths from $L_0$ and $L_1$ induces the distribution of packets lengths to be close to the empirically obtained distribution of normal traffic.

To build such a covert channel, the sender must have one of the following possibilities:

- to modify lengths of transmitted messages;
- to form packets with undefined lengths;
- to buffer packets to be sent and transfer them to a channel at a specified moment.

The investigation proposes a technique to limit the capacity of covert channel based on random traffic padding. After $i$ data packets have been sent, random length dummy packets are created, the number of packets $i$ between dummy packets is the value of random variable that is uniformly distributed at the $N_k$, $k \in N$ where $k$ is the parameter of a counteraction tool. Let $\mu$ be the capacity of a communication channel, then a counteraction tool decreases the capacity of a communication channel and it equals

$$\frac{k+1}{k+3}\mu. \tag{2}$$

The countermeasure using traffic padding generation after equal number of packets passed is not resistant against the attack of traffic padding tracing. If the violator detects traffic padding ones, data transmitting via covert channel has no errors and can be processed without synchronization. The investigated countermeasure is resistant to this type of attack.

After a dummy packet is received, the mismatch between the hidden sender and hidden receiver takes place. To negotiate this fact SOF packets [25] are utilized after transferring $T-1$ packets within a covert channel. A receiver fixes $T-1$ packets gained after SOF packet and waits for the next SOF packet. Thus, $T$ is the parameter of a covert channel which estimates the synchronization frequency.

## IV. The Capacity of the Covert Channel

In 1987 Millen was the first to suggest the use of information theory to estimate a capacity of covert channels with noise [26]. The investigation was continued by Ventakraman [27]. The authors determine network covert channels and analyze techniques to audit and limit a capacity of covert channels utilizing indirect routing.

The capacity $C$ of the investigated covert channel is

$$C = \max_X I(X,Y) \tag{3}$$

where $I(X,Y)$ is the mutual information of random variables describing the input and output properties of the covert channel properly, the dimensionality of covert channel capacity is one bit per packet.

Let us consider the case when synchronization is done more rarely than a dummy packet sending, i.e. $T > k$. After a dummy packet is received, mismatch between sender and receiver occurs, therefore identification of the following received bits would be wrong until the next synchronization happens. Consequently, in order to build a covert channel the inequality $T < k+1$ is required.

Let the synchronization be not less frequent than dummy packet sending, i.e. $T < k+1$. Corresponding choice of parameters is explained in Fig. 1.

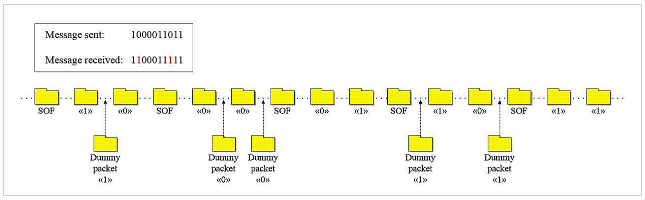

Fig. 1. The scheme of data transfer in the covert channel ($T = 3$, $k = 5$)

Since each $T$-th packet sent via a covert channel is not a data packet but a synchronization packet, the mutual information can be calculated using the following formula

$$I(X,Y) = \frac{T-1}{T} I^*(X,Y) \tag{4}$$

where $I^*(X,Y)$ is a mutual information of random variables describing the input and output properties of a covert channel without synchronization accordingly.

The mutual information $I^*(X,Y)$ is equal to the form of

$$I^*(X,Y) = H(Y) - H(Y|X) \tag{5}$$

where the entropy of random variable $Y$ is

$$H(Y) = -\sum_{y\in\{0,1\}} p(y)\log_2 p(y), \tag{6}$$

the conditional entropy of random variable $Y$ comparatively to random variable $X$ is expressed as

$$H(Y|X) = \\ = -\sum_{x\in\{0,1\}} \Big(p(x)\Big(\sum_{y\in\{0,1\}} (p(y|x)\log_2 p(y|x))\Big)\Big). \tag{7}$$

Since sizes of sets $L_0$ and $L_1$ are equal and lengths of passing through the covert channel dummy packets are chosen randomly and equiprobable, then

$$H(Y) = 1. \tag{8}$$

Whereas the values of conditional probabilities $p(x|y)$, $x, y \in \{0,1\}$ depend on the number of packets sent via a covert channel between the moment of synchronization and the moment of dummy packet receiving, the mutual information $I^*(X,Y)$ can be found using the following formula

$$I^*(X,Y) = \frac{\binom{k-T+2}{2} + \sum\limits_{i=0}^{T-2}\Big((k-i)(1-H_i(Y|X))\Big)}{\binom{k+1}{2}} \tag{9}$$

where $H_i(Y|X)$ is the conditional entropy of random variable $Y$ compared to random variable $X$ and it is evaluated when $i$ packets received between a moment of synchronization and the dummy packet's arrival.

The mutual information $I(X,Y)$ could be estimated as

$$I(X,Y) = \frac{(T-1)\Big(\binom{k-T+2}{2} + kS_1(T) - S_2(T)\Big)}{T\binom{k+1}{2}} \tag{10}$$

where

$$S_1(T) = \sum_{i=0}^{T-2}(1-H_i(Y|X)), \tag{11}$$

$$S_2(T) = \sum_{i=0}^{T-2} i(1-H_i(Y|X)). \tag{12}$$

Since

$$H_i(Y|X) = -\Bigg(\frac{T-1-i}{2(T-1)}\log_2\frac{T-1-i}{2(T-1)} + \\ + \frac{T-1+i}{2(T-1)}\log_2\frac{T-1+i}{2(T-1)}\Bigg) \tag{13}$$

then

$$S_1(T) = -(T-1)\log_2(T-1) + \\ + \frac{1}{2(T-1)}\Big(\sum_{i=0}^{T-2} f^+(i) + \sum_{i=0}^{T-2} f^-(i)\Big), \tag{14}$$

$$S_2(T) = \frac{1}{2(T-1)}\Big(\sum_{i=0}^{T-2} f^{2,+}(i) - \sum_{i=0}^{T-2} f^{2,-}(i) + \\ +(T-1)\sum_{i=0}^{T-2} f^{+}(i) - (T-1)\sum_{i=0}^{T-2} f^{-}(i)\Big), \tag{15}$$

where

$$f^{+}(i) = (T+i-1)\log_2(T+i-1), \tag{16}$$

$$f^{-}(i) = (T-i-1)\log_2(T-i-1), \tag{17}$$

$$f^{2,+}(i) = (T+i-1)^2\log_2(T+i-1), \tag{18}$$

$$f^{2,-}(i) = (T-i-1)^2\log_2(T-i-1). \tag{19}$$

In order to analyze functions $f^{+}(i)$, $f^{-}(i)$, $f^{2,+}(i)$, $f^{2,-}(i)$ we will examine analogue variable $\tilde{i}$, $\tilde{i} \in [0, T-2]$ instead of discrete variable $i$, in which case $f^{+}(\tilde{i})$, $f^{2,+}(\tilde{i})$ are strictly increasing and $f^{-}(\tilde{i})$, $f^{2,-}(\tilde{i})$ are strictly decreasing defined and continuous functions in the interval $[0, T-2]$. Then the values of the following forms

$$\sum_{i=0}^{T-2} f^{+}(i), \sum_{i=0}^{T-2} f^{-}(i), \sum_{i=0}^{T-2} f^{2,+}(i), \sum_{i=0}^{T-2} f^{2,-}(i) \tag{20}$$

could be approximated by means of functions $f^{+}(\tilde{i})$, $f^{-}(\tilde{i})$, $f^{2,+}(\tilde{i})$, $f^{2,-}(\tilde{i})$ integrating in the interval $[0, T-2]$ accordingly.

Now we explain how to gain the approximate value of the sum $\sum\limits_{i=0}^{T-2} f^{2,+}(i)$ and the other sum can be estimated in a similar,

$$\sum_{i=0}^{T-2} f^{2,+}(i) \approx \int\limits_{0}^{T-2} f^{2,+}(\tilde{i})d\tilde{i} + f^{2,+}(T-2) - \\ -\sum_{j=0}^{T-3}\frac{f^{2,+}(j+1) - f^{2,+}(j)}{2} = \int\limits_{0}^{T-2} f^{2,+}(\tilde{i})d\tilde{i} + \\ +\frac{f^{2,+}(0) - f^{2,+}(T-2)}{2}. \tag{21}$$

Values of the integrals could be found using the variable substitution and integration by parts

$$\int\limits_{0}^{T-2}(T+\tilde{i}-1)^2\log_2(T+\tilde{i}-1)d\tilde{i} = \\ =\mid T+\tilde{i}-1 = p \mid = \\ = \int\limits_{T-1}^{2T-3} p^2\log_2 p dp = \frac{1}{3}\int\limits_{T-1}^{2T-3}\log_2 p d(p^3) = \\ = \frac{1}{3}(p^3\log_2 p)\Big|_{T-1}^{2T-3} - \frac{1}{3}\int\limits_{T-1}^{2T-3} p^3 d(\log_2 p) = \\ = \Big(\frac{1}{3}p^3\log_2 p - \frac{p^3}{9\ln 2}\Big)\Big|_{T-1}^{2T-3}. \tag{22}$$

It follows that

$$I(X,Y) \approx \frac{(T-1)\Big(\binom{k-T+2}{2} + kA(T) + B(T)\Big)}{T\binom{k+1}{2}} \tag{23}$$

where

$$A(T) = \frac{2T-3}{2}\log_2\frac{2T-3}{T-1} - \frac{T-2}{2\ln 2}, \tag{24}$$

$$B(T) = -\binom{T-1}{2}\log_2(T-1) - \\ -\frac{(T-1)^2\log_2(T-1)}{6} + \frac{(T-2)^2}{12\ln 2} - \\ -\frac{(2T-3)(2T^2-6T+3)\log_2(2T-3)}{12(T-1)}. \tag{25}$$

Graphs of function $I(X,Y)$ from $k$ where $T \in \{2,3,4\}$ are illustrated in Fig. 2.

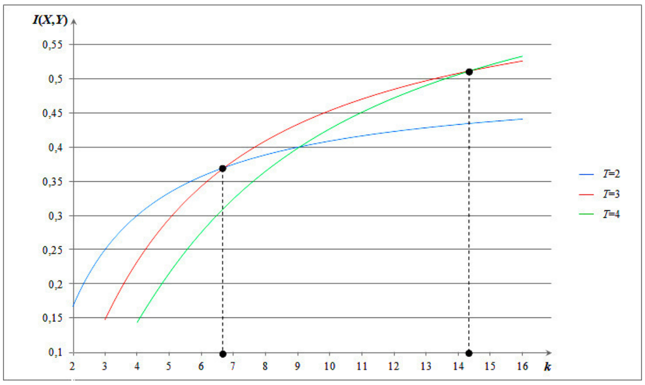

Fig. 2. $I(X,Y)$ function as a function from $k$ graph, $T \in \{2,3,4\}$

To build a covert channel the parameter $T$ is chosen while $I(X,Y)$ has a maximum value. Fig. 2 shows that when $k \in \{2,...,6\}$, parameter $T$ should be equal to 2, when $k \in \{7,...,14\}$, parameter $T$ should be equal to 3.

## V. The Practical Using of the Obtained Results

Let functioning of a covert channel with capacity less than $v_{\max}$ has no influence upon security (the dimensionality of $v_{\max}$ is one bit per sec) and the capacity of communication channel is $\mu$ bits per sec. Hence if the average length of transmitted packets is $\bar{l}$ bits, then the residual communication channel capacity is

$$\frac{(k+1)\mu}{(k+3)\bar{l}} \tag{26}$$

packets per sec. In case of the full using of the communication channel by the sender and the receiver the capacity of the covert channel is

$$v = \frac{(k+1)\mu C}{(k+3)\bar{l}} \tag{27}$$

bits per sec, where $C$ is the capacity of covert channel with the dimensionality bits per packet. Therefore when the allowable capacity of covert channel in limited, the following inequality is true

$$v \leq v_{\max}. \tag{28}$$

For example, according to [4] the functioning of a covert channel with capacity less than $v_{\max} = 100$ bits per sec can be acceptable in some cases. Let the capacity of the communication channel be $\mu = 100$ Mbits per sec (standard 100Base-T). The maximum length of IP packet is 65535 bytes, from which 20 bytes is a header length ($l_{fix} = 20$ bytes and $L = 65515$ bytes). Then the average length of sending packets is $\bar{l} = 262220$ bits in case of random equipropable choice of packets lengths from equinumerous sets $L_0$ and $L_1$.

Table I presents the relation between parameters of the covert channel and the counteraction tool (the symbol «*» means that the value of $v$ is round up to 2 digits).

TABLE I
RELATION BETWEEN PARAMETER OF COVERT CHANNEL, PARAMETER OF COUNTERACTION TOOL AND CAPACITY OF COVERT CHANNEL

| *k* | *T* | *C* | *v* |
|---|---|---|---|
| 2 | 2 | 0,17* | 41 |
| 3 | 2 | 0,25 | 67 |
| 4 | 2 | 0,30 | 86 |
| 5 | 2 | 0,33* | 100 |
| 6 | 2 | 0,36* | 112 |
| 7 | 3 | 0,38* | 122 |

Table I shows that in order to limit the capacity of covert channel up to 100 bits per sec the parameter of counteraction tool should be $k = 5$.

## VI. Conclusion

In this work the capacity of a packet size covert channel was examined using the information theory statements. The counteraction tool based on random traffic padding generating was designed. We proposed selecting the parameter of the counteraction tool when an allowable covert channel capacity is given.

The topic of the further work is to estimate the residual capacity in multi-symbol covert channels with traffic padding and to investigate the technique to limit covert channel capacity by random increase of packets sizes.

# Software Risk Assessment for Measuring Instruments in Legal Metrology

Marko Esche, Florian Thiel
Physikalisch-Technische Bundesanstalt
Abbestr. 2-12
10587 Berlin, Germany
Email: {marko.esche, florian.thiel}@ptb.de

***Abstract*—In Europe, measuring instruments subject to legal control are responsible for an annual turnover of 500 billion Euros and need to pass a conformity assessment with respect to European directives or national legislation before they can be used. Today, measuring instruments are frequently integrated into open networks and even branch into the areas of cloud computing and Internet of Things. Since software is one of the key components of such devices, Germany's national metrology institute, the Physikalisch-Technische Bundesantalt, is developing a method to assess the risks and evaluate current threats associated with software. The method uses the structure of and combines elements from the international ISO/IEC standards 27005 and 15408. It could be helpful for conformity assessment bodies and industry alike and supports the comparability of risk assessment results. Despite its focus on legal metrology, the method is applicable to other areas where software risk assessment is required, too.**

## I. Introduction

CERTAIN types of measuring instruments, like gas meters, taximeters, fuel pumps and grain moisture meters are subject to legal control in the European Union. Before making them available on the market, such measuring instruments have to undergo a conformity assessment according to the Measurement Instruments Directive (MID) 2014/32/EU [1]. The entire area of measuring instruments even including individual measurements regulated by either national or European legislation is referred to as legal metrology. According to estimations, about four to six percent of the gross national income in European countries is accounted for by legal metrology. In Germany alone, 130 million of such instruments are installed. These are responsible for economic transactions worth roughly 157 billion Euros each year. For a more detailed description of the role of legal metrology in general see [2].

In most cases, the conformity assessment is performed by so-called Notified Bodies, which have proven that they have at their disposal "(a) personnel with technical knowledge and sufficient and appropriate experience to perform the conformity assessment tasks, (b) descriptions of procedures in accordance with which conformity assessment is carried out, ensuring the transparency and the ability of reproduction of those procedures" [1]. One such Notified Body that performs conformity assessments is the Physikalisch-Technische Bundesanstalt (PTB), Germany's national metrology institute. The assessment itself is conducted according to a combination of modules (A to H1) which encompass different roles for manufacturers and Notified Bodies [1]. For most of these modules, a new general requirement has been introduced in 2014 concerning the submitted manufacturer's documentation. It states, "The documentation shall make it possible to assess the instrument's conformity to the relevant requirements, and shall include an adequate analysis and assessment of the risk(s)." Such a risk assessment does not only need to cover the physical measuring instrument itself but also the metrologically relevant software running on it. In this context, harmonization between European Notified Bodies obviously becomes necessary to ensure fair and comparable software risk assessment within the common trade zone. In this paper, an approach for software risk assessment is presented that

- makes use of established international standards as far as possible and
- identifies risks with reproducible numeric values to better ensure comparability between evaluation results.

The remainder of the paper is structured as follows: In Section II, a literature overview covering other methods in the field of software risk assessment is provided. In order to obtain reproducible analysis results, a clear definition of assets and threats to these assets is required. A derivation of such assets from the requirements of the MID is, therefore, provided in Section III. An algorithmic description of the risk assessment approach proposed here, may be found in Section IV. Afterwards, the new approach is compared with other existing methods based on two real-world examples in Section V. Section VI summarizes the paper and provides an overview of planned future work.

## II. Overview of existing methods

Before giving a list of reference approaches to software risk assessment, it is necessary to clearly identify what kind of risk assessment is required in the context of the MID. The directive establishes a common baseline by listing a number of essential requirements which all measuring instruments have to fulfill. Since the most important target of the MID is to ensure free and fair trade as well as to protect the consumer, these essential requirements are mainly targeted at protecting measuring results from accidental and intentional manipulation and to make both correct measuring results and detected manipulations traceable. Further details may be found in Section III. In this context, the term *risk* can be seen as the

978-83-60810-66-8/$25.00©2015, IEEE

product of the probability that the essential requirements are no longer met and the legal impact resulting from such a breach of the MID. It is important to note, that no financial loss needs to be associated with the risk, instead, the sole basis for the analysis are the essential requirements.

### A. *ISO/IEC 27005*

Probably most important to mention is the ISO/IEC 27000 family of standards which covers all aspects of an information security management system (ISMS). According to ISO/IEC 27005 [3], ”risk is a combination of the consequences that would follow from the occurrence of an unwanted event and the likelihood of the occurrence of the event.“ Thus, three different components are needed to calculate risk, namely

- a list of unwanted events,
- consequences resultig from such events,
- and the likelihood of occurence of individual events.

In order to derive all three components [3] gives details on generalized procedures to conduct risk assessment. The standard places risk assessment in a logical chain comprising context establishment, risk assessment, and risk treatment, where risk assessment consists of risk identification, risk estimation, and risk evaluation.

During the risk identification phase, assets are to be identified first. These are derived from a ”list of constituents with owners, location, function“, resulting in a list of assets to be managed. Afterwards, for each possible asset, threats are collected based on information from reviewed incidents, accounts from asset owners, and possibly external threat catalogs. These threats correspond to the ”unwanted events“ mentioned above. The next step consists of identifying existing risk control mechanisms which could, for instance, be determined from the provided documentation. Risk identification is completed by an identification of vulnerabilities which can be used to implement certain threats. In this context, a vulnerability can only cause harm if it can be used to realize a threat. Equivalently, threats without a corresponding exploitable vulnerability do not pose a risk.

The next part of ISO/IEC 27005, concerned with risk estimation, is likely the most relevant in the context of this paper. The standard considers both qualitative and quantitative approaches to calculate risk probability, where the quantitative approach ”uses a scale with numerical values for both consequences and likelihood, using data from a variety of sources.“ Such numerical values are a prerequisite for ensuring comparability among risk assessment results for different products conducted by different examiners. To derive at actual probabilities, ISO/IEC 27005 first assigns certain impacts or consequences to incidents that could result from realized threats by means of exploited vulnerabilities. Possible examples of impacts include loss of confidentiality of certain assets as well as a breach of asset integrity. In a final step, the probability, with which a threat is realized, is estimated. Important factors, in this context, are the frequency at which certain threats occur in real life and the difficulty of exploiting a vulnerability. For intentional exploitation of threats, ISO/IEC 27005 suggests a valuation of motivation and capabilities, resources available to the attackers as well as the perception of individual vulnerabilities. This approach will later be revisited in Section IV where certain aspects of ISO/IEC 27005 are reflected in the risk assessment approach presented here. Nevertheless, the standard does not prescribe a reference model to calculate individual numeric threat probabilities. The choice of such a model is instead left up to the user of the standard. One possible method to calculate risks quantitatively may, for instance, be found in [4], where the author proposes to define risks as probability functions that describe the likely gains or losses obtained from security incidents. The final components of risk assessment according to ISO/IEC 27005 are evaluation of the risk level and risk evaluation. The aim of these steps is to prioritize the identified risks according to the predetermined evaluation criteria.

### B. *WELMEC Guide 5.3*

In order to harmonize the work of Notified Bodies in Europe, a number of non-mandatory guides have been established within the European Legal Metrology Cooperation (WELMEC). The guide 5.3 ”Risk Assessment Guide for Market Surveillance: Weigh and Measuring Instruments“ deals with risk assessment from a market surveillance perspective and originates from Regulation 765/2008/EC [5]. Its main goal ”is to understand the impact the instrument will have on the end user/consumer“ [6]. The guide establishes a list of evaluation criteria which should help ”the market surveillance authority to define priorities and to determine the choice of strategies to achieve their goals.“ Since the guide is solely targeted at market surveillance authorities, the expected impact is not clearly defined but rather encompasses everything from ”economic implications, public health, consumer confidence [to] legal issues“ [6]. Even if only legal issues are considered, the spectrum of the guide is still too broad to objectively evaluate software in measuring instruments. Instead, the guide provides a clear rule to eventually calculate the risk associated with non-compliance but does not provide means for calculating individual threat probabilities.

### C. *Van Deursen et al. ”Source-Based Software Risk Assessment“*

One approach, that does not have this shortcoming, is the one by van Deursen et al. in [7]. There, risk assessment is defined as ”an independent assessment of the risks involved in building, operating or maintaining a software system.“ The method then calculates the risk based on so-called primary and secondary facts, where primary facts are data acquired through automatic source code analysis and secondary facts are obtained using user questionnaires. The primary facts are mainly needed to identify subsystems that show features not usually found in software systems. After the primary facts have been used to validate the secondary data, a final result can be computed. This method could readily be adapted for the use in legal metrology. However, source code is usually not a required part of the documentation for MID conformity assessment.

### *D. Foo et al. "Software Risk Assessment Model"*

Another method to objectively evaluate and compare risks associated with software was presented by Foo et al. in [8]. There the basic abstraction technique used by the authors is a software risk assessment model (SRAM) which is constructed based on an extensive questionnaire to be answered by the risk assessor of a software product. Within [8] the term risk is defined as "factors that may cause late delivery, cost overrun or low quality of a software product." Nevertheless, the authors list the productive level of the staff, flexibility of the delivery schedule and most importantly complexity of software as having a significant impact on the risk evaluation. In the context of a MID conformity assessment, the first two sources of information are of no importance since the MID is not concerned with business processes. The complexity of the software can again not be used due to lack of available information. Moreover, the risk assessor required by the SRAM approach needs to have access to resources such as source code and error statistics that are not available to a MID evaluator. For comparison, a description of a risk assessment approach for measuring instruments with a similar scope covering the entire life cycle of a device can be found in [9].

### *E. Sadiq et al. "Software Risk Assessment and Evaluation Process (SRAEP) using Model Based Approach"*

In [10] a different software risk assessment method was proposed that is also model-driven. Sadiq et al. therein describe the Software risk assessment and evaluation process (SRAEP) which is based on the software risk assessment and evaluation model (SRAEM). Their approach is targeted at highlighting threats to the success of a software project rather than threats to a finished software product. Nevertheless, a number of useful formalized steps are included in their method which shall be reused later. For this reason, the basic steps of the SRAEP will be revisited here.

According to the authors the motivation for using a model-based assessment strategy is two-fold:

- With the help of a model, precise descriptions of the target system, its context, and security features can be formulated. These are prerequisites for performing risk assessments.
- The modeling technology facilitates a more precise documentation of risk assessment results and of the assumptions on which their validity depends. This is expected to reduce maintenance costs by increasing the possibilities of reuse of the documentation.

The SRAEP itself can be divided into two steps: the identification of a context for the analysis and the identification of risks themselves. Sadiq et al. here split the context identification into an identification of areas of concern, a description and evaluation of assets, and, finally, an identification of security requirements. These three steps will be used again during asset derivation, see Section III, and in the risk assessment method that is proposed here as described in Section and IV. Before beginning with the risk analysis, the SRAEP requires an evaluator to acquire detailed knowledge of the analysis target. Based on this knowledge, all security issues related to software should be discussed making reference to common vulnerabilities or the results of tool-based vulnerability checks.

### *F. ISO/IEC 15408 (Common Criteria)*

An international standard for software security that explicitly does not address risk assessment is ISO/IEC 15408 also known as the "Common Criteria" (CC) [11]. In the CC, a set of functional security requirements is defined, which can be used to describe both product requirements in the form of Protection Profiles and product specifications in the form of Security Targets. An implemented Security Target, i.e. a product to be tested, is referred to as a Target of Evaluation (TOE). The standard also provides a list of assurance components, a chosen subset of which is also included in said Protection Profiles and Security Targets. These assurance components are then used to validate the design, the development, and finally the completed IT product itself. In which manner the assurance components are to be checked is not described in the CC themselves but rather in the Common Evaluation Methodology (CEM) [12] which accompanies the CC. Two building blocks from the CC with details provided in the CEM are of special interest here: Firstly, each Security Target includes a Security Problem Definition in which assets to be protected are identified. The CC initially list primary assets that represent objects or information of a given value whose authenticity, integrity or availability are to be protected. Certain aspects of an IT product can also become assets themselves when they play an integral role in realizing security functionality. These are referred to as secondary assets. Both types of assets are examined and listed in the security problem definition. Afterwards, possible threat agents and adverse actions that could be executed on the assets are investigated and described in a semi-formal manner. The combination of threat agent, asset, and adverse action is referred to as a threat. This construct will here again be used since it facilitates the implementation of reproducible risk assessment results.

Secondly, one part of validating a Security Target consists of a so-called vulnerability analysis which is specified in the CC's AVA_VAN class. The assurance components associated with this class allow an examiner to execute both white box and black box tests on the Security Target based on the knowledge acquired during the evaluation procedure. The vulnerability analysis uses a point score, where each adverse action to be executed on an asset is evaluated with respect to five different aspects ranging from the time required to the equipment needed to implement an attack, for details see Section IV. In each category mentioned a point score is determined. Based on the total sum of all points the TOE's resilience to an attack is checked. This is done with the aid of matrix, details on which will also be provided in Section IV. More information concerning the general mechanisms of the vulnerability analysis will be given there as well.

### G. ETSI TS 102 165-1

The European Telecommunications Standards Institute (ETSI) in an international non-profit organization that publishes industrial standards in the area of telecommunications systems. These are targeted at manufacturers of communication equipment and network operators. One of these standards is ETSI TS 102 165-1 ”Telecommunications and Internet converged Services and Protocols for Advanced Networking“ [13] (TISPAN), where in part 1 ”Method and proforma for Threat, Risk, Vulnerability Analysis“ are detailed. The so-called technical specification describes a risk assessment approach consisting of nine individual steps that comprise everything from a definition of the device to be examined (TOE) up to the establishment of risks and an identification of countermeasures. The method starts by defining clearly the boundaries of the TOE and by identifying its security functionalities using terminology from the common criteria. Afterwards, all assets are identified. In [13] these have to fall into one of the following categories: equipment, human assets or information stored. It will be shown in Section IV that this definition is to narrow for most applications outside the area of communication systems. Moreover, the standard does not describe a way to derive abstract assets resulting, for instance, from legal requirements. Next, possible ”attack interfaces“ are identified that a threat agent can use to implement a threat. In order to assess the likelihood of occurrence for an individual threat, elements from the CC's AVA_VAN class are used as described earlier. Details on the method may be found in Section IV. According to [13], ”threats to a telecommunications system are fairly restricted and fall into a small set of easily identified operations.“ Consequentially, [13] only lists a very small number of possible threats namely interception, manipulation, repudiation, and denial of service. While well suited to the area of telecommunication networks, these are to limited for general-purpose IT devices. The same is true for the definition of threat agents where [13] only allows a very small number of different roles. Finally, impact in the context of TISPAN is defined as a function of the intensity of an attack. For measuring instruments, as discussed here, a different definition is needed which will be given in Section III. Nevertheless, the method has certain properties which are of use to the scenario discussed here:

- calculation of the probability of an attack based on the AVA_VAN class from the CC,
- evaluation of impact and attack likelihood based on simple numeric scores (1 to 3 points),
- extension of the AVA_VAN class to account for multiple attacks being executed simultaneously.

## III. Formal derivation of security requirements from the Directive 2014/32/EU

Before beginning with the algorithmic description of the new risk assessment method for software itself, a specific set of assets and associated security properties for measuring instruments will be derived here. These will later be reused in the experimental evaluation. The derivation should be seen as an example on how to formalize legal or contractual requirements with respect to software. In application scenarios not related to the conformity assessment of measuring instruments, other assets such as human health or monetary values etc. would, of course, be used. The latest version of the MID lists several requirements relating to software as plain text, which will be formalized here.

### A. Exemplary Asset Derivation

The actual procedure of defining security requirements based on legal specifications will be highlighted with an example: Annex I of the MID lists so-called essential requirements for measuring instruments that have to be fulfilled before putting them on the European market. As an example clause 8.4 will be used here. It reads, ”Measurement data, software that is critical for measurement characteristics and metrologically important parameters stored or transmitted shall be adequately protected against accidental or intentional corruption.“ [1, L 96/173]

The requirement specifically mentions three asset candidates, namely measurement data, software that is critical for measurement characteristics, and metrologically important parameters stored or transmitted. All three assets are required to be protected against accidental or intentional corruption. Firstly, this can be interpreted as a requirement for guaranteeing integrity of these assets. Secondly, however, an intentional replacement of a parameter set also represents a viable way to invalidate parameter integrity. Thus, authenticity of said assets also appears to be required. This is not specifically mentioned in the MID but is common understanding among Notified Bodies [14]. Consequentially, the assets measurement data, software critical for measurement characteristics, and metrological parameters are associated with the security properties of integrity and authenticity. Availability of the software, however, is not mandatory since an instrument with no running measurement software cannot produce false measuring results.

Another requirement related to software can be found in Annex I of the MID, clause 7.6. It states, ”When a measuring instrument has associated software which provides other functions besides the measuring function, the software that is critical for the metrological characteristics shall be identifiable and shall not be inadmissibly influenced by the associated software.“[1, L 96/173] Again, two assets are specifically mentioned. The first is the identification of the software. The second one is an inadmissible influence by other software which is not a physical object or an IT object itself but rather is a property of the software. In the language of the CC, prohibiting external influence on the software can be expressed by stating, that the inadmissible influence shall be unavailable. This again enables the use of a fixed scheme to describe security functionality by identifying dedicated security properties associated with an asset.

### *B. Complete List of Assets*

An overview of all MID requirements for software in measuring instruments may be found in Table I. The two examples discussed here are listed there for completeness as well.

Apart from the measurement software itself, the assets to be protected include an identifier for the software, measurement, results and parameters that determine the behavior of the instrument. In addition, the presentation of the measurement result as well as the presentation of the identifier for the software have to meet special requirements. Details on how these requirements are usually fulfilled may be found in [14] where the paragraphs from the MID are translated into implementation specific requirements and into so-called acceptable (technical) solutions. Even though [14] is usually of great value for both software developers and software examiners, it will not be used here since the new risk assessment procedure (see Section IV) aims to be generic and independent from a limited number of established technical realizations.

## IV. Algorithmic Description of the Risk Assessment Procedure

The risk assessment method described in this paper follows the structure defined in [3] and consists of three main parts, namely identification of assets, identification of attack vectors, and calculating the probability of occurrence for an individual attack. Each of these will now in turn be described. A flowchart that links all three parts and incorporates details for each step may be found in Figure 1.

### *A. Identification of Assets*

As has been detailed in Section III, assets to be protected can be derived directly from the legal requirements for measuring instruments as laid down in the MID. This is in accordance with [3], which states that the risk evaluation process can take ”legal and regulatory requirements, and contractual obligations“ into account and should also consider the ”criticality of the information assets involved“. In addition to the asset definition, one or more attacker models are needed, see upper right corner of Figure 1. In the simplest case, a Notified Body will assume all market players to be untrustworthy with equal motivation to manipulate measurement results and measuring instruments. This includes manufacturers or distributors of such devices, users or maintainers, and customers. These only differ in their respective capabilities to implement an attack. Subsequently, the risk assessment procedure can use the market player with the most detailed knowledge and with the highest skills (normally manufacturer or user) as a representative model. The basic structure for both the attacker model and the formulation of adverse actions may be found in the Security Problem Definition as described in [11]. When examining an individual measuring instrument, it may make sense to individually differentiate between attackers/authenticated users with different levels of access. If the authentication data is available to any of the market operators mentioned, then the highest access rights granted to any of these will be allocated to the modeled attacker. The only entity to be considered trustworthy in this context is the market surveillance which may hold administrator level authentication data for certain devices.

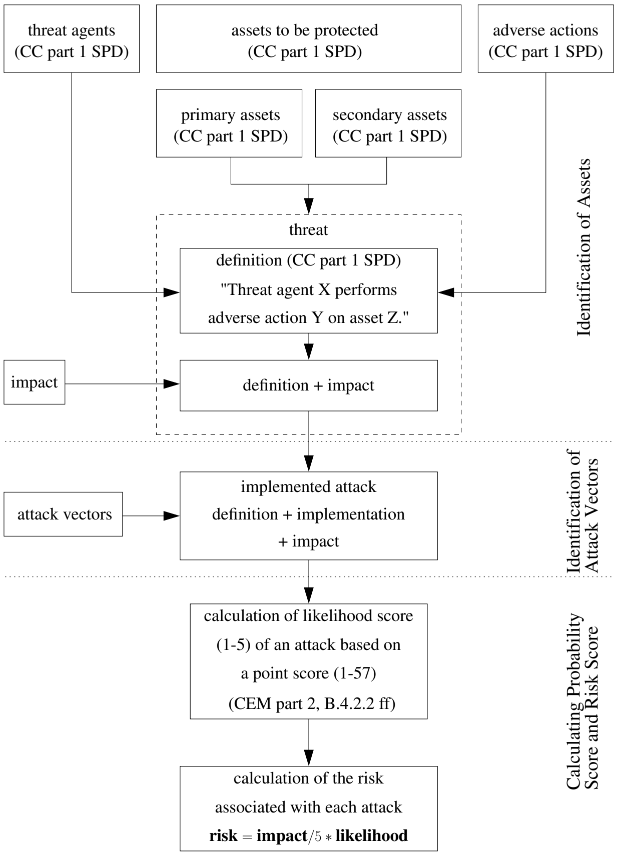

Fig. 1. Flowchart of the proposed risk assessment procedure. The notes on the right hand side indicate the division into the three main steps of the method.

Yet another action to be performed during the asset identification phase is the collection of certain adverse actions that can cause harm to the assets. Here again, a generic approach from the CC [11] can be used: Each modeled attacker may harm any of the identified assets by invalidating one or more of their security properties, i.e. availability, integrity or authenticity as applicable. Such an adverse action may then read for example, ”An attacker with the access rights of a local administrator manages to invalidate the availability of the proof of an intervention.“ The formulation of a complete threat may be found within the dashed box in Figure 1. The complete set of possible adverse actions derived from these basic combinatorics then only has to be checked for consistency and for possible duplicates. In a final step, the implemented attack, consisting of an adverse action and an attack vector, will be assigned an individual impact score between 1 and 5. Since all legal requirements are generally assumed to be equally important, the highest score (5) will usually be used. A smaller score will only be chosen if the attack only applies to a single measurement or can later be

TABLE I
REQUIREMENTS FROM THE MID [1] RELATING TO SOFTWARE AND THEIR FORMALIZATION AS ASSETS AND SECURITY PROPERTIES. THE NUMBERS IN BRACKETS AFTER EACH ASSET (A1 TO A10) REPRESENT THERE UNIQUE IDENTIFIER.

| **Requirement in the MID [1] Annex I** | **Asset** | **Security Property** |
|---|---|---|
| 7.6 ”When a measuring instrument has associated software which provides other functions besides the measuring function, the software that is critical for the metrological characteristics shall be identifiable and shall not be inadmissibly influenced by the associated software.“ | identification of the software (A9) | availability, integrity |
| | inadmissible influence on the software (A5) | unavailability |
| 8.1 ”The metrological characteristics of a measuring instrument shall not be influenced in any inadmissible way by the connection to it of another device, by any feature of the connected device itself or by any remote device that communicates with the measuring instrument.“ | inadmissible influence on the software (A5) | unavailability |
| 8.3 ”Software identification shall be easily provided by the measuring instrument.“ | presentation of the software identification (A10) | availability |
| 8.3 ”Evidence of an intervention shall be available for a reasonable period of time.“ | evidence of an intervention (A2) | availability, integrity |
| 8.4 ”Measurement data, software that is critical for measurement characteristics and metrologically important parameters stored or transmitted shall be adequately protected against accidental or intentional corruption.“ | measurement data (A3) | integrity, authenticity |
| | software critical for metrological characteristics (A1) | integrity, authenticity |
| | metrologically important parameters (A4) | integrity, authenticity |
| 10.1 ”Indication of the result shall be by means of a display or hard copy.“ | indication of the result (A6) | availability, integrity |
| 10.2 ”The indication of any result shall be clear and unambiguous and accompanied by such marks and inscriptions necessary to inform the user of the significance of the result.“ | marks and inscriptions (A7) accompanying the indication of a result | availability, integrity |
| 11.1 ”A measuring instrument other than a utility measuring instrument shall record by a durable means the measurement result accompanied by information to identify the particular transaction, when: the measurement is non-repeatable; and the measuring instrument is normally intended for use in the absence of one of the trading parties.“ | record of a measurement result (A8) | availability, integrity, authenticity |

detected by market surveillance.

### B. Identification of Attack Vectors

The second stage of the risk assessment phase is certainly the least formalized one. It begins with a careful study of the submitted manufacturer's documentation of the measuring instrument to be examined. This process is shown in the middle section of Figure 1. The evaluator then collects possible attack vectors consisting of actions to be performed, that would enable an attacker to realize any of the previously identified threats. This represents a clear difference to the TISPAN method detailed in Section II. Some of these attack vectors may be as simple as trying a number of password combinations on a keypad in order to gain a higher level of access. Others may comprise complex cross-site-scripting (XSS) attacks in conjunction with the preparation of a root kit to take over a device in the field and subsequently install unapproved software on the device. One relatively simple attack vector from this category is the execution of a denial-of-service (DoS) attack on a measuring instrument connected to the Internet. In many cases, such an attack will lead to the generation of an arbitrary number of error messages written to an audit log which is subject to legal control. Should the log be restricted in size, an earlier intervention may no longer be traceable later if the log is flooded with a huge amount of automatically generated errors. This would be a direct breach of the essential requirements as laid down in Section III.

### C. Calculating Probability Score and Risk Score

Once an adverse action with one or more associated attack vectors has been identified, it remains to calculate the likelihood with which the attack will actually be implemented, see lower part of Figure 1. A similar activity is in detail described in the vulnerability analysis (class AVA_VAN) in [12]. There, an evaluator estimates the resistance of an IT product (TOE in the language of the CC) to certain attacks. The evaluation in [12] is done based on five different scores describing the resources needed for the attack:

- Elapsed Time (0-19 points)
- Expertise (0-8 points)
- Knowledge of the TOE (0-11 points)
- Window of Opportunity (0-10 points)
- Equipment (0-9 points)

The score for elapsed time represents the amount of time required by the selected attacker to implement the chosen attack. A score of 0 usually signifies work of less than a day. Required work of less than a week would give a point score of 1, whereas a score of 19 represents an estimated work period of more than half a year. Further examples will be given in Section V. A table with details on all five score criteria and additional explanations for the choice of the criteria may be found in [12, p. 429].

The logarithmic progression of the scores ensures that with every additional point assigned to an attack, it becomes significantly more complex to implement. This also means that the score is more easily reproducible since evaluators

TABLE II
CALCULATING THE RESISTANCE OF A TOE. THE THIRD COLUMN MAPPING THE TOE RESISTANCE LEVEL TO THE APPROPRIATE PROBABILITY SCORE IS NOT PART OF THE ORIGINAL TABLE AS GIVEN IN [12].

| Sum of Points | TOE Resistance | Probability Score |
|---|---|---|
| 0-9 | No rating | 5 |
| 10-13 | Basic | 4 |
| 14-19 | Enhanced Basic | 3 |
| 20-24 | Moderate | 2 |
| >24 | High | 1 |

will certainly come up with estimated attack times of the same magnitude even if the actual times differ slightly. In the second category (expertise), between 0 and 8 points can be assigned, where 0 represents layman capabilities and 8 points are given when the attacker needs to be an expert in more than one field. The third category refers to the required knowledge concerning the attacked device. Again, a score of 0 is given if only publicly available knowledge is needed, such as information easily available from the web. 3 points represent restricted knowledge as might be found in the user documentation. The maximum of 11 points would stand for critical inside information only available to employees of the manufacturer. One very important score criterion is the window of opportunity available to the respective attacker. In the case of unlimited access, as would be usual for devices connected to the Internet, 0 points will be given, where 1 point signifies easy access. Should access, however, be difficult to obtain, 10 points can be assigned. In the ideal case, where access is impossible, no rating is done and the respective attack vector is removed from the list of candidates. At this point, there exists a simple way to include the motivation of threat agents into the score. Should an attacker lack the motivation to implement a threat even though he is able to realize the attack vector, the respective threat should be removed from the list.

When the assignment of score points has been done according to the five categories mentioned, the sum total of all scores is calculated. During a CC evaluation the so-called TOE resistance is then derived as indicated by Table II. A score between 10 and 13 points would, for instance, demonstrate a basic resistance to attacks, while a score above 24 indicates high resilience. In the context of the CC, the resistance to attacks would then be used to validate the selected evaluation assurance level (EAL). Here, however, the resistance rating is mapped to a probability score between 1 and 5, where 5 represents high probability of occurrence for an attack and 1 states that an attack is very unlikely to occur. The mapping of TOE resistance to probability score is also shown in Table II.

Calculating the risk associated with a threat subsequently consists of multiplying the impact score (between 1 and 5) for the given threat with the probability score of the most probable attack vector, that could realize the threat:

$$\text{risk score} = \frac{\text{impact score}}{5} \cdot \text{probability score} \qquad (1)$$

Dividing the impact score by 5 simply ensures, that the risk score is in the range between 1 and 5, too. As will be shown in the experimental evaluation, the risk score thus calculated can easily be used to rank risks associated with a single instrument or even to compare different instruments and their risks with one another.

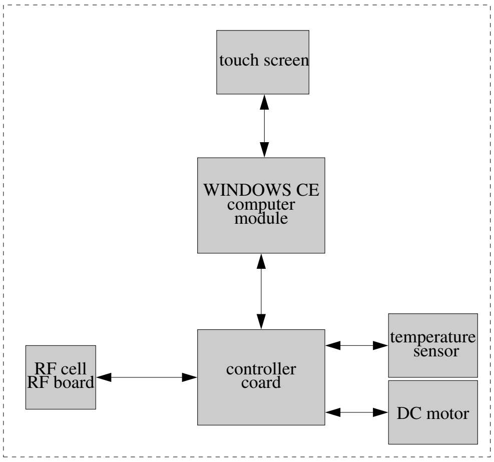

Fig. 2. High-level schematic for the grain moisture analyzer that was evaluated as an illustrative example. Parts lying physically inside the instrument are surrounded by the dotted line.

## V. EXPERIMENTAL EVALUATION AND COMPARISON WITH OTHER METHODS

### A. Grain Moisture Meter

The first measuring instrument that was examined during evaluation of the proposed software risk assessment method is a grain moisture analyzer. Such devices usually take a small sample of grain and calculate the moisture level within the sample by submitting it to infrared light and observing the absorbed wavelength spectrum. The relative moisture is economically important since it has a significant influence on the price of the grain. In this example, the measuring instrument is a stand-alone unit that is physically closed except for a touch screen, the sample inlet, as well as a serial and a USB port. As an operating system Windows CE is used. Certain types of grain can be selected via the touch screen, which is also used to start the measurement process and to show the current and past measurement results. In addition, the instrument contains a so-called audit log in which changes to both software and relevant measurement parameters are recorded. If an empty USB stick is plugged into the unit, it will write all available measurement results together with the respective date and time of the measurement to the stick. The measuring process can also be started via the serial port, which uses a proprietary protocol. Through this protocol measurement results can be read out, too. Access to the relevant system parameters and to the operating system are protected by a 6-digit password. A high-level schematic of the system may be found in Figure 2.

Based on the described system architecture and the documentation supplied by the manufacturer, a list of possible attack vectors can be compiled. The following list is just a short extract from the complete one and is used here for illustration purposes:

- **A_PASSWORD**: An attacker gains access to the administrator password by trying all 6-digit combinations.
- **A_SW_REPLACE**: An attacker retrieves the administrator password and replaces the legally relevant software.
- **A_INT_SERIAL**: An attacker exploits a vulnerability of the proprietary serial protocol and causes the instrument to malfunction.
- **A_INT_SERIAL_VALUE**: An attacker exploits a vulnerability of the proprietary serial protocol and manipulates a measurement value by interrupting the measurement.
- **A_INT_USB**: An attacker manages to install malicious code on the measuring instrument by disabling the USB-port's protection.

For each threat, as described above, an evaluator now has to go through the list of attack vectors and select those vectors that can realize the threat. In some cases, a combination of attack vectors might be necessary. An excerpt from the complete mapping between threat scenarios and attack vectors can be found in Table III. Each threat can then be rated individually. Both the point score for each aspect and its meaning are supplied in the table as well. The first threat (T1) here is a replacement of the legally relevant software by a local attacker. Since the only individual with adequate access to the measuring instrument is the operator of the device, he is also assumed to be the most likely attacker. This, of course, has an influence on the assigned point scores (see Table III). To realize T1, the attacker first has to retrieve the password for the operating system. In addition, a software needs to be written that mimics the behaviour of the approved one without raising suspicion from customers. The development of such a software is deemed to be very complex, giving it a time rating of more than half a year with an associated point score of 19. In addition, the attacker needs to be an expert in the area of software development or needs to have access to somebody who has such skills. The expertise score is therefore set to 6. Restricted knowledge of the device such as a description of the system behavior and its components is also required. Finally, the owner of the measuring instrument has unlimited access to it and to write software no special equipment aside from an off-the-shelf PC is required. The sum score for this scenario is 29, which even in the context of the CC is so high, that virtually no attack likelihood remains. Table II subsequently assigns the lowest probability score for this threat.

Subsequently, threats T2 to T5 are rated in the same manner. Threat T5 has a probability score of 2 which is identical to those of threats T3 and T4. Nevertheless, the associated risk score is only 1 since T5 will only affect one single measurement result and thus has a fairly low impact. For all other threats, there is no difference between risk and probability score since they were classified as having the highest possible impact score of 5.

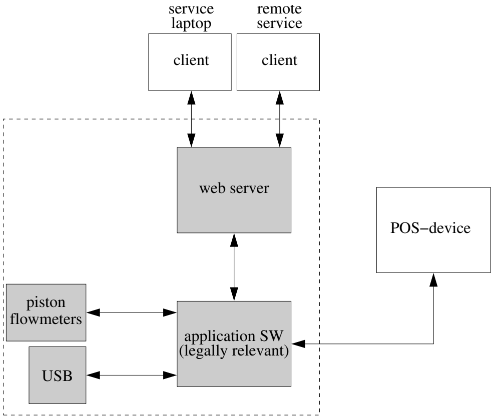

Fig. 3. High-level schematic for the fuel pump calculator that was evaluated as an illustrative example. Parts lying physically inside the instrument are surrounded by the dotted line.

### B. Fuel Pump

The second measuring instrument, that was evaluated according to the new scheme proposed here, is the calculator unit of a fuel pump. The device communicates externally with a point-of-sales (POS) device and reads data from a number of flow piston meters. As an operating system a common Linux distribution is used. Measurement results are displayed locally on a seven-segment-display and are also transmitted over a LAN to the POS device. The communication with the POS device is unidirectional. Parameters that influence the metrological behavior of the system and the operating system can be changed and accessed when a USB stick with a 32-bit key is plugged into the unit. This key is usually only in the possession of an authorized inspector. In addition, the instrument possesses a web server that can be accessed over the Internet. Through the web interface, the status of the machine can be queried and parameters can be set.

A rough schematic of the measuring instrument and its surroundings can be found in Figure 3. With reference to the documentation supplied by the manufacturer a list of possible attack scenarios can again be identified. The easiest way of deriving meaningful attack vectors is focusing on interfaces available to the outside world. Here, these include both the USB port and the communication with the POS device as well as the web interface. The communication with the POS device is physically sealed since it is also under legal control. The USB port is easily accessible for the owner of the pump, while the web interface is freely accessible for anybody in possession of the IP address. The web server in question, as a commonly used IT product, has several entries in the public CVE database [15] which is maintained by MITRE, a non-profit company operating multiple research and development centers financed by the US government. The database provides an extensive list of known vulnerabilities for virtually all software components

TABLE III
Evaluation of a small number of selected threats according to their attack vector for the example no. 1 ”grain moisture analyzer“

| **Threat** | **Description** | **Impact** | **Attack Vector** | **Elapsed Time** | **Expertise** | **Knowledge of the TOE** | **Window of Opportunity** | **Equipment** | **Sum** | **Score** | **Risk** |
|---|---|---|---|---|---|---|---|---|---|---|---|
| T1 | Local admin (S1) invalidates integrity or authenticity of the metrological software (O1). | 5 | A_SW_REPLACE | (>180d)<br>19 | (expert)<br>6 | (restricted)<br>3 | (unlimited)<br>0 | (standard)<br>0 | 28 | 1 | **1** |

| T4 | Local admin (S2) invalidates the availability of the evidence of an intervention (A2) by deleting the evidence. | 5 | A_PASSWORD | (>180d)<br>19 | (layman)<br>0 | (restricted)<br>3 | (unlimited)<br>0 | (standard)<br>0 | 22 | 2 | **2** |
| T5 | Local admin (S2) invalidates integrity, authenticity or availability of a measurement result (A8). | 2 | A_INT_USB | (>60d)<br>7 | (expert)<br>6 | (restricted)<br>3 | (unlimited)<br>0 | (specialized)<br>4 | 20 | 2 | **1** |

publicly available. A short excerpt from the compiled list of possible attack vectors will be supplied here:

- **A_USB_SCRIPT**: An attacker fakes an authorized key on a USB stick thus gaining access to the operating system.
- **A_WEB_XSS**: An attacker utilizes CVE-2011-4273 for a XSS attack to execute arbitrary javascript code on the web server and to subsequently download a root kit to the system.
- **A_WEB_DOS**: An attacker exploits CVE-2009-5111, CVE-2003-1568 or CVE-2002-2429 by executing a DoS attack via partial HTTP requests.
- **A_WEB_SOCKET**: An attacker executes arbitrary malicious code while establishing a connection making use of CVE-2002-2431.

As was the case with the first example, all known threats are iteratively examined. For each of them, the evaluator has to decide whether there are any attack vectors that could be used to realize the respective threat. Afterwards, the combination of threat and attack vector is again evaluated using the point score from the CC. Here too, the threat T1 consists of a replacement of the legally relevant software after gaining access to the operating system. Since the password is entered via the USB port, there is the possibility to execute and automated brute-force attack on the authentication data. This will, however, require significant resources. In addition, a replacement software needs to be written that mimics the original one. Again, the time needed for implementing of T1 is very high, resulting in a point score of 19. Also, the attacker in question needs to be an expert software engineer (point score 6) with detailed knowledge of the measuring instrument (point score 3). Should the operator of the pump also be the attacker, unlimited access to the device is obviously given resulting in a respective score of 0. The sum total of 29 points is still so high, that the resulting probability score of 1 is negligible. This has to be seen in conjunction with the fact that the selected combination of attacker and capabilities is highly improbable in any case.

Much more likely appears a local attack on the web server (see threat T2). Since exploits for the servers vulnerabilities can be downloaded from the web, no significant implementation time (point score 4) is needed. The attacker still needs to be an expert (point score 6) in the field of software engineering to correctly use the exploit. A certain amount of detail with respect to the measuring instrument such as its IP address (point score 3) is also required. But since the attack is web-based, access is virtually unlimited. Given specialized equipment like a platform to test the attack, the resulting total point score of 17 is relatively low. This results in an medium threat probability. The evaluation of the remaining threats progresses in a similar manner. The evaluation results may be found in Table IV. Again, it is important to mention, that some threats (T5 and T6) have a low risk score despite a medium probability score since their impact is limited to one single measurement at a time.

### C. Comparison with WELMEC Guide 5.3

WELMEC Guide 5.3 uses the same definition of risk as the approach discussed here: a product of impact and probability of occurrence for a threat. Additionally, the guide proposes to calculate an average impact score based on economic

implications, public health, consumer confidence, and legal issues. The assets identified in Section III, which fall into the latter category, could thus also be used in the context of the guide. However, the likelihood estimation in WELMEC Guide 5.3 clearly has the aim of assessing ”the probability of non-compliance“. It addresses both behavior of manufacturer and consumer as well as the production cycle of the instrument. The assessment is clearly focused on the manufacturer of the instrument. Unintended, implementation-based vulnerabilities of a measuring instrument are not within the scope of WELMEC Guide 5.3 since technical details with respect to the instrument's components are not taken into account at all. Instead, much more emphasis is placed on the perception of legal requirements and statistics concerning malfunctions observed in the field. While the latter may provide helpful hints, it cannot be used to assess risks associated with a new product in advance. The Guide is thus not able to produce comparable evaluation results.

### *D. Comparison with ISO/IEC 27005*

The most significant difference between the approach presented here and ISO/IEC 27005 [3] is the addition of the probability calculation based on the vulnerability analysis from the CC and the CEM. ISO/IEC 27005 explicitly states that likelihood estimation techniques should take into account ”the motivation and capabilities, which will change over time, and resources available to possible attackers“. Both motivation and capabilities (including equipment, required skills, and knowledge) can clearly be mapped to the CC-based probability estimation as detailed in Section IV. The new risk assessment approach can thus be seen as a practical realization of ISO/IEC 27005, which does itself not specify ways of calculating individual threat probabilities. The identification of assets as described in Section III is also clearly compatible with ISO/IEC 27005, since it follows the same three-step approach of risk identification, risk estimation and risk evaluation. Nevertheless, a number of additional hints can be found in the standard on how to improve the proposed method further:

- Motivation or resources of attackers may change over time, so a risk assessment for a specific measuring instrument may have to be conducted again after a certain time interval to keep it up to date.
- Even though a possible attacker may have access to a device, he might lack the motivation or the skills to carry out an attack. Thus, each implemented threat with an associated attack vector could be checked against a list of likely attackers. Unlikely combinations of skill and window of opportunity could then be removed from the evaluation table, resulting in a more clearly defined risk scenario.

## VI. SUMMARY AND FUTURE WORK

The method for software risk assessment for measuring instruments in legal metrology described here follows the guidelines of ISO/IEC 27005 [3]. In addition, elements from ISO/IEC 15408 [11] and ISO/IEC 18045 [12] were used to derive meaningful probability scores for certain threats. In order to make the evaluation process more objective, legal requirements for measuring instruments as laid down in [1] have been formalized, resulting in a list of assets to be protected and their respective security properties. With the aim of showing the feasibility of the approach, two real-world examples of measuring instruments were examined giving results that could be used as a feedback into the manufacturers design and production phase. Even though all application scenarios discussed here are from the sector of legal metrology, the approach may be of interest to evaluators of software in general. The formalization of assets and security requirements can, of course, be adapted to fit other legal or contractual obligations apart from the MID. The evaluation scheme can then be used in the same manner as was demonstrated here.

The two examples used for demonstrative purposes showed that the scheme can indeed provide meaningful results based on the information available to a Notified Body when assessing a manufacturer's design. If the source code also were available, the method from [7] could be applied to further validate the determined risk scenario. Even without additional information there are a number of steps that could be taken to improve the proposed approach:

In a first step, different evaluators will be asked to assess generic measuring instruments in a field test. To this end, the approach is currently being tested in a subgroup of WELMEC Working Group 7 ”Software“. During testing, the reproducibility of the assessment results can be investigated under realistic circumstances. Secondly, better developed attacker models will be incorporated to include more information about a measuring instrument's field of usage in the assessment. In this step, the motivation of certain attackers could also be added as another individual evaluation component. This change would also necessitate a modification of the point scores from the CC and will thus require very careful adjustments.

Email: {anna.felkner, adam.kozakiewicz}@nask.pl

***Abstract*—Trust management is an approach to access control in distributed open systems, where access control decisions are based on policy statements made by multiple principals. The family of Role-based Trust management languages (RT) is an effective means for representing security policies and credentials in decentralized, distributed, large scale access control systems. It provides a set of role assignment credentials. A credential provides information about the privileges of users and the security policies issued by one or more trusted authorities.**

**The main purpose of this paper is to show how extensions can make the $RT$ family languages more useful in practice. It shows how security policies can be made more realistic by including timing information, maintaining the procedure or parameterizing the validity of credentials.**

## I. Introduction

THE modern human life is heavily reliant on trust. The complexity of tasks we are dealing with makes it practically impossible to succeed without delegating some of them. It is therefore not surprising that the issue of trust became a very active area of research quite long ago. The trust between humans has been thoroughly analysed both from the social sciences and economic point of view, as it is an important enabler of delegation. Attempts to transfer the concept of trust to different domains were made by computer scientists, including security, electronic commerce, semantic web or even social networks areas. In any network, be it computer or social one, trust remains an essential factor. The definition of trust is however not perfectly clear, different authors show slightly different definitions. Most often it is defined either on the basis of personal experience, reputation or recommendation.

The concept of trust is closely related to the notion of reputation – the opinion about a person held by others, e.g. the opinion about an Internet seller by his customers or the opinion about the behavior of a node in a wireless sensor network built by other nodes as a result of previous interactions. Reliability is another concept related to trust. Originally, this was a measure of the length of the period during which a machine can be considered trustworthy. In general, trust can be presented a a derivation of an entity's reputation.

Access control systems, based on traditional access control models (like Mandatory Access Control (MAC), Discretionary Access Control (DAC) and Role Based Access Control (RBAC)), are in essence identity based. Authorization decisions are based entirely on the role or – more directly – identity of the requesting party and can only be made if the requester is known to the owner of the resource. The decision is based on the relation of the only two entities involved – the owner of the protected resource, who is responsible for granting access, and the requester, who requires access.

In closed, centralized environments this approach is actually correct. As identity of the users of the system is established in advance, basing access decisions on it is a natural and easy to implement choice. Unfortunately this scenario does not scale well as the system becomes decentralized and highly distributed over a network. In such open systems the set of users is not only large, but may change dynamically, leading to entirely new challenges, such as the problem of propagation of information about the changes. A central database of user's identities is only a partial solution – although it enables the implementation of classic approaches to access control, it also introduces a single point of failure, where temporary lack of access to the central database makes any authorization decisions impossible system-wide. In absence of such a central identity repository it is no longer possible to assume that the identities of the requester and the resource owner are mutually recognized. A more flexible approach is needed, one which enables requesters to cross security domains and access resources owned by non-related entities. One such solution is called trust management.

Consider a simple example of a bookstore which offers special discounts to returning customers who are students. There is no obvious way to determine whether a given customer is eligible based only on his/her identity. Requesting a proof of identity will not resolve this problem. On the other hand, the problem can be solved efficiently using credentials, such as a bookstore card and a student card. The access rights are then determined not based on the users identity, but on the sufficiently documented information about the user's privileges assigned by other authorities and trust for those authorities. This requires a new, different approach to access control.

The rest of this paper is organized as follows. Trust management concept is shown in Section II and Role-based Trust management family of languages is shown in Section III. Section IV presents the Role-based Trust management language syntax with an example of $RT^T$ credentials. Inference system over $RT^T$ language is described in Section V. Section VI describes a few extensions of $RT^T$ language (time validity and determination of the order). Section VII shows an inference system over new $RT_+^T$ language time constraints. Final

remarks are given in the Conclusions.

## II. Trust Management

*Trust management* was first introduced as a term by Blaze et al. [2] in 1996. The term was defined as a unified approach to specify and interpret security policies, credentials and trust relationships. The privileges of an entity in such a system are based not on its identity, but on its attributes. Multiple principals have the right to issue credentials which are then used to demonstrate the entity's attributes. The definition of a *credential* is an attestation of authority, competence or qualification of an individual issued by a third party. The information contained in a credential includes privileges of a given user and/or security policies issued by trusted authorities. Real life examples of credentials are easy to propose – all sorts of academic diplomas, driver's licenses, identification documents, certificates or membership cards are clearly credentials. In fact, a real-life credential does not need to be a document in the traditional sense of the world – e.g. keys can be treated as a form of credential. In a computer system credentials may either be records available from one or more repositories, or – more flexibly – digitally signed documents which can be provided by the requester on demand. In the first case trust for the credential follows from trust for the repository and its own access control, in the second case it is provided by the signature, obviously requiring a trusted method of propagation or verification of public keys.

In literature, the earliest described example of a trust management application was PolicyMaker [3]. An assertion language defined in this system was capable of expressing locally trusted policy statements, as well as credentials requiring a digital signature using a private key. The second generation of trust management languages includes SPKI/SDSI [6], an enhanced version of PolicyMaker called KeyNote [4] and several other languages [7]. In these languages the privileges were still assigned directly to entities and delegation of permissions through credentials was performed only directly from the issuer to the subject. This generation still did not provide any mechanism enabling delegation to be separated from identity of the entity. Introduction of delegation based on atributes (as opposed to identity) was introduced in the next generation, represented by a family of Role-based Trust management (RT) languages [8], [16], [17]. Security policies are represented by defining a formalism using credentials to establish trust in distributed, decentralized access control systems.

## III. Role-based Trust Management Family Languages

The family of Role-based Trust management languages is used for representing security policies and credentials in decentralized, distributed access control systems. Several types of role assignment credentials are provided in $RT$ languages, depending on the language. $\mathbf{RT_0}$ [17] forms the core of the family, providing basic abilities – localization of authority for roles, delegation of that authority, role hierarchies and role intersections. These features are available in all $RT$ languages, who extend this set with new features. To represent relationships between entities, parametrized roles were introduced in $\mathbf{RT_1}$. To provide similar flexibility for resources as that provided for entities by roles, $\mathbf{RT_2}$ extends $RT_1$ with the notion of logical objects, enabling simple assignment of access rights for entire groups of logically related objects (resources). Note that both extentions presented so far do not actually change the expressive power of the language. They allow much more concise notation, but the same policy can in fact be expressed in $RT_0$, although with a much larger set of credentials, mapping each combination of parameters or each real instance of logical objects to a separate role. The first language actually adding new capabilities not present in other members of the family is the $\mathbf{RT^T}$ language, the main focus of this paper. The new capabilities include the ability to express agreement of multiple principals, even from disjoint sets, via manifold roles and separation of duties or threshold policies, via role-product operators.

A manifold role differs from a normal (singleton) role as instead of defining a set of principals, it defines a set of sets of principals. It is a wider term, since a singleton role can be expressed as a manifold role, whose principal sets are singletons, effectively meaning that cooperation is required from a group consisting of a single entity. Therefore, introduction of manifold roles does not affect the ability to express $RT_0$ credentials in the $RT^T$ language.

A threshold policy is used to specify a common occurrence, where agreement of multiple principals is required to initiate a given action. More formally, at least $k$ entities from a set satisfying certain conditions must agree on some fact. E.g. in banking certain transations require authorisation by two cashiers. Separation of duties policy is similar, but the agreeing entities fulfill different roles (e.g. in the banking example some transactions may also require authorisation by a controller). Both types of policies specify requirements that cannot be fulfilled by a single entity and therefore cannot be expressed in $RT_0$.

The $RT$ family includes one more important language, $\mathbf{RT^D}$, which provides mechanisms to describe delegation of role activations and selective use of role membership. However, this language is out of scope of this paper. More in-depth information about the $RT$ family of languages can be found in paper [16].

The main advantage of trust management approach is the ability to use *delegation*. A principal's authority over a resource may be transferred in a limited fashion to other principals by simple means of a credential. The notion of ownership is no longer central – the access control strategy and all decisions on who is authorized to use which resource is defined by a set of credentials. One upside of such approach is that the authority is easy to transfer over a network – as long as a credential can be transferred and trusted in another location, there is no need to involve the identity of the resource owner. However, although such decentralization of credential storage is very useful, it does present a variety of new problems.

In the years since its creation, the concept of trust management has evolved significantly, made applicable to new, broader contexts, such as assessment of reliability or trustworthiness of systems and individuals [15]. In this paper we restrict the meaning of trust management only to its original context of access control. A lot of different work connected with the possibility of using RT in different types of network, eg. Role based Trust management model for Peer-to-Peer networks [5], a trust management system for Ad-Hoc Networks [1], or Wireless Sensor Networks [11], and also Role-based Trust Management Model in Multi-domain Environment [18] have been studied recently.

Our approach is another type of extension of trust management languages. It shows how to make RT family languages more useful in practice by including time validity constraints and order of entities which can appear in the execution context.

## IV. The Syntax of $RT$ Family Languages

RT languages use a set of basic elements, such as entities, role names, roles and credentials. *Entities* are principals controlling access to resources by defining roles and issuing credentialsas well as requesters willing to access resources. The entity may be a person, but it might just as well be an application, identifying itself in a computer system by a user name or a public key. *Role names* represent permissions and can be issued to entities or groups of them by other entities. *Roles* represent sets of entities for which the access control policies grant particular permissions. *Credentials* define roles by appointing a new member of the role or by delegating authority to members of other roles.

$RT^T$ includes six different types of credentials, the first four in common with the less expressive $RT$ languages:

$A.r \leftarrow B$ – *simple membership*: entity $B$ is a member of role $A.r$.

$A.r \leftarrow B.s$ – *simple inclusion*: role $A.r$ includes (all members of) role $B.s$. This type of credential involves delegation of authority over role $r$, since by issuing new credentials defining $B.s$ $B$ may add new members to role $A.r$. This type of credential is also used to define role hierarchies.

$A.r \leftarrow B.s.t$ – *linking inclusion*: role $A.r$ includes role $C.t$ for each $C$, which is a member of role $B.s$. This is a delegation of authority from $A$ to all the members of the role $B.s$. The expression $B.s.t$ is called a *linked role*.

$A.r \leftarrow B.s \cap C.t$ – *intersection inclusion*: role $A.r$ includes all members of both roles $B.s$ and $C.t$. This is a partial delegation from $A$ to $B$ and $C$. The expression $B.s \cap C.t$ is known as an *intersection role*.

$A.r \leftarrow B.s \odot C.t$ – role $A.r$ can be satisfied by a union set containing one member of each of the two roles ($B.s$ and $C.t$). A single entity being a member of both roles suffices.

$A.r \leftarrow B.s \otimes C.t$ – role $A.r$ includes two *different* entities, one of which is a member of role $B.s$ and one a member of role $C.t$.

Since the models used in practice can be very complex, this paper uses some simplified examples. We focus on $RT^T$-specific credentials and intend to illustrate the basic notions and notation, not the full expressive power of the language.

*Example 4.1 (Example of $RT^T$ - subject):*

Suppose that a university will only activate a subject if at least two of four students apply and among the applicants at least one is a PhD student. $RT_0$ would require a long list of credentials listing all possible satisfactory combinations, changed whenever the list of students changes. $RT^T$ allows us to express this rule as just two policy credentials and a list of simple membership credentials, easy to manage along with the official list of students. The policy credentials are:

$$F.students \leftarrow F.student \otimes F.student \tag{1}$$

$$F.activeSubject \leftarrow F.students \odot F.phdStudent \tag{2}$$

Now, if the following membership credentials are added::

$$F.student \leftarrow \{Alex\} \tag{3}$$

$$F.student \leftarrow \{Betty\} \tag{4}$$

$$F.student \leftarrow \{David\} \tag{5}$$

$$F.student \leftarrow \{John\} \tag{6}$$

$$F.phdStudent \leftarrow \{John\} \tag{7}$$

$$F.phdStudent \leftarrow \{Emily\} \tag{8}$$

we can conclude that any pair of students from the set $\{Alex, Betty, David, John\}$ fulfills the role $F.students$ and that the subject can be activated if the pair includes John or if Emily is willing to attend.

*Example 4.2 (Example of $RT^T$ – signature):* Suppose that we have a situation in which we need to collect the signatures of the requester, accountant, his official superior, the manager of financial department and the director of a company to accept some transaction. Such a policy can be described using the following credentials:

$$\begin{gathered} Company.signature \leftarrow Company.requester \\ \odot\ Company.accountant \odot Company.superior \\ \odot\ Company.fdManager \odot Company.director \end{gathered} \tag{9}$$

Now suppose that we have such people, who play those roles, so the following credentials have been added to our security policy:

$$Company.requester \leftarrow \{Jacob\} \tag{10}$$

$$Company.accountant \leftarrow \{Jacob\} \tag{11}$$

$$Company.accountant \leftarrow \{Eliot\} \tag{12}$$

$$Company.accountant \leftarrow \{Alexander\} \tag{13}$$

$$Company.superior \leftarrow \{William\} \tag{14}$$

$$Company.superior \leftarrow \{Michael\} \tag{15}$$

$$Company.fdManager \leftarrow \{Jacob\} \tag{16}$$

$$Company.director \leftarrow \{William\} \tag{17}$$

As we can see, to complete the set of signatures we need just two people: $Jacob$, who can play a role of $requester$, $accountant$, $fdManager$ and $William$ who plays the role of $superior$ and $director$, but as may be required, groups of people $\{Jacob$, $Eliot$, $William\}$, $\{Jacob$, $Eliot$, $Michael$, $William\}$, $\{Jacob$, $Alexander$, $William\}$, and $\{Jacob$, $Alexander$, $Michael$, $William\}$ can also play a manifold role, and cooperatively complete the set of signatures.

## V. Inference System over $RT^T$ Credentials

$RT^T$ credentials define roles, which in turn are used to represent permissions. The set of member entities for a role is defined by a set $\mathcal{P}$ of $RT^T$ credentials. This set can be more conveniently calculated using an inference system, which defines an operational semantics of $RT^T$ language. The system consists of a set of inference rules used to derive credentials from existing ones and an initial set of formulae considered true.

Let $\mathcal{P}$ be a set of $RT^T$ credentials. The inference rules can be applied to create new credentials, derived from credentials of the set $\mathcal{P}$. A derived credential $c$ will be denoted using a formula $\mathcal{P} \succ c$, meaning that credential $c$ can be derived from a set of credentials $\mathcal{P}$.

The initial set of formulae of an inference system over a set $\mathcal{P}$ of $RT^T$ credentials are all the formulae: $c \in \mathcal{P}$ for each credential $c$ in $\mathcal{P}$. The inference rules of the system are the following:

$$\frac{c \in \mathcal{P}}{\mathcal{P} \succ c} \qquad (\mathbf{W_1})$$

$$\frac{\mathcal{P} \succ A.r \leftarrow B.s \qquad \mathcal{P} \succ B.s \leftarrow X}{\mathcal{P} \succ A.r \leftarrow X} \qquad (\mathbf{W_2})$$

$$\frac{\begin{array}{c}\mathcal{P} \succ A.r \leftarrow B.s.t \qquad \mathcal{P} \succ B.s \leftarrow C \\ \mathcal{P} \succ C.t \leftarrow X\end{array}}{\mathcal{P} \succ A.r \leftarrow X} \qquad (\mathbf{W_3})$$

$$\frac{\begin{array}{c}\mathcal{P} \succ A.r \leftarrow B.s \cap C.t \qquad \mathcal{P} \succ B.s \leftarrow X \\ \mathcal{P} \succ C.t \leftarrow X\end{array}}{\mathcal{P} \succ A.r \leftarrow X} \qquad (\mathbf{W_4})$$

$$\frac{\begin{array}{c}\mathcal{P} \succ A.r \leftarrow B.s \odot C.t \qquad \mathcal{P} \succ B.s \leftarrow X \\ \mathcal{P} \succ C.t \leftarrow Y\end{array}}{\mathcal{P} \succ A.r \leftarrow X \cup Y} \qquad (\mathbf{W_5})$$

$$\frac{\begin{array}{c}\mathcal{P} \succ A.r \leftarrow B.s \otimes C.t \qquad \mathcal{P} \succ B.s \leftarrow X \\ \mathcal{P} \succ C.t \leftarrow Y \qquad\qquad X \cap Y = \phi\end{array}}{\mathcal{P} \succ A.r \leftarrow X \cup Y} \qquad (\mathbf{W_6})$$

The inference systems of a language may not be unique – many different systems may be defined. There are however two properties required for the system to be useful in practice – the system must be sound an complete. Soundness guarantees that any formula derived by the system must be valid with respect to the semantics of the language, while completeness ensures that any valid formula is derivable.

All the credentials, which can be derived in the system, either belong to set $\mathcal{P}$ (rule $W_1$) or are of the type: $\mathcal{P} \succ A.r \leftarrow X$ (rules $W_2$ through $W_6$). Proof of soundness of the inference system involves showing that for each new formula $\mathcal{P} \succ A.r \leftarrow X$, the triple $(A, r, X)$ belongs to the semantics $S_{\mathcal{P}}$ of the set $\mathcal{P}$. Completeness is proved by showing that every formula $P \succ A.r \leftarrow X$ can be derived using inference rules for each element $(A, r, X) \in S_{\mathcal{P}}$. Both proofs can be found in [10], showing that the inference system is a valid alternative way of presenting the semantics of $RT^T$.

*Example 5.1 (Inference system for Example 4.1):* We will now derive the set of entities that can cooperate to activate a subject using an inference system, using a limited set of credentials for brevity: ((1), (2), (4), (6), and (7)). Using credentials (1), (2), (4), (6), and (7) according to rule $(W_1)$ we can infer:

$$\frac{F.students \leftarrow F.student \otimes F.student \in \mathcal{P}}{\mathcal{P} \succ F.students \leftarrow F.student \otimes F.student}$$

$$\frac{F.activeSubject \leftarrow F.students \odot F.phdStudent \in \mathcal{P}}{\mathcal{P} \succ F.activeSubject \leftarrow F.students \odot F.phdStudent}$$

$$\frac{F.student \leftarrow \{Betty\} \in \mathcal{P}}{\mathcal{P} \succ F.student \leftarrow \{Betty\}}$$

$$\frac{F.student \leftarrow \{John\} \in \mathcal{P}}{\mathcal{P} \succ F.student \leftarrow \{John\}}$$

$$\frac{F.phdStudent \leftarrow \{John\} \in \mathcal{P}}{\mathcal{P} \succ F.phdStudent \leftarrow \{John\}}$$

Then, using credentials (1), (6) and (4) and rule $(W_6)$ we infer:

$$\frac{\begin{array}{c}\mathcal{P} \succ F.students \leftarrow F.student \otimes F.student \\ \mathcal{P} \succ F.student \leftarrow \{John\} \\ \mathcal{P} \succ F.student \leftarrow \{Betty\} \\ \{John\} \cap \{Betty\} = \phi\end{array}}{\mathcal{P} \succ \mathbf{F.students} \leftarrow \{\mathbf{John}, \mathbf{Betty}\}}$$

These newly inferred credential and (2) and (7) with the rule $(W_5)$:

$$\frac{\begin{array}{c}\mathcal{P} \succ F.activeSubject \leftarrow F.students \odot F.phdStudent \\ \mathcal{P} \succ F.phdStudent \leftarrow \{John\} \\ \mathcal{P} \succ F.students \leftarrow \{John, Betty\}\end{array}}{\mathcal{P} \succ \mathbf{F.activeSubject} \leftarrow \{\mathbf{John}, \mathbf{Betty}\}},$$

we can show that the set of entities $\{John, Betty\}$ is sufficient to activate the subject.

*Example 5.2 (Inference system for Example 4.2):* We use the inference system to formally derive a set of entities who are essential to accept some transaction, i.e. the signatures of the requester, accountant, his official superior, the manager of financial department and the director of a company. To make the notation shorter, let us use $C$ instead of $Company$.

Using credentials (9)-(17) according to the rule $(W_1)$ we can infer:

$$\frac{\begin{array}{c} C.signature \leftarrow C.requester \\ \odot\ C.accountant\ \odot\ C.superior \\ \odot\ C.fdManager\ \odot\ C.director \in \mathcal{P} \end{array}}{\begin{array}{c} \mathcal{P} \succ C.signature \leftarrow C.requester \\ \odot\ C.accountant\ \odot\ C.superior \\ \odot\ C.fdManager\ \odot\ C.director \end{array}}$$

$$\frac{C.requester \leftarrow \{Jacob\} \in \mathcal{P}}{\mathcal{P} \succ C.requester \leftarrow \{Jacob\}}$$

$$\frac{C.accountant \leftarrow \{Jacob\} \in \mathcal{P}}{\mathcal{P} \succ C.accountant \leftarrow \{Jacob\}}$$

$$\frac{C.accountant \leftarrow \{Eliot\} \in \mathcal{P}}{\mathcal{P} \succ C.accountant \leftarrow \{Eliot\}}$$

$$\frac{C.accountant \leftarrow \{Alexander\} \in \mathcal{P}}{\mathcal{P} \succ C.accountant \leftarrow \{Alexander\}}$$

$$\frac{C.superior \leftarrow \{William\} \in \mathcal{P}}{\mathcal{P} \succ C.superior \leftarrow \{William\}}$$

$$\frac{C.superior \leftarrow \{Michael\} \in \mathcal{P}}{\mathcal{P} \succ C.superior \leftarrow \{Michael\}}$$

$$\frac{C.fdManager \leftarrow \{Jacob\} \in \mathcal{P}}{\mathcal{P} \succ C.fdManager \leftarrow \{Jacob\}}$$

$$\frac{C.director \leftarrow \{William\} \in \mathcal{P}}{\mathcal{P} \succ C.director \leftarrow \{William\}}$$

Then, using credentials (9), (10), (11), (14), (16) and (17) and rule $(W_5)$ we infer:

$$\frac{\begin{array}{c} \mathcal{P} \succ C.signature \leftarrow C.requester \\ \odot\ C.accountant\ \odot\ C.superior \\ \odot\ C.fdManager\ \odot\ C.director \\ \mathcal{P} \succ C.requester \leftarrow \{Jacob\} \\ \mathcal{P} \succ C.accountant \leftarrow \{Jacob\} \\ \mathcal{P} \succ C.superior \leftarrow \{William\} \\ \mathcal{P} \succ C.fdManager \leftarrow \{Jacob\} \\ \mathcal{P} \succ C.director \leftarrow \{William\} \end{array}}{\mathcal{P} \succ \mathbf{C.signature} \leftarrow \{\mathbf{Jacob}, \mathbf{William}\}}$$

showing that the set of entities $\{Jacob, William\}$ is sufficient to complete the set of signatures.

Or, using credentials (9), (10), (12), (14), (16) and (17) and rule $(W_5)$ we infer:

$$\frac{\begin{array}{c} \mathcal{P} \succ C.signature \leftarrow C.requester \\ \odot\ C.accountant\ \odot\ C.superior \\ \odot\ C.fdManager\ \odot\ C.director \\ \mathcal{P} \succ C.requester \leftarrow \{Jacob\} \\ \mathcal{P} \succ C.accountant \leftarrow \{Eliot\} \\ \mathcal{P} \succ C.superior \leftarrow \{William\} \\ \mathcal{P} \succ C.fdManager \leftarrow \{Jacob\} \\ \mathcal{P} \succ C.director \leftarrow \{William\} \end{array}}{\mathcal{P} \succ \mathbf{C.signature} \leftarrow \{\mathbf{Jacob}, \mathbf{Eliot}, \mathbf{William}\}}$$

showing that here we need more people to complete the set of signatures, i.e. $\{Jacob, Eliot, William\}$.

Or, using credentials (9), (10), (13), (15), (16) and (17) and rule $(W_5)$ we infer:

$$\frac{\begin{array}{c} \mathcal{P} \succ C.signature \leftarrow C.requester \\ \odot\ C.accountant\ \odot\ C.superior \\ \odot\ C.fdManager\ \odot\ C.director \\ \mathcal{P} \succ C.requester \leftarrow \{Jacob\} \\ \mathcal{P} \succ C.accountant \leftarrow \{Alexander\} \\ \mathcal{P} \succ C.superior \leftarrow \{Michael\} \\ \mathcal{P} \succ C.fdManager \leftarrow \{Jacob\} \\ \mathcal{P} \succ C.director \leftarrow \{William\} \end{array}}{\mathcal{P} \succ \mathbf{C.signature} \leftarrow \{\mathbf{Jacob}, \mathbf{Alexander}, \mathbf{Michael}, \mathbf{William}\}}$$

showing that here we need four people to complete the set of signatures, i.e. $\{Jacob, Alexander, Michael, William\}$.

Depending on which credentials at the moment we have (because not all the credentials are always available), we can determine the sets of people who can cooperatively sign the document.

## VI. Credential extensions

This section shows a few extensions of $RT^T$ languages which make it more useful in practice.

### A. Time Validity in $RT^T$

Real security policies involve time restrictions. Allowing the credentials to have limited time validity can make the $RT^T$ language more useful in practice. Inference rules with time validity for $RT_0$ were originally introduced in a slightly different way in [14]. In [13] we tried to extend the potential of $RT^T$ language by adding time validity constraints. Most permissions are in fact given for fixed periods of time, permanent permissions are less common. Time dependent credentials take the form: $c$ **in** $v$, meaning "the credential $c$ is available during the time $v$". Finite sets of time dependent credentials are denoted by $\mathcal{CP}$ and the new language is called $RT_+^T$. $c$ is used to denote "$c$ **in** $(-\infty,\ +\infty)$" to make notation lighter.

Most trust management languages are monotonic: adding new assertion to a query can never result in canceling an action, which was accepted before [9]. Therefore, each policy statement or credential added to the system may only increase the capabilities and privileges granted to others, making revocation of rights impossible. Introduction of time constraints does not invalidate the monotonicity of the system, but achieves some of the utility of negation.

Time validity can be denoted as follows:
$[\tau_1,\tau_2]; [\tau_1,\tau_2); (\tau_1,\tau_2]; (\tau_1,\tau_2); (-\infty,\tau]; (-\infty,\tau);$
$[\tau,+\infty); (\tau,+\infty); (-\infty,\ +\infty); v_1 \cup v_2; v_1 \cap v_2; v_1 \backslash v_2$
and $v_1$, $v_2$ of any form in this list, with $\tau$ ranging over time constants.

*Example 6.1 (Time validity for Example 4.1):*
Assuming that $Alex$, $Betty$, $David$ and $John$ in our scenario will not be student forever seems quite natural. $John$ and $Emily$'s PhD student status is similar. Thus, credentials (3)–(8) should be generalized to:

$$F.student \leftarrow \{Alex\} \textbf{ in } v_1 \tag{18}$$

$$F.student \leftarrow \{Betty\} \textbf{ in } v_2 \tag{19}$$

$$F.student \leftarrow \{David\} \textbf{ in } v_3 \tag{20}$$

$$F.student \leftarrow \{John\} \textbf{ in } v_4 \tag{21}$$

$$F.phdStudent \leftarrow \{John\} \textbf{ in } v_5 \tag{22}$$

$$F.phdStudent \leftarrow \{Emily\} \textbf{ in } v_6 \tag{23}$$

stating that (3) – (8) are only available during $v_1$, $v_2$, $v_3$, $v_4$, $v_5$, and during $v_6$, respectively. The policy itself, described by credentials (1) and (2) may however be permanent. By using (1), (2) and (18)–(23), we want to be able to derive that for example the set $\{Alex, Betty, John\}$ can cooperatively activate the subject during all of the period: $v_1 \cap v_2 \cap v_5$ or $\{Betty, John\}$ during the time $v_2 \cap v_4 \cap v_5$ or $\{Alex, David, Emily\}$ during the time intersection $v_1 \cap v_3 \cap v_6$. Another set of people can cooperatively activate the subject (depending of the time).

*Example 6.2 (Time validity for Example 4.2):* In our scenario, it is quite natural to assume that $Jacob$ are a requester only for a fixed period of time. The same with $Jacob$, $Eliot$ and $Alexander$ as a company accountants, also $Wiliam$ and $Michael$ as a superior, and $Jacob$ as a financial department manager, as well as $William$ as a director. Thus, credentials (10)–(17) should be generalized to:

$$Company.requester \leftarrow \{Jacob\} \textbf{ in } v_1 \tag{24}$$

$$Company.accountant \leftarrow \{Jacob\} \textbf{ in } v_2 \tag{25}$$

$$Company.accountant \leftarrow \{Eliot\} \textbf{ in } v_3 \tag{26}$$

$$Company.accountant \leftarrow \{Alexander\} \textbf{ in } v_4 \tag{27}$$

$$Company.superior \leftarrow \{William\} \textbf{ in } v_5 \tag{28}$$

$$Company.superior \leftarrow \{Michael\} \textbf{ in } v_6 \tag{29}$$

$$Company.fdManager \leftarrow \{Jacob\} \textbf{ in } v_7 \tag{30}$$

$$Company.director \leftarrow \{William\} \textbf{ in } v_8 \tag{31}$$

stating that (10) – (17) are only available during $v_1$, $v_2$, $v_3$, $v_4$, $v_5$, $v_6$, $v_7$, and during $v_8$, respectively. On the other hand, credential (9) can be always valid, as it expresses some time-independent fact. Now, by using (9) and (24)–(31), we want to be able to derive that for example the set $\{Jacob, William\}$ can cooperatively sign the document during all of the period: $v_1 \cap v_2 \cap v_5 \cap v_7 \cap v_8$, where $Jacob$ plays the role of *requester*, *accountant* and *financial department manager* and $William$ acts as a *superior* and *director of the company*. But during the time $v_1 \cap v_3 \cap v_6 \cap v_7 \cap v_8$ it has to be the set consisting of $\{Jacob, Eliot, Michael, William\}$.

While in both examples the policy defining credentials were assummed to be permanently valid, this is not required. Some policies are naturally time-limited (eg. seasonal sales).

### *B. Determination of the order*

Another powerful feature which would be useful to model more realistic policies is the ability to determine the order in which a member of a role or an entity (entities) can appear.

If we want to maintain a procedure, we have to add two new types of credentials at the syntax level. These are:

$A.r \leftarrow B.s \overset{\odot}{\rightarrow} C.t$ – role $A.r$ is satisfied by a union set of one member of role $B.s$ and one member of role $C.t$ in this exact order or by one entity satisfying the intersection role $B.s \cap C.t$.

$A.r \leftarrow B.s \overset{\otimes}{\rightarrow} C.t$ – role $A.r$ is satisfied by a set of two different entities: one member of role $B.s$ and one member of role $C.t$ in this order.

In our Example 4.1 we can want to have such situation:

$$F.activeSubject \leftarrow F.students \overset{\odot}{\rightarrow} F.phdStudent$$

which means that the order is important. First we need to have two students and just after that one PhD student.

That extension can be extremely useful in a large variety of situations. For example, if we have a situation, when one person is a member of a few roles, it can be useful to have some restrictions connected with appearing in particular roles during the execution context when the credential is used.

*Example 6.3 (The right order of signature):*
When we have a situation in which we need to collect the signatures of people who are essential to accept some transaction, we can imagine at least a few scenarios in our security policy.

Suppose that we need a signature of the requester, accountant, his official superior, the manager of financial department and the director of a company, in such order.

Now we can use the data from *Example* 4.2 and we can have three different scenarios:

1) The order is strictly obeyed and it is important that an accountant can give his signature after having

received the signature of a requester, and accountant's superior can give his signature after having received the signature of an accountant, even if it is one person. This means that in a first step $Jacob$ can sign the document as a $requester$, in a second step as an $accountant$, after that $William$ can give his signature as a $Jacob's$ official superior. In the next step $Jacob$ can sign the document as a financial department manager, and at the end $William$ can sign the document as a director of the company. Table I presents the signature order in our first scenario.

It can be important in some situation to strictly keep the order of signatures, but in a huge implementation it can be a little bit inefficient. That is why we can propose two other scenarios.

2) We can allow signing the document by one person who plays a few roles at once if the roles appear in credentials successively without any role between. In our example it can look like in the Table II (to make our example easier, we can use just credentials (10), (11), (14), (16), (17)).
   In such a simple example, we have one step less than in the previous scenario. It shows how such change can be useful in real large systems.
3) In our third scenario we can allow that one person, who plays more than one role, can give all the signatures at once. It can be very useful in an automatic implementation. Table III shows how it can look in our third scenario.
   That situation means that $Jacob$ accepts his signature as a financial department manager if $William$ signs the document as his official superior and $William$ accepts his signature as a $director$ if $Jacob$ signs the document as a financial department manager. We have to have a possibility to accept or not accept our signature, which is dependent on another person's signature.

If we want to mandate that the entity can appear in particular roles during the execution context exactly when the credential is used, we can put a new type of role denoted by underlined identifiers (e.g. $\underline{r}, \underline{s}, \underline{t}$). In such situation, when we change the credential:

$$\begin{gathered} Company.signature \leftarrow Company.requester \\ \overset{\odot}{\rightarrow} Company.accountant \overset{\odot}{\rightarrow} Company.superior \\ \overset{\odot}{\rightarrow} Company.fdManager \overset{\odot}{\rightarrow} Company.director \end{gathered}$$

into:

$$\begin{gathered} Company.signature \leftarrow Company.requester \\ \overset{\odot}{\rightarrow} Company.accountant \overset{\odot}{\rightarrow} Company.superior \\ \overset{\odot}{\rightarrow} Company.fdManager \overset{\odot}{\rightarrow} Company.\underline{director} \end{gathered}$$

in our third scenario we will have the situation described in Table IV, meaning that $William$ has to wait with his signature as a $director$ untill the time $Jacob$ approves his signature as $fdManager$.

All the semantics previously defined for $RT^T_+$, set-theoretic (which maps roles to a set of entity names), operational semantics (where credentials can be derived from the initial set of credentials using a set of inference rules [13]), and logic-programming (where credentials are translated into a logic program [12]), are still valid, meaning that proofs of the soundness and the completeness of that semantics are also valid.

This section shows how we can explore the potential of RT languages. It shows how security policies can be made more realistic by including timing information or maintaining the procedure.

## VII. Inference System for $RT^T$ Credentials with Time Validity

All the semantics previously defined for $RT$ languages are still valid for determined order, but they have to be changed for credentials with time validity. Because of that reason we have to take on it. This section is showing an inference system for $RT^T$ credentials with time validity.

We will now adapt the inference system over $RT^T$ credentials to respect time validity. Let $\mathcal{CP}$ be a set of $RT^T$ credentials, from which new credentials may be derived. A derived credential $c$ valid in time $\tau$ will be denoted using a formula $\mathcal{CP} \succ_\tau c$, meaning that the credential $c$ can be derived from a set of credentials $\mathcal{CP}$ during the time $\tau$. The initial set of formulae of an inference system over a set $\mathcal{CP}$ of $RT^T_+$ credentials are all the form: $c \ \mathbf{in} \ v \ \in \mathcal{CP}$ for each credential $c$ valid in time $v$ in $\mathcal{CP}$. The inference rules of the system are the following:

$$\frac{c \ \mathbf{in} \ v \in \mathcal{CP} \quad \tau \in v}{\mathcal{CP} \succ_\tau c} \qquad (\mathbf{CW_1})$$

$$\frac{\mathcal{CP} \succ_\tau A.r \leftarrow B.s \quad \mathcal{CP} \succ_\tau B.s \leftarrow X}{\mathcal{CP} \succ_\tau A.r \leftarrow X} \qquad (\mathbf{CW_2})$$

$$\frac{\begin{gathered}\mathcal{CP} \succ_\tau A.r \leftarrow B.s.t \qquad \mathcal{CP} \succ_\tau B.s \leftarrow C \\ \mathcal{CP} \succ_\tau C.t \leftarrow X\end{gathered}}{\mathcal{CP} \succ_\tau A.r \leftarrow X} \qquad (\mathbf{CW_3})$$

$$\frac{\begin{gathered}\mathcal{CP} \succ_\tau A.r \leftarrow B.s \cap C.t \qquad \mathcal{CP} \succ_\tau B.s \leftarrow X \\ \mathcal{CP} \succ_\tau C.t \leftarrow X\end{gathered}}{\mathcal{CP} \succ_\tau A.r \leftarrow X} \qquad (\mathbf{CW_4})$$

$$\frac{\begin{gathered}\mathcal{CP} \succ_\tau A.r \leftarrow B.s \odot C.t \qquad \mathcal{CP} \succ_\tau B.s \leftarrow X \\ \mathcal{CP} \succ_\tau C.t \leftarrow Y\end{gathered}}{\mathcal{CP} \succ_\tau A.r \leftarrow X \cup Y} \qquad (\mathbf{CW_5})$$

$$\frac{\begin{gathered}\mathcal{CP} \succ_\tau A.r \leftarrow B.s \otimes C.t \qquad \mathcal{CP} \succ_\tau B.s \leftarrow X \\ \mathcal{CP} \succ_\tau C.t \leftarrow Y \qquad X \cap Y = \phi\end{gathered}}{\mathcal{CP} \succ_\tau A.r \leftarrow X \cup Y} \qquad (\mathbf{CW_6})$$

All the derived credentials either belong to set $\mathcal{CP}$ (rule $CW_1$) or are of the type: $\mathcal{CP}_\tau \succ A.r \leftarrow X$ (rules $CW_2$ through $CW_6$). This new inference system is based on an extension of the inference rules from section V, where rules

TABLE I
SIGNATURE ORDER IN THE FIRST SCENARIO

| **Step** | **requester** | **accountant** | **superior** | **fdManager** | **director** |
|---|---|---|---|---|---|
| **1** | $Jacob$ | $\phi$ | $\phi$ | $\phi$ | $\phi$ |
| **2** | $Jacob$ | $Jacob, Eliot, Alexander$ | $\phi$ | $\phi$ | $\phi$ |
| **3** | $Jacob$ | $Jacob, Eliot, Alexander$ | $William, Michael$ | $\phi$ | $\phi$ |
| **4** | $Jacob$ | $Jacob, Eliot, Alexander$ | $William, Michael$ | $Jacob$ | $\phi$ |
| **5** | $Jacob$ | $Jacob, Eliot, Alexander$ | $William, Michael$ | $Jacob$ | $William$ |

TABLE IV
SIGNATURE ORDER IN THE THIRD "UNDERLINED" SCENARIO

| **Step** | **requester** | **accountant** | **superior** | **fdManager** | **director** |
|---|---|---|---|---|---|
| **1** | $Jacob$ | $Jacob$ | $\phi$ | $Jacob$ | $\phi$ |
| **2** | $Jacob$ | $Jacob$ | $William$ | $Jacob$ | $\phi$ |
| **3** | $Jacob$ | $Jacob$ | $William$ | $Jacob$ | $William$ |

$(W_i)$ are replaced with $(CW_i)$ and only valid time-dependent credentials from $\mathcal{CP}$ are considered.

The proof of soundness of the inference system requires showing that for each new formula $\mathcal{CP}_\tau \succ A.r \leftarrow X$, the triple $(A, r, X)$ belongs to the semantics $S_{\mathcal{CP}}$ of the set $\mathcal{CP}$. All the formulae $\mathcal{CP}_\tau \succ A.r \leftarrow X$, such that $A.r \leftarrow X \in \mathcal{CP}$ are sound, as shown in [12].

Completeness of the inference system over a set $\mathcal{CP}$ of $RT_+^T$ credentials can be proved by showing that a formula $\mathcal{CP} \succ A.r \leftarrow X$ can be derived using inference rules for each element $(A, r, X) \in S_{\mathcal{CP}}$. The proof is presented in [12].

### *A. Inferring time validity of credentials*

The proposed inference system can also derive the maximal time validity of a credential $c$ from $\mathcal{CP}$. Formula $\mathcal{CP} \succ_\tau c$ is modified to $\mathcal{CP} \succ\!\succ_v c$, meaning that at any time $\tau \in v$ in which $\mathcal{CP}$ has a semantics, it is possible to infer the credential $c$ from $\mathcal{CP}$. The inference rules of the system are the following:

$$\frac{c \textbf{ in } v \in \mathcal{CP}}{\mathcal{CP} \succ\!\succ_v c} \qquad (\mathbf{CWP_1})$$

$$\frac{\mathcal{CP} \succ\!\succ_{v_1} A.r \leftarrow B.s \quad \mathcal{CP} \succ\!\succ_{v_2} B.s \leftarrow X}{\mathcal{CP} \succ\!\succ_{v_1 \cap v_2} A.r \leftarrow X} \qquad (\mathbf{CWP_2})$$

$$\frac{\begin{array}{c}\mathcal{CP} \succ\!\succ_{v_1} A.r \leftarrow B.s.t \\ \mathcal{CP} \succ\!\succ_{v_2} B.s \leftarrow C \quad \mathcal{CP} \succ\!\succ_{v_3} C.t \leftarrow X\end{array}}{\mathcal{CP} \succ\!\succ_{v_1 \cap v_2 \cap v_3} A.r \leftarrow X} \qquad (\mathbf{CWP_3})$$

$$\frac{\begin{array}{c}\mathcal{CP} \succ\!\succ_{v_1} A.r \leftarrow B.s \cap C.t \\ \mathcal{CP} \succ\!\succ_{v_2} B.s \leftarrow X \quad \mathcal{CP} \succ\!\succ_{v_3} C.t \leftarrow X\end{array}}{\mathcal{CP} \succ\!\succ_{v_1 \cap v_2 \cap v_3} A.r \leftarrow X} \qquad (\mathbf{CWP_4})$$

$$\frac{\begin{array}{c}\mathcal{CP} \succ\!\succ_{v_1} A.r \leftarrow B.s \odot C.t \\ \mathcal{CP} \succ\!\succ_{v_2} B.s \leftarrow X \quad \mathcal{CP} \succ\!\succ_{v_3} C.t \leftarrow Y\end{array}}{\mathcal{CP} \succ\!\succ_{v_1 \cap v_2 \cap v_3} A.r \leftarrow X \cup Y} \qquad (\mathbf{CWP_5})$$

$$\frac{\begin{array}{c}\mathcal{CP} \succ\succ_{v_1} A.r \leftarrow B.s \otimes C.t\\ \mathcal{CP} \succ\succ_{v_2} B.s \leftarrow X \quad \mathcal{CP} \succ\succ_{v_3} C.t \leftarrow Y\\ X \cap Y = \phi\end{array}}{\mathcal{CP} \succ\succ_{v_1 \cap v_2 \cap v_3} A.r \leftarrow X \cup Y} \qquad (\mathbf{CWP_6})$$

$$\frac{\mathcal{CP} \succ\succ_{v_1} c \quad \mathcal{CP} \succ\succ_{v_2} c}{\mathcal{CP} \succ\succ_{v_1 \cup v_2} c} \qquad (\mathbf{CWP_7})$$

Rule is $(CWP_1)$ claims that $\mathcal{CP}$ can be used whenever it is valid. Rules $(CWP_2)$ - $(CWP_6)$ simply claim that inference rules can be used iff all their premises are true. Finally, the rule $(CWP_7)$ is used to join validity periods, meaning that if $c$ can be inferred both with validity $v_1$ and validity $v_2$, then it can also be inferred with validity $v_1 \cup v_2$. $\mathcal{CP} \succ\succ_v$ generalizes $\mathcal{CP} \succ_\tau$. They are both equivalent whenever $v = [\tau, \tau]$. Note that inferring a certain $c$ from $\mathcal{CP}$ may be possible in several different ways, resulting in different validity periods. Rule $(CWP_7)$ can then be used as many times as necessary to broaden $c$'s validity.

Maximal inference is the process, where in each step we infer with maximal time validity.

An inference terminating in $\mathcal{CP} \succ\succ_v c$ is called maximal if and only if:

1) there exists no $v' \supset v$ such that $\mathcal{CP} \succ\succ_{v'} c$, and
2) every its sub-inference terminating in $\mathcal{CP} \succ\succ_{v''} c'$, for $c' \neq c$ is maximal.

The first condition ensures that further use of rule $(CWP_7)$ will not extend the validity of $c$. The second condition ensures that this property is propagated through the whole inference tree. Maximal inferences guarantee that $v$ in $(CWP_1)$ is the maximal time validity for $A.r \leftarrow X$.

For these inferences we can prove soundness and completeness of $\mathcal{CP} \succ\succ_v$, as shown in [12].

*Example 7.1 (Time validity in inference system for Example 4.1):* Let us get back to our example and to make long example shorter, let us use less credentials: (1), (2), (19), (21), and (22). According to rule $(CWP_1)$ we can infer:

$$\frac{F.students \leftarrow F.student \otimes F.student \in \mathcal{CP}}{\mathcal{CP} \succ\succ F.students \leftarrow F.student \otimes F.student}$$

$$\frac{F.activeSubject \leftarrow F.students \odot F.phdStudent \in \mathcal{CP}}{\mathcal{CP} \succ\succ F.activeSubject \leftarrow F.students \odot F.phdStudent}$$

$$\frac{F.student \leftarrow \{Betty\} \textbf{ in } v_2 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_2} F.student \leftarrow \{Betty\}}$$

$$\frac{F.student \leftarrow \{John\} \textbf{ in } v_4 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_4} F.student \leftarrow \{John\}}$$

$$\frac{F.phdStudent \leftarrow \{John\} \textbf{ in } v_5 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_5} F.phdStudent \leftarrow \{John\}}$$

When we want to check when two different students can cooperate, from credentials (1), (19), (21) and rule $(CWP_6)$ we infer:

$$\frac{\begin{array}{c}\mathcal{CP} \succ\succ F.students \leftarrow F.student \otimes F.student\\ \mathcal{CP} \succ\succ_{v_2} F.student \leftarrow \{Betty\}\\ \mathcal{CP} \succ\succ_{v_4} F.student \leftarrow \{John\}\\ \{Betty\} \cap \{John\} = \phi\end{array}}{\mathcal{CP} \succ\succ_{v_2 \cap v_4} \mathbf{F.students} \leftarrow \{\mathbf{Betty}, \mathbf{John}\}}$$

In next step we use it and additionally credentials (2), (22) and rule $(CWP_5)$:

$$\frac{\begin{array}{c}\mathcal{CP} \succ\succ F.activeSubject \leftarrow F.students \odot F.phdStudent\\ \mathcal{CP} \succ\succ_{v_5} F.phdStudent \leftarrow \{John\}\\ \mathcal{CP} \succ\succ_{v_2 \cap v_4} F.students \leftarrow \{Betty, John\}\end{array}}{\mathcal{CP} \succ\succ_{v_2 \cap v_4 \cap v_5} \mathbf{F.activeSubject} \leftarrow \{\mathbf{Betty}, \mathbf{John}\}}$$

showing that the set of entities that can cooperatively activate a subject is: $\{Betty, John\}$ during the time: $v_2 \cap v_4 \cap v_5$.

*Example 7.2 (Time validity in inference system for Example 4.2):* Let us get back to our example and use credentials (9) and (24)–(31) (to make the notation shorter, let us use $C$ instead of $Company$). According to rule $(CWP_1)$ we can infer:

$$\frac{\begin{array}{c}C.signature \leftarrow C.requester\\ \odot\ C.accountant\ \odot\ C.superior\\ \odot\ C.fdManager\ \odot\ C.director \in \mathcal{CP}\end{array}}{\begin{array}{c}\mathcal{CP} \succ\succ C.signature \leftarrow C.requester\\ \odot\ C.accountant\ \odot\ C.superior\\ \odot\ C.fdManager\ \odot\ C.director\end{array}}$$

$$\frac{C.requester \leftarrow \{Jacob\} \textbf{ in } v_1 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_1} C.requester \leftarrow \{Jacob\}}$$

$$\frac{C.accountant \leftarrow \{Jacob\} \textbf{ in } v_2 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_2} C.accountant \leftarrow \{Jacob\}}$$

$$\frac{C.accountant \leftarrow \{Eliot\} \textbf{ in } v_3 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_3} C.accountant \leftarrow \{Eliot\}}$$

$$\frac{C.accountant \leftarrow \{Alexander\} \textbf{ in } v_4 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_4} C.accountant \leftarrow \{Alexander\}}$$

$$\frac{C.superior \leftarrow \{William\} \textbf{ in } v_5 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_5} C.superior \leftarrow \{William\}}$$

$$\frac{C.superior \leftarrow \{Michael\} \textbf{ in } v_6 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_6} C.superior \leftarrow \{Michael\}}$$

$$\frac{C.fdManager \leftarrow \{Jacob\} \textbf{ in } v_7 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_7} C.fdManager \leftarrow \{Jacob\}}$$

$$\frac{C.director \leftarrow \{William\} \textbf{ in } v_8 \in \mathcal{CP}}{\mathcal{CP} \succ\succ_{v_8} C.director \leftarrow \{William\}}$$

Now, when we want to check when $Jacob$ and $William$ are the only people, who are necessary to cooperatively sign the document we use credentials (9), (24), (25), (28), (30), (17) and rule $(CWP_5)$:

$$\frac{\begin{array}{c}\mathcal{CP} \succ\succ C.signature \leftarrow C.requester\\ \odot\ C.accountant\ \odot\ C.superior\\ \odot\ C.fdManager\ \odot\ C.director\\ \mathcal{CP} \succ\succ_{v_1} C.requester \leftarrow \{Jacob\}\\ \mathcal{CP} \succ\succ_{v_2} C.accountant \leftarrow \{Jacob\}\\ \mathcal{CP} \succ\succ_{v_5} C.superior \leftarrow \{William\}\\ \mathcal{CP} \succ\succ_{v_7} C.fdManager \leftarrow \{Jacob\}\\ \mathcal{CP} \succ\succ_{v_8} C.director \leftarrow \{William\}\end{array}}{\begin{array}{c}\mathcal{CP} \succ\succ_{v_1\ \cap\ v_2\ \cap\ v_5\ \cap\ v_7\ \cap\ v_8} \mathbf{C.signature}\\ \leftarrow \{\mathbf{Jacob}, \mathbf{William}\}\end{array}}$$

showing that the set of entities $\{Jacob, William\}$ is sufficient to complete the set of signatures during the time $v_1 \cap v_2 \cap v_5 \cap v_7 \cap v_8$.

Or, using credentials (9), (24), (26), (28), (30) and (31) and rule $(CWP_5)$ we infer:

$$\begin{array}{c}
\mathcal{CP} \succ\!\succ C.signature \leftarrow C.requester \\
\odot\ C.accountant\ \odot\ C.superior \\
\odot\ C.fdManager\ \odot\ C.director \\
\mathcal{CP} \succ\!\succ_{v_1} C.requester \leftarrow \{Jacob\} \\
\mathcal{CP} \succ\!\succ_{v_3} C.accountant \leftarrow \{Eliot\} \\
\mathcal{CP} \succ\!\succ_{v_5} C.superior \leftarrow \{William\} \\
\mathcal{CP} \succ\!\succ_{v_7} C.fdManager \leftarrow \{Jacob\} \\
\mathcal{CP} \succ\!\succ_{v_8} C.director \leftarrow \{William\} \\
\hline
\mathcal{CP} \succ\!\succ_{v_1 \cap v_3 \cap v_5 \cap v_7 \cap v_8} \mathbf{C.signature} \\
\leftarrow \{\mathbf{Jacob}, \mathbf{Eliot}, \mathbf{William}\}
\end{array}$$

showing that here we need more people to complete the set of signatures, i.e. $\{Jacob, Eliot, William\}$ during the time $v_1 \cap v_3 \cap v_5 \cap v_7 \cap v_8$.

Or, using credentials (9), (24), (27), (29), (30) and (31) and rule $(CWP_5)$ we infer:

$$\begin{array}{c}
\mathcal{CP} \succ\!\succ C.signature \leftarrow C.requester \\
\odot\ C.accountant\ \odot\ C.superior \\
\odot\ C.fdManager\ \odot\ C.director \\
\mathcal{CP} \succ\!\succ_{v_1} C.requester \leftarrow \{Jacob\} \\
\mathcal{CP} \succ\!\succ_{v_4} C.accountant \leftarrow \{Alexander\} \\
\mathcal{CP} \succ\!\succ_{v_6} C.superior \leftarrow \{Michael\} \\
\mathcal{CP} \succ\!\succ_{v_7} C.fdManager \leftarrow \{Jacob\} \\
\mathcal{CP} \succ\!\succ_{v_8} C.director \leftarrow \{William\} \\
\hline
\mathcal{CP} \succ\!\succ_{v_1 \cap v_4 \cap v_6 \cap v_7 \cap v_8} \mathbf{C.signature} \\
\leftarrow \{\mathbf{Jacob}, \mathbf{Alexander}, \mathbf{Michael}, \mathbf{William}\}
\end{array}$$

showing that here we need four people to complete the set of signatures, i.e. $\{Jacob, Alexander, Michael, William\}$ during the time $v_1 \cap v_4 \cap v_6 \cap v_7 \cap v_8$.

## VIII. Conclusions

In the paper we model the use of trust management systems in decentralized and distributed environments. The modelling framework is a family of Role-based Trust management language $RT^T$. The core part of the paper is introduction of time validity constraints and especially maintaining the procedure – modifications aimed at making the $RT^T$ language more realistic. While the inference systems presented in this paper are simple, they are well-founded theoretically. The utility of the proposed extentions is most visible in large-scale distributed systems, where users have only partial view of their execution context.

Email: apostolos.malatras@jrc.ec.europa.eu, laurent.beslay@jrc.ec.europa.eu

***Abstract*—Harnessing the power and popularity of participatory or opportunistic sensing for the purpose of providing added value security and surveillance services is a promising research direction. However, challenges such as increased privacy concerns, as well as technological issues related to the reliable processing and meaningful analysis of the collected data, hinder the widespread deployment of participatory surveillance applications. We present here our work on addressing some of the aforementioned concerns through our related participatory application that focuses on crisis management and in particular buildings' evacuation. We discuss the technical aspects of our work, the viability and practicality of which is validated by means of a real experiment comprising 14 users in the context of an emergency evacuation exercise.**

## I. Introduction

RECENT developments regarding the capabilities of smartphones that are increasingly equipped with middle- to high-end sensors and their widespread penetration in modern society have spawn a novel paradigm of information generation and sharing, that of participatory sensing [1]. In this bottom-up paradigm illustrated in Figure 1, users of smartphones take advantage of the capabilities of the devices that they are carrying in terms of sensing and collect data regarding their surrounding environment and themselves, e.g. acceleration, temperature, light, sound, etc. They then proceed with sharing this information with other users either by uploading it to a common repository accessible to everyone (perhaps in the form of a map service where the location of the collected data is also pinpointed), or by sending their data to a centralized entity that provides them with related services [2].

The paradigm of participatory sensing is applicable to a wide range of application domains. Of particular interest is its consideration in light of security applications, in which case a new research domain, i.e. that of participatory surveillance, emerges [3]. Participatory surveillance refers to the use of principles from participatory sensing in order to monitor, control, and assess a variety of events for the purpose of security [4]. For example, the evacuation of a building could be enhanced when having access to data collected from the evacuees through their smartphones or in case of criminal activities the legal and police authorities could have a wealth of data coming from smartphones of nearby people to support their investigations [5], even in the absence of operational networking infrastructures. The latter data yield no significant information as such, but subject to processing using machine learning techniques they could be used to deduce useful knowledge about the activities the users were conducting at the time of data collection.

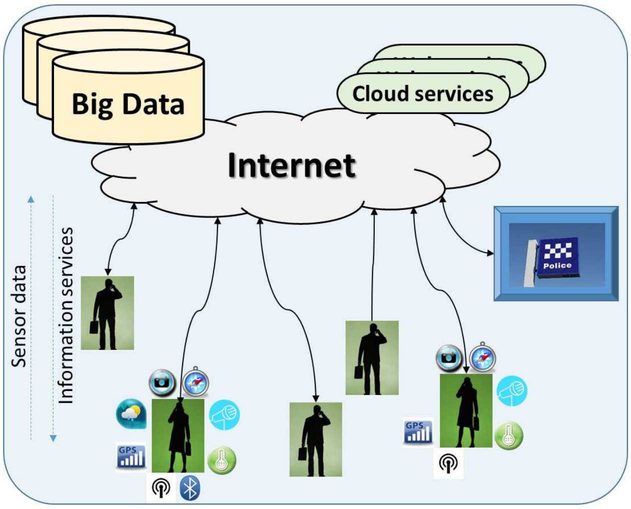

Fig. 1. Principles of operation of participatory surveillance.

To examine the viability of such scenarios we built a prototype participatory surveillance application and staged an evacuation exercise to validate its viability and practicality in real settings. We also designed a participatory surveillance framework and an experimental methodology to collect and analyze the data gathered throughout the exercise. One of the main goal of this research work was to examine the potential knowledge that can be derived from raw data stemming from the participatory sensing tasks. The driving objective was our ability to infer the different types of activities that the users were engaged in during the experiments, using only raw sensor data as input. We were also interested in examining how much information can be extracted from a minimal set of data and the results discussed later were quite interesting in terms of privacy.

We report here on our findings utilizing artificial intelligence and in particular machine learning algorithms to preprocess and analyze the collected data in order to infer the type of activities the users were conducting when the data was being collected. The results are very promising, with various configurations of our framework being able to identify up to

978-83-60810-66-8/$25.00©2015, IEEE

99% of users' activities (walking, standing still, climbing stairs or descending stairs) on the actual data collected from the evacuation exercise.

The remaining of this paper is structured as follows. After this brief introduction, Section II reviews related work in the area of participatory sensing in the context of security. Section III discusses the design of our participatory surveillance application together with potential scenarios of its use, whereas Section IV outlines privacy concerns and considerations regarding participatory surveillance. Section V presents the proposed generic framework to support analysis of data collected through such applications, evaluation of the accuracy and performance of which is the subject of Section VI. The paper concludes with Section VII where the limitations of this work are underlined and opportunities for further research in the domain are pinpointed.

## II. Related Work

Sensors on mobile phones can be used to infer different types of information regarding the users of the phones, as well as the surrounding environment. Accordingly, an extensive review is presented in [6]. Accelerometers, gyroscopes, and other sensors have been used to detect human activities with typical cases presented in [7], [8], [9]. Such works are significant for security reasons, because they can reveal the state of users, e.g. running or laying still, and thus in combination with other contextual information they can hint on possibly suspicious actions of users, e.g. running away from a crime scene, while everybody else around the user is walking. Moreover, considering a smartphone's microphone as input, audio recordings regarding noteworthy events could be recorded in an inconspicuous manner, whereas the phone camera could serve as an additional channel of information reporting, as discussed in [10].

The prominence and ubiquity of current smartphones that are equipped with a variety of embedded sensors has spurred applications related to user-centric sensing and monitoring of the surroundings, namely the paradigm of participatory sensing [1]. Such applications have found applicability in environmental monitoring [11], green vehicle routing [12], noise mapping in urban environments [13] and lately in security and surveillance operations [4]. Despite the fact that there are several potential shortcomings from such an approach, i.e. regarding privacy [14] and the quality and accuracy of data collection [15], its benefits nonetheless are far from negligible.

In the context of security, participatory sensing applications can provide great data collection services at high granularity (spatial and temporal) and at a low cost. Current surveillance practices rely mostly on video monitoring, e.g. CCTV, which has several shortcomings in person identification [16] and cannot inherently cover extended areas. While there has been work on using sensors as information side channels for security operations, e.g. microphone [17], accelerometers and PIR [18], and magnetometers [19], such techniques have however not been envisaged at a large scale. Limited number of sensors were deployed in previous works and such approaches therefore also suffer from poor range and poor data records. Participatory sensing builds on the use of sensors on smartphones that are nowadays pervasive and ubiquitous and can thus provide information for large geographical areas, assuming a large volunteer user base. The associated costs are minimal compared to the installation and deployment of infrastructure-based solutions, while additionally the ease of deployment is great since nowadays users carry their phones with them for the major party of the day and it is always on, collecting sensor data. Another benefit of participatory sensing applications for security purposes can be found in the straightforward identification of people that is supported through the cell IDs of the phones and allows the association of users with the data related to them. The *Cell-All* project from the US Department of Homeland Security on the use of chemical sensors on mobile phones to detect chemical attack related emergency situations was one of the first efforts towards crowdsensing being put in use for security purposes [20].

Furthermore, one of the biggest concerns in participatory sensing is ensuring that users are actively contributing and sharing their data [21], [22] since it could eventually lead to poor performance due to the lack of accurate and informative representations. This problem has been considered in the context of noise mapping, where a persuasive, motivating game was considered in [23] to stimulate user data collection and sharing. In terms of participatory surveillance, we postulate that the citizens' sense of engagement and contribution in securing their environments will be the driving factor for their engagement. Nevertheless, in order to promote such engagement the fundamental issue raised by users, i.e. privacy, should be addressed. In this respect, there has been significant research work on the anonymization of shared user data with prominent examples being reported in [24] and [25].

## III. Participatory Surveillance Scenarios

Participatory surveillance as a concept aims at utilizing the notions of participatory sensing and the ubiquity of smartphones equipped with a wealth of sensors in order to provide services related to surveillance and public security. This paradigm shift aims at empowering both the citizen and the police authorities and raising public awareness and citizen engagement [3]. Citizens on one hand feel more empowered since they are contributing in securing their neighborhoods and acquire thus a more active role in their society. Police authorities on the other hand gain from the wealth of data coming from citizens' smartphones and other monitoring means. It is an inexpensive and efficient way of enriching the data coming from traditional sources of surveillance, e.g. CCTV, as well as reaching areas where deployment of CCTV-like systems is not possible or allowed. Moreover, data coming from smartphones is not only limited to pictures or videos, but it can also include data from the embedded sensors such as accelerometer, gyroscope, pressure, magnetometer, etc. This kind of data supports the police authorities in gaining a better understanding of potentially noteworthy incidents [4].

In this respect, we considered a scenario that involved a variety of actors in order to collect experimental datasets from smartphone sensors and also to test the feasibility of the notion of participatory surveillance. We chose to avoid scenarios that would seem invasive and that might be considered as threatening citizens' privacy, e.g. continuous localization using GSM signals or recording the audio and video signals surrounding citizens at all times. The scenario we considered involved crisis management and in particular an evacuation exercise of an office building in case an emergency occurs, e.g. fire. People inside the building, namely employees, safety staff, building delegates (in charge of enforcing standard evacuation procedures) and visitors, were assumed to have a smartphone equipped with a custom application that monitored the values registered from their sensors and reported the data back to a centralized control room.

In terms of participatory surveillance, the principal goal was the utilization of the collected sensor datasets to provide the remotely located control room supervisors with useful knowledge regarding the progress of the evacuation, e.g. bottlenecks in exits indicated by users standing still, running in stairs indicating panic, users in peculiar situations (lying down or falling). Accordingly, the collected datasets that contained raw sensor data, e.g. from accelerometers or gyroscopes, had to be processed and analyzed in a manner that would allow us to extract useful information about user activities related to the collected data. The motivation behind this exercise was to examine whether data from smartphones alone would be sufficient to support surveillance tasks during an emergency when infrastructure surveillance mechanisms such as CCTV would be unavailable, namely to study the potential use of smartphones and participatory applications as a backup channel for surveillance.

The evacuation exercise scenario is in our view typical of prospective participatory surveillance applications, since it exhibits the majority of desired characteristics. In particular, it considers the use of a variety of sensors and a large number of people; it is privacy-friendly since it allows people to decide when and what type of data they wish to share; it is easily extensible to include further features and data sources; it provides solid motivation for the use of smartphones for security operations, since in such a case the lack of infrastructure surveillance network would be detrimental to police operations. Undoubtedly, the major concern of user privacy is present in this scenario as well as in every other participatory sensing application, albeit at a smaller scale. In the following, we discuss relevant privacy concerns and describe our approach in alleviating them.

## IV. Privacy Considerations

While the benefits stemming from participatory surveillance applications are evident, the privacy risks involved are not clear and need to be carefully considered. The mere concept of participatory surveillance comes along with a series of potential privacy risks. Users are required to share personal data coming from the sensors embedded on their phones, in order to support and improve security operations and promote the communal sense of safety. We illustrate in Section VI that even with the use of data coming from just the accelerometer, it is possible to infer the activities that the user was conducting at the time of data collection. Use of additional sensors could exacerbate this risk, providing more detailed information on user activities. Indicative of relevant privacy risks, is the recent work presented in [26] that considered RF-sensing to infer the state of device-free individuals without their cooperation. Taking into account the capabilities of modern smartphones and the wealth of data available to participatory surveillance applications, it becomes clear that proper privacy enhancing technologies need to be put in place.

A major concern refers to the fact that user data can easily be traced back to their owner, because of the nature of cellular networks and the uniqueness of phone identifiers. Since data can be used to expose potential private user information, anonymization techniques need to be utilized to hinder such exposure. A comprehensive review of related solutions can be found in [24], with the most prominent approaches considering techniques such as k-anonymity and l-diversity [25]. Moreover, the entire space of sensors on smartphones needs to be carefully examined. The latter are nowadays carrying a large number of sensors and the knowledge that can be extracted from them (by processing the corresponding sensed data) is still not fully chartered. Studies like the one presented in this paper, expose the privacy risks related to the accelerometer, however the need to perform similar studies for the entirety of available sensors is paramount. Accordingly, guidelines could be provided to the end users to instruct them on the potential risks involved in sharing data coming from diverse sensors. This is particularly important since users are quite sensitive about sharing photos or location data for example, but are unaware of the risks involved in sharing data from low level sensors that could be equally detrimental to their privacy [14].

Access to this data should also be protected, so as not to allow its unauthorized viewing and processing. Participatory surveillance is the context in which this data is being collected and therefore police authorities should access this data under this particular context. The role of national Data Protection Authorities (DPAs) naturally emerges as a safepoint of supervisory control regarding participatory data protection. In addition to any such effort, participatory surveillance applications should also be designed with privacy in mind, in which case they should record any access to data and the processing method invoked on them to assist in prospective inquiries. Furthermore, who will have ownership of this data and for how long it should be kept and processed remains an open issue that could trigger conflicting situations. One could for example postulate that data should be retained by police authorities only when a criminal activity took place and then stored indefinitely. However, the exposure of such an activity cannot be foreseen and therefore data should be kept to ensure its availability if needed. Another conflict that might arise involves the user wishing to remove his shared data (right to be forgotten), whereas the police authorities might not permit this due to ongoing or forthcoming investigations. There is no panacea to resolve such conflicts, with application- and context-dependent solutions usually being the norm. Undoubtedly, appropriate legislation and rule systems should be introduced to regulate this newly established field and thus promote its prosperity.

## V. Data Analysis Framework Design

The notion of participatory surveillance refers to the collection of data from a variety of smartphones and other mobile devices and in particular from the on-board sensors carried by such devices. Processing and analyzing this wealth of data could lead to the inference of interesting information and knowledge regarding various surveillance aspects, namely the identification of distinct human activities, the location of a user and his/her surroundings (physical and social) and the occurrence of abnormal conditions, e.g. extreme sound levels potentially attributed to screaming or intense physical stress possibly attribute to user falling. The goal of the data analysis part of any effective participatory surveillance system is therefore to deduce such useful information. In the following we present a generic framework that has been devised for such purposes of data analysis and discuss its various aspects.

Analyzing data to extract useful patterns and accordingly use these to identify human activities and distinguish between them has been a very active research domain over the years [27]. The goal is to have computing systems capable of inferring knowledge by themselves using only raw data as input. The main elements of machine learning for the purposes of activity recognition using smartphones include the following:

- Data collection: collection of data using sensors located on the users' smartphone.
- Data training: the collected raw data need to be processed in order to deduce some useful information features and characteristics that will assist in its classification.
- Data classification: use of the aforementioned features in conjunction with machine learning classification algorithms to classify data, i.e. assign classes to data instances.

Figure 2 depicts these 3 different steps in the machine learning process. We applied these steps on both the collected reference data and the test data for our experiments and appropriately configured the classification process to enhance its performance in respect to our requirements. During the training phase the most appropriate and appropriately configured classifier is selected, so as to be applied in the testing phase over new data and classify them accordingly.

As previously discussed, sensor data can be exploited to detect human activities and thus provide insight on the actions and whereabouts of the smartphone users in a non-intrusive manner. We decided to use a systematic approach to tackle this problem and for this reason introduced a generic framework for the analysis of data coming from participatory surveillance activities. The main goal is to build a comprehensive dataset for training statistical classifier and applying this to actual, i.e. test, data to establish possible patterns/matches and thus identify human activities for the purposes of surveillance. The reason why we chose to define a generic framework is to establish a methodological framework of doing similar experiments, as well as to facilitate further developments in the domain. The framework is presented in Figure 3, while its elements are detailed in the following:

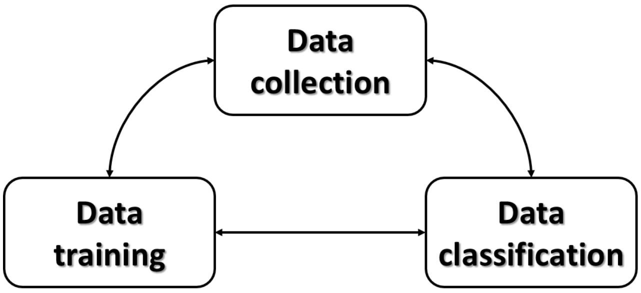

Fig. 2. Machine learning stages for activity recognition applied on both training and testing phases.

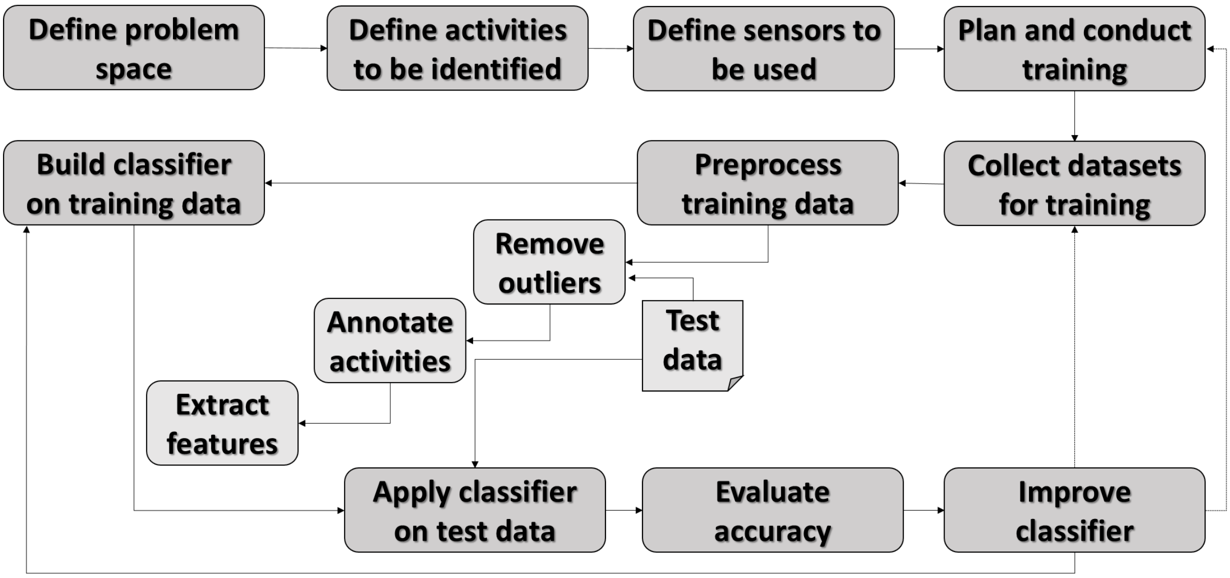
- Define problem space: the particulars of the participatory surveillance tasks need to be carefully defined at a high level, namely what needs to be achieved. They will serve as the requirements that will drive the rest of the analysis process.
- Define activities to be identified: not all scenarios for participatory surveillance rely on the identification of the same set of activities. However, the selection of the interesting activities is important at an early stage since it drives the definition of the required data and sensors to monitor these activities.
- Define sensors to be used: having defined the activities we are interested in, the next step concerns the selection of the most appropriate sensors to support the identification of these activities.
- Plan and conduct training experiments: the training phase is the first phase in the machine learning process and it involves a set of base experiments to collect reference data for the activities in question. The planning of these experiments is therefore of paramount importance, so as no configuration parameters or testing conditions become neglected during the following phase.
- Collect datasets for training: collect training data referring to elementary activities related to participatory surveillance as defined in previous steps of the process. The data should refer to more than one repetitions of the activity over a span of time.
- Pre-process training data: the collected data is in most cases noisy and needs to be pre-processed prior to being used by machine learning classifiers. Raw data usually has very fine granularity making it difficult to discern relevant statistical properties. Therefore it needs to be processed in order to extract statistical features over time, as well as in the frequency domain. The pre-processing tasks involve the removal of outliers from the original dataset, the annotation of the data for classification pur-



Define problem space

poses (applies only to training data, since the classifier will ¿predictř the class of the test data) and the extraction of statistical features.

- Build classifier based on training data: amongst the large number of classification algorithm available in the related literature, the optimal one for the particular type of collected data and extracted features should be selected. Each classifier has a set of configuration parameters and a sensitivity analysis of each of them and their influence on the accuracy of the classifier needs to be performed in order to conclude on the most appropriate classifier for the considered experimental settings.
- Apply classifier on test data: having decided on the optimal classifier, it needs to be applied on the collected test data (a posteriori or at runtime depending on the experimental settings). The classifier should be able to identify the class to which each of the test data belongs and decide upon that.
- Evaluate accuracy: the accuracy of the classifier is evaluated against the ground truth, hence the need to properly and accurately annotate both the training and test data.
- Improve classifier: test and training data are of the same type but a lot of irregularities might appear on the test data that might not have been present in the training data. There are many reasons for this, most important of which is the fact that training data users are rarely the same as test data users and thus do not have the same physiological patterns. Therefore, the classifier might not predict the test data as efficiently as expected and further modifications need to be applied on it and accordingly the experiments might need to be performed again.

In what follows we elaborate on the elements of our proposed framework in the context of our participatory surveillance evaluation case-study, i.e. the evacuation exercise.

## VI. Evaluation

To validate the feasibility of participatory surveillance and evaluate its efficiency we conducted an evacuation exercise experiment, where the main goal was to establish whether the use of smartphones' sensors as a backup channel for information collection can yield information about users' activities. In this respect, we built a comprehensive dataset for training a statistical classifier and applied this to the test data collected during the experiment to establish possible pattern matches and subsequently analyze the results to augment the design of the assumed participatory surveillance system.

### A. *Implementation*

In order to collect data from the sensors embedded on the smartphones of the users we experimented initially with the Funf open sensing framework [28] running on Android platforms, but we finally opted for a custom built application to avoid the unnecessary complexity in configuring Funf. In particular, Funf allows the developer to set preferences in regards to data collection, such as the types of sensors to be monitored, the duration of the monitoring and recording phase and the interval between two consecutive recording phases. A limitation of this framework is the fact that the actual frequency of data collection, while seemingly subject to a user's preferences, is actually a compromise between the value set by the user and the frequency that Android itself and the corresponding sensors can actually support. Android allows for 4 different rates for data collection from sensors, i.e. *normal, UI, game, fastest*. However, the actual values for these frequencies differ between different sensors, which further complicates matters when it comes to data collected using Funf. For these reasons we built our custom application to collect sensor data, the main distinguishing feature of which is that it allows explicit setting of data collection frequency per sensor.

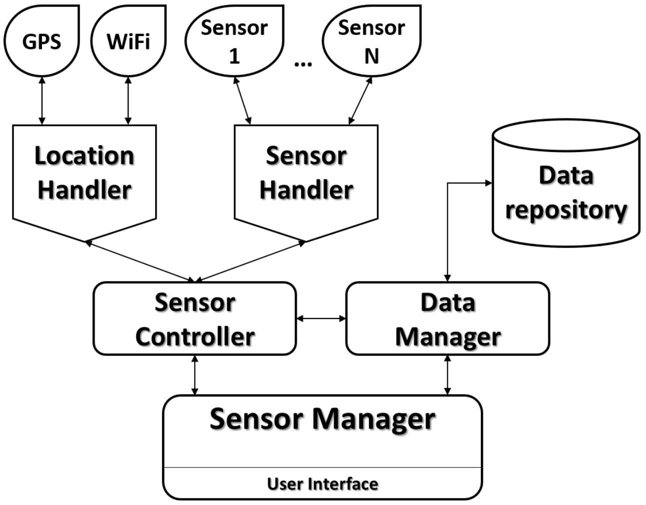

Fig. 4. Architecture of sensor data collection application.

The application we built has a modular and extensible architecture that is shown in Figure 4. The *Sensor Manager* is the main entry point for the app, currently running on Android phones, by means of a dedicated GUI that allows the user to select the sensor the values of which she is interested in recording. Two main elements of the architecture are the *Sensor Controller* and the *Data Manager*. The former interacts with the *Location Handler* to retrieve current location and the *Sensor Handler* to get low level system access to the embedded sensors and retrieve their values, while the latter parses this information into an appropriate data format and stores it to a local *Data Repository*. Moreover, the *Data Manager* supports management of this repository, i.e. search, update, delete data, applying access control policies to avoid unauthorized access to private data and logging every request for data.

### B. Experimental setup

The evacuation exercise experiment was conducted in a public building at the JRC premises and it comprised both floors of the building, as well as the parking space, where the actual evacuation meeting points is located. The participatory surveillance exercise was part of a larger experiment that aimed amongst others at evaluating additional techniques such as indoor localization using smartphones and facial recognition through the cameras on the smartphones. For the participatory surveillance tasks, 14 actors were involved: 1 building delegate and 13 regular users carrying their smartphones. The latter had our custom application deployed in order to collect sensor data, e.g. accelerometer, and the users were also instructed at times (via SMS from the control room) to use their smartphones to record video of their surroundings. Users and the building delegate were equipped with different types of smartphones (Samsung Galaxy Nexus, Sony Xperia S, HTC One) to account for the diversity of existing platforms and embedded sensors.

Upon completion of the evacuation exercise we had a total of 13 datasets from a corresponding number of phones that had collected sensor data through our application. Unfortunately, the instability of the application and of the smartphones' platform led to not all phones having recorded data (only 6 out of 13 phones reported worthwhile data). It has to be clarified that the reasons for the erroneous, wrongly timed and limited data collection cannot be pinpointed to a particular event. They can be attributed to users not having activated all services, e.g. location reporting services, networking hindrances due to obstacles or other reasons that collectively prevented timely data reporting, smartphone being overloaded, smartphone battery having been depleted, etc. The major problem that we encountered was the concurrent and synchronized collection of sensor and localization data. This was necessary in order to be able to reason about the sensor data and to pinpoint the location of interesting events. In the future a larger user test base should be considered and an extensive preparation phase prior to the experiments should take place to ensure proper operation. Moreover, test users should not be left to freely interact with the considered applications and services, but instead they should follow a strict script/set of actions in order to ensure that the results we obtain will not be biased by the individual users' attitudes.

The frequency of data collection from the sensors was set to 500Hz (every 2ms), which intuitively is rather high to allow for distinguishing between differences in human activities. Moreover, it reduces the battery level significantly since the device is constantly operational and collecting data. In future experiments we plan to perform a thorough sensitivity analysis of this variable, as well as of other variables in our configuration. The sensors involved in data collection include the triaxial accelerometer, microphone, battery, gravity sensor, gyroscope, light sensor, magnetometer, orientation, WiFi and Bluetooth wireless interfaces and the proximity sensor. While data was collected for all the aforementioned sensors, we focus our analysis here on those collected by accelerometers. The reason behind this decision lies in the fact that in this evacuation exercise, identification of human activities, e.g. walking or running, was the main goal and in this respect the accelerometer has been the sensor most widely used for this purpose in related research works [29].

Moreover, due to the established limitations of the sensing capabilities of modern smartphones and their issues with calibration (see for example [30], [31]), sensors such as the gyroscope, magnetometer and orientation are considered to be of limited accuracy and this placed constraints on their use in our experimental design. An additional reason for not using these sensors was the fact that they are dependent on many external features, e.g. the way the phone is being held, specific rooms/configurations where the experiments took place, so it would have been harder to deduce any useful context from such sensors considering the difficulties in repeating experimental settings and conditions. We therefore opted to place emphasis on data collection by the triaxial accelerometer present in all current smartphones for the analysis of the data collected in the participatory surveillance project. Evidently, the training dataset can be easily expanded to include data from the other sensors in order to establish whether useful knowledge about the users' status and activities can be extracted from them.

### *C. Training phase*

The focal objective of building a reference training dataset is to establish a solid and wide ground truth to be used for the evaluation of the participatory surveillance experiments, i.e. the identification of distinct human activities. In this respect, we collected training data with a specific focus on data that corresponds to the activities expected to take place during the evacuation exercise; walking, walking up stairs, walking down stairs, standing still. It should be clarified that the more activities we consider, the more accurate the prediction will be since there will be more details and more patterns derived for each of these activities. However, the increase in the number of considered activities brings a corresponding increase in the complexity of the data pre-processing and classification processes. Considering this trade-off we opted for a training dataset containing accelerometer data corresponding to the 4 basic activities mentioned before.

The training dataset contains 5 minutes worth of data collected for each of the aforementioned activities, which were conducted independently and annotated immediately after completion to limit possible annotation errors. Users were asked to retain constant gait and velocity as much as possible. We performed 10 recording sub-sessions, i.e. 40 second sub-sessions, for each activity to eliminate possible user fatigue that would influence data collection. In addition, only 30 seconds were considered out of each sub-session; we trimmed the first and last 5 seconds to omit outliers during initialization and finalization of the activity. Lastly, we used the exact same settings in terms of data collection frequency, smartphone devices and phone placement as in the actual evacuation exercise.

### *D. Data preprocessing*

The collected training data refers to 3 streams of measurements, one for each axis of the accelerometer. They represent continuous discrete samples that need to be pre-processed prior to making any analysis based on them. In accordance with typical activity recognition algorithms, we commence by cleaning the raw data and removing the outliers, followed by the application of a windowing technique to extract groups of data that could potentially expose repetitive activities or tasks with common characteristics, both of which are representative of the majority of human activities. We built a set of custom Java tools that facilitate the automation and efficient preprocessing of the raw data and hence allow to invest more time on the data analysis tasks. All the data are stored as CSV files, the first line of which indicates the type of data.

Removing outliers is a very important task in data preprocessing, since these values could influence the outcome of the analysis process as they are not conforming to the rest of the data and have thus been potentially generated by side activities to the one currently under examination. The most common technique we use to clean the dataset is to remove the influence stemming from the initialization and finalization of activities. We are interested in the execution of the actual activity and therefore we trim the dataset on both ends accordingly. This is similar to the technique used in [7] and we also take into account the risk of significantly reducing the size of the dataset; this is the reason why we collected additional data as previously described. More advanced techniques, e.g. mean, Kalman, particle filters, could also be applied, but since the application of these filters is subject to intense processing requirements, we opted against applying any such technique on the collected accelerometer data.

Subsequently we applied a windowing algorithm to create logical instances, i.e. windows, of the original dataset. The windows are used to reduce the problem space on one hand, but also to assist in grouping similar samples on the other hand. Generally speaking there exist three different windowing techniques, namely sliding, event-based and activity-based windows, applied to raw data for the purpose of recognition of human activities, as discussed in [32]. We used the sliding window technique with overlap 50% over the entire training data population, for a total of over 60,000 samples. Table I illustrates the different values for the window size that we experimented with and the corresponding duration of the window and generated instances in the dataset based on the assumed data collection frequency. We should note that the same techniques for data preprocessing are applied in both the training data as well as the test data during the actual classification process.

TABLE I
WINDOW SIZE, DURATION AND SIZE OF INSTANCES IN DATASETS

| Window size | Duration | Instances in dataset |
|---|---|---|
| 64 | 1.28s | 1875 |
| 128 | 2.56s | 937 |
| 256 | 5.12s | 468 |
| 512 | 10.24s | 232 |

The sampling frequency of the original training dataset is too high for individual samples to exhibit any interesting properties, especially in regards to human activities that normally have a duration lasting at least a few seconds. To alleviate this concern, we extract features over the different instances (windows) of the data. The notion of features refers to statistical properties of the windows of data and provides some qualitative or quantitative information on them. We examined time domain and frequency domain features in the related literature and we selected a total of 105 features to compute for all the data contained in each of the windows in the dataset. Out of these 105 features, 75 were in the time domain and 30 in the frequency domain. The latter necessitated that we first apply a Fast Fourier Transform (FFT) over the windows' data and then calculate the corresponding features. Table II summarizes the selected features that were applied on the accelerometer values for each of the three axes, the magnitude of acceleration and the tilt on all three axes.

TABLE II
TIME AND FREQUENCY DOMAIN FEATURES FOR CLASSIFICATION

| Time domain | Frequency domain |
|---|---|
| Mean | Mean |
| Median | Median |
| Minimum | Minimum |
| Maximum | Maximum |
| Harmonic mean | Spectral energy |
| Geometric mean | Entropy |
| Pearson's correlation | Pearson's correlation |
| Variance | |
| Standard deviation | |
| Root mean square | |
| Covariance | |

Cyclic patterns of human activities can be easier observed using frequency domain features and this is the main reason for their significance. Indicatively, Figure 5 depicts the mean FFT for the 3 axes of acceleration; cyclic, identifiable patterns can be clearly seen in the activities involving stairs as expected.

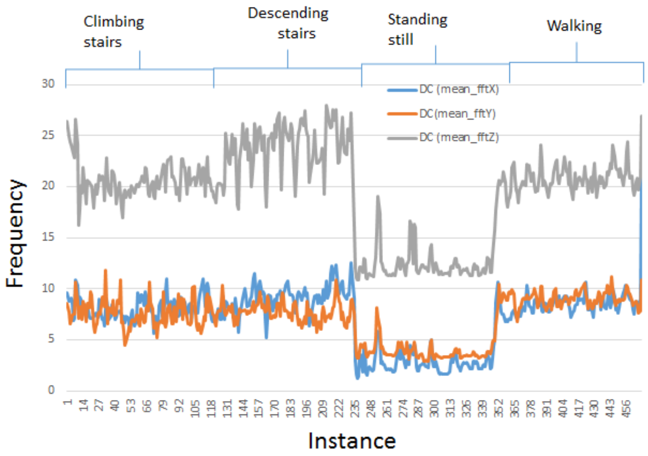

Fig. 5. Mean FFT of acceleration in the 3 axes and the activities that it corresponds to.

### E. Data classification

Having completed the aforementioned procedures and in accordance to our generic framework, the next step in the process involves training the classifier in order for it to be able to correctly analyze the collected data, but also to be able to respond to prospective queries on how new data should be classified, i.e. annotated, in line with previous data. We used the Weka toolkit [33] to experiment with a variety of machine learning algorithms, namely KStar, C4.5 decision tree, Bayes (Bayes Network with K2 search algorithm), Support Vector Machines (SVM), Sequential Minimal Optimization (SMO), k-NN, MultiClass (meta-classifier) and MultiLayer Perceptron Neural Network(MLP).

We indicatively present in the following results on the training of the classifiers based on training data coming from a Sony Ericsson phone, where the data collection frequency was set to be 500, the window size 256 with 50% overlap, the user conducted all 4 activities and she did so holding the phone in her hand at the waist level. In order to test the accuracy of the various classifiers, we used Weka and performed a comparative analysis of the aforementioned 8 algorithms using cross-validation with 10 folds and 10 iterations using all the training data. The annotated test data were used for the evaluation and that is where the corresponding results refer to. To gain a level of statistical confidence in the results obtained by Weka, we applied the well-known statistical hypothesis test Students' T-Test, with a requested confidence of 0.05 (indicates statistical difference threshold when performing pairwise comparison between schemes), and managed to acquire measurements for a variety of aspects regarding accuracy and the performance of the classifiers accordingly. Results regarding these classifiers are presented in Table III and discussed in the following.

All classifiers exhibited very high accuracy rates, reaching up to 99.5%. It becomes therefore evident that the use of just the accelerometer in detecting and distinguishing between human activities yields very promising results. Additionally, it exposes the privacy risks involved in participatory sensing, since it illustrates the level of knowledge that can be gained with the use of a non-intrusive sensor on board a smartphone.

### F. Analysis of results

Table III clearly highlights the optimal performance of the SVM classifier over all others, with the C4.5 one a close second. SVM has an accuracy level of 99.5%, whereas C4.5 98.8% and the worst performing classifiers are the Bayes Network and KStar with accuracies of 85% and 86.6%, respectively. It is interesting to examine this observation in light of the mean absolute and root mean squared error metrics. A simplistic analysis would expect the Bayes Network and KStar classifiers to have the largest degrees of errors, due to their low accuracy. However, while Bayes Networks and KStar do not indeed fare well, it is actually the SMO and MLP classifiers that exhibit the largest mean errors and root mean squared errors despite high accuracy levels of 97.01% and 97% respectively. The reason for this is the fact that while the latter classifiers managed to correctly classify a larger number of instances, the misclassifications were so big that they succeeded in significantly increasing the mean errors. This observation is consistent with our belief that evaluation of a machine learning classifier is not a simple process of computing a couple of metrics, but rather an extensive procedure where a series of quantitative metrics should be taken into account and considered in parallel, while additionally one should not neglect qualitative analysis, as discussed later.

Two very important metrics in assessing classifiers are the precision and the recall (borrowed from the field of Information Retrieval - IR). Precision measures successful assignments to a class over all assignments to that class (including incorrect ones) and in this respect it refers to the

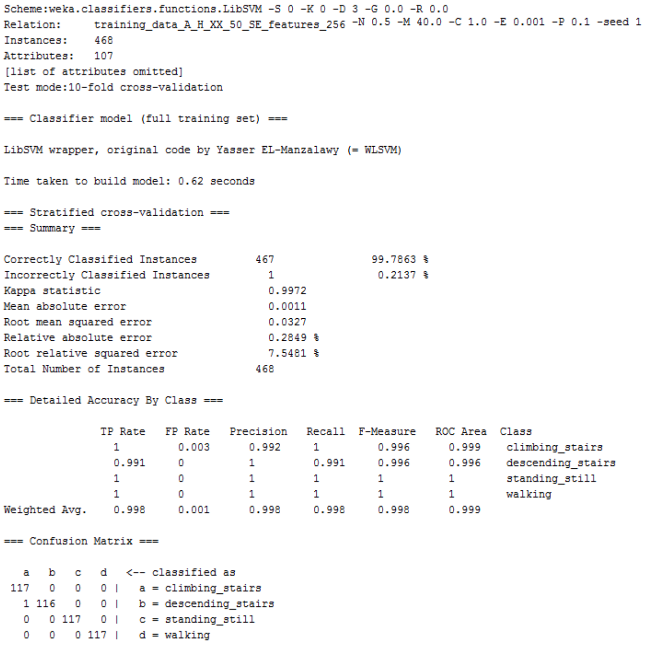
fraction of classified instances that are relevant, i.e. correct. Conversely, recall refers to the fraction of relevant instances that have been classified. Therefore, high recall values indicate that the classifier was successful in classifying correctly most of the instances, whereas high precision means that the classifier performed more correct classifications than incorrect ones. In our experiments, it is the C4.5 classifier that has the best precision with a value of 1.0, followed by the SVM with a value of 0.99, while the Bayes Network and KStar classifiers have the lowest precision with value of 0.77 for both of them. In general, precision follows the same pattern as accuracy, which was to be expected since these two metrics are conceptually close. Similar results (top two algorithms being SVM and C4.5 and lower two Bayes Network and KStar) can be seen for the recall metric, albeit with more distinguish values. Interestingly enough, while the MultiClass classifier had the third best precision at 0.98, it is the SMO classifier that has the third best recall at 0.98. This indicates a different performance between these two, where MultiClass is better at classifying more instances correctly than incorrectly and SMO outperforms MultiClass in performing more correct classifications. Nevertheless, SMO had a much higher root mean squared error than MultiClass, so in general one can expect better performance of the latter.

Another very important metric is the F-measure that combines both precision and recall (also known as F1 score or F1 measure since precision and recall are evenly weighted). It is actually the harmonic mean of precision and recall and is used to express the accuracy of the classification process and is widely considered to be more useful than the percent of correct classifications as expressed by the accuracy metric. According to the F-measure, the SVM and C4.5 perform the best, while the Bayes Network and KStar the worst. Moreover, the area under ROC (receiver operating characteristic) metric has also proven to be extremely useful in evaluating classification algorithms [34], although its value has been recently heavily criticized and thus undermined, e.g. in [35]. The area under the ROC curve is equal to 1 for a perfect classification and drops as classification quality drops. In our experiments MLP performs the best in terms of the area under ROC with a value very close to 1, followed by SVM and MultiClass, while Bayes Networks and KStar perform the worst. It has to be clarified nonetheless that even the worst performing classifier, i.e. Bayes Network, has a value equal to 0.95 that broadly speaking is very good for classification purposes.

Other metrics that we considered in order to compare the performance of the considered classifiers include the Kappa statistic and the KB mean information. Kappa statistic is used to indicate the agreement of prediction compared to the ground truth and is important since it is a probabilistic value that takes into account not only the comparison to the ground truth, but also the probability that a correct assignment to a class was by chance. As before the SVM and C4.5 classifiers were the ones with higher Kappa statistic value at 0.99 and 0.98 respectively (the higher the value, the better matching the agreement), while KStar and Bayes Network had the lowest values, 0.82 and 0.8 respectively. Kononenko and Bratko [36] introduced an information-based evaluation criterion for each classifier's performance, which excludes prior class probabilities and thus assesses better the performance of the classifier under uncertain conditions. Once again SVM and C4.5 had the highest performance in regards to this metric, but surprisingly MLP did not perform well enough. In our view, the reason is based on the construction of the MLP construction network that inherently requires knowledge of prior class probabilities (back-propagation error correction is at its core), so when these probabilities are excluded its performance is bound to be reduced.

The last metric that we considered was the aspect of time. In particular, we examined the time required to train the classifiers and the time required for them to perform classifications over the test data. Since the classifiers were trained and tested on the same sets of data the values obtained for these metrics are directly comparable. MLP, which is the most complex of the considered classifiers, requires the most time for training, averaging 176.35 seconds. This is however not reflected in the testing phase that only takes 0.15 seconds. The fastest classifier to train is KStar followed closely by k-NN, whereas apart from the MLP classifier, the SVM one at 1.15 seconds is also relatively slow to train. Conversely, when it comes to testing times SVM is quite fast at 0.1 seconds but the fastest ones are C4.5 and SMO. The slowest classifier for testing was KStar with the remaining algorithms exhibiting small variance in their values.



```

Fig. 6. Confusion matrix for the SVM classifier.

It is clear that there are tradeoffs to be considered when choosing the optimal classifier for participatory surveillance needs such as identifying human activities. We need to consider accuracy, precision, recall, as well as the overhead in terms of time for each of the classifiers since they will need to be considered in real time operation. The training phase will only occur once, so long timespans for this phase can be sidestepped, but long times for testing can be used to exclude certain classifiers from our candidates' list. Evidently, quantitative results as those previously presented are important, since they provide a thorough evaluation of the performance of the different classifiers in regards to a variety of aspects. It is however equally important to be able to qualitatively analyze the classification process and in particular to be able to analyze why classification errors occur. The best way to do this is by checking the confusion matrix (also known as contingency table) of the classification process that represent the classification results versus the ground truth. Indicatively, Figure 6 shows the confusion matrix for the SVM classifier and Figure 7 for the C4.5 one. Confusion matrices are important because they allow us to diagnose which classes were confused to each other and therefore be able to draw conclusions as to why this occurred in the first place.

Based on the aforementioned extensive analysis and evaluation of the considered classifiers we came to the conclusion that the most suitable ones for participatory surveillance needs include the SVM and C4.5 one. They exhibited the optimal balance between performance, accuracy and quality of classification.

## VII. Conclusion

In this paper we presented our work on designing and developing a solution for participatory surveillance. We aim at involving end users in the tasks related to security and surveillance and thus on one hand assist and promote the overall perceived level of safety, while on the other hand promoting users' sense of contribution and participation in the society and hence their awareness. By utilizing the numerous sensors on smartphones that are nowadays ubiquitous we postulate that significant information regarding critical, security-related events can be inferred. As a proof of concept, we built a system to collect such data from users in the context of an emergency evacuation exercise and we presented here relevant results on the use of this data. By using just one sensor, namely the accelerometer, very high levels of accuracy in predicting users' activities were reached. In our view, this validates the great potential that exists in the field of participatory surveillance, in particular for the management of emergency/crisis events. Even with quite a few limitations that we encountered in our study, e.g. sensors accuracy or user participation, and with the limited amount of collected data, intelligence on the different activities of users was deducible.

Based on the collected results and our analysis, we are confident that with the integration of additional sensors, as well as with the collection of a far more detailed reference dataset, we would definitely be able to discern between distinct human activities at a much greater level of detail and with quantifiable assessment metrics. These aspects are among the ones we plan to investigate further in the future. To test the feasibility of our machine learning approach on participatory surveillance data we did not check against all possible testing conditions; this extensive sensitivity analysis is nonetheless the focus of our ongoing work. We are also planning work on examining the potential benefits that might arise from exploiting additional sensors such as the magnetometer, gyroscope, etc.

The usefulness of participatory surveillance is extremely high if one considers the fact that such a framework could for example allow groups of rescuers to gain access to information about the current and ongoing status and activities of people inside a building, e.g. static user for a long time or user suffering a physical shock. The analysis of the results and the possibility of detecting with high accuracy the class of previously unclassified data has highlighted the great potential of participatory surveillance systems. However, it has also exposed the great privacy risks regarding users sharing data from their smartphones from such systems. We believe that the use of additional sensors and the information fusion emerging from the use of multiple sensors will exacerbate these privacy risks and allow for more accurate detection of the users' activities, as well as the context of her surroundings. Typical examples of such risks reported in the literature include the possibility to infer the PIN of users on smartphones or the password that they type using accelerometers and gyroscopes [37]. We therefore also plan to examine the risks involved from the potential sharing of data from a variety of sensors and not only the accelerometer.

# Frontiers in Network Applications, Network Systems and Web Services

SYMPOSIUM SoFAST-WS focuses on modern challenges and solutions in network systems, applications and service computing.  The Symposium builds upon the success of Frontiers in Network Applications and Network Systems (FINANS'2012) and 4th International Symposium on Web Services (WSS' 2012) held in 2012 in Wroclaw, Poland. These two events are now integrated into one event to fully exploit the synergy of topics and cooperation of research groups.

The topics discussed during the symposium include different aspects of network systems, applications and service computing. The primary objective of the symposium is to bring together researchers and practitioners analyzing, developing and administering network systems, with particular emphasis on Internet systems. Authors are invited to submit their papers in English, presenting the results of original research or innovative practical applications in the field.

### Topics

Topics include (but are not limited to):

-
- Architecture, scalability and security of Open API solutions,
- Technical and social aspects of Open API and open data,
- Service delivery platforms - architecture and applications,
- Telecommunication operators API exposition in Telco 2.0 model,
- The applications of intelligent techniques in network systems,
- Mobile applications,
- Network-based computing systems,
- Network and mobile GIS platforms and applications,
- Computer forensic,
- Network security,
- Anomaly and intrusion detection,
- Traffic classification algorithms and techniques,
- Network traffic engineering,
- High-speed network traffic processing,
- Heterogeneous cellular networks,
- Wireless communications,
- Security issues in Cloud Computing,
- Network aspects of Cloud Computing,
- Control of networks,
- Standards for Web services,
- Semantic Web services,
- Context-aware Web services,
- Composition approaches for Web services,
- Security of Web services,
- Software agents for Web services composition,
- Supporting SWS Deployment,
- Architectures for SWS Deployment,
- Applications of SWS to E-business and E-government,
- Supporting Enterprise Application Integration with SWS,
- SWS Conversational Protocols and Choreography,
- Ontologies and Languages for Service Description,
- Ontologies and Languages for Process Modeling,
- Foundations of Reasoning about Services and/or Processes,
- Composition of Semantic Web Services,
- Innovative network applications, systems and services.

***Abstract*—Transmission Control Protocol (TCP) is still used by vast majority of Internet applications. However, the huge increase in bandwidth availability and consumption during the last decade has stimulated the evolution of TCP and introduction of new versions that are more suited for high speed networks. Many factors can influence the performance of TCP protocol, starting from scarcity of network resources, through client or server misconfiguration, to internal limitations of applications. Proper identification of the TCP performance bottlenecks is therefore an important challenge for network operators. In the paper we proposed the methodology for finding root causes of througput degradation in TCP connections based on passive measurements. This methodology was verified by experiments conducted in a live network with 4G wireless Internet access.**

## I. Introduction

Since the foundation of the Internet the vast majority of network data is transmitted using Transmission Control Protocol (TCP). TCP underlies many ‘traditional’ Internet applications such as web browsing, email, bulk data transfer etc., but also the relatively new ones, such as HTTP adaptive streaming that is quickly becoming the preferred method for Over-The-Top video delivery. All this makes the TCP performance analysis one of the most important research areas of the Internet networking. Since the beginning of TCP’s public use in 1989 a lot of research effort was devoted to improve its performance, and the protocol itself has evolved significantly.

The early TCP version used RTO (Retransmission Time-Out) timer to recover from packet loss which was inefficient even on low speed links. The TCP Reno/NewReno version [1] introduced fast retransmit & recovery mechanism that improved the TCP performance in presence of packet loss. For a long time the TCP Reno was a de-facto standard widely deployed in the Internet. However, the significant increase in network capacity observed during the last decade has stimulated introduction of new TCP congestion control algorithms that are more suited for high speed links, such as Fast TCP [2], BIC [3], STCP [4], CUBIC [5] [6] [7], HTCP [8] [9] [10], HSTCP [11] [12], Compound TCP [13], TCP Westwood [14] etc. The new versions of Linux operating system do even allow switching between different congestion control algorithms without the need to recompile the kernel.

This paper presents the methodology of finding the root causes of throuput degradation in TCP connections on the base of passive measurements obtained from probes capturing traffic on the network links. This methodology combines the detection of TCP source application type (greedy vs non-greedy) [15] with estimation of coefficients related to transmission effectiveness that are based on the RFC 6349 [16]. The proposed approach is supported by results obtained from measurements conducted in the live 4G mobile network of Orange Poland.

## II. Sources of TCP performance bottlenecks

TCP uses congestion and flow control mechanisms to control the transmission rate of the sender process by limiting the amount of data that can be transmitted without waiting for acknowledgement (called the *window size*). Changing transmission rate in response to receiver’s limitation in processing incoming data (*flow control*) is based on the current size of the receiver’s window ($awnd$). This value is advertised to TCP sender process in segments that are sent as acknowledgements to the received data. Too small values of the receiver’s window can however negatively affect the performance of the TCP protocol. Therefore, in newer implementations it can be adapted algorithmically depending on the characteristics of the transmission path (such as throughput and delay).

Congestion control is done by algorithms that aim to ‘sense’ the bottleneck throughput on the transmission path and adapt the transmission rate to this limit. The sender process keeps the state variable called the congestion window ($cwnd$) that works in a similar way as advertised window, except that its value is set by an algorithm running on the sender side. Usually, the sender starts with a small value of $cwnd$ and tries to increase it each time when an acknowledgement for the previously sent data segment is received. The initial phase of aggressive $cwnd$ increase is called a *slow start* - the $cwnd$ is increased by 1 segment after each acknowledgement which leads to exponential growth in the amount of transmitted data. After encountering data loss the $cwnd$ shrinks; the following increase is usually slower and TCP sender enters the phase called *congestion avoidance*. There are many different congestion control algorithms and their variants - for an excellent review see [17]. However, they all share the same purpose - to maximize the usage of capacity available on the transmission path while also minimizing the probability of data loss.

978-83-60810-66-8/$25.00©2015, IEEE

For the TCP sender process the actual window size is the minimum of the advertised receiver's window ($awnd$) and its own congestion window ($cwnd$). After sending full window of data, TCP must stop transmission and wait for acknowledgement. The acknowledgement related to the earliest outstanding segment that was transmitted will start to arrive after the RTT (Round Trip Time) between the sender and the receiver. Each arriving acknowledgment will trigger transmission of the next segment of data awaiting in the output buffer. Hence, the TCP process can send at most $min(cwnd, awnd)$ of data per round trip time cycle and the instantaneous TCP throughput can be roughly estimated as:

$$TCP_{th} = \frac{min(cwnd, awnd)}{RTT} \tag{1}$$

TCP window that is too small may severely limit the performance of TCP connection. In order to obtain high throughput, TCP must be able to fill the network pipeline with data that will keep the network busy. Therefore, the TCP sender's window size must be greater than the bandwidth delay product:

$$min(cwnd, awnd) \geq C * RTT \tag{2}$$

where $C$ denotes the capacity available for TCP connection on the tranmission path.

There are various ways to set the values of $awnd$ and $cwnd$. As it was noted earlier, especially for $cwnd$ there is a number of different congestion control algorithms that react differently to the potential congestion detected either by the Retransmission Time-Out (a timer on sender's side) or by receiving a duplicate acknowledgement (Dup-ACK) from the receiver. Both events lead to segment retransmission and $cwnd$ window scaling, and appear in result of changes in the network environment, such as increased load, change in traffic mix, change in link parameters etc.

Another factor limiting the TCP performance is related to sizing TCP socket buffers on both sides of the connection. The problem of buffers being too small is especially visible in the networks with high bandwidth delay product (the maximum buffer space for TCP sockets depends on the operating system in case of typical Internet hosts). The receiver's socket buffer size can significantly influence the performance of TCP connection (receiver's buffer can limit the sending rate of the TCP source). Therefore, proper configuration of the sockets' buffers is very important to assure high TCP throughput [18]. Modern operating systems introduce automated algorithms for tuning the TCP buffers [19] [20] [21] [22] [23].

Similar case is related to sizing the buffers of network devices [25]. TCP sender can emit data in bursts (up to the current $cwnd$ window size). If network buffers are too small, the inevitable data loss will prevent the congestion window from growing and TCP connection will not be able to ramp up the transmission rate to available capacity. It is generally advised that network buffers should be at least twice the size of the network bandwidth delay product to assure high TCP throughput.

Another factor influencing the achievable TCP throughput is related to packet reordering [26] [27] that can be introduced for example by parallel packet processing in network devices. Receiving out-of-order segments can result in duplicate acknowledgements being sent and interpreted as data loss. This may in turn lead to unnecessary retransmissions, $cwnd$ reduction and throughput degradation. On the receiver's side frequent segment reordering may lead to extensive buffering and potential reduction in receiver's window size.

Finally, the throughput limitation can lie within the application itself. For example, in adaptive HTTP streaming the client requests chunks of video file from the server with frequency related to the encoding rate, even if the available capacity would allow transmitting data faster. In this context, TCP sources can be divided into greedy (always trying to utilize the most of available transmission capacity) and non-greedy (where rate is limited by internal behavior of the source). This classification is utilized in the methodology discussed in section III-B.

## III. Detection of the root causes of TCP performance degradation

In this section we describe the algorithm for detecting the root causes of the TCP performance bottlenecks using passive TCP measurements.

### A. Network measurements

Following the recommendations from RFC 6349, it is advised to perform the MTU (Maximum Transmission Unit) discovery procedure (see [28] for reference) before starting measurements, to avoid unwanted packet fragmentation.

We assume that the TCP traffic is monitored near the sender (at the client or at the server, depending on the direction of the transmission). The monitoring point must be close enough to the sender in order to precisely estimate the RTT parameter which is required by the proposed bottleneck detection algorithm. The monitored network traffic is saved by the probes in *.pcap* format for further processing.

The throughput of the TCP connection $TCP_{th}$ can be estimated directly from data captured by passive probes as a ratio of data sent and acknowledged during a measurement period to the length $t$ of this period:

$$TCP_{th} = \frac{ACK(t)}{t} \tag{3}$$

$ACK(t)$ denotes the highest acknowlegement sequence number observed up to time $t$. It can be obtained directly from the headers of the captured TCP segments.

Due to the nature of congestion and flow control mechanisms, the TCP sender needs some time before it can reach the desired transmission speed. This time may vary from few seconds to even hours depending on the network RTT, bandwidth, TCP congestion and flow control algorithms etc. For example, during congestion avoidance phase the TCP source needs approximately 30 seconds to increase the transmssion rate by 10 Mbps if the network RTT is 200 ms. Therefore, for proper estimation of the TCP throughput the measurement time should be long enough. The following approach is suggested to assure that. Assuming some interval $\Delta t$ and threshold $c$, seek for time instant $t$ that satisfies the following condition:

$$\left| \frac{TCP_{th}(t + \Delta t) - TCP_{th}(t)}{\Delta t} \right| < c \tag{4}$$

The above formula approximates the derivative of TCP rate estimator. The measurement time should be long enough to assure that the TCP rate estimator does not significantly change over time. In the experiments presented further in this paper we assumed $\Delta t = 1s$ and $c = 100$ KB/$s^2$.

In addition to the typical traffic traces captured at measurement points, the proposed methodology requires running some additional measurements to calculate certain TCP performance indicators (described in section III-D). The first measurement is related to estimation of reference (bottleneck) bandwidth $C_{REF}$. This can be achieved by probing the network bottleneck with UDP traffic. There are many variants of this approach - for examples see [29] or [30]. In our measurements we have used the latter: a train of 50 UDP packets was sent to the receiver and the available capacity was measured simply by dividing the total length of the received UDP packets by the total reception time (under the condition of no packet loss).

To verify if the buffers are properly dimensioned, the *back to back frames* test should be also performed. This test consists of sending the specified number of UDP packets with the maximum possible rate and repeating it while increasing the number of transmitted packets in each trial. The maximum batch size that can be sent without observing packet loss is an indirect measure of buffer size on the transmission path of the stream.

### B. Categorizaton of TCP sources

TCP throughput depends on the amount of data the TCP source emits during a single RTT period, as this value is controlled by the congestion and flow control mechanism. At any time instant the amount of outstanding data (sent but not acknowledged) is limited to $min(cwnd, awnd)$. As was explained in section II the TCP source can send at most $min(cwnd, awnd)$ bytes per RTT period. Therefore, the amount of outstanding data in relation to the RTT is an indicator of instantaneous TCP performance.

If the amount of outstanding data is less than what $cwnd$ and $awnd$ parameters allow, it means that the sender is not fully exploiting the available transmission capacity. The cause may be related to internal sender faults (such as application software or hardware issues, CPU overload etc.), but more often is a result of the consent behavior of TCP source (that may not require more throughput, as it is in case of typical streaming applications where transmission speed is related to the bitrate of the video stream). In the opposite case (if the outstanding data is close to the $cwnd$ or $awnd$), the bottlenecks are introduced either by the network or by the receiver.

Summing up the above discussion, the TCP source may fall into one of the following categories:

- *Internally limited*
  Non-greedy source i.e. a TCP connection that is not fully exploiting the capacity available in the network; the amount of outstanding data is significantly lower than the $cwnd$ and $awnd$ windows would allow.
- *Receiver limited*
  TCP source whose transmission rate is limited by the receiver; the amount of outstanding data is close to the $awnd$ and also lower than the $cwnd$.
- *Network limited*
  TCP source whose transmission rate is limited by the network, i.e. by the available capacity, packet loss rate or network RTT; the amount of outstanding data is close to the $cwnd$.

In order to classify the TCP source into one of the above categories we need the following parameters: outstanding data, RTT, receiver's window size and congestion window size. The first three parameters can be easily obtained from the packet traces captured by the passive probes. However, the congestion window is not directly measurable as it is an internal parameter of the TCP stack at the sender and cannot be directly inferred from the TCP traces. In order to cope with this problem we follow the approach of [15]. The TCP connection state is emulated using the recorded TCP traces to recover the $cwnd$ parameter. We also recover the value of RTO to distinguish between retransmissions induced by the fast retransmit phase and those due to the timer expiration. This is required to precisely track the changes in the $cwnd$ parameter.

### C. Emulation of TCP connection state

The internal state of TCP congestion control mechanism is defined by three main parameters: size of congestion window ($cwnd$), threshold for switching between slow start and congestion avoidance phase ($ssthr$), and the retransmission timer (RTO). These parameters are essential for emulation of the TCP connection state.

After a 3-way handshake procedure, the TCP process enters the established state and the TCP sender starts to transmit data. The sender sets its $cwnd$ parameter to some initial value and begins transmitting in the slow start mode. While in slow start, TCP adds one segment to the $cwnd$ for each acknowledged segment, doubling its $cwnd$ with every RTT period. Therefore, during slow start TCP throughput grows exponentially. The aim of this phase is to quickly probe the network capacity and to estimate the optimum window size without heavily overloading the network.

Slow start phase ends when either the $ssthr$ is reached or the segment loss is detected. TCP detects segment loss by two mechanisms: expiration of RTO timer or reception of duplicate acknowledgements (Dup-ACKs). In the first case the TCP sender retransmits all outstanding data and enters the slow start mode again. In the second case, after receiving 3 consecutive Dup-ACKs the TCP sender enters the recovery phase and employs fast retransmit & recovery mechanism to recover the lost segment. In contrary to the RTO mechanism, only one segment is retransmitted. The assumption behind this approach is that in this case only one segment is most likely lost and there is no need to follow the go-back-N protocol and retransmit all outstanding data.

The sender sets the $ssthr$ to the half of the $cwnd$ window before the segment loss, sets the $cwnd$ to $ssthr$+3 segments and retransmits the segment pointed by Dup-ACKs. Each time another Dup-ACK arrives, the sender adds one segment to the $cwnd$ (inflating the congestion window). The aim of this is to sustain the TCP throughput (as Dup-ACK indicates that the network is still able to deliver packets).

In the recovery phase, the TCP sender is allowed to transmit new data as indicated by $cwnd$. The recovery phase ends when all outstanding data from the beginning of this phase is acknowledged. When leaving the recovery phase the TCP sets the $cwnd$ back to the $ssthr$ and enters the congestion avoidance mode.

In TCP Reno/NewReno versions, during congestion avoidance phase one segment is added to the $cwnd$ in each RTT period. This means that the $cwnd$ grows linearly over time, increasing TCP throughput more conservatively then in slow start phase. However, it may take long time to recover TCP throughput in the network with high bandwidth delay product. Therefore, new congestion control mechanisms introduce more aggressive approaches for increasing the $cwnd$ during congestion avoidance phase.

In order to track the sender's $cwnd$ we emulate the behavior of the TCP protocol. To obtain high accuracy of the emulation we used the original source code of the Linux kernel version 3.18 [24]. The H-TCP congestion control algorithm code was used as this protocol was employed in our test setup. The code was taken from the following TCP modules:

- `tcp_input.c` - estimation of the RTO algorithm; the following function was used:
  - $tcp\_rtt\_estimator$
- `htcp.c` - estimation of the H-TCP congestion control algorithm; the following functions were used:
  - $measure\_achieved\_throughput$
  - $htcp\_cong\_avoid$
  - $tcp\_slow\_start$
  - $htcp\_alpha\_update$
  - $htcp\_beta\_update$
  - $htcp\_recalc\_ssthresh$

Each time the data or acknowledgment segment is observed, we run an appropriate piece of the Linux kernel code. When the acknowledgement segment with higher sequence number is observed we calculate the RTT sample (the time difference between reception of acknowledgement segment and observation of data segment for the given sequence number at the monitoring point) and run the $tcp\_rtt\_estimator()$ function to update the value of the RTO timer.

Next, the $measure\_achieved\_throughput()$ and $htcp\_cong\_avoid()$ functions of the H-TCP algorithm are called to update the internal state of the congestion control algorithm. The $htcp\_cong\_avoid()$ function runs the algorithm for slow start or congestion avoidance phase (depending on whether the $cwnd$ is less or greater then $ssthr$) and updates the $cwnd$ value accordingly.

When 3 duplicate acknowledgements are observed we assume that TCP enters the recovery phase of the fast retransmit & recovery mechanism. We call the $htcp\_recalc\_ssthresh()$ to update the $ssthr$ value according to the H-TCP algorithm. Each time next DupACK segment is observed, we inflate the $cwnd$ by one segment (as specified by NewReno algorithm).

When all outstanding data at the beginning of the recovery phase is acknowledged, the code for regular acknowledgments is executed (emulating congestion avoidance phase). When out-of-sequence data packet is observed that was not acknowledged and the time since transmission of the original segment is greater than the RTO, we assume retransmission due to the timer expiration. The $cwnd$ is reset to the initial value and the slow start code is executed by the $htcp\_cong\_avoid()$ function. When the $cwnd$ exceeds $ssthr$, the $htcp\_cong\_avoid()$ function executes the H-TCP congestion avoidance code again for each observed acknowledgement segment.

To validate the implemented TCP state tracking one can compare the outstanding data calculated from measurements with estimated values of the $cwnd$ (as the amount of outstanding data can approximate the $cwnd$, especially for greedy TCP sources).

For automated detection whether the TCP connection is network, receiver or internally limited, we have implemented the algorithm proposed and described in detail in [15]. Unlike in the original algorithm, we do not however divide the TCP flow into chunks and categorize each chunk individually, but rather do the categorization for the TCP connection as a whole.

An example based on network measurements is shown in Fig. 1 and Fig. 2 for H-TCP-based source. Fig. 1 shows the comparison of outstanding data with the value of $cwnd$ estimated by emulation of the H-TCP congestion control algorithm using Linux kernel source code.

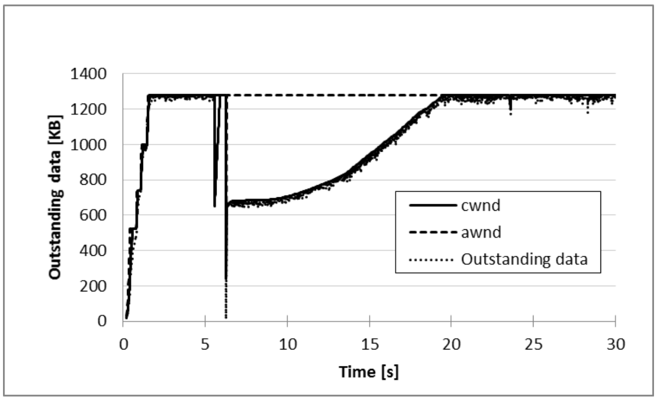

Fig. 1. H-TCP $cwnd$ emulation

The estimated $cwnd$ almost exactly matches the amount of measured outstanding data. Similar results are obtained for the estimation of RTO parameter for the same source (Fig. 2).

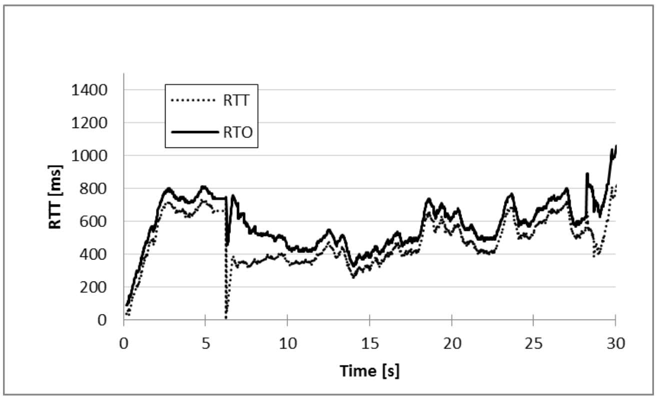

Fig. 2. H-TCP RTO estimation

The following figures present analogous results for the TCP Reno/NewReno based source. The accuracy of $cwnd$ emulation is shown in Fig. 3, RTO estimation in Fig. 4.

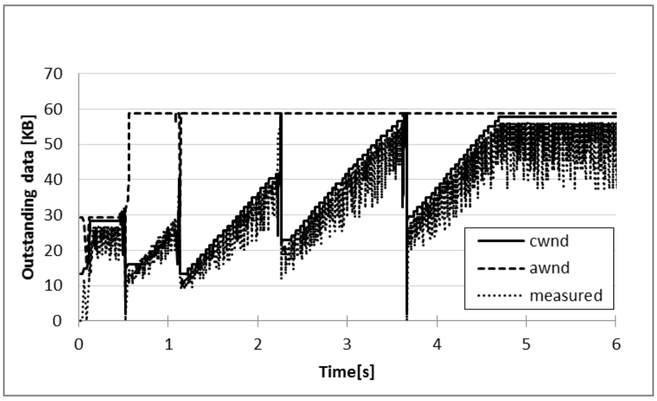

Fig. 3. TCP Reno $cwnd$ emulation

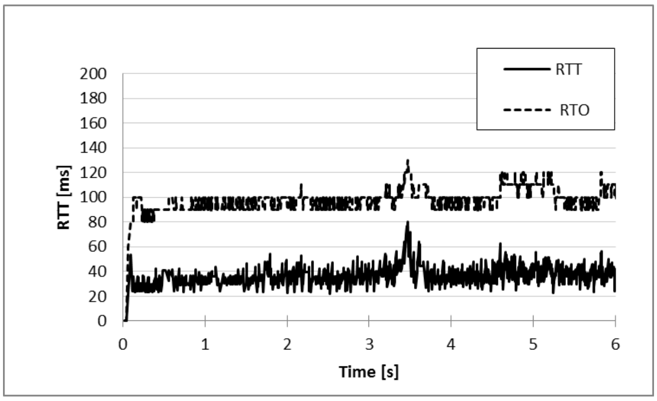

Fig. 4. TCP Reno RTO estimation

### D. TCP performance metrics

Based on RFC 6349, the following metrics are recommended to test the TCP effectiveness.

- *TCP Throughput Ratio* $W$. This metric is calculated as a percentage ratio of achieved throughput $TCP_{th}$ to the reference throughput $C_{REF}$ and should approach 100% for good connections.

$$W = \frac{TCP_{th}}{C_{REF}} * 100 \tag{5}$$

- *TCP transmission effectiveness* $E$. It is a percentage ratio of non-retransmitted data to the total amount of data sent during the measurement period and should also approach 100% for effective connections.

$$E = \frac{D - D_{RET}}{D} * 100 \tag{6}$$

$D_{RET}$ denotes the amount of data retransmitted during the measurement period.

- *Buffer Delay* $T$. To calculate this parameter one needs the reference delay $RTT_{MIN}$ calculated beforehand from measurements taken when the network load is minimal. The *tcptrace* tool can be used for this task. Alternatively, $RTT_{MIN}$ may be approximated by the minimal RTT observed during the actual measurement period. Denoting an average RTT observed within the measurement period as $RTT_{AVG}$, the Buffer Delay can be calculated as:

$$T = \frac{RTT_{AVG} - RTT_{MIN}}{RTT_{MIN}} * 100 \tag{7}$$

As the name implies, this parameter is related to buffer size in the network nodes and can be interpreted as a measure of buffer load imposed by the measured TCP connection (mostly related to the buffer at the bottleneck link). If we assume that buffer size $B$ conforms to the following formula:

$$B > 2 * C_{REF} * RTT_{MIN} \tag{8}$$

then the Buffer Delay should be greater than 200%.

### E. Root cause analysis

For the root cause analysis we use the emulation of the TCP sender state derived from passive measurements and the metrics of TCP connection performance calculated on the base of measurements. The general algorithm is depicted in Fig. 5.

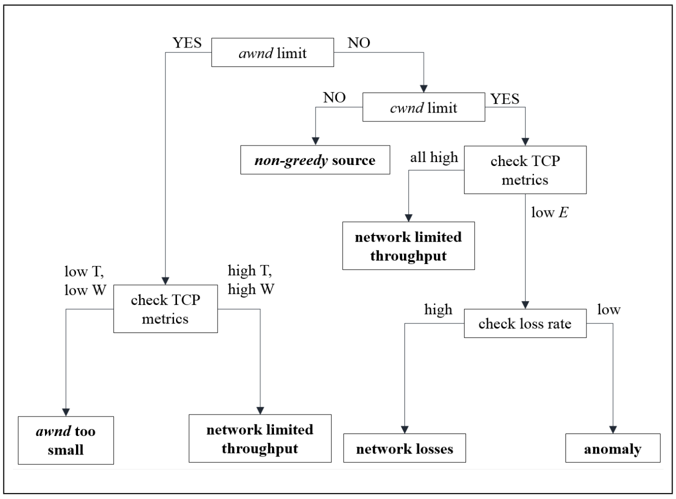

Fig. 5. General algorithm for root cause analysis

In the proposed approach the first task is to check if the throughput is not limited by $awnd$. This can be done by analyzing the behavior of the outstanding data using emulation of the TCP sender state. If it is the case, then it is advised to check the TCP connection metrics. Low $T$ (low buffering) and low $W$ (low bandwidth utilization) together with large $T$ (lack of retransmissions) support the hypothesis that the advertised $awnd$ value is indeed limiting the sender's performance. If however the $T$ and $W$ are relatively large, the true limitation may lie in the network itself and the $awnd$ value reached by the sender is large enough for high connection efectiveness.

If neither $awnd$ nor $cwnd$ (estimated from emulation of TCP sender state) is the limiting factor then the achieved throughput results from the internal sender constraints (non-greedy source). Low value of Buffer Delay may additionally support this hypothesis.

If the $cwnd$ imposes the limit on achieved throughput, it is advised to check TCP connection metrics. High effectiveness of transmission together with large Buffer Delay confirm that TCP throughput is limited by a bottleneck link in the network. However, if the level of observed retransmissions is high (low $E$), then the reason behind low throughput may lie in excessive packet loss in the network resulting e.g. from faults, bad conditions on wireless access link etc. It has to be noted that TCP retransmissions occur naturally in result of congestion control algorithm continuous attempts to fit the transmission rate to the bottleneck bandwidth, but the excessive level of retransmissions is suspicious and has to be checked further.

Finally, the case when transmission effectiveness is low but the packet loss is also low has to be treated as an anomaly that requires further investigation.

### *F. Validation of the proposed approach*

The proposed approach was validated by conducting measurements in the real network. The measurement setup is depicted in Fig. 6.

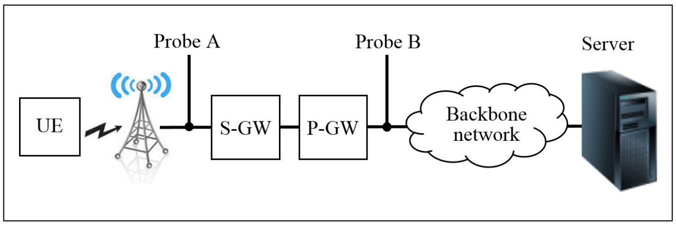

Fig. 6. Measurement setup

Measurements were done in commercial 4G mobile network of Orange Poland with real user traffic served in the background. The setup consisted of the UNIX-based web server connected to the backbone network. The TCP traffic can be monitored at the server and/or at the mobile device (with *tcpdump*). Additionally, two hardware monitoring probes were installed in the mobile access network. The monitored TCP traffic was saved in *.pcap* format for further processing.

We ran a number of tests based on downloading files from the server to the mobile device. Two types of experiments were carried out. In the first case the files were downloaded from the server in a greedy mode. The server was configured to transmit data with maximum possible rate so that the network available capacity was the only limiting factor for TCP throughput.

In the second type of the experiment the socket buffer size at the server was limited below the bandwidth delay product of the network which is approximately 100 KB (40 $ms\ RTT * 20\ Mbps\ C_{REF}$). As can be seen from Fig. 7, the tested TCP connection begins in slow start and within few seconds the $awnd$ and $cwnd$ parameters reach their maximum sizes. This is possible due to large network buffers that can accommodate thousands of packets. After the next few seconds there is a packet drop (signalled by 3 Dup-ACK segments), TCP connection retransmits the lost segment and enters the congestion avoidance phase.

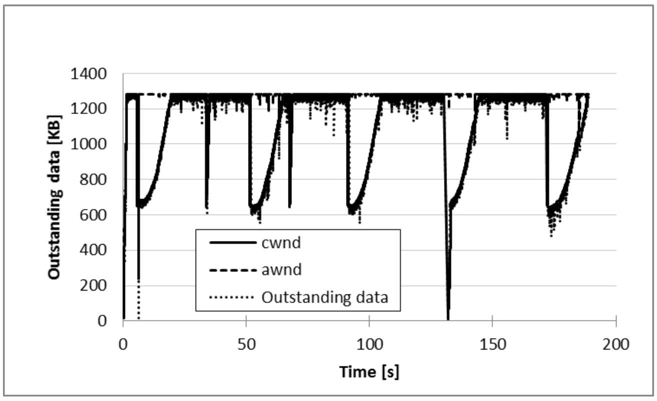

Fig. 7. Network limited TCP connection

While in congestion avoidance the $cwnd$ follows the H-TCP congestion control algorithms. At 130 sec. time instant we observe a retransmission due to the RTO expiration. TCP falls back to the slow start mode and after reaching $ssthr$ (set to 0.5 of the $cwnd$ before segment loss) it switches again to congestion avoidance phase. Notice that the estimated $cwnd$ follows the amount of measured outstanding data very accurately.

**Network limited TCP connection**

min rtt [ms] = 23.5
avg rtt [ms] = 462
avg out data [B] = 1103400
avg awnd [B] = 1275910
avg cwnd [B] = 1114465
measured throughput [Mbps] = 15.8
outstanding data/rtt [Mbps] = 19
fast retransmits = 6
RTO expirations = 5
TCP efficiency (E) [%] = 99.98
buffer delay (T) [%] = 1866

According to the proposed TCP throughput measurement methodology, the tested TCP connection is clearly network limited. The outstanding data follows the $cwnd$ closely while the TCP efficiency $E$ is high which means no excessive packet loss inside the network. The buffer delay $T$ is also very high indicating that TCP connection is transmitting a lot of data to the network (see text in the relevant frame). The network capacity $C_{REF}$, measured with the UDP protocol immediately before starting the test transfers (in the same conditions that influenced maximum throughput achievable in the location during the experiment), is about 18 Mbps. Therefore, the TCP connection in this case utilizes almost 90% of available capacity (TCP throughput ratio $W$ is also high).

In the second experiment the socket buffer of the receiver was limited to about 60 KB. In this case the outstanding data follows the $awnd$ (see Fig. 8) indicating that the TCP connection is limited by the client.

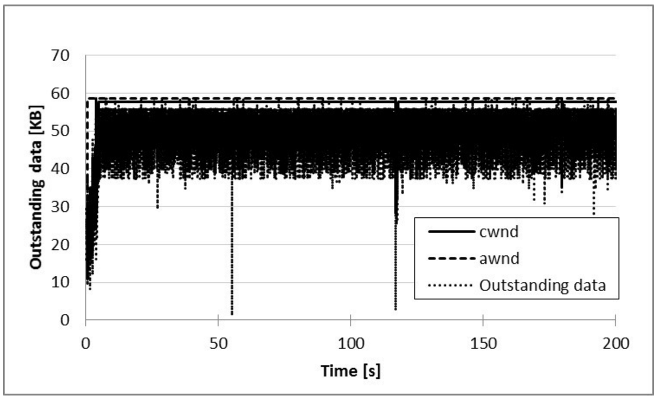

Fig. 8. Receiver limited TCP connection

This reasoning is also justified by low value of buffer delay $T$ which is now below 100%, meaning that TCP is not filling the network with data (see frame). The achieved TCP throughput is about 12.7 Mbps.

**Receiver limited TCP connection**
min rtt [ms] = 17.5
avg rtt [ms] = 32.4
avg out data [B] = 50956
avg awnd [B] = 58616
avg cwnd [B] = 57615
measured throughput [Mbps] = 12.7
outstanding data/rtt [kbps] = 12.5
fast retransmits = 5
RTO expirations = 0
TCP efficiency (E) [%] = 99.99
buffer delay (T) [%] = 85

## IV. Conclusions

The paper presents the methodology for identifying the root cause of the TCP connection performance bottlenecks. We have used the Linux kernel source code to implement the algorithm for estimation of the internal TCP connection state. Such approach allows to infer the dynamics of the TCP congestion window which is otherwise unavailable from passive TCP monitoring. The knowledge of the internal TCP state ($cwnd$, $ssthr$, RTO) is essential in understanding the observed behavior of the TCP connection and allows identifying the source of the TCP throughput limitations. In our approach it is used together with analysis of the TCP performance metrics proposed in RFC 6349. Such combined approach, complimented with additional active measurements (probing available capacity, measuring bottleneck buffers) can be helpful in tracing down network problems related to TCP-based applications.

*Abstract*—**The increasing diversity of end-devices used by users to access their applications and systems strengthens the need for device-independent methods for implementing these applications. The Device-Independent Architecture (DIA) is one of the available approaches to this problem, but it does not directly address the issue of user interface (UI) device-independency. This issue can be addressed by real-time UI adaptation, but it is not clear whether the DIA architecture requires new UI adaptation methods or may use existing ones. This paper presents results of our analysis of this issue. Through theoretical model-based analysis of UI adaptation in various application architectures and through case studies of practical UI adaptation solutions we came up with a conclusion that the DIA-based systems may use existing real-time UI adaptation methods. Although, they have to be used with a different set of optimization criteria.**

## I. Introduction

THE development of software applications that use end-devices to communicate and interact with users becomes a complex and time-consuming issue. The increasing diversity of Internet-connected end-devices (especially mobile devices) forces application developers to implement multiple variants of each application. Each software platform (Windows, Android, iOS, etc.) and each device type (smartphone, tablet, laptop, watch, glasses, smart TV, etc.) has its own requirements and constraints, which makes it difficult to address all of them with a single uniform implementation. Device-independency of the application logic and data is hindered by different programming languages and disparate APIs provided by different software platforms. Device-independency of the application user interface (UI) is even harder to address because of the number and diversity of possible input and output user communication channels – starting with screen sizes and resolutions and ending with non-standard symbolic interfaces popular in Internet of Things solutions.

To cope with this problem we have proposed the Device-Independent Architecture (DIA) [1] which solves the logic and data device-independence issues. However the DIA does not directly address the UI device-independence aspect, which is supposed to be solved with proper UI design [2], [3] and UI adaptation [4], [5].

To make sure the DIA does not hinder the ability to use UI adaptation to provide UI device-independence in the reported research we have sought to answer the following question: **Does DIA-based software may use existing real-time UI adaptation methods?**

To be able to properly analyze the problem we have defined a model of the run-time UI adaptation and generation process. We have used this model to theoretically examine the run-time UI adaptation and generation process in various software architectures similar to the DIA. Additionally we have performed a series of case studies of real implementations of UI adaptation methods to check if these practical solutions confirm our theoretical conclusions.

Our main findings are the following. Through our research we have shown that DIA-based software may use existing real-time UI adaptation methods designed for client-server systems. Moreover, we have learned that the main limiting factor for DIA-based implementations of these UI adaptation methods is not the performance of an end-device, but network latency and throughput. Therefore, to provide properly optimized UIs for DIA-based solutions, existing real-time UI-adaptation methods have to be used with a different set of key metrics and guidelines.

The paper is composed of five sections. Section I is the introduction. Sections II and III provide background information on the topics of UI adaptation and Device-Independent Architecture. Section IV contains the main discussion and overview of case studies. Finally, the paper is briefly concluded in Section V.

## II. UI adaptation

UI adaptation activities can be split into two phases: design-time UI adaptation and run-time UI adaptation. These two UI adaptation phases focus on different aspects that may influence the UI adaptation process. The whole process, with its various aspects, is best described by the CAMELEON Reference Framework [6], which provides designers and developers with generic principles for structuring and

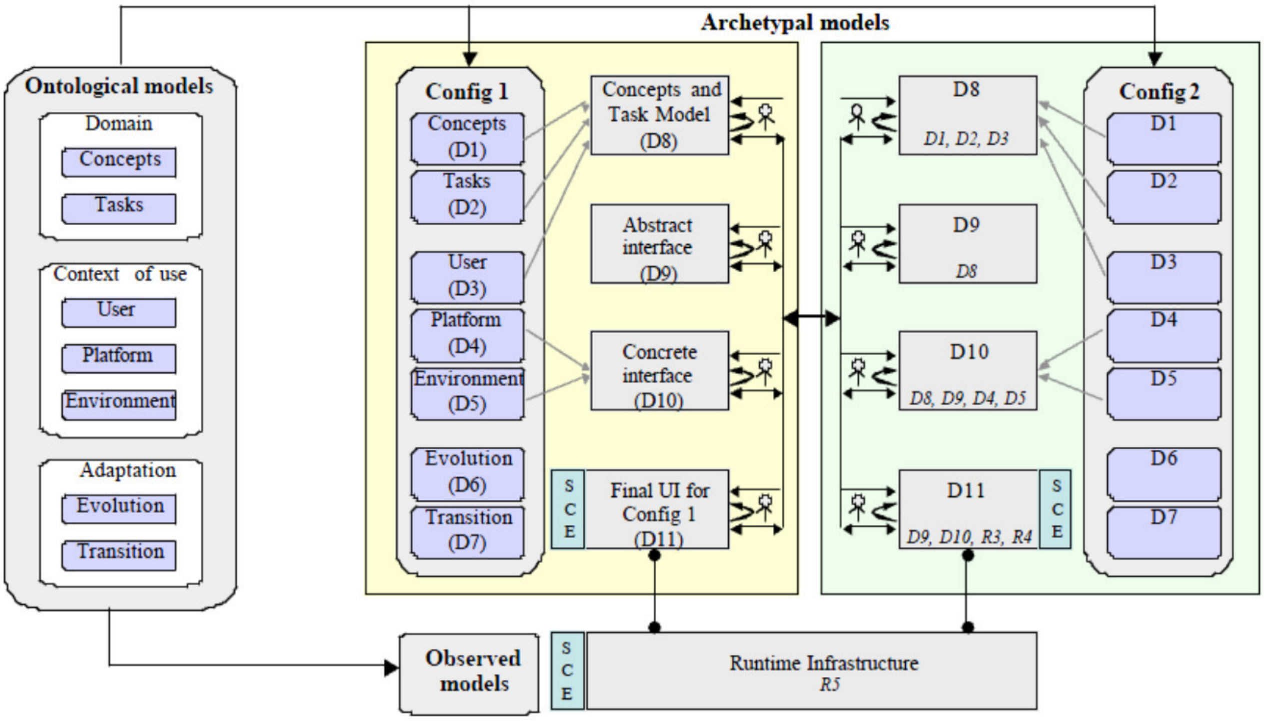

Fig. 1 CAMELEON Reference Framework

understanding a model-based UI development process. Model-based approaches [7], which rely on high-level specifications, provide the foundations for code generation and code abstraction. The framework fuses together different models that influence the overall UI adaptation. As shown in Figure 1, the framework covers the inference process from high-level abstract descriptions to run-time code, using a four-step reification process: from Concepts-and-Tasks Model (CTM), to Abstract User Interface (AUI), to Concrete User Interface (CUI), to Final User Interface (FUI). The CTM brings together concepts and tasks descriptions produced by designers for a particular interactive system and a particular target. The AUI is a universal description of the domain concepts and functions in a way that is independent of the UI implementation (in terms of UI widgets). At the CUI level the look and feel of a UI is defined, but the description is still device-independent. Finally, the FUI is expressed in a format suitable for a specific end-device and is tailored for this device. At each step the reification is influenced by the "context of use", defined as a set of parameters describing a user, a platform and the environment. Most of this process belongs to the design-time phase. The run-time phase includes the last reification from the CUI (device-independent) to the FUI (device-specific) and translations between FUI variants.

Both UI adaptation phases are different in nature. In our research on device-independent systems we do not address general UI design issues and we focus on the run-time UI adaptation phase, assuming that the design-time phase produces a device-independent UI description, which is used as a starting point for the run-time UI adaptation.

## III. Device-Independent Architecture

The Device-Independent Architecture (DIA) has been proposed to facilitate analysis and development of applications that can be made available to users via any capable device from the large, diverse and fast growing pool of Internet-enabled end-devices – i.e., devices that are used directly by users to interact with an application, but not sensors that passively record a state of an environment. As presented in [8], the idea of DIA originates from the Service-Oriented Architecture, where systems are decomposed into atomic services, and processes use such services without knowing much about their implementation. A similar approach can be used to decompose an end-device. Each end-device, be it a laptop or a smartphone, provides: resources, services, and user interaction channels. Resources encompass processing power, memory and storage. Services are providers of context information, such as location, temperature, light intensity, and data from other types of sensors. User interaction channels (both incoming and outgoing) are the means to communicate with a user and include: screen, vibration, keyboard, microphone, camera, etc. The key concept is to use external resources, instead of what is provided by an end-device, and to generalize the way services and user interaction channels are accessed. Therefore, in DIA, the separation of application from end-

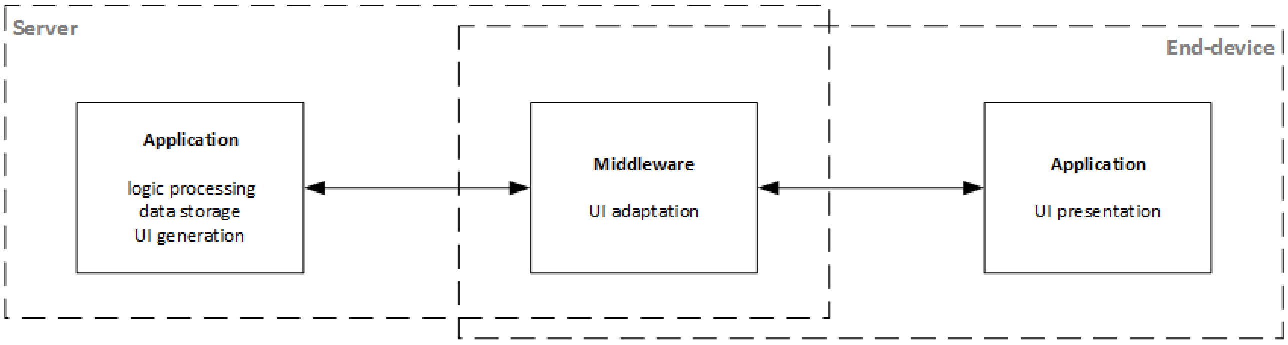

Fig. 2 Device-Independent Architecture diagram

devices, which enables the device independence, is achieved by:

- executing an application outside of end-devices,
- accessing sensor data provided by a device via a standardized API,
- using universal UI descriptions, and
- communicating with a user via a set of well-defined user interaction channels.

The execution of the application on external resources ensures that the application logic does not depend on the hardware or software platform of an end-device. The interesting consequence is that, in this architecture, end-devices could be deprived of their general purpose resources, as these resources are not needed. Services publish data in service-specific formats (e.g., location coordinates for a geolocation service, numerical data for a temperature sensor, and so on) independently of their implementation on a particular end-device. Therefore, it is feasible to build a middleware providing a device-independent API, such as the one proposed in Wolfram Language [9], to access such services. The usage of a universal UI description is a key requirement for making the UI of an application independent of parameters of user communication channels available on a given end-device (e.g. screen size and pixel density).

However, to enable a UI presentation tailored to parameters of a specific end-device, the generic UI description has to be properly adapted before reaching the user. That is why we have decided to research whether DIA-based software may use existing real-time UI adaptation methods.

## IV. Model and Analysis

Run-time UI adaptation is a process that transforms a high-level, device-independent UI description (often model-based) prepared at design-time into a final UI presentation. In ideal situations, the high-level UI description may be presented in different ways depending on the UI modality of available user communication channels. For example, presentation of the same UI could be done on screen (Graphical User Interface (GUI)) or via speakers (e.g. Voice User Interface (VUI)). In general, the execution of a run-time UI adaptation process requires three parameters: the UI description, the content and a context of use. The content is used to fill-in the UI. The context of use influences the UI adaptation process and allows tailoring the final UI to the user, her end-devices and situation (location, time, etc.).

### *A. Run-time UI adaptation model*

To be able to analyze the UI adaptation in different application architectures we have defined a simplified model of the UI adaptation and generation process. We call it the GARP model. The GARP model, presented in Figure 3, is composed of four main steps:

*Step 1: input gathering (G).* At the beginning of the process it is necessary to gather all input required for UI adaptation. The result of this step is a triplet of: UI

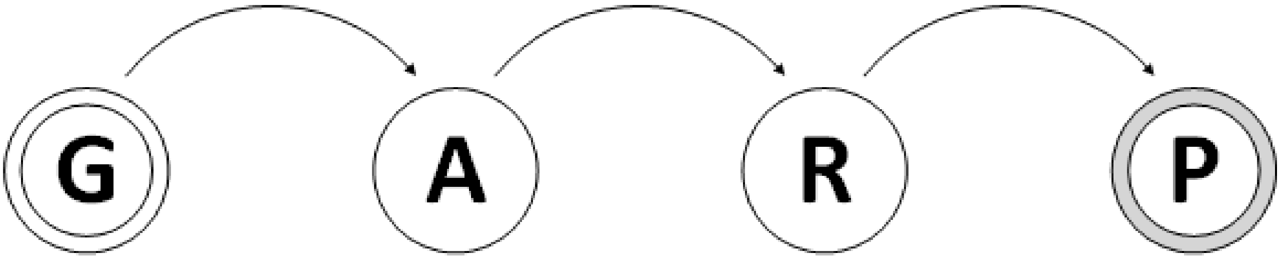

Fig. 3 Model of the UI adaptation and generation process

description, content and context.

*Step 2: adaptation (A).* In this step the content is used to fill-in the UI and the context is used to guide the transformation of the UI description into a final UI tailored for the user, her end-devices and situation. The result of this step is a device-specific UI description encoded with a specialized UI language such as HTML, QML, etc.

*Step 3: rendering (R).* The device-specific UI description provided by step 2 is interpreted here, in step 3 and the final UI presentation form is calculated. The final UI presentation form is data prepared for a specific user communication channel, e.g. pixels for screen or audio bits for speakers.

*Step 4: presentation (P).* The last step of the process is about presenting the UI to the user using a specific user communication channel of a specific end-device, e.g. showing images on screen or playing audio through speakers.

To make the analysis easier to follow, the model represents only the way towards a user and ignores the process of recording and interpreting user actions. Nevertheless, the path from a user can be modelled in a similar way, so our claims are valid for the whole user interaction loop.

For the analysis we have identified three classes of systems:

*Client-side adaptation systems* (CSA). Systems of this class include applications that are executed entirely on an end-device (a.k.a. local applications) and client-server applications with UI adaptation done on the client side.

*Server-side adaptation systems* (SSA). This class includes client-server applications with UI adaptation performed on the server side.

*DIA-based systems* (DIA), which include applications based on the Device-Independent Architecture.

Our goal is to see how the UI adaptation process differs among these classes of systems and how these differences influence the applicability of known UI adaptation methods. We acknowledge existence of in-between solutions. However, these three classes were selected to clearly show differences in the UI adaptation process.

### B. UI adaptation in CSA systems

The UI adaptation and generation process in CSA systems is done either entirely on an end-device (client side) or the G step is supported by the server side, which provides for example the content, UI description or user preferences. However, the fragment of the context gathering related to the end-device is local, so the G step can be seen as a task performed jointly by the server side and the client side. The way the G step is performed (locally or split between server and client sides) does not influence the actual UI adaptation, because from the point of view of the A step the results of the G step are always provided in the same way – locally.

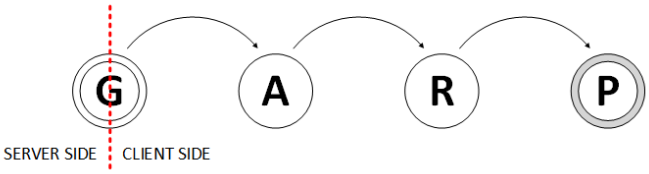

Fig. 4 GARP model in CSA systems

In CSA systems the A step may be implemented using existing UI adaptation methods designed for the use on an end-device. These methods are optimized for potentially limited processing capabilities of end-devices and are closely related to end-device characteristics and usage scenarios.

The local UI adaptation methods include solutions built-in into iOS and Android mobile operating systems and used by multiple mobile applications that run on various smartphones and tablets. On these mobile platforms the main issue is the diversity of screen sizes and pixel densities, so it is assumed that each application provides multiple variants of graphical assets (tailored to different screen densities) and some kind of a flexible layout that can be recalculated for any screen size. The drawback of these UI adaptation methods is that they are designed to cope with hardware parameters of a ‘standard device’ (in most cases a device with a touchscreen). Any UI adaptation that is supposed to take into account for example user preferences or non-standard devices, is not supported by the platform and has to be implemented manually.

The use of the server side for the G step usually does not change the fact that the adaptation implemented on the client side is somehow bound to the characteristic of an end-device. In our previous research [10] - [12] we have analyzed solutions that go beyond this local-only approach and use the server side to provide UI adaptation hints embedded in the high-level UI description provided by the G step, but even such extensions do not change the fact that the UI adaptation itself is device-specific, which makes it hard to reuse on other types of devices (devices with different hardware components, e.g. with two screens).

### C. UI adaptation in SSA systems

In SSA systems the two initial steps: G and A, are performed on the server side, and the two other steps: R and P, are performed on the client side. The server gathers all input data, runs the UI adaptation and sends the device-specific UI description to the client. The client then interprets the UI description and presents it to a user.

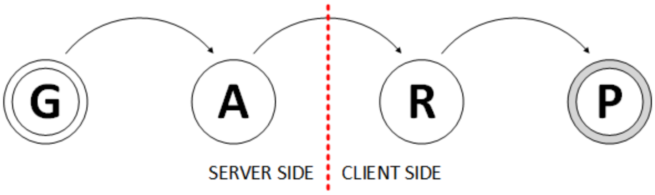

Fig. 5 GARP model in SSA systems

The SSA systems approach the issue of portability of the UI adaptation, shown for CSA systems, by implementing the A step on the server side. Such approach means that the UI adaptation is not bound by the performance of an end-device and can use external services to support the UI adaptation task (e.g. multimedia converters). Results of our previous research on UI adaptation in SSA systems [12] - [15] confirm that the A step in SSA systems may accommodate end-devices with disparate hardware configurations by using multiple or dynamic UI adaptation scenarios. However, the result of the A step is still interpreted on an end-device. Therefore is susceptible to differences in the final rendering and presentation on different end-devices. So full control of the resulting UI is not possible.

### *D. UI adaptation in DIA systems*

The Device-Independent Architecture is based on an assumption that the whole processing is done outside of an end-device (the client side) and the end-device receives a pre-rendered UI ready for presentation, without the need for any interpretation. So in the case of DIA systems all three initial steps of the GARP model are done on the server side and only the P step is performed on the client side. The data transferred between the server and the client is usually a stream (e.g. a video or audio stream) or a static UI state (e.g. an image of the UI to be presented on screen or audio file to be played through speakers) ready to be presented on an end-device.

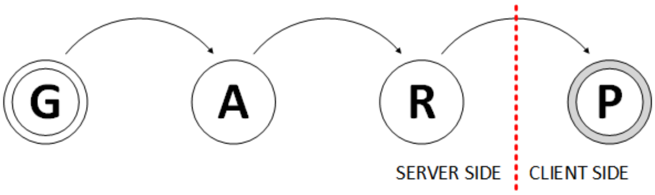

Fig. 6 GARP model in DIA systems

The DIA approach enables full control over the final UI presented to a user by implementing also the R step on the server side. UI adaptation methods used in DIA systems can be still the same as for SSA systems, but the fact that the end-device handles only the P step ensures that devices will not show a UI in a way that deviates from the designer intentions. The consequence of moving the R step to the server side is a different kind of data being transferred between the server side and the client side. In SSA systems, the client side receives a device-specific UI description encoded in a specialized UI language. In DIA systems, the server side has to send either a continuous stream of data tailored for specific user communication channels (e.g. video stream for a screen or an audio stream for speakers) or a static UI state composed of multiple files that are targeted at different user communication channels (e.g. image files to be shown on a screen or audio files to be played through speakers). The main difference here is the increased size of data that has to be transferred. More data to transfer could mean longer response times, but our previous research [16] showed that in analyzed scenarios DIA-based systems can still maintain proper response times to UI interactions initiated by a user, despite the increased size of transferred data.

## V. CONCLUSION

The Device-Independent Architecture can be treated as a special case of a client-server architecture, in which the client side is assumed to be an extremely thin client and in which all the processing is done on the server side. The DIA takes it even further and defines the client side as a set of user communication channels, which makes it possible to model multiple end-devices as a complex client device, but this distinction does not necessarily change the way the UI adaptation is performed. Therefore, DIA systems may use the same existing UI adaptation methods that were designed for SSA systems, or for client-server systems in general.

The main difference is related to the fact that in DIA systems the data transferred between the server side and the client side tends to be larger than in the case of SSA systems. Therefore, network usage optimization is crucial. Especially that the transmission delay will directly influence the UI responsiveness. Moreover, used communication protocols and formats of presentation data sent to an end-device have to be negotiated beforehand, to make sure that the end-device is able to receive and present it properly.

Summarizing, despite using a different implementation of the GARP model, the DIA systems may use existing real-time UI adaptation methods. The difference in the implementation of GARP model influences only the optimization of the UI adaptation and generation process. In CSA systems the key optimization aspect is end-device performance. In SSA systems the key optimization aspect is uniform interpretation of the device-specific UI description. While, in DIA systems the key optimization aspects are network-related. First, it is necessary to use data formats that minimize the amount of bits that have to be transmitted. Second, it is crucial to use the best possible data transfer protocols. The best are the ones with low overhead, low latency and support for QoS. Both points should be taken into account by the run-time UI adaptation task, because the nature of a UI (state-based or continuous) may influence the set of suitable transmission protocols.

We expect that different protocols will be best suited for different user interaction scenarios. Our next research goal in this area is be to identify user interaction patterns and UI design patterns, which could be used to define rules for selecting the best protocol and data formats for a given user interaction scenario.

***Abstract*****—** In this paper, the problem of determining the most effective server placement in the hypercube network structure was considered. The algorithm consisting of two stages: first stage for the server placement and the second for generating the appropriate communication structure was described. The correctness of the algorithm has been verified through simulation tests, prepared and implemented in Riverbed Modeler environment. The results of these tests for exemplary structures were presented. Some properties of the server placement in the 4-dimensional hypercube network with soft degradation were investigated.

## I. Introduction

The computer networks with a regular structure as torus or hypercube ([1]–[4]) could be used in many kinds of specialized critical application (for instance military, aerospace or medical systems). An interconnection network with the hypercube logical structure is a well-known interconnection model for multiprocessor systems ([5]–[6]) and still hypercube networks are the field of interest of many theoretical studies concerning (among others) resource placement problem, which has been intensively studied in [7]–[12].

Specialized systems with critical application are usually used in real-time mode and required both very high reliability and high efficiency of data processing throughout all the network life cycle. In order to achieve high reliability of the system the network could be considered as soft degradable computer network [12]–[13]. In this kind of networks a processor identified as faulty is not repaired (or replaced) but access to it is blocked. New (degraded) network continues work after resources reassigning and under the condition that it meets special requirements. In turn, the efficiency of the system will depend heavily on the availability of resources (data bases, files or web data), which is determined by their placement in the network. So, for this kind of networks there is necessity for applying effective methods of resources placement. In the work [12] an analysis of the different schemas of resources placement in the 4-dimensional hypercube network with soft degradation was conducted.

Designing and exploitation of special networks in critical application is a comprehensive task that requires addressing a number of theoretical and practical problems. One of the problems is a skillful resources deployment in the network and modification of resources deployment after each phase of the network degradation. One of considered in the literature the resource placement problem is a combination the distance-$d$ and the $m$ adjacency problems, where a non-resource node must be a distance of at most $d$ from $m$ processors nodes [7]-[10], [12]. In [10] a perfect deployment has been introduced and analyzed which is defined as the minimum number of resources processors which are accessible by working processors. The definition - perfect deployment is a characteristic of the value of the generalized cost of information traffic in the network at a given load of tasks. In [12] the notion of $(m,d)$-perfect resources placement in the hypercube type structure $G$ has been extended to the such allocation of $k$ resources which minimizes the average distances between the working processors and resource processors in the structure $G$.

We investigate the case when a specialized computer system is based on the 4-dimensional hypercube skeleton network with communication nodes which could communicate between themselves via cable connections. The main task of the hypercube network is to provide efficient access to resources managed by the server (or cluster of servers) connected directly to one of the network nodes and semi-stationary clients communicating with the assigned network nodes via wireless links. The execution of applications by a client processor requires an access to server services and resources, also some results returned by the server must be submitted to other clients. We assume that all clients are responsible for performing the same or very similar tasks. Thus all clients will generate similar workload of the network. The problem which arises for the given network structure is to determine the most effective server placement in the network structure.

The main goal of this paper is to give an effective method of solving the server placement problem for the hypercube network along with its soft degradation process.

978-83-60810-66-8/$25.00©2015, IEEE

A generalized cost of a network traffic with a specified resources deployment and workload of a network is usually tested through experimental measurements or examined with the use of simulation methods. In the paper we apply a two phased approach. In the first stage we solve the problem of a server placement in the given network structure on the base of analytically determined attainability measure, which was proposed in [12]. It should be noticed that real cost of information traffic in a network for a given deployment of the server with resources depends on the nature of the tasks performed by clients in the network. In the second stage we have examined this problem with the use of simulation methods for the specified server deployment determined by the simple analytical method and given type of task load of the network.

We see our contributions as follows. Firstly, we have extended the approach proposed in [12] to the determining server placement in the hypercube network with soft degradation on the base of nodes attainability calculation. Secondly, we propose the algorithm of the communication structure assignation with the use of dendrite calculation. Next, we show the feasibility of this approach by applying obtained results to some possible structures of degraded 4-dimensional hypercube network and verifying effectiveness of server placement by simulation experiments.

The rest of the paper is organized as follows. In Section II, a basic definitions and properties were introduced. The calculation of radius and attainability for exemplary structures were presented. In Section III, the proposal of the algorithm determining server placement was presented. An illustration of the main algorithm steps for the exemplary structure was given. In Section IV, the results of simulation tests for verification the algorithm (implemented in Riverbed Modeler environment) were described. In Section V, some concluding remarks were presented.

## II. BASIC DEFINITIONS AND ASSUMPTIONS

**Definition 1.** The logical structure of processors network we call the structure of $n$-dimensional cube if is described by coherent ordinary graph $G = \langle E, U \rangle$ ($E$ – set of computer, $U$ – set of bidirectional data transmission links), which nodes can be described (without repetitions) by $n$-dimensional binary vectors (labels) in such a way that

$$[\delta(\varepsilon(e'), \varepsilon(e'')) = 1] \Leftrightarrow [(e', e'') \in U] \qquad (1)$$

where $\delta(\varepsilon(e'), \varepsilon(e''))$ is Hamming distance between the labels of nodes $e'$ and $e''$.

The Hamming distance between two binary vectors ε(e') and ε(e'') complies with the dependency:

$$\delta(\varepsilon(e'), \varepsilon(e'')) = \sum_{k\in\{1,\dots,n\}} (\varepsilon(e')_k \oplus \varepsilon(e'')_k)$$

where:

- $\varepsilon(e')_k$ – the $k$-th element of the binary vector ε(e'),
- $\oplus$ – modulo 2 sum.

We investigate the case when skeleton of the network has the logical structure of 4-dimensional hypercube (Fig. 1). A topology of the hypercube may be represented by an ordinary consistent graph whose nodes are described by 4-dimensional binary vectors such that the Hamming distance between vectors (labels) of the adjacent nodes equals one. If $|E| = 2^4$ and $|U| = 2|E|$, then such graph we called (non labeled) 4-dimensional cube and will be denote by $H^4$. Thus $H^4$ is a regular graph of degree of 4 i.e. such that the degree of a node $e \in E$ we determine as $\mu(e) = |E(e)|$, where $E(e)$ is a set of nodes adjacent to the node $e \in E$ and $\mu(e) = 4$ for each node $e$ of the graph $H^4$.

Let $d(e, e'|G)$ be the distance between nodes $e$ and $e'$ in a coherent graph G, that is the length of the shortest chain (in the graph $G$) connecting node $e$ with the node $e'$.

Let $r(e|G) = \max_{e'\in E(G)} d((e, e')|G)$ be the greatest distance from the node $e \in E(G)$ to another node of the set $E(G)$, and $r(G)$, and $D(G)$ (respectively) denote the radius and the diameter of a graph $G$ i.e. $r(G) = min\{r(e|G): e \in E(G)\}$ and $D(G) = max\{d(e', e''|G): \{e', e''\} \subset E(G)\}$.

**Property 1.** For the 4-dimensional cube $H^4$ the equation is complied

$$D(H^4) = r(H^4) = 4.$$

It is known that $D(G) \leq 2r(G)$.

If $r(e|G) = r(G)$ then the node $e$ is called the central node of the network $G$.

Denote by $E^{(d)}(e|G) = \{e' \in E(G): d(e, e'|G) = d\}$ for $d \in \{1, \dots, D(G)\}$, and by

$$\varsigma(e|G) = \left(\varsigma_1(e|G), \dots, \varsigma_{r(e|G)}(e|G)\right) \text{ for}$$

$$\varsigma_d(e|G) = \left|E^{(d)}(e|G)\right| \qquad (2)$$

**Definition 2.** Let $\varphi(e|G) = \sum_{e'\in E(G)} d(e, e'|G)\ \left(e \in E(G)\right)$ be attainability of the computer $e$ in the network $G$ and by $\Phi(G) = \sum_{e\in E(G)} \varphi(e|G)$ attainability of the network $G$.

Using (2) we have

$$\varphi(e|G) = \sum_{d=1}^{r(e|G)} d\varsigma_d(e|G) \qquad (3)$$

**Property 2.** $\Phi(H^4) = 512$ because $\forall_{e\in E(H^4)}: \left(r(e|H^4) = 4 \wedge \varsigma_d(e|H^4) = \binom{4}{d}\right)$. Using (3) we have $\forall_{e\in E(H^4)}: \varphi(e|H^4) = 32$ and $|E(H^4)| = 2^4$, then $\Phi(H^4) = |E(H^4)|\ \varphi(e|H^4)$ [12].

**Example 1.** Figure 1 presents all the seven possible cyclic structures upon the occurrence of $k = 7$ consecutive failures of processors of the network $H^4$ which are the subgraphs of $H^4$ [13].

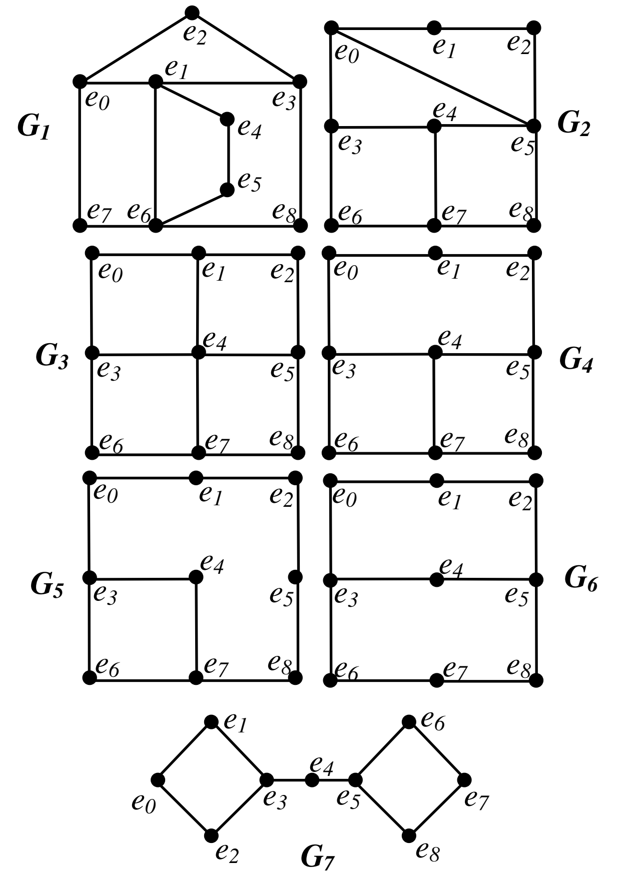

Fig. 1 Example of cyclic subgraphs of $H^4$ order 9 [13]

TABLE I.
THE $r(e|G), r(G)$ AND $D(G)$ FOR THE STRUCTURES PRESENTED ON THE FIGURE 1

| $r(e\|G_i)$ / $e \in E(G)$ | $r(e\|G_1)$ | $r(e\|G_2)$ | $r(e\|G_3)$ | $r(e\|G_4)$ | $r(e\|G_5)$ | $r(e\|G_6)$ | $r(e\|G_7)$ |
|---|---|---|---|---|---|---|---|
| $e_0$ | 3 | 3 | 4 | 4 | 4 | 4 | 6 |
| $e_1$ | 2 | 4 | 3 | 4 | 4 | 4 | 5 |
| $e_2$ | 4 | 4 | 4 | 4 | 4 | 4 | 5 |
| $e_3$ | 3 | 3 | 3 | 3 | 4 | 3 | 4 |
| $e_4$ | 3 | 3 | 2 | 3 | 4 | 3 | 3 |
| $e_5$ | 4 | 3 | 3 | 3 | 4 | 3 | 4 |
| $e_6$ | 3 | 4 | 4 | 4 | 4 | 4 | 5 |
| $e_7$ | 3 | 4 | 3 | 4 | 4 | 4 | 6 |
| $e_8$ | 3 | 3 | 4 | 4 | 4 | 4 | 5 |
| $r(G)$ | 2 | 3 | 2 | 3 | 4 | 3 | 3 |
| $D(G)$ | 4 | 4 | 4 | 4 | 4 | 4 | 6 |

It should be noticed, that for the given network structure $G$ on the base of the obtained measures $r(e|G)$ it would be rational to choose the server placement at the central node of the network or in the node with the minimum value $r(e|G)$. In some cases (let's consider the structures $G_2, G_4, G_5, G_6$) we are not able to choose the best server placement. Then we can have determined $\varsigma(e|G)$ using (2) and $\varphi(e|G)$ using (3) for these structures. The determined values of $\varsigma(e|G)$, $\varphi(e|G)$ and $\Phi(G)$ are presented in table II.

**Definition 3.** Let $T = \langle E, U^* \rangle$ be the dendrite i.e. such coherent acyclic partial graph of $G$ that:

$$\exists \langle e', e'' \rangle \in U \Rightarrow \langle e', e'' \rangle \in U^* \Leftrightarrow$$
$$\left[ \left( d(e_i, e') \neq d(e_i, e'') \right) \wedge d(e', e'') = 1 \right] \text{for } r(e_i) = \underset{e \in E(G)}{min} r(e).$$

The dendrite $T$ is a communication structure of $G$. The method for determined the dendrite $T$ is presented in section III.

## III. THE METHOD AND THE ALGORITHM FOR DETERMINING A SERVER PLACEMENT AND COMMUNICATION STRUCTURE

The method consists two stages. In the first stage for $G$, as the first node we choose a node that $r(e_i) = \underset{e \in E(G)}{min} r(e)$ or $\varphi(e_i|G) = \underset{e \in E(G)}{min} \varphi(e|G)$ – *server placement*. In the second stage for the chosen node we determine the dendrite $T$, which is a communication structure satisfying the condition $d_{max}(e_i|T) = r(e_i)$. Based on the presented method the algorithm for determining *the server placement* and the communication structure was developed**.**

*The algorithm for determining the server placement and communication structure.*

**Step 1.**

Determine $r(e|G)$ for $e \in E(G)$.

**Step 2.**

Choose a node $e_i \in E(G)$ such that $r(e_i) = \underset{e \in E(G)}{min} r(e)$. If $|\{e_i\}| > 1$ go to step 3 else go to step 5.

**Step 3.**
Determine $\varphi(e|G)$ for $e \in E(G)$.

**Step 4.**
Choose a node $e_i \in E(G)$ such that $\left(\varphi(e_i|G) = \min_{e\in E(G)} \varphi(e|G)\right) \wedge \left(\mu(e_i) = \max_{e\in E(G)} \mu(e)\right)$.
Selected node $e_i$ will be a central node of dendrite.

**Step 5.** *(second stage)*
Set $k = 1$ and $(E(T) = E^0(e_i|G) = \{e_i\})$.

**Step 6.**
$E(T) = E(T) + E^k(e_i|G)$.
$U^* = U^* \bigcup_{(e' \in E^{k-1}(e_i|G)) \wedge (e'' \in E^k(e_i|G))} \langle e', e'' \rangle$.

**Step 7.**
$k = k + 1$.
Check if $k > r(e_i)$.
YES
  Go to step 8.
NO
  Return to step 6.

**Step 8.**
The end of the algorithm.

Figure 2 is an illustration of the algorithm. In the first stage of the algorithm (steps 1-4) the central node $e_1$ for the structure $G_1$ (figure 1) was appointed. In the table III the results of determining radius (A) and attainability (B) of $G_1$ nodes are presented. Determination of the attainability of $G_1$ nodes is unnecessary, and should be used only if the steps 1-2 of the algorithm will not allow unambiguous to determine the central node for given structure $G$.

Dendrite $T$ determined in the second stage of the algorithm for the central node $e_1$, is one of the possible (but optimal ) communication structure.

TABLE III
THE RESULTS OF DETERMINING THE RADIUS (A), AND THE ATTAINABILITY (B) OF THE $G_1$ NODES

A

| $r(e\|G_1)$ / $e \in E(G_1)$ | $r(e\|G_1)$ |
|---|---|

## IV. THE RESULTS OF SIMULATION STUDIES

Procedure for determining the best location of resources in the hypercube network specified in the section III has been verified through simulation tests. The aim of the test was to confirm the correctness of the theoretical considerations and arguments.

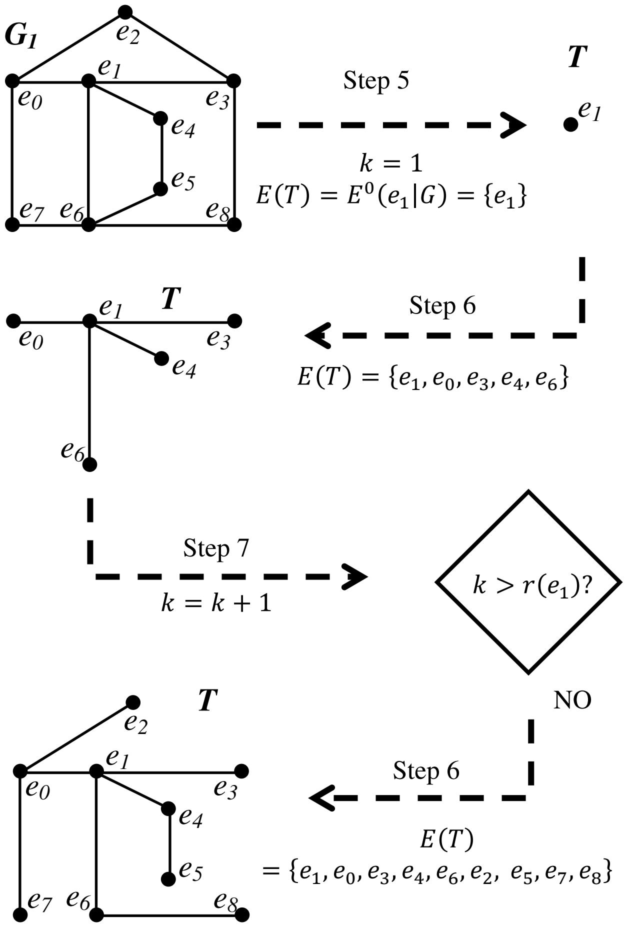

Fig. 2 An illustration of the algorithm steps

Simulation studies have been prepared and implemented in Riverbed Modeler environment. Subgraph $G_1$ (figure 1) has been the subject of research.

Nodes have been modeled as routers and LAN segments attached to them. The cases when the server (with different typical and popular network services, chosen arbitrarily by authors) is connected to the selected node within $T$ set of $G_1$ structure were examined. In the figure 3 different $T$ set of substructures (communication structures) correspond to different simulation scenarios is shown. The circle indicates node which the server is connected to.

For example, the network topology of the single scenario with $T$'s dendrite 1 was shown in the figure 4.

The name of the simulation scenario (*Dend_1* in figure 4) was associated with the node's number, which the server was connected to (number of the dendrite's central node).

The server was acting as a database server, ftp server, web server, and the node with which it was possible to communicate through VoIP (*Voice over IP*). Workstations within LAN segments (ten workstations in each segment) were functioning as the server's clients. All network services have used the standard application models, available at Riverbed Modeler ("High Load" ftp and database models, "Heavy Browsing" http model and "PCM Quality Speech" voice model) [15].

The communication structure (skeleton of the network) was modeled as a set of routers connected via 1,5 Mb/s links.

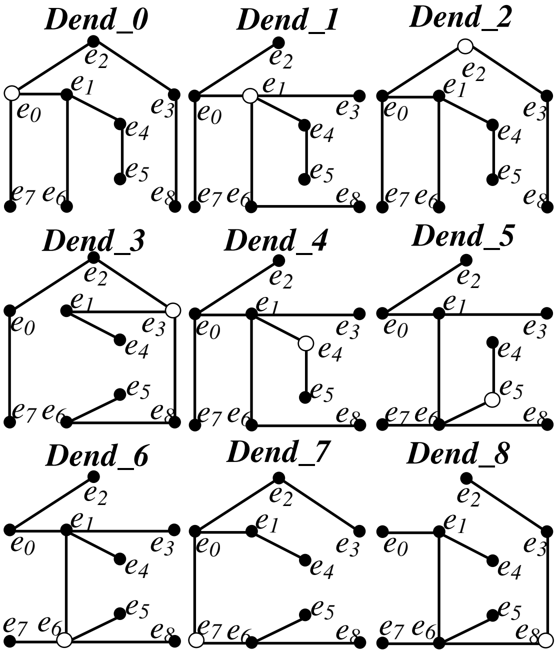

Fig. 3 The $T$ of dendrites of $G_1$

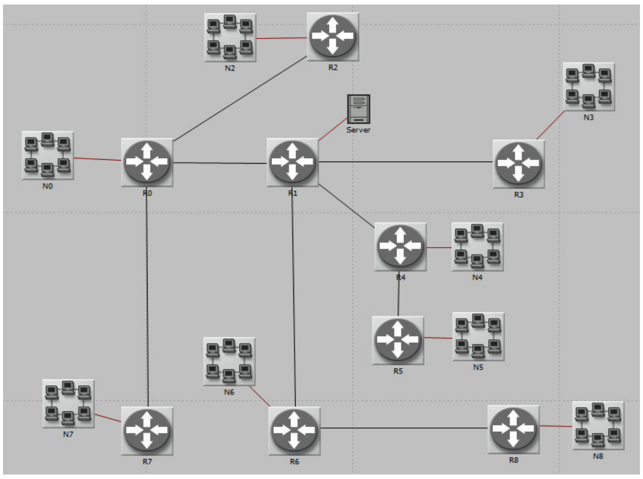

Fig. 4 Network topology of *Dend_1* scenario

Some interesting results, confirming the correctness of the procedure for determining the server placement and communication structure, are shown in the figures below. The dotted lines (e.g. Fig. 5) corresponds to the results obtained for the structure *Dend_1*, which is, according to the procedure, the most effective (the best) communication structure for subgraph $G_1$.

For each simulation scenarios (*Dend_0* to *Dend_8*) five characteristics were determined.

### A. End-to-end delay (EE_Del)

End-to-end delay is average delay in seconds for all LAN segments nodes communicating with the server through VoIP. The lowest value of *EE_Del* is desired (it is the best score).

Results obtained during the simulation are presented in the figure 5. The figure 6 shows the average values of *EE_Del*.

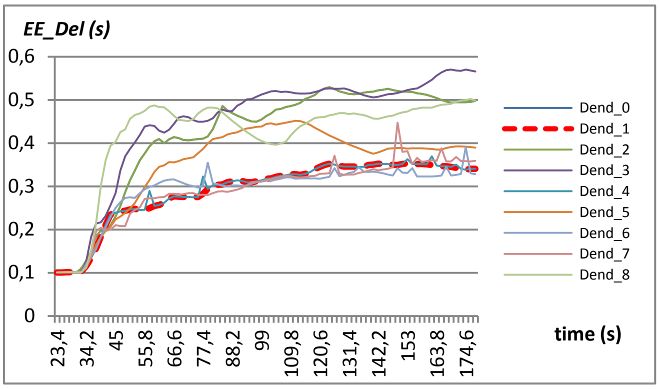

Fig. 5 *End-to-end delay* for VoIP transmission

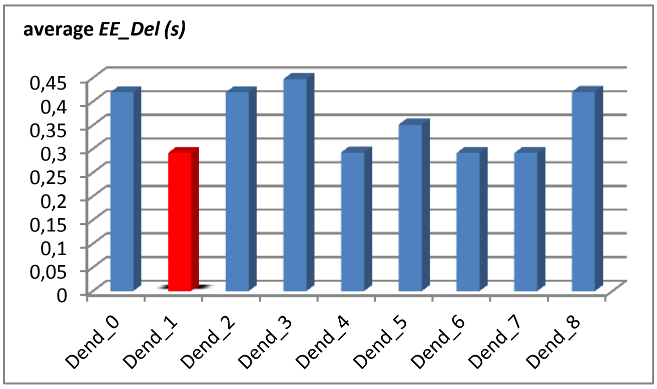

Fig. 6 Average *End-to-end delay* for *Dend_0* to *Dend_8* structures

### B. TCP Delay (TCP_Del)

TCP_del represents delay of TCP packets in seconds. This value is measured from the time an application data packet is sent from the source TCP layer to the time it is completely received by the TCP layer in the destination node. It is average delay in the complete network, for all connections. The lowest values are the best.

The results are presented in figures 7 and 8.

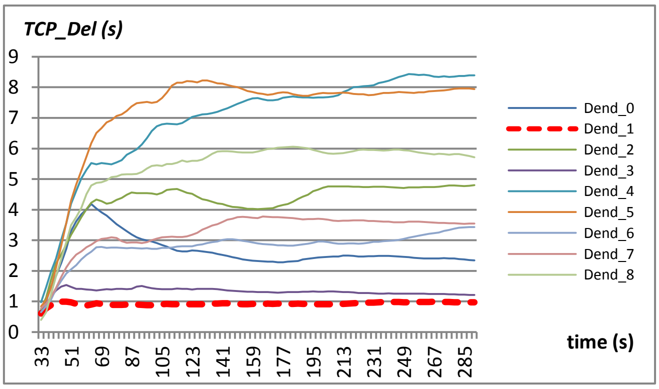

Fig. 7 *TCP delay* for TCP-based services

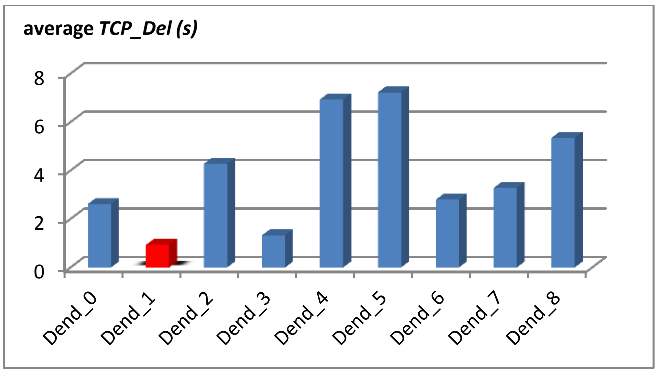

Fig. 8 Average *TCP delay* for TCP-based services

### C. Number of Hops (Nr_Hops)

*Nr_Hops* represents an average number of IP hops taken by data packets reaching at a destination node.

We expected the lowest value for *Dend_1* structure and results are presented in the figure 9.

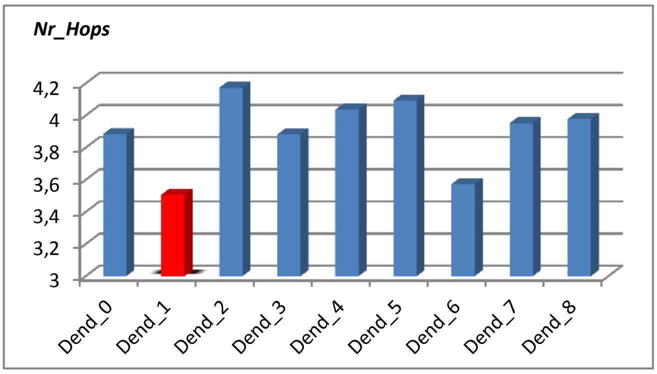

Fig. 9 Average *Number of Hops* for *Dend_0* to *Dend_8* structures

### D. Response Time (Res_Time)

Res_Time is average time elapsed between sending a request and receiving the response packet in seconds. It was measured for all the server's services (database, WWW and FTP).

The selected graph, *Response Time* for the database service was presented in the figure 10.

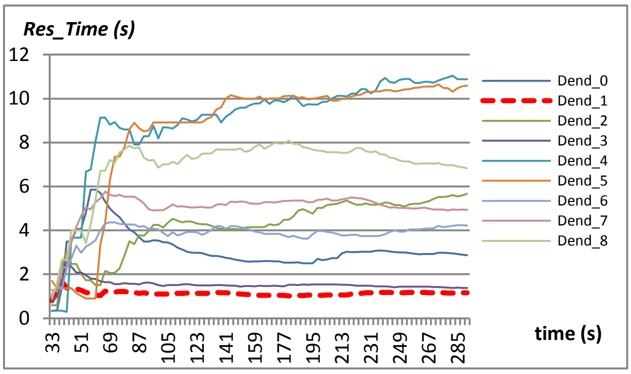

Fig. 10 *Response Time* for database service

Average values of the database server's response time for each simulation scenario are shown in the figure 11.

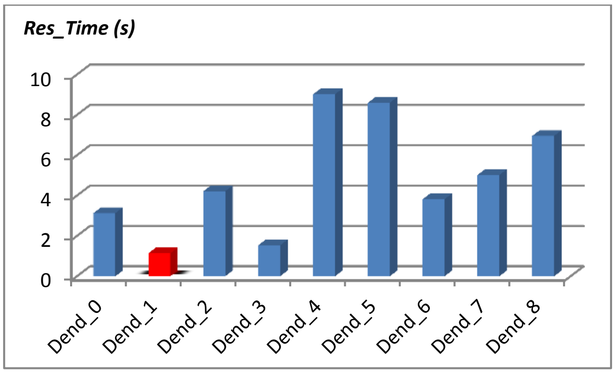

Fig. 11 Average *Response Time* for database service for all $G_1$'s dendrites

### E. Traffic Received (Traf_Rec)

*Traf_Rec* is an average number of bytes per second forwarded to server's application by the transport layer in the complete network. It was measured for all the server's service and treated as a transmission speed indicator, so we expected highest values for the best communication structure (*Dend_0* in the drawings of the selected service – Fig.12 and Fig.13).

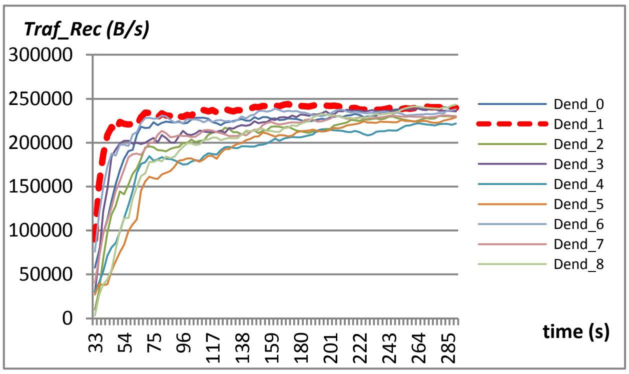

Fig. 12 *Traffic Received* for the FTP server

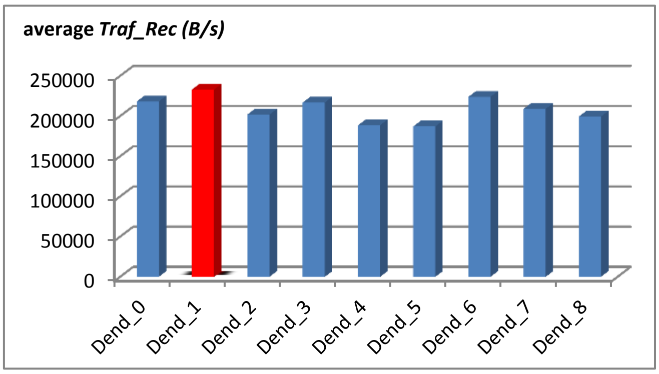

Fig. 13 Average FTP *Traffic Received* for all $G_1$'s dendrites

All the results are presented in Table III. It should be noted that the best result was reported in most measurements for *Dend_1* structure (winning factor - 78%).

TABLE IV
THE SIMULATION RESULTS FOR DENDRITES OF G 1 STRUCTURE

## V. CONCLUSION

Correctness of developed algorithm and its usefulness for determining server placement and the optimal communication structure in the hypercube network with soft degradation on the base of nodes attainability calculation was confirmed by simulation tests. Although the simulation tests conducted mainly related to typical network services that results could be transferred to the network-critical applications. One of tested services which might be regarded as the critical application was capability of communicating through VoIP (Voice over IP). Obviously different system parameters aren't equally important and their importance depends on the application type. In the paper the influence of the network communication structure for obtained values of exemplary parameters was investigated.

Further work will address adaptation of the algorithm for various types of network structures. Work will focus on networks with dynamic structure reconfiguration.

*Abstract*— **This paper presents an innovative real-time information system for enhanced support to flood risk emergency in urban and nearby coastal areas, targeting multiple users with distinct access privileges. The platform addresses several user requirements such as 1) fast, online access to relevant georeferenced information from wireless sensors, high-resolution forecasts and comprehensive risk analysis; and, 2) the ability for a two-way interaction with civil protection agents in the field. The platform adapts automatically and transparently to any device with data connection. Given its specific purpose, both data protection and tailored-to-purpose products are accounted for through user specific access roles. This paper presents the platform's overall architecture and the technologies adopted for server-side, focusing on communication with the front-end and with the wireless sensor network, and the user interface development, using state-of-the-art frameworks for cross-platform standardized development. The advantages of the adopted solution are demonstrated for the Tagus estuary inundation information system.**

## I. Introduction and Motivation

NATURAL and hydraulic structures related floods are severe threats to life and property. The main goal of flood risk management in aquatic environments is to reduce human losses and the damages related to floods, and should be supported by adequate hazard monitoring and timely early warning of the events.

Some of the world's most densely populated cities are located in estuarine low-lying areas facing thus a high risk of inundation with a potential for significant economic costs and the loss of lives. These areas are highly vulnerable due to the growing human activity in their margins. Simultaneously, the hazards in these environments are severe due to the combined effects of oceanic, atmospheric and river forcings. Furthermore, they are increasing due to the effects of climate change, such as sea level rise, growing storminess and more extreme river flows. Floods in estuaries are associated to particular climatological conditions, namely very high tidal levels and large fresh-water discharges, or of high tides and storm surge conditions [1]. In addition to these progressive, slow phenomena, that are possible to predict a few days in advance, episodes of very intense and concentrated in time rainfall can lead to urban flooding in areas with insufficient drainage conditions and flash floods in small watershed tributaries to the estuary [2]. The effects of high water levels in estuaries can also be exacerbated by human interventions in the system, particularly in urban areas where drainage system behavior has to be considered.

Recently, the processes of prediction, detection, notification and population warning are becoming increasingly assured by automated systems, such as SAGE-B [3]. These information systems can be valuable assets for risk management, supporting all fundamental data related to flood events and the emergency elements needed for rescue in the predicted flooded areas. Unfortunately, most flood management systems still suffer from significant functional limitations, due to the difficulties in the access to monitoring data and unreliable, scattered, multiple sources of information, the use of inadequate flood forecasting due to inaccurate modeling tools, that either neglect relevant processes or are coarsely applied to the site at risk, and insufficient sharing of information across multiple emergency actors [4].

With the recent use of reliable automatic data acquisition systems and highly efficient and accurate numerical models, the most important constraints for the operational use of real-time information systems have been minimized, allowing for adequate forecasting of relevant events [5], [6]. The integration of these tools into interactive and flexible computational GIS-based platforms has paved the way to a change of paradigm in routine and emergency management of coastal resources and harbor operations [7], [8]. These platforms take advantage of novel technologies to provide on-line, intuitive and geographically-referenced access to real-time data and model predictions, and to produce on-demand services. However, much remains to be done on the interoperability between data providers and data consumers,

This work was funded by the Portuguese National Foundation for Science and Technology through project MOLINES (PTDC/AAG-MAA/2811/2012)

978-83-60810-66-8/$25.00©2015, IEEE

cross-platform and multiple users' flexibility and speed of access to data.

The project MOLINES (*Modelling floods in estuaries. From the hazard to the critical management*) aims at integrating existing and new wireless sensor networks, accurate model forecasts at both urban and estuarine scales and IT technology to create a Web platform that can contribute to a fast, coordinated mobilization of emergency agents and other managing entities for a timely response to inundation events in the Tagus estuary. The proposed platform is generic, interactive, facilitating the coordination between emergency agents and the individual contribution of civil protection agents in the field, and can be deployed elsewhere. It aims at contributing to a coordinated strategic planning and emergency response in urban and nearby estuarine regions, optimizing the alert to authorities, duly supported by real time monitoring and predictions of inundation.

This paper describes the platform, its architecture, and all innovative aspects related to the UI, product creation and choice of technologies. Besides this introduction, chapter 2 provides a background on IT technologies and platforms for real time information access, identifying the key aspects to be addressed. Chapter 3 presents the concept and implementation of the solution, focusing on requirements and technology choices. The application to the MOLINES case study is briefly presented in Chapter 4, and Chapter 5 closes the paper with some considerations for future work.

## II. Background

Technology is dramatically changing our ability to prepare for and respond to extreme events, facilitating the management of crisis incidents [9]. Information systems and technologies contribute to a better communication and action in complex systems, by helping in disaster response and in collecting information, analyzing it, sharing it, and timely disseminating it to the people at risk. In particular, timely information sharing amongst emergency actors is critical in emergency response operations [10]. Several research projects have been devoted to emergency and disasters management to create modelling and simulation techniques and tools for the emergency management. Relevant examples are the dynamic and adaptive models for operational risk management [11], [12].

Information technology is enhancing disaster management and communications through tools such as computer networks, virtual reality, remote sensing, GIS, and decision support systems. During the mitigation and preparation phases of an emergency the use of satellite communications and spatial analysis systems can be extremely valuable [13]. In recent years, many web-based emergency response systems have been developed and several studies shown the great complexities surrounding the design of this kind of systems [14]. Often, developments in other areas are overlooked and resources are spent looking for a solution that has been already implemented and proved in other environments. An example of an IT system to manage emergency situations is the Global Disaster Information Network (GDIN www.state.gov/www/issues/ relief/gdin.html). More elaborated examples with complex architectures, integrating geographic information systems, spatial databases and the internet are described in [15] and [16]. In [17] a WebGIS is presented addressing risk management related issues, providing authenticated users access to queryable information, depending on their authorization level. Hence, they achieve the goal of having a platform accessible anywhere with an internet connection, and multiple levels of access to different hierarchic roles. This is a similar approach to the one presented herein, except an existing tool has been adapted to the use-case, when compared with a tailored-made solution.

Building on these experiences and in the scope of several projects (INTERREG SPRES; FP7 Prepared), LNEC has been developing and applying a suite of Web platforms denoted as WIFF - Water Information Forecast Framework [7] to provide access to real time information to decision makers. These platforms were conceived for a single type of users and to provide full access to real time sensor data and model predictions, constituting at the same time a repository of past information, being available at each deployment site to the relevant end-users. For the SPRES platform, real time products were integrated with emergency planning information (hazard, vulnerability and risk maps as well as mitigation action sheets) to constitute a one-stop-shop for all data relevant to oil spill prevention and mitigation [7].

These platforms take advantage of novel technologies to provide on-line, intuitive and geographically-referenced access to real-time data and model predictions, and to produce on-demand services in support of routine management of coastal resources and harbor operations. Technology support include a) Drupal, a PHP-based Content Management System, to access model metadata, status and products, b) map server support (Geoserver) providing Web Map Services (WMS) to allow for geospatial placement of monitoring and forecast products, and model output query capabilities, and c) Flex, using the OpenScales library to handle geospatial information, for the WebGIS development.

However, the need for interaction between the multiple emergency actors and to have fast access to real time information (of both conventional data streams and on-the-fly in-the-field information during flood emergencies) from several users simultaneously, raises new requirements for these new platforms. Additionally, the new system should be cross-platform, i.e., to be built in a way that it is automatically and transparently adaptable to any device with a data connection, providing access to emergency information anywhere.

## III. Concept and implementation of the solution

The main goal for the platform described herein, is to provide a quick and responsive tool for flood risk forecast and assessment. End-users should be able to access information on the platform with no hassle and in any device from anywhere, providing that a data connection is available.

Moreover, since we are working directly with the civil protection agents as project partners, there is a major focus on developing on important issues for them. Specifically, our platform aims at fulfilling ease on usability and providing tools for quick decision taking by them, providing a product tailored for their needs. This tool is also being developed with modularity and reusability in mind, so that very little modifications to the platform code need to be made if the forecast product changes from "water levels" to other variables of interest. To achieve this, back and front-end are bind in such a way that the former provides access to the data while the front-end consumes (via a set of REST services) and displays the products without being content-aware, i.e., it shows data without considering data types. Since the front-end is not content-aware, a new instance of the platform, for visualizing and analyzing other types of data, can be created simply by changing the products made available by the back-end and performing basic adaptations to the front-end. Moreover, since the back-end serves data in a standard way (REST services), the front-end itself may also be substituted by another consuming service, be it a mobile application, a web-page or other data consuming service. This allows for interoperability between platforms, allowing other users to use these services straightforwardly, after being successfully authenticated and authorized.

This flow of information is illustrated in Fig. 1, where a separation of concepts, between back-end and front-end is clearly visible. The back-end consists of an instance of CakePHP, a MVC PHP framework, with a PostgreSQL storage database (with PostGIS extension), coupled with several instances of Geoserver and Perl and Python scripts.

The code developed with CakePHP handles user control and user accesses, based on access control lists and roles, and streamlines access to the database via REST requests from the front-end. Geoserver, an open source server for geospatial data sharing, manages the georeferenced imagery (both in raster and vector formats) and serves them using open standards, such as WMS. This also promotes interoperability by allowing that different systems exchange data with each-other using known standards. Geoserver uses data, both from the PostgreSQL/PostGIS database, but also from results produced by the flood prediction models, in the form of shapefiles, allowing for model results probing directly on the data served through the UI.

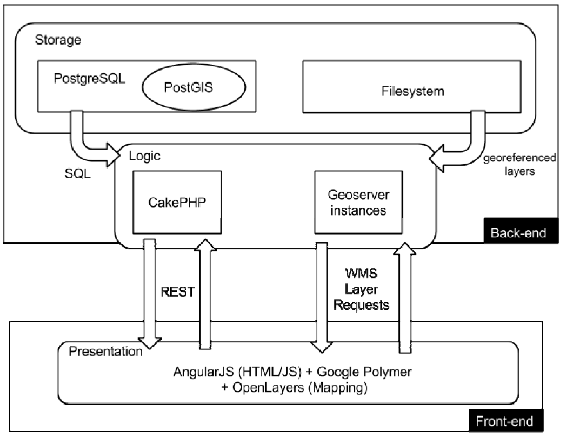

Fig. 1 Technological Architecture of the solution

Since a huge amount of requests are made to Geoserver, and it lags when cluttered with data, some maintenance must be performed on a recurrent basis. Instead of keeping all the data content in Geoserver' memory, existing content is moved to a secondary location on the filesystem daily through a script running as a cronjob. Reloading the products to Geoserver is performed on-demand by the user through a set of Perl and Python scripts, initiated by client request performed on the front-end. This strategy allows for a considerable performance increase in data access and gives the best priority of access to today's flood predictions.

The front-end consists of a single-page responsive web application which allows users to visualize all the products served by the back-end, in an intuitive interface available for multiple devices. With the goal of ubiquitousness in mind, less-intensive technologies were chosen: 1) HTML5 and CSS3, as the building base of all web-applications, 2) AngularJS, a javascript framework that offers dynamic templating and two-way databinding, 3) Google Polymer, a Google design specification implementation library, and 4) OpenLayers, a library for handling geospatial data and mapping tools on the client-side. Although some technologies, like AngularJS and Google Polymer, are still in a beta stage, they are supported and maintained by Google and have a huge community contributing for their development (AngularJS has over 6K commits on github, more than older and well-known javascript libraries such as JQuery with less than 6K commits). Using these technologies appears thus a good choice for future developments, since they shape the way we build the web (www.polymer-project.org) and fully fulfill the user requirements.

As referred before, the front-end maintains communication with the back-end via a set of REST services made available by the back-end. Responses to these request come in JSON, a lightweight data-interchange format easy to read/write by humans and to parse/create by machines.

The server-side information flow system has been planned and built to easily gather real-time data from the wireless sensor network, to parse the relevant information and store it in a persistent database system, to use the measurements to run forecasting models, and to provide the forecast results to the end-user. A detailed description of this flow of information can be seen in Fig. 2. From top to bottom, this system building blocks are 1) a wireless sensor network (WSN), comprised of several sensor nodes; 2) a data gathering server, which communicates with the WSN gathering and parsing real-time data; 3) prediction model instance and corresponding redundancy instance (to guarantee a fallback), that produce forecasting results with real-time data as one of the inputs; 4) several instances of Geoserver (again to guarantee a fallback, but also to guarantee data availability for a great amount of web-requests), that start by consuming forecast results in the form of visual imagery which later renders to the end-user in the form of WMS layers. All the instances of Geoserver are managed by a load-balancer that decides which instance should handle the client requests. The WSN consists of several real-time station nodes scattered in the domain of interest, which record water level data and transmit it to a central server. This central server is basically a set of scripts that trigger the transmission via either GPRS into an FTP server or Circuit Switched Data (CSD) directly into the file system. After the transmission is performed successfully, data is handled by the central-server to parse and store it, and to create input files for the prediction models. On their side, prediction models produce water level forecast results for the next 48 hours which are then consumed by the geographical web server. Geoserver accepts both raster images (geotiff) and vector files (shapefiles), but can also produce images from Postgis database data. These images are georeferenced and then presented in the user interface on a layer map.

## IV. Application to the Case Study

The flexibility and usefulness of the platform is illustrated here, applied to the MOLINES case study, mainly through examples of the functionalities available on the interface. For this project, the requirements were the following: 1) the platform would account for different user roles, providing differentiated access to dedicated products; 2) the platform should be able to host georeferenced products from the static risk analysis (hazard, vulnerability) and the dynamic real time forecast; 3) the platform should be agile, providing fast access to the alerts and their products; and 4) the platform should be prepared to incorporate and show in a georeferenced way the information uploaded by the civil protection agents in the field during emergencies.

This application user interface is composed of a top header with title, a sidebar for displaying the various links to the main functionalities offered and a detailed content area. The sidebar hides when opening the application in smaller devices (smartphones or tablets), and is accessible by a button on the top header, as seen in Fig. 3. This allows the main content to be shown in full screen, taking advantage of all available space on the device screen.

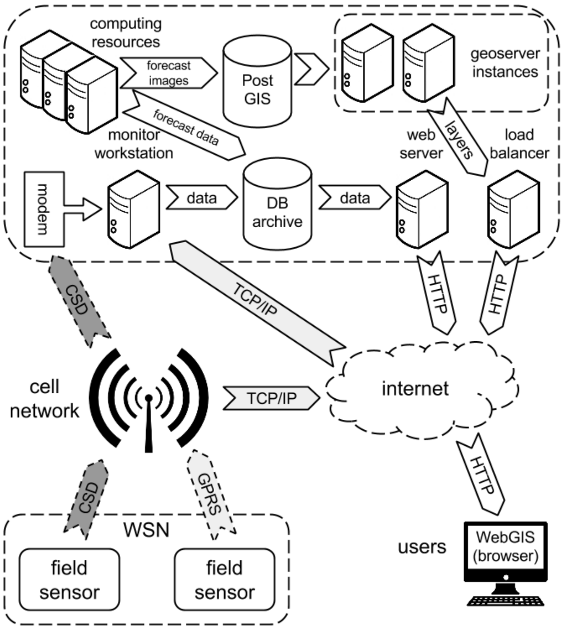

Fig. 2 Network information data flow

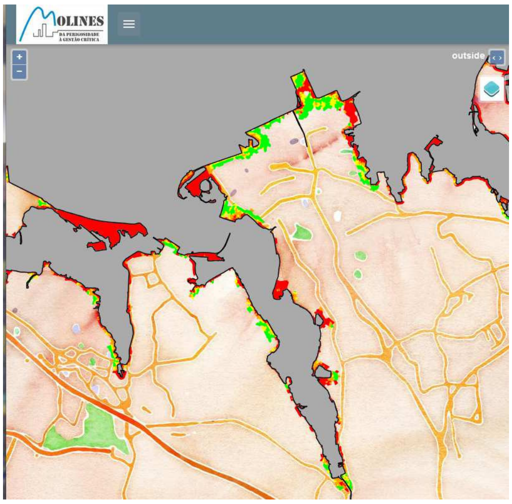

Fig. 3 Example of the interface adapted to a mobile device

Since this is a platform for support of detailed risk management, it must provide the users with multiple ways to access all the risk events detected: a quick way, through both geographical representation of a specific area and a short list of areas, and a very detailed listing, supported by clear identification of the most vulnerable locations. This functionality can be seen in a) Fig. 4: a summary of study zones and risk alerts triggered for each zone as well as their risk type, b) Fig. 5: a detailed listing of locations at risk and the alert bulletins. Also, when hovering over the zones on the table in Fig. 4, the corresponding zone on the map gets highlighted for a better notion of where this zone is and provides a direct link to the detailed listing of Fig. 5.
Similarly, each zone name is a link for the more detailed description of the risk events occurring at that specific zone.

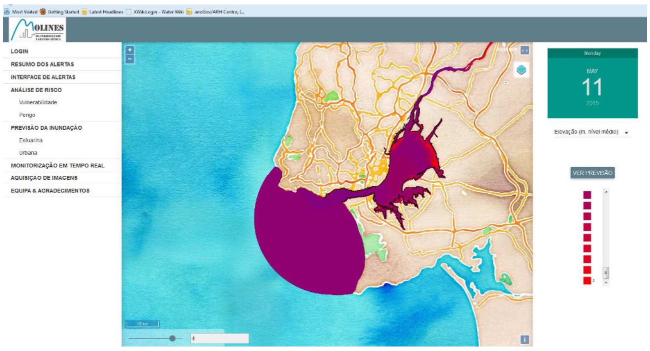

Fig. 6 Water level forecast

Other functionalities include a section to provide access to the real-time data gathered from WSN, which also allows an automatic comparison with model forecast results. This functionality allows the end-users to access data being measured at a point of interest but also to validate model predictions with real-time data. Indeed, this comparison is fundamental for the emergency agents and other decision-makers to provide them a measure of reliability on the model predictions and confidence on the actions to be promoted in the field.

## V. Discussion and Future Work

Herein, an interactive, flexible and multiple user roles Web platform is presented, which takes advantage of novel technologies to provide fast access to all relevant online, intuitive and geographically referenced real-time data and model predictions for urban and estuarine floods.

Future work on the platform is planned to further improve its performance. For instance, one of the strategies includes using GeoJSON, an open standard format for encoding geographical information features using Javascript Object Notation, on the client-side to render georeferenced data layers on top of maps, instead of depending on Geoserver to serve those layers. This would put the workload on the client-side instead of the server-side, which would produce faster results overall.

At the same time, the overall goal of these IT platforms is to have them integrated in the everyday's workflow of end-users. Their operation requires considerable computational efforts that may not available in many decision-makers IT infrastructures. As LNEC's computational resources are finite and often related with on-going scientific projects, a solution should be looked up to provide the best solution for end-users. In order to allow for stakeholders to run their own prediction model instances and operate these IT platforms, future work also includes the creation of prediction model deployments on the cloud.

For the MOLINES application, the future work will be concentrated on the integration, in the interface, of the uploaded data provided by the agents in the field. Challenges are the automatic check on the reliability of this information and the way to integrate them in the interface in a simple and easy to probe manner. Other add-ons include also the issuing of the alert based on the model predictions.

## VI. Acknowledgment

The authors thank Paula Freire and Ana Rilo, from LNEC, Alexandre Tavares and Pedro Santos, from CES, and Luis Sá, from the Portuguese Civil Protection, for helping with the definition of the platform requirements. They also thank the SCHISM community for making their model code available at http://ccrm.vims.edu/schism/.

***Abstract*—The paper compares two formulations of dynamic power management in energy-aware computer networks. In the first approach the only criterion is energy consumption, in the second there is an additional one - the quality of service. It is shown, that the second approach is appropriate when the routing problem with fixed demands is inadmissible. Fortunately, by some optimization modeling transformations it still allows for using the same standard mixed integer solvers as the first approach.**

## I. Introduction

METHODS for increasing energy efficiency of computer networks gained much attention last years. The reason is, that we are witnessing a rise of energy costs, customer increase, more on-demand services using cloud architectures, mobile Internet, a diffusion of broadband access and a growing number of services offered by Internet service providers. The growth of the energy consumption by network infrastructure may be well illustrated by the overall energy requirements of European Internet operators: in 2005 they needed 14 TWh, in 2010 - 21 TWh, and the forecast for 2020 is 36 TWh [1].

At the same time the capacity surplus becomes a standard in almost all networks. Consequently, so-called green network technologies are quickly becoming a high-priority issue for the Internet [1], [2].

In the European Union an additional motivation is 2020 Energy Strategy, which, among other goals, assumes achieving by 2020 a 20% improvement in energy efficiency [3].

Efforts to reduce power consumption in telecommunication networks follow in two mutually related directions – design of a more efficient equipment and development of energy-aware network control strategies and protocols. Initial efforts were aimed at assessment of energy characteristics of network equipment and building elementary models [4]. Upon this knowledge some local, i.e., concerning single device, strategies were built – see e.g., [5].

However, it is possible to save even more energy by employing network-wide solutions.

The paper [6] presented a model of energy-aware router, an architecture of a control framework and various formulations of a network-wide energy saving optimization problem. They start from the exact mixed integer linear programming (MILP) formulation, which is aimed at solving the problem of a minimum energy routing. The objective is the minimization of the total power utilized by network components while ensuring end-to-end Quality of Service (QoS). The basic link-node formulation (*LNb*) is a network management problem with binary decision variables describing full routing in a network and corresponding energy state assignments to all routers, line cards and communication ports. A more advanced version may be proposed, in which some parts of the network can be shifted to low energy mode as a result of the optimization algorithms, where both paths and flow rates are decision variables. It will exploit the fact, that Internet traffic used to be elastic in a large part, which means, that a quality of service is little aggravated by small deviations from assumed flow rate.

In this paper first a model with fixed flow rates inspired by the paper [6] will be shortly presented and assessed. Then, an improved version of it with flexible rates - in the authors' opinion much more practical - will be proposed and discussed.

## II. A model with given demands

A hierarchical network model proposed in [6] considers every single communication port $p \in \{1,\ldots,P\}$ of every line card of a router $r \in \{1,\ldots,R\}$. In our paper, for simplification, we do not consider individual cards of the router, because they do not bring anything into the model except additional summations.

Directed links connecting pairs of ports are denoted by $l \in \{1,\ldots,L\}$; any network component can operate in

978-83-60810-66-8/$25.00©2015, IEEE

$k \in \{1,\ldots,K\}$ energy states, but two ports connected by a link are in the same state. A demand $d \in \{1,\ldots,D\}$ is characterized by its source $s_d$ and the destination $t_d$ node (router) and the volume $V_d$.

The topology of the physical network is described by four matrices of binary indicators: $g_{pr}, a_{lp}, b_{lp}$, which indicate, whether, respectively: port $p$ belongs to the router $r$, link $l$ is incoming to the port $p$ and link $l$ is outgoing from the port $p$. If $l$ is a link outgoing from the port $p$, the link $\tilde{l}$ denotes its partner link in the edge going in the opposite direction, that is:

$$b_{lp} = 1 \Longleftrightarrow a_{\tilde{l}p} = 1 \tag{1}$$

We assume that the numbers $l$, $\tilde{l}$ have different parities (e.g., they are consecutive numbers). The decision variables are two vectors of binary indicators $x_p, z_r$ - whether the port $p$ or router $r$ is used for data transmission and two incidence matrices with elements: $y_{lk}$ - whether the link $l$ is in the state $k$ and $u_{dl}$ - whether the demand $d$ uses the link $l$.

The full optimization problem is as follows:

$$\min_{\substack{x_p, y_{lk}, z_r, u_{dl} \\ p\in\overline{1,P}, l\in\overline{1,L}, \\ k\in\overline{1,K}, r\in\overline{1,R}, \\ d\in\overline{1,D}}} \Bigg[ F_{LNb} = \sum_{l=1,3,5,\ldots}^{L-1} \sum_{k=1}^{K} \xi_{lk} y_{lk} + \\ + \sum_{p=1}^{P} W_p x_p + \sum_{r=1}^{R} T_r z_r \Bigg] \tag{2}$$

subject to the constraints:

$$\forall_{\substack{d=1,\ldots,D, \\ p=1,\ldots,P}} \quad \sum_{l=1}^{L} a_{lp} u_{dl} \le x_p \tag{3}$$

$$\forall_{\substack{d=1,\ldots,D, \\ p=1,\ldots,P}} \quad \sum_{l=1}^{L} b_{lp} u_{dl} \le x_p \tag{4}$$

$$\forall_{\substack{r=1,\ldots,R, \\ p=1,\ldots,P}} \quad g_{pr} x_p \le z_r \tag{5}$$

$$\forall_{l=1,\ldots,L} \quad \sum_{k=1}^{K} y_{lk} \le 1 \tag{6}$$

$$\forall_{\substack{d=1,\ldots,D, \\ r=1,\ldots,R}} \sum_{p=1}^{P}\sum_{l=1}^{L} g_{pr} a_{lp} u_{dl} - \sum_{p=1}^{P}\sum_{l=1}^{L} g_{pr} b_{lp} u_{dl} = \\ = \begin{cases} -1 & r = s_d \\ 1 & r = t_d \\ 0 & \text{otherwise} \end{cases} \tag{7}$$

$$\sum_{d=1}^{D} V_d u_{dl} \le \sum_{k=1}^{K} M_{lk} y_{lk}, \ l = 1,3,\ldots,L-1 \tag{8}$$

$$\sum_{d=1}^{D} V_d u_{dl} \le \sum_{k=1}^{K} M_{\tilde{l}k} y_{\tilde{l}k}, \ l = 2,4,\ldots,L \tag{9}$$

$$x_p, z_r \in \{0,1\} \ p \in \overline{1,P}, r \in \overline{1,R}, \tag{10}$$

$$y_{lk}, u_{dl} \in \{0,1\} \ l \in \overline{1,L}, k \in \overline{1,K}, d \in \overline{1,D} \tag{11}$$

where $M_{lk}$ and $\xi_{lk}$ are, respectively, the capacity and the power consumption of the edge comprising links $l, \tilde{l}$ in the state $k$, and $W_p$ and $T_r$ are power cost coefficients of the port $p$ and the router $r$.

As in the paper [6] constraints (3)-(5) determine the number of ports and routers that are used for data transmission. The conditions (6) assure, that each edge can be in one energy-aware state. The constraints (7) are formulated according to 1st Kirchhoff's law applied to source, destination and transit nodes, and finally, the constraints (8),(9) assure, that the flow will not exceed the capacity of a given edge.

Any MILP algorithm can be used to solve (2)-(11) problem. Popular solvers such as CPLEX and Gurobi may be applied.

## III. Shortcomings of the *LNb* model and possibilities to overcome them

In the *LNb* model (2)-(11) the issue of determining the flow demand matrix, which is crucial for implementing the control system, is not addressed. The simplest approach is to measure the actual flow rates carried by the network (averaged over a selected timescale), and adopt it as optimization constraints. Then, this model can help to answer the question whether it is possible and worthwhile to temporarily reduce network capacity and maybe also reroute some paths in order to save some energy without sacrificing the QoS, that is maintaining the current values of the flow rates. It should work especially in the case, when the network is underutilized.

Shortcomings of the method may manifest themselves however in more complex scenarios, when the controlled network, or at least a part of it, works on its capacity limit. The measured traffic is no longer a good estimate of the demanded bandwidth, because flows are already truncated by the network. The demand matrix must be provided in some other way, e.g., by predictive model or educated guess.

It is then crucial, that demands, coupled through link capacity constraints, do not exceed the bandwidth offered by the network in any spot, which can be hard to assure in nontrivial network topologies. Otherwise, a feasible solution will not exist.

In such cases, a modified approach can be proposed, in which flow rates are represented by variables rather than constants. It exploits the fact, that Internet traffic used to be elastic in a large part, which means, that the QoS is only a little aggravated by small deviations from the assumed flow rate. The combined routing and rate control problem has to be solved, which leads to the solution feasible in terms of the formulated model, even when the traffic demand is greater than the capacity offered by the network.

Moreover, in some cases a minor reduction of flow rates, which is accepted by the comprehensive model taking into account the elasticity of a demand, may allow to accommodate the traffic in a smaller number of links, thus allowing for further great reduction of power consumption.

## IV. A GENERALIZATION – TWO-CRITERIA ROUTING PROBLEM

The most important modification of the *LNb* model consists in relaxing flow rates - from now on they are variables denoted by $v_d$. In a consequence, the objective function $F_{LNb}$ (2) has to be augmented with a QoS related criterion $Q_d$, which represents a penalty for not achieving the assumed flow rate $V_d$ by the flow $d$. $Q_d(v_d)$ is a convex and continuous function, decreasing on interval $[0, V_d]$. It is reaching minimum (zero) at $V_d$, the point in which user expectations are fully satisfied. The convexity of $Q_d(v_d)$ is associated with the conviction, that small deviations from the nominal throughput $\Delta = V_d - v_d$ are neglected by network users, while large deviations are noticed and should be avoided. Moreover, since $Q_d(v_d)$ is monotonically decreasing, it assures that the slope of the curve becomes steeper, as the rate $v_d$ approaches zero.

A two criteria - i.e., reflecting energy costs and QoS - mixed integer network problem of simultaneous optimal bandwidth allocation and routing may be formulated in the following way:

$$\min_{\substack{x_p, y_{lk}, z_r, u_{dl}, v_d, \\ p\in\overline{1,P}, l\in\overline{1,L}, k\in\overline{1,K} \\ r\in\overline{1,R}, d\in\overline{1,D}}} \Bigg\{ F_{2C} = \alpha F_{LNb} + (1-\alpha) \sum_{d=1}^{D} Q_d(v_d) =$$

$$= \alpha \left[ \sum_{l=1,3,5,\ldots}^{L-1} \sum_{k=1}^{K} \xi_{lk} y_{lk} + \sum_{p=1}^{P} W_p x_p + \sum_{r=1}^{R} T_r z_r \right] +$$

$$+(1-\alpha) \sum_{d=1}^{D} Q_d(v_d) \Bigg\} \tag{12}$$

subject to constraints (3)-(7), (10)-(11) from *LNb* and

$$\sum_{d=1}^{D} v_d u_{dl} \leq \sum_{k=1}^{K} M_{lk} y_{lk},\ l = 1, 3, \ldots, L-1 \tag{13}$$

$$\sum_{d=1}^{D} v_d u_{dl} \leq \sum_{k=1}^{K} M_{\tilde{l}k} y_{\tilde{l}k},\ l = 2, 4, \ldots, L \tag{14}$$

$$0 \leq v_d \leq V_d,\ d \in \overline{1,D} \tag{15}$$

The parameter $\alpha \in [0, 1]$ is a scalarizing weight coefficient, which can be altered to emphasize any of the objectives.

Such a problem in the particular case when $\alpha = 0$, i.e., without the energy components, was first addressed by Jaskóła and Malinowski [7] and independently by Wang et al. [8]. A decomposed algorithm to solve it was proposed by Karbowski [9].

A two-criteria optimal routing and bandwidth allocation problem, taking into account the energy component, for a completely different network and cost model than that of Section II was presented in [10].

In general, the formulation (12)-(15), (3)-(7), (10)-(11) has some drawbacks: it defines a mixed-integer nonlinear programming problem with nonconvex, bilinear link capacity constraints (13),(14). At present the leading solvers - e.g., CPLEX, Gurobi - can solve efficiently convex quadratic mixed-integer quadratically constrained problems MIQCP, with positive semidefinite matrices of constraints quadratic forms, which is not the case of (13),(14) constraints. The general nonlinear, mixed-integer, nonconvex solvers are very slow.

Fortunately, the problem (12)-(15), (3)-(7), (10)-(11) can be quite easily transformed to the form accepted by fast mixed-integer solvers, what we describe below. The reformulation of nonlinear network problems to the input format of standard MILP or MIQP solvers seems to be a very promissing approach nowadays [11].

## V. ELIMINATION OF THE NONLINEARITY FROM CONSTRAINTS

From the QoS components of the objective function $F_{2C}$ (12) it is usually expected, that they assure so-called proportional-fairness of the allocations of the bandwidth, when the network is subject to a congestion [12]. Quadratic functions may be used to achieve it [13] (unfortunately, linear - not), so the objective function $F_{2C}$ can be quadratic and convex.

The only problem that still remains to solve is nonconvex nonlinearity of the constraints (13), (14). It can be eliminated by a transformation proposed in [14].

It consists in the introduction of auxiliary variables $w_{dl} = v_d u_{dl}$, $d \in \overline{1,D}$, $l \in \overline{1,L}$ (denoting the part of a traffic rate in the link $l$ assigned to the flow $d$) and the substitution of these inequalities with subsequent set of linear inequalities:

$$\forall_{l=1,3,\ldots,L-1} \quad \sum_{d=1}^{D} w_{dl} \leq \sum_{k=1}^{K} M_{lk} y_{lk} \tag{16}$$

$$\forall_{l=2,4,\ldots,L} \quad \sum_{d=1}^{D} w_{dl} \leq \sum_{k=1}^{K} M_{\tilde{l}k} y_{\tilde{l}k} \tag{17}$$

$$\forall_{\substack{d=1,\ldots,D, \\ l=1,\ldots,L}} \quad w_{dl} \leq V_d u_{dl} \tag{18}$$

$$\forall_{\substack{d=1,\ldots,D, \\ l=1,\ldots,L}} \quad w_{dl} \leq v_d \tag{19}$$

$$\forall_{\substack{d=1,\ldots,D, \\ l=1,\ldots,L}} \quad w_{dl} \geq v_d - V_d(1 - u_{dl}) \tag{20}$$

$$\forall_{\substack{d=1,\ldots,D, \\ l=1,\ldots,L}} \quad w_{dl} \geq 0 \tag{21}$$

## VI. THE FINAL FORMULATION OF THE PROBLEM

Summing up, the final formulation of our two criteria energy-aware integrated routing and flow control problem is as follows:

$$\min_{\substack{x_p, y_{lk}, z_r, u_{dl}, v_d, w_{dl} \\ p\in\overline{1,P}, l\in\overline{1,L}, k\in\overline{1,K} \\ r\in\overline{1,R}, d\in\overline{1,D}}} \Bigg\{ F_{2C} = \alpha F_{LNb} + (1-\alpha) \sum_{d=1}^{D} Q_d(v_d) =$$

$$= \alpha \left[ \sum_{l=1,3,5,\ldots}^{L-1} \sum_{k=1}^{K} \xi_{lk} y_{lk} + \sum_{p=1}^{P} W_p x_p + \sum_{r=1}^{R} T_r z_r \right] +$$

$$+(1-\alpha) \sum_{d=1}^{D} Q_d(v_d) \Bigg\} \qquad (22)$$

subject to the constraints:

$$\forall_{\substack{d=1,\ldots,D,\\ p=1,\ldots,P}} \quad \sum_{l=1}^{L} a_{lp} u_{dl} \leq x_p \qquad (23)$$

$$\forall_{\substack{d=1,\ldots,D,\\ p=1,\ldots,P}} \quad \sum_{l=1}^{L} b_{lp} u_{dl} \leq x_p \qquad (24)$$

$$\forall_{\substack{r=1,\ldots,R,\\ p=1,\ldots,P}} \quad g_{pr} x_p \leq z_r, \qquad (25)$$

$$\forall_{l=1,\ldots,L} \quad \sum_{k=1}^{K} y_{lk} \leq 1 \qquad (26)$$

$$\forall_{\substack{d=1,\ldots,D,\\ r=1,\ldots,R}} \sum_{p=1}^{P} g_{pr} \sum_{l=1}^{L} \left(a_{lp} - b_{lp}\right) u_{dl} = \begin{cases} -1 & r = s_d \\ 1 & r = t_d \\ 0 & \text{otherwise} \end{cases} \qquad (27)$$

$$\sum_{d=1}^{D} w_{dl} \leq \sum_{k=1}^{K} M_{lk} y_{lk}, \; l = 1, 3, \ldots, L-1 \qquad (28)$$

$$\sum_{d=1}^{D} w_{dl} \leq \sum_{k=1}^{K} M_{\tilde{l}k} y_{\tilde{l}k}, \; l = 2, 4, \ldots, L \qquad (29)$$

$$\forall_{\substack{d=1,\ldots,D,\\ l=1,\ldots,L}} \quad w_{dl} \leq V_d u_{dl} \qquad (30)$$

$$\forall_{d=1,\ldots,D,} \quad w_{dl} \leq v_d \qquad (31)$$

$$\forall_{\substack{d=1,\ldots,D,\\ l=1,\ldots,L}} \quad w_{dl} \geq v_d - V_d(1 - u_{dl}) \qquad (32)$$

$$\forall_{\substack{d=1,\ldots,D,\\ l=1,\ldots,L}} \quad w_{dl} \geq 0 \qquad (33)$$

$$\forall_{d=1,\ldots,D} \quad 0 \leq v_d \leq V_d \qquad (34)$$

$$x_p, z_r \in \{0,1\} \;\; p \in \overline{1,P}, r \in \overline{1,R}, \qquad (35)$$

$$y_{lk}, u_{dl} \in \{0,1\} \;\; l \in \overline{1,L}, k \in \overline{1,K}, d \in \overline{1,D} \qquad (36)$$

When QoS components $Q_d(v_d)$ are quadratic and convex, the obtained mixed-integer quadratic problem can be solved by effective MILP/MIQP solvers, such as CPLEX, Gurobi.

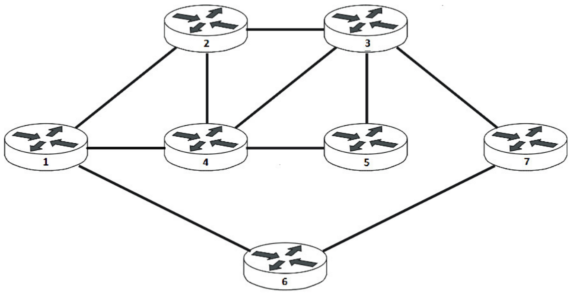

Fig. 1. Test network

## VII. Numerical evaluation

The problem (22)- (36) was formulated, implemented and solved with the help of the CPLEX solver for the test network presented in Fig. 1, with: $R = 7$, $L = 20$, $P = 20$. Every edge between two routers had two unidirectional links. We performed the experiments for three demands ($D = 3$) : $1 \rightarrow 7, 1 \rightarrow 7, 5 \rightarrow 6$. It was possible for each link to operate in five energy-aware states ($K = 5$). As their (penalty for not achieving) QoS functions we took [7]:

$$Q_d(v_d) = \frac{1}{2} V_d^2 - v_d \cdot (V_d - v_d/2) \qquad (37)$$

The throughput of a given link $l \in \overline{1,L}$ and the power consumption in energy-aware state $k \in \overline{1,K}$ were as follows: ($M_{l1} = 20$, $\xi_{l1} = 15$), ($M_{l2} = 40$, $\xi_{l2} = 30$), ($M_{l3} = 60$, $\xi_{l3} = 40$), ($M_{l4} = 80$, $\xi_{l4} = 60$), ($M_{l5} = 100$, $\xi_{l5} = 75$). As the power cost coefficients we took for ports $W_1 = W_2 = \ldots = W_{20} = 30$ and for routers $T_1 = T_2 = \ldots = T_7 = 300$. The maximum demand volumes were: $V_1 = 100, V_2 = 50, V_3 = 150$. The scalarizing coefficient was taken $\alpha = \frac{1}{2}$.

From calculations we got the following optimal paths: $d = 1,2 : 1 \rightarrow 6 \rightarrow 7$; $d = 3 : 5 \rightarrow 3 \rightarrow 7 \rightarrow 6$ and the objective function $F_{2C} = 1957.499221$. It means, that only routers $1, 3, 5, 6, 7$ were used and the links and ports connecting them, that is, the rest of the network was in the sleeping mode. The obtained optimal transmission rates were: $\hat{v}_1 = 75, \hat{v}_2 = 25, \hat{v}_3 = 100$. All the used links worked at the highest energy levels.

## VIII. Conclusions

We modified the dynamic power management of energy-aware computer networks model presented in [6] to capture these situations, when the users' demands are so high, that there is no admissible solution of the problem *LNb* (2)-(11). We suggest to use then a two-criteria model with flow rates as additional decision variables. When the QoS functions are quadratic and convex, it is possible to reformulate the problem in such a way, that the same standard solvers, e.g., CPLEX or Gurobi, can be used to find the solution. The resulting mixed-integer programming problem has more variables, but the new are only real, not binary, what should not influence too much the time of calculations.

The performed numerical test confirmed the appropriateness of the formulation.

***Abstract*—Recently, there has been an increasing need for secure, efficient and simple notification methods for mobile systems. Such systems are meant to provide users with precise tools best suited for work or leisure environments and a lot of effort has been put into creating a multitude of mobile applications. However, not much research has been put at the same time into determining which of the available protocols are best suited for individual tasks. Here a number of basic notification methods are presented and tests are performed for the most promising ones. An attempt is made to determine which methods have the best throughput, latency, security and other characteristics. A comprehensive comparison is provided, which can be used to select the right method for a specific project. Finally, conclusions are provided and the results of all the tests conducted are discussed.**

## I. Introduction

THE PURPOSE of this paper is the analysis and tests of several selected notification methods for mobile platforms. The reason for this research is the need to determine the best way of sending simple as well as more advanced messages about the events involved in the operation of grid systems or telemetric networks. This makes it possible to use the optimal approach in numerous projects that need to inform users about their current status. This aspect is currently of utmost importance for the industry as such notification methods enable developers to engage users much more fully and keep them in constant contact with their leisure and work interests. These considerations have guided us throughout our research and affected all our decisions on the selection and ways of testing of the methods in question.

Several protocols and methods were considered based on their purposes and current industry standards. The main candidates were: CoAP (Constraint Application Protocol), XMPP (Extensible Messaging and Presence Protocol) and XMPP over SOAP (Simple Object Access Protocol), MQTT (Message Queuing Telemetry Transport), MQTT-SN (Message Queuing Telemetry Transport for Sensor Networks), AMQP (Advanced Message Queuing Protocol), Cloud notification systems (Google Cloud Messaging, Urban Airship), SMS (Short Message Service) and Restful HTTP (Hypertext Transfer Protocol).

Of course, these are not all the protocols that could be used for mobile notifications, but these listed appear to hold the most promise and therefore the purpose is to discern their usefulness in the best way possible.

In addition to the protocols and methods above, we investigated other solutions, such as the Apple push notification or Line application which, for various reasons, were not considered further. The Apple push notification technology is a good solution, but it is proprietary, i.e. limited to Apple devices and that is why we decided to test more universal solutions first. There are also solutions (applications) that use their own protocols. A good example is Line application, which uses a proprietary protocol. We considered testing this solution; however, there are significant difficulties with accessing the documentation for this protocol.

## II. Related Work

Mobile systems are a relatively new field of study and picking a specific topic such as comparing available notification methods does not return many related work results. Some of the protocols have been covered in separate articles and while these took the sending of notifications into account, tests were not always conducted in mobile systems.

The one available article [1] that compared notification methods only covered cloud systems [2] and applications. It discussed the following methods: C2DM (Google Cloud to Device Messaging—the predecessor to GCM), Xtify, XMPP and Urban Airship. As during our research that article was relatively new, one might think that the information contained there would still be relevant, but it turned out to be already out of date. Google has meanwhile redesigned and rebranded its notification system and Xtify was purchased by IBM. Only Urban Airship is still available on the market in the same configuration as previously. The article is more a comparison of available commercial products than a real world testing suite. As expected, the conclusion was that the fastest protocol of the four tested was XMPP, but it had a characteristic slightly different from the others.

Another article [3] only tested the MQTT protocol. The author believed that it was the best possible choice and only aimed to describe its main features and capabilities. Just a single simple test and its averaged results together with the amount of data transferred and power consumption over a period of time were provided. In the conclusion, the author

978-83-60810-66-8/$25.00©2015, IEEE

described the MQTT protocol as being both lightweight and perfect for mobile platforms.

In [4], the authors investigated XMPP in the field of collaborative applications. Its main purpose was to assess the usefulness of XMPP in exchanging location data between mobile clients and web servers. No testing was conducted, but a thorough description of XMPP and the Android platform was provided while also taking into account the ways of integrating them. The article described XMPP as a general purpose messaging protocol that is easily extensible.

An important aspects in the context of notification methods are SLA parameters [5] and the power consumption of battery-powered devices. In [6], the authors discussed the problem of sending notification data using GPRS connectivity from remote telemetry stations [7]. They proposed the concept of adaptive message aggregation which extends the MQTT-SN protocol, adjusting its behaviour to the GPRS (General Packet Radio Service) connectivity profile in order to decrease the energy consumption related to data transmission.

## III. Notification methods

The following section generally describes and analyses the possible notification methods for mobile devices mentioned in the introduction. As a result of this analysis, it was decided to select some of them in order to perform the thorough tests described later in this paper.

### A. SMS

It is possible to use the Short Message Service as a notification mechanism. An application would have to intercept the SMS messages received by an Android phone and analyse them to check whether they contain notifications from the system. One could just use simple text messages without a dedicated client application, but this would severely limit the functionality available to users.

This approach has several major issues. First, the cost of sending multiple messages to numerous clients could be immense. Secondly, it is not guaranteed that the message will be delivered on time or (sometimes) even on the same day. What is more, all text messages have a maximum undelivered period (which cannot exceed 7 days), and this means that some notifications would not be delivered at all.

### B. Google Cloud Messaging

In order to simplify the development of applications and to extend phone battery life, Google has created a simple built-in notification system for the Android platform, which only maintains a single connection at any time.

This approach has some obvious drawbacks. Firstly, the number of messages sent concurrently is limited to four per application and there is no guarantee that the message will be delivered, especially while the service is shared. Secondly, there is no specified maximum delay, which is not acceptable for most modern systems. Moreover, in posts like [8] it is claimed that the method is not all that well documented and it is not easy to make an application work reliably with Google Cloud Messaging (GCM). Another problem with GCM is that some people do not trust Google not to abuse its capabilities, citing privacy or security concerns. One must also keep in mind that GCM can be used by some malware applications as described in [9].

### C. Restful HTTP

Another possible solution would be to use a RESTful HTTP service based on a pull queue model [10]. Such an implementation would have to pull notifications from the server at certain intervals or when the user turns on the application. Currently creating such a service is a very simple process and does not require additional knowledge from most developers, which is the main advantage of this approach.

However, using this method is very inefficient as it is not clear at what intervals requests should be made. Using too long an interval between requests may result in multiple notifications being sent all at once, making the older messages meaningless. Conversely, if the interval were too short, it would use too much device resources. Moreover, much of the workload is shifted to the mobile device and the amount of data sent between server and client is sometimes doubled.

Some ideas for REST notification systems are discussed in [11], however using a pure REST approach is highly discouraged. Using the AMQP/REST mixed approach seems much more plausible.

### D. XMPP

XMPP is basically an open technology for real-time communication, using XML (Extensible Markup Language) as the base format for exchanging information. It was designed to be easily extensible and one of its main uses are publish-subscribe systems. It is the most mature protocol among all the solutions selected as it was already in use in 1999. Throughout its history it was used by companies such as Google in the Google Talk communicator, by Microsoft in Skype or by Facebook in WhatsApp Messenger.

The idea behind XMPP is similar to that of e-mail, with a distributed server network in which each and every server can create its own service. The XMPP standard enables message encryption and XML support allows for the use of such technologies as SOAP or EDI (Electronic Data Interchange).

A standard that is tightly coupled with XMPP is SOAP over XMPP, which can be tested using the same means, as sending a SOAP message is basically sending some content over XMPP, which provides effective and reliable messaging—both asynchronous and synchronous.

XMPP is a general purpose protocol that is easily extensible. It was only designed to meet mobile platform requirements and was not expected to outperform any other protocols. However, its flexibility makes it a choice worth considering. In [4], a few add-ons are mentioned like group chats or streaming services with a possibility to transfer files.

### E. SOAP over HTTP

SOAP is a lightweight protocol for message exchanges that is independent from the system platform programming language. Its specification does not define a specific transport layer protocol, but most implementations use HTTP. It is important to mention, however, that HTTP is of no use for asynchronous messaging and because of that SMTP is often used instead. The protocol makes it possible to send many short messages.

In the discussion on the use of SOAP in notification systems, the following solutions should be considered: polling, both endpoints having their SOA interfaces, using WS-notification and using the message queueing solution encapsulated in HTTP.

All the solutions above have been analysed and none of them are easy to adapt to the needs of mobile notification systems. The first solution requires the client to make requests at certain points in time, which generates a lot of unnecessary traffic and is quite resource-heavy on small devices. The second idea is better, but would not work for most mobile devices as not all requests would pass from the server to the device since such HTTP requests are often blocked. A good solution is to use WS-notification, but the problem with making requests from the server is still present. What is more, it is not a standard supported by all web servers. The final solution uses queueing, but it involves a lot of unnecessary technology, especially given that there are ready-made queueing mechanisms that do not have to be encapsulated in HTTP requests.

### *F. MQTT/MQTT-SN*

MQTT is a publish-subscribe lightweight messaging protocol based on TCP/IP. It was designed to be open, simple, lightweight and easy to implement, since it was intended to be used in constrained environments with limitations such as: expensive, low bandwidth, unreliable network, limited processor or memory resources.

The entire protocol is based upon a central message broker, which distributes messages published on a topic to all the interested consumers. The "MQ" part of the name comes from "Message Queueing", however this protocol does not support queuing by default. It has three types of quality of service for message delivery, which are "At most once", "At least once" and "Exactly once". It also has a mechanism that can be used to inform interested parties about an abnormal disconnection using the "Testament" and "Last Will" features.

What is interesting is the fact that MQTT has already been used in numerous applications. The first implementation of GCM(C2D)[1] used exactly this protocol. DeltaRail's latest version of their IECC (Integrated Electronic Control Centre) also uses MQTT for communications within their signalling system, which is covered in [12].

This standard was created by IBM and because of that fact the IBM MQTT client Java library was used for testing and the Mosquitto open source message broker for distributing messages. Mosquitto's simple construction allowed us to create a bash script sending a set number of messages. The Android client connects to the broker using the IBM library and is fed the messages sent by the script.

MQTT-SN is a variation of MQTT designed to be used in sensor networks. In particular, it is supposed to be lightweight and easily implementable on small devices (e.g. in non-TCP/IP[2] networks).

### *G. CoAP*

CoAP[3] is a specialised web transfer protocol for use with constrained nodes and networks based on UDP (User Datagram Protocol). Its main task is to allow for communication between small devices such as sensors, switches, etc. It was designed on the basis of HTTP in order to simplify its architecture and allow for multicast. It also provides a simple mapping between CoAP and HTTP, which can be used to create RESTful services. The messages are sent in a binary format and their size is limited by the maximum size of a datagram. Messages can be sent with acknowledgements or without them depending on the designer's needs. Although it is a relatively new standard, it already has some additional features proposed like "Observable", which makes it possible to notify all the clients subscribed about changes to the resource.

### *H. AMQP*

AMQP is an open standard application layer protocol for message-oriented middleware that uses a binary format to send its messages. It was designed to solve the problem of interoperability between heterogeneous systems and message brokers. It was first used in 2006 by JP Morgan. It offers both point-to-point and publish-subscribe messaging types.

The most important advantage of AMQP is the fact that it is independent of programming languages and platforms unlike most messaging standards, for example JMS (Java Message Service) [13]. Moreover, it offers several types of quality of service in terms of delivery guarantees; these types are at-most-once, at-least-once or exactly-once guarantees. It also allows to encrypt messages, which is important especially in the case of valuable scientific data. Currently it is a widely used standard and has a large number of implementing libraries like Apache Qpid, RabbitMQ [14] or StormMQ.

## IV. Tests

There are currently three main mobile operating systems (Android, iOS and Windows Phone) available on the market and numerous devices that support them. As it would be neither possible nor sensible to test each and every one of them, only one testing platform and device was chosen.

Google's Android system was selected as the mobile platform for testing purposes because of the considerable availability and open nature of the solution. All major protocols and methods selected have working implementations for this system.

[1] Android Developer Central - GCM Advanced Topic - http://developer.android.com/google/gcm/adv.html

[2] Transmission Control Protocol/Internet Protocol

[3] CoAP RFC 7252 - http://tools.ietf.org/html/rfc7252

As a mobile device the Nexus 5 (LG D821) was used with Android version 4.4.3 using the standard Dalvik engine. At this point Android Runtime was already available but it seemed not yet ready for serious testing. All data (from a mobile device) was transmitted using an HSPA technology (operator: T-Mobile).

In order to conduct all tests, a server platform was also needed, which consisted of an Asus laptop with the Intel i5-3320M processor and 8GB of RAM with Ubuntu 12.04LTS and Oracle Java 1.7.0_60 installed. All data (from a server platform) was transmitted over the Wi-Fi network using the 802.11g standard (54 Mbps).

For time-related test cases ClockSync[4] was used to synchronise with time servers on the mobile device. All applications launched their message connectors in separate threads. Services were not used so all memory usage diagrams show the combined values of the connector and activity screen.

All useful notification methods should meet most of the specifications listed below:

- the financial cost should be low—mostly for open source and university projects;
- it should be possible to transmit more than just simple text—to enable interaction between the application and the main system;
- energy and memory usage should be minimal—the solution is to be used on mobile devices;
- message contents should be secure—confidential information could be transmitted;
- minimal message loss—important data could be transmitted;
- minimal delay—fast interaction is sometimes needed.

As a result of analysing the notification methods available (see Section III) and taking the above assumptions into account, it was decided to test the following protocols: XMPP, SOAP, MQTT, CoAP and AMQP.

In order to conduct testing for each protocol, the following solutions were used:

- XMPP—in order to prepare the XMPP test, the Smack library was used to implement the mobile client. It has been ported to Android in a version called Asmack. ejabber was used as a message broker. The second client, which was sending messages to the mobile client, was implemented in Python using the SleekXMPP library. The mobile solution was plain and simple with its task limited to keeping an open connection to the broker.
- SOAP—an attempt was made to test a basic polling mechanism using a simple Python SOAP server[5] and a basic Android client[6]. It involved making a number of requests for stress testing and a single request to measure single message performance. After obtaining initial results this method was discarded as it was more than 10 times slower than any other and used a lot of resources for polling, which is unacceptable for mobile devices. It was decided to concentrate efforts on other solutions specifically intended for such devices. The results collected are shown together with the other protocols tested, but are not included in graph comparisons (in Figure I) as they were much worse than for any other test conducted.
- MQTT/MQTT-SN—a broker that works with the MQTT/MQTT-SN protocol is the RSMB (Really Small Message Broker) from IBM and while it is quite easy to find, locating an appropriate client library (especially for MQTT-SN) is much more difficult. The one that is available for MQTT-SN[7] is written in the C programming language so it was of no use whatsoever for Android devices. The project also appeared to have been abandoned (no recent contributions). A further search led to a library written in Python[8], which was then used to implement a client that would be run using the QPython interpreter. After a certain amount of research and testing a stage was reached where messages were delivered from the broker to the device but never reliably. Attempts to change QoS settings failed as it appeared that the client library implementation was not complete yet. For these reasons MQTT-SN was excluded from testing and only MQTT was tested. It appears that the protocol is not mature enough yet to be used on a larger scale and that it has no reliable or finished implementations.
- CoAP—there is a limited number of implementations. The main Java libraries are jCoAP and nCoAP. jCoAP is not up to date with the RFC (Requests for Comments) 7252 and therefore nCoAP was used which additionally implements the “Observable” feature. To test the protocol, a simple server was created with a time service and a mobile client that was sending GET requests to the server. At first it was intended to use the “Observable” feature, but during stress testing it turned out that messages cannot be sent too often using this implementation because of errors. As a consequence, although “Observable” can be quite useful, especially in mobile systems, it was decided to have each notification sent as an answer to a separate GET request.
- AMQP—RabbitMQ was selected, which is one of the best documented and popular libraries. For testing purposes a simple Python script was developed that can send a set number of simple messages containing timestamps and an Android client application. The client connects to the RabbitMQ message broker and then the Python script is used to send messages.

To assess the efficiency and usefulness of the notification methods selected, several test cases were created and run for each protocol. It is not claimed that it is a complete test suite,

[4] ClockSync - http://amip.tools-for.net/wiki/android/clocksync

[5] Python simple and lightweight SOAP Library (a.k.a. soap2py) - https://code.google.com/p/pysimplesoap/wiki/SoapServer

[6] A simple SOAP client for Android - https://code.google.com/p/droidsoapclient

[7] MQTT-SN client in C - https://github.com/njh/mqtt-sn-tools

[8] MQTT-SN client in Python - http://git.eclipse.org/c/mosquitto/org.eclipse.mosquitto.rsmb.git/tree/rsmb/src/MQTTSClient/Python

but rather preliminary testing. More work remains to be done in this field.

### A. Time per message

Each of the four applications designed to check how much time it takes to process a single message while stress testing was used with different numbers of concurrent messages sent. Set sizes of 10, 50, 100, 200, 300, 400 and 500 messages were chosen. Each message contained its timestamp in order to enable the calculation of exact delay. Figures 1 (nCoAP), 2 (MQTT), 3 (RabbitMQ), 4 (XMPP), 5 (SOAP over HTTP) show how much time it took to process a single message for different stress test set sizes.

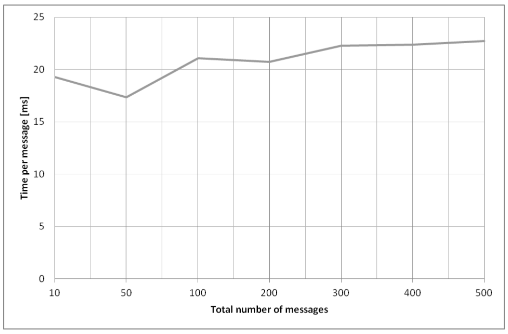

Fig. 1. nCoAP

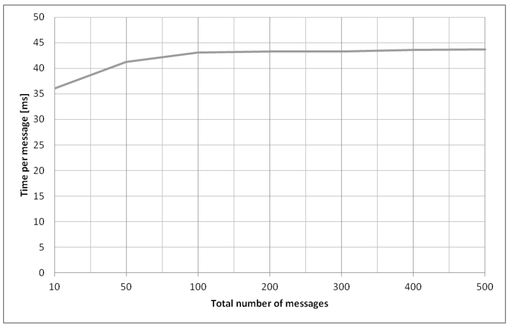

Fig. 2. MQTT

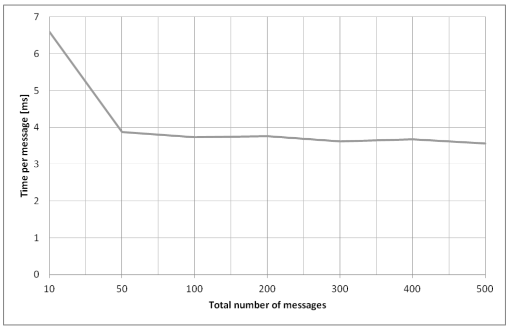

Fig. 3. RabbitMQ

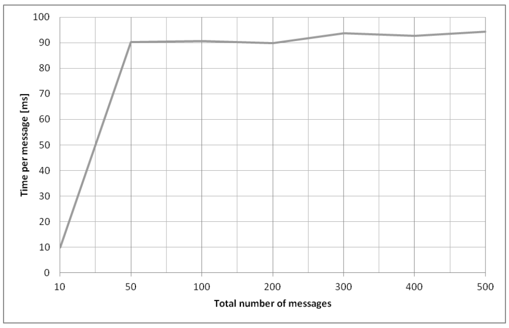

Fig. 4. XMPP

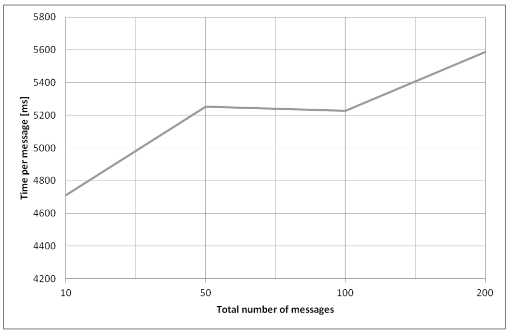

Fig. 5. SOAP over HTTP

Based on the graphs generated it can be stated that RabbitMQ is the fastest in terms of performance and its performance actually improves as more messages are sent concurrently. The nCoAP was also quite effective, but it should be kept in mind that each message was sent in response to a GET request, so it could be faster yet. Both MQTT and XMPP exhibit quite long message sending times. However SOAP over HTTP being definitely the slowest solution. In this test, RabbitMQ was the clear winner.

### B. Resource usage

The second most important criterion after performance was resource usage. It is crucial to use as little device resources as possible on a mobile platform in order to consume less power and allow for greater efficiency. In this section, peak memory usage (shown in Table I - "RAM (Random Access Memory) usage peak") and CPU (Central Processing Unit) power consumption (by using PowerTutor tool [15]) were measured as presented in Figures 6 (nCoAP), 7 (MQTT), 8 (RabbitMQ), 9 (XMPP), 10 (SOAP over HTTP), while sending 1000 messages concurrently to be processed by each of the mobile clients developed.

It is clearly visible that almost all protocols used similar amounts of memory, with the only outlier being MQTT with 10 MB less RAM usage than others. A much larger difference can be seen in power consumption levels. These seem to be strongly correlated with each individual protocol's processing time. nCoAP and RabbitMQ consumed the least power. About two times more power was consumed by XMPP and SOAP

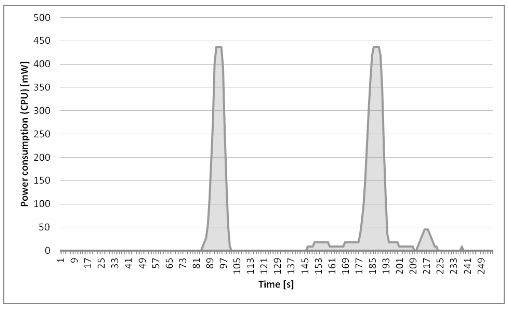

Fig. 6. nCoAP (2 consecutive runs shown)

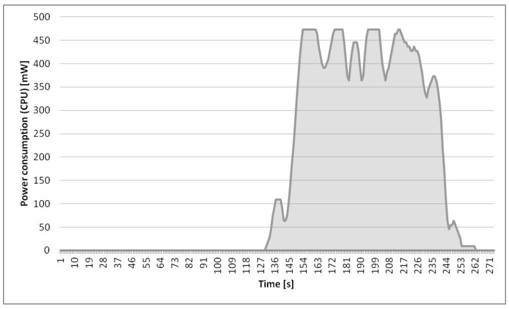

Fig. 7. MQTT

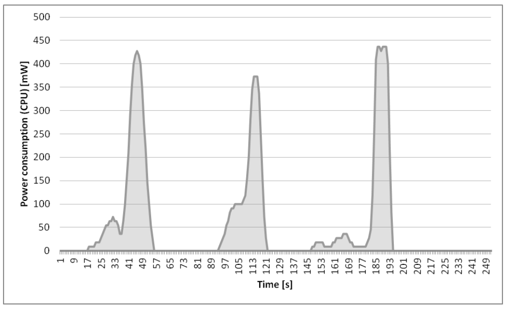

Fig. 8. RabbitMQ (3 consecutive runs shown)

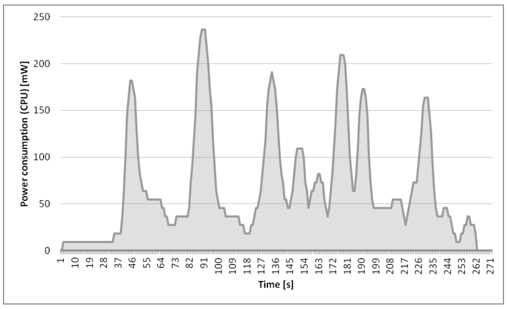

Fig. 9. XMPP

over HTTP. The worst result was achieved by the MQTT protocol.

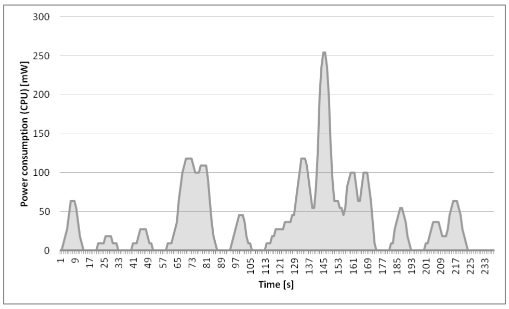

Fig. 10. SOAP over HTTP

### C. Reliability

Message sending reliability was also tested as it is one of the crucial issues to be tackled in mobile notification applications. Especially important is the issue of what happens to messages in a queue when the connection to the client is lost. This was simulated by reconnecting to a Wi-Fi network while sending a set of 1000 messages. All protocols were tested using default settings. It turned out that only nCoAP managed to deliver all messages, while the other protocols lost some or most of the messages sent. Developers must take care to use the correct settings for each protocol as QoS is not usually switched on by default.

### D. Ordering

This test case was meant to show whether protocols deliver messages in the same order in which they were sent. Similarly to the first test, a set of messages was sent containing timestamps and the comparison of arrival times of successive messages made it possible to determine whether they were correctly ordered. Only nCoAP changed the order of messages, which is most probably caused by using UDP. All other protocols delivered messages in the correct order even during high load.

### E. Average delay

The final test case was used to calculate the average delay when sending a single isolated message using each of the five protocols (Table I - “Average delay”). It turns out that nCoAP is the fastest when it comes to sending individual messages and SOAP over HTTP is the slowest one among all the protocols tested.

## V. Conclusions

The results as shown in Figure 11 clearly demonstrate that in terms of the maximum number of messages delivered per second RabbitMQ is the leader; however, when it comes to minimal delay, nCoAP tends to be able to deliver single messages much quicker. This means that if large numbers of notifications are to be sent, RabbitMQ could be used, while in a sparse notification system CoAP should perhaps be recommended. In the power consumption test the best results were also achieved by RabbitMQ and nCoAP.

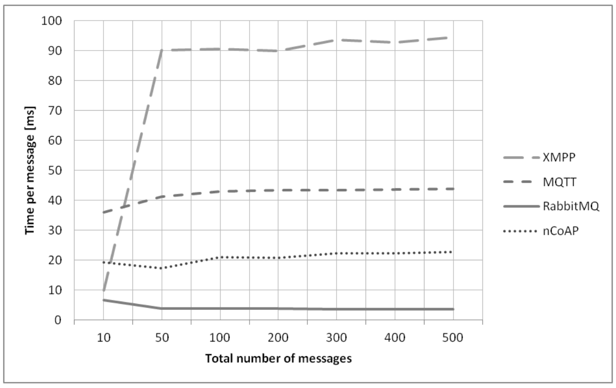

Fig. 11. Comparison of protocols

It should also be noted that not all protocols are able to easily pass through firewalls and NATs like XMPP, which is the most mature of all the protocols tested. When it comes to RAM usage, MQTT turned out to require the least megabytes, which can be of great importance on mobile devices. A summary of test results is shown in Table I.

In conclusion, the most promising solution seems to be RabbitMQ but none of the protocols proposed outperformed all the others in all test cases. This test suite only demonstrates the performance of some implementations currently available and the results might change for future releases or different platforms. Before any protocol is selected, it is important to specify the needs of the project in question and then compare the protocols to determine which one best suits these needs.

TABLE I
OVERVIEW OF PROTOCOL PROPERTIES

| | nCoAP | RabbitMQ | MQTT | XMPP | SOAP |
|---|---|---|---|---|---|
| RAM usage peak [MB] | 47 | 44 | 35 | 46 | 38 |
| Average delay [ms] | 91 | 185.5 | 339.6 | 192.3 | 972.2 |
| Ordered | no | yes | yes | yes | yes |
| Lost messages | no | yes | yes | yes | yes |
| Content | binary | binary | binary | text | text |
| Based on | UDP | TCP | TCP | TCP | TCP |
| SSL support | no | yes | yes | soon | yes |

***Abstract* — This paper presents concept and prototype of universal easy-to-use and self-configurable mobile application dedicated for open data sets collection and sending them to the central database storage based on CKAN platform. This article describes the concept of open data collection in crowdsourcing model using mobile phones and also an architecture of end user application (CKAN client) dedicated for Android operating system.**

## I. Introduction

The concept of Open Data has been known in science and business environments for many years. The main definition of such kind of information describes that “certain data should be freely available to everyone to use and republish as they wish, without restrictions from copyright, patents or other mechanisms of control” [1], [2].

In the world there are many installed platforms, exposed open data sets produced by: cities, government institutions, scientific, and private companies. Large sets of this information being offered under open licenses such as mentioned in [3] are exposed in up to bottom model. Main part of such data comes from government institutions collecting and processing a large number of information about: their citizens, financial data or statistical information. Another idea regarding open data collection is concentrated on up to button approach. This model is based on idea of crowdsourcing and allows citizens to collect data.

Because of growing popularity of mobile devices (e.g. smart phones or smart watches) in recent years this kind of devices becomes the most convenient tool for collecting and aggregating open data sets. Therefore, dedicated, easy-to-use mobile application use mobile phone functions such as GPS receiver and photo camera. In many cases it becomes the best tool for the data acquisition using crowdsourcing.

## II. Existing Solutions

On the Internet we can find large set of mobile applications dedicated to open data collecting. For example Yanosik [4] – the most popular, based on crowdsourcing model, mobile application in Poland. This service allows drivers to report information about dangerous situations on the roads: accidents, construction zones, police patrols locations etc. Other application users, basing on the data collected and exposed in this system, can adapt their behavior to local conditions and thus improve the safety on the roads. Another exemplary system based on crowdsourcing concept is mobile application 19115 [5] developed by City of Warsaw. This service (mobile application is only one component of the 19115 system) is dedicated to report non-emergency incidents in Warsaw. Residents using this service can report any information about the city (road damage, problems with garbage, problems which needs the intervention of the municipal guard, etc.). It could be noticed that applications presented above are dedicated only to specific use cases (road traffic reporting or processing interventions in City of Warsaw) and it is not possible to use them to collect any kind of open data. These solutions are dedicated to specific usage, not configurable and closed from systems integration point of view.

In literature we can find some open solutions dedicated to open data collection. Another type of mobile applications are those, mostly concentrated on processing and transferring open data from end user in universal form in which the scope and type of collected open data is configurable by the system administrators. The very good example is Open Data Kit [6]- set of tools which manages mobile data collection. Open Data Kit allows to build a data collection in survey form, collect the data

978-83-60810-66-8/$25.00©2015, IEEE

using mobile device and send data to the server. Tool supports also aggregation of data on the server side and visualize them.

In literature, there can be found also applications dedicated for CKAN platform [7] - open source framework de'facto standard in open data exposition. First one is Ukansearch - mobile web application to improve access and availability to open data. Unfortunately actually Ukansearch allows only to search using tags datasets on the www.data.ug portal [8] and doesn't support open data collection process. The second solution is sample CKAN Android client [9]. This tool was developed about 3 years ago and still exists only in beta version.

## III. CKAN

CKAN (Comprehensive Knowledge Archive Network) – is open source data portal and open data exposition platform. This project was started in March 2006 [7] and is maintained by The Open Knowledge Foundation [10]. After 9 years of development CKAN is world-leading open data platform and there are more than 60 instances [11] of the system installed worldwide such as: data.gov - a portal of the United States government [12] British data.gov.uk [13], or the publicdata.eu European Union open data portal [14].

Fig. 1. Example data set in CKAN platform

CKAN platform allows for storage and management of open data repository, publication, search and visualize of data sets. System also allows developers to download and upload data sets via rich JSON based on API (Application Programming Interface). CKAN is open source software distributed under open license Affero GNU GPL v3.0.

## IV. IDEA OF CROWDENABLER

Because currently there is no universal mobile application dedicated to open data collection using CKAN portal the main goal was to build the concept, development and to test this type of application.

Crowd Enabler is an application dedicated to the collection of open data. With it, users of smartphones with the Android operating system can complement the individual datasets hosted on the CKAN platform. Native application function allows to add individual records to CKAN using geolocation information based on implemented in the phone GPS receiver. The main feature of the Crowd Enabler application allows to add objects containing text data, image files and the geographical coordinates by the end-user of the mobile phone. A user with the application, may, at any place (with enabled internet access and GPS location), take a photo of any object, add descriptions, and add its geolocation.

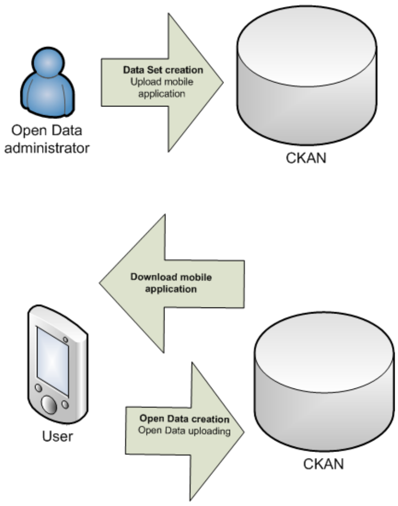

Fig. 2. Idea of Crowd Enabler

From the CKAN administrator and mobile application end user point of view the application usage looks as follows:

1) Data Set creation and upload Crowd Enabler.
In this step system administrator creates in CKAN an empty data set, prepares and uploads it as an CKAN resource. Then installs version of Crowd Enabler mobile application. The url to the Crowd Enabler is distributed (by e-mail or web page) to the end application users.
2) Download Crowd Enabler mobile application.
In this step application users responsible for open data collection download and install mobile application on their phones. It should be noticed that because of not publishing Crowd Enabler in Google Play application shop the option install from "Unknown sources" in mobile devices during this step must be turned on.
3) Data collection.
In this step application user can collect and store

data sets using mobile application. Application after start retrieves all information from CKAN platform using RDF metadata extension and reconfigures (changes names of the buttons and hints for editable fields). Application process open data in three following steps:

a) collected geographic location based on GPS receiver,

b) collected object description (in text form),

c) collected photo,

d) sending data to the repository (CKAN).

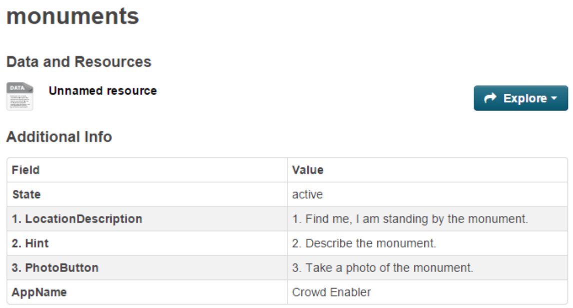
## V. RDF ONTOLOGY USAGE

Resource Description Framework (RDF) [15] is a standard for describing web resources. RDF using some of the extension such as Data Catalog Vocabulary (DCAT) can be used for description of any resources on the Internet and used for building semantic Web concept. Semantic internet is the vision of Tim Berners-Lee and in data layer it's architecture is based on Linked Data principles. These principles are as follows [16], [17]:

- Usage URIs as names for things.
- Usage HTTP URIs so that people can look up those names.
- When someone looks up a URI, provides useful information, using the standards (RDF, SPARQL).
- Exposition links to other URIs, so that they can discover more things.

In presented in this paper application nonstandard RDF usage was proposed and implemented – this additional elements describing web resources were used for exposition of configuration data for mobile application.

In Crowd Enabler RDF extensions were used to define some application parameters. (e.g. Text box description etc.). Application uses RDF extension in Data Catalog Vocabulary (DCAT) standard implemented in CKAN platform.



monuments

Data and Resources

Unnamed resource

Additional Info

| Field | Value |
|---|---|
| State | active |
| 1. LocationDescription | 1. Find me, I am standing by the monument. |
| 2. Hint | 2. Describe the monument. |
| 3. PhotoButton | 3. Take a photo of the monument. |
| AppName | Crowd Enabler |

Fig. 3. DCAT RDF extension in CKAN platform

In CKAN in format key-value there were 4 parameters defined and described in the table below:

Table 1. DCAT RDF parameters defined in CKAN dedicated for Crowd Enabler

|  | Parameter | description |
|---|---|---|
| 1 | LocationDescription | Task name / name of collected object |
| 2 | Hint | Collected object detailed description |
| 3 | PhotoButton | Task name (photo) |
| 4 | AppNAme | Name of application |

Based on RDF XML extension in CKAN parameters presented above are accessible for developers during access to the data set via API using additional header in HTTP request **Accept: application/rdf+xml.**

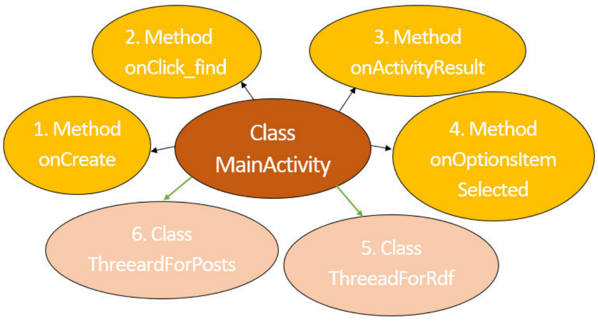
## VI. SYSTEM ARCHITECTURE

This section of this publication contains the architecture and functionality of Crowd Enabler application. This mobile application is dedicated for Android operating system and was developed using Eclipse and Android Development Tools (ADT)

### *A) Programing environment*



2. Method onClick_find
3. Method onActivityResult
1. Method onCreate
Class MainActivity
4. Method onOptionsItem Selected
6. Class ThreeardForPosts
5. Class ThreeadForRdf

Fig. 5. Application class structure

The main methods and classes implemented in the application are as follows:

1. Method onCreate handles methods which are connected to buttons and starting ThreeadForRdf and ThreeadForPosts.
2. Method onClick_find sets GPS coordinates.
3. Method onActivityResult makes sure that our photo exists and is displayes in the app.
4. Method onOptionsItem Selected handles pressing Settings.
5. The main Method getRdfXml in Class ThreeadForRdf, gets useful informations from rdf about dataset. Using this, sets descriptions of buttons and editText.
6. Method makeRequestImage in Class ThreardForPosts sends image to dataset. Method makeRequest sends full data (in JSON) of record to dataset.

-

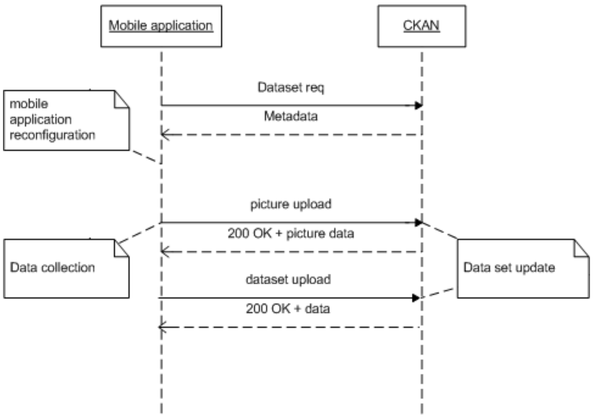


Fig. 6. Application data flow

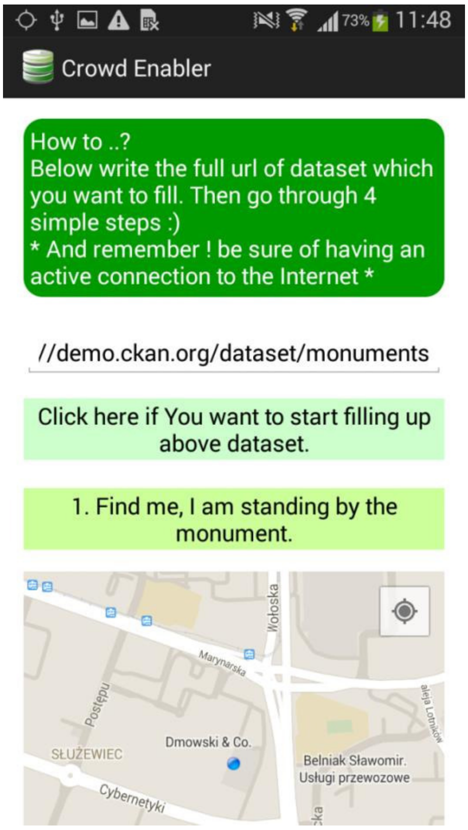
Data flow between Crowd Enabler and CKAN platform is presented on Fig.6

1) Dataset request – application after launch based on defined http resource connects with CKAN Platform, downloads metadata and RDF extensions in key – value form used for Crowd Enabler configuration.
2) Crowd Enabler self-configures and shows GUI.
3) User takes photo and uploads it on the CKAN server as open data resource.
4) User performs an additional description of data record (text ,GPS coordinates), uploads and sets it to the CKAN.

### *B) Application GUI*

End application user is a person who uses Crowd Enabler on it's mobile phone – and collects open data records. After start, application connects to CKAN and catches from RDF scheme of metadata to change names of buttons and hints defined in the application GUI.

When user wants to collect data using geolocation, must stand with his smartphone nearby an object which he wants to upload (e.g. memorial or monument).



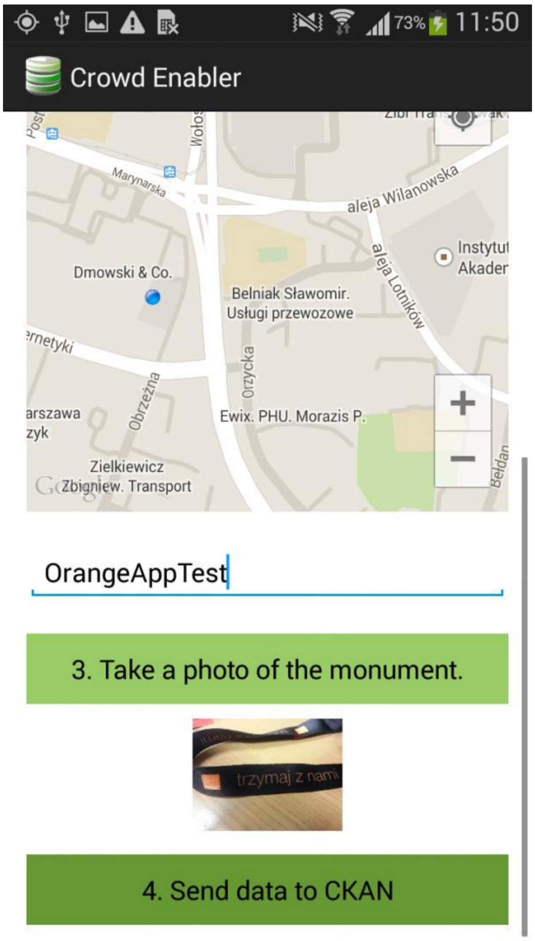
How to ..?
Below write the full url of dataset which you want to fill. Then go through 4 simple steps :)
* And remember ! be sure of having an active connection to the Internet *

//demo.ckan.org/dataset/monuments

Click here if You want to start filling up above dataset.

1. Find me, I am standing by the monument.

Fig. 7. Application GUI



OrangeAppTest

Fig. 8. Application GUI

After taking photo and adding additional description end application user sends data to a server by pressing Send Button.

## VII. MEASURENMENT

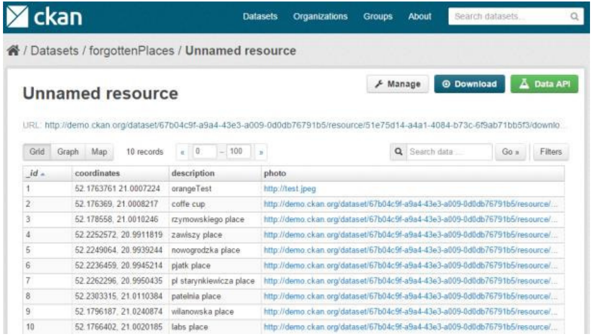
Using Crowd Enabler application several data sets were collected

1) monuments - historic buildings and monuments in Warsaw

2) forgottenPlaces - some interesting places in the city

3) Trees - the test group of trees

The Figures bellow shows the example data sets with forgottenPlaces and monuments in Warsaw



/ Datasets / forgottenPlaces / Unnamed resource

It needs to be stressed that for application test only small data sets in the amount of several records each were collected.

## VIII. SUMMARY AND FUTURE WORK

In the future, authors intend to make some modifications in the Crowd Enabler application

1) Improvement of application installation process - application can be exposed in Google Play application shop and installed after connection and download without "install from unknown source" Android option usage

2) Usage of another geolocation sources instead of GPS (e.g. location based on Telco operator infrastructure, Wifi infrastructure etc.).

The main goal of this project was to build a mobile client for CKAN open data platform.

The universality of developed application based on self-configuration capabilities as well as proposed and tested nonstandard RDF meta data usage needs to be emphasized. It should be mentioned that Crown Enabler application has been created in Open Middleware Model using Open Application Programming Interfaces allowing in ease way to create innovative applications and services such as: [17], [19], [20], [21].

The potential of usage of the presented application is very wide. End application users can store large sets of data, that can be described by location, photos and extended text description.

Prototype of Crowd Enabler application was made as part of the Open Middleware 2.0 Community by Orange Labs program [22]

# 4th International Conference on Wireless Sensor Networks

A FEW years ago, the applications of WSN were rather an interesting example than a powerful technology. Nowadays, this technology attracts still more and more scientific audience. Theoretical works from the past, where WSN principles were investigated, grew into attention-grabbing applications practically integrated by this time in a real life. It could be said, that countless application fields, from military to healthcare, are already covered by WSN. Together with this technology expansion, still new and new tasks and interesting problems are arising. Simultaneously, such application actions stimulate the progress of WSN theory that at the same time unlocks new application possibilities. The typical examples are developments within the "Internet-of-Things" field as well as advancements in eHealth domain with WBAN IEEE 802.15.6 standard progress.

Wireless sensor networks, as the spatially distributed networks consisted of a number of relatively simple, low-cost, low-power components interconnected mutually, provide quite wide application portfolio for different branches of economy. As the main examples could be mentioned military, industry, transport, agriculture and healthcare. However, in the near future, even stronger expansion of WSN application assortment is expected. In order to make this expansion possible, it is necessary to continually work on the solving of typical questions/problems related to the WSN development, e.g. standardization of communication protocols; the lack of energy-efficient power sources; the development of new ultra-low-power microelectronic components; etc.

An integration of WSN within the public data networks as well as within the domains where confidential and private data are processed (e.g. E-Health) brings along problems related to the ethical and legal questions too. Therefore, the terms as social safety or ethical safety should not be neglected.

The problematic of WSN is one of actual activities getting to the fore in the European Research Area since the issue of sensor networks was covered through "IoT" in FP7 program and strong continual extension is planned to be included also in Horizon 2020 program, especially in sections such Smart Transport; Health; Climate Action covered under Societal Challenges Pillar.

It is therefore essential to create an experience-sharing platform for scientific researchers and experts from research institutes, SMEs and companies who work in WSN domain where they can exchange some relevant skills and experiences as well as discuss upcoming trends and new ideas from this field. Moreover, the conference should also serve a function of a kind of networking platform facilitating interconnectivity between participants in case of a future collaboration.

## Topics

Original contributions, not currently under review to another journal or conference, are solicited in relevant areas including, but not limited to, the following:

*Development of sensor nodes and networks*

- Sensor Circuits and Sensor devices – HW
- Applications and Programming of Sensor Network – SW
- Architectures, Protocols and Algorithms of Sensor Network
- Modeling and Simulation of WSN behavior
- Operating systems

*Problems dealt in the process of WSN development*

- Distributed data processing
- Communication/Standardization of communication protocols
- Time synchronization of sensor network components
- Distribution and auto-localization of sensor network components
- WSN life-time/energy requirements/energy harvesting
- Reliability, Services, QoS and Fault Tolerance in Sensor Networks
- Security and Monitoring of Sensor Networks
- Legal and ethical aspects related to the integration of sensor networks

*Applications of WSN*

- Military
- Health-care
- Environment monitoring
- Transportation & Infrastructure
- Precision agriculture
- Industry application
- Security systems and Surveillance
- Home automation
- Entertainment – integration of WSN into the social networks
- Other interesting applications

peter.sarafin@fri.uniza.sk

***Abstract*—This paper presents real-time scheduler in operating system running on ARM Cortex (M0, M3, M4) usable in small mobile robotics with kernel response around 1ms. Thanks to the strong modularity, advanced sleep modes and event driven programming ability, it can be used for WSN applications too.**

***Index Terms*—operating system, ARM Cortex M, mobile robotics, WSN node, low-power, real-time**

## I. Introduction

REAL-TIME scheduler provides added value for embedded software development in the form of strong modularity, reusable code and rapid development [1]. Many embedded applications work without operating system - usually single purpose tasks or interrupt driven tasks. For more complex applications, operating system can provide better results when some common problems occure [2] [3] :

- Multiple sensors (or any inputs) reading
- Multiple control loops with different sampling time
- Communication (routing, resending)
- Power management
- System modularity and extension posibilities
- GUI running on background of the main process

From these, we can consider following operating system requirements:

- Multiple parallel threads (often with priority scheduling)
- Real-time processing ability
- Code size acceptable for microcontroller abilities
- Sleep modes support
- Multiplatform compilation ability
- Modular architecture

## II. Sytem architecture

The operating system runs on a single chip microcontroller. Supported cores are ARM Cortex M0, M0+, M3, M4 and M4F. For testing, TI TivaC TM4C123G [5] (Fig. 1) with cortex M4F core has been used. This MCU is running on 80MHz and it disposes 256K flash memory and 32K SRAM. Other devices, such as STM32L053, STM32F103, STM32F407, LPC812, MKL02Z32 and MKL25Z4 have also been tested.

All parts are compiled using GNU GCC (using C99 standard) into single binary file, which can be loaded into flash memory [4]. Recent source files can be downloaded from [6].

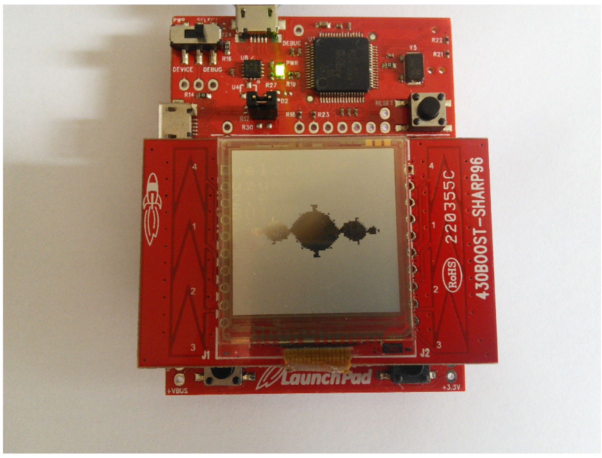

Fig. 1. TI TivaC launchpad testing board

Presented operating system consists of these parts:

- User application
- User libraries
- Kernel
- OS libraries
- Device low level libraries

All parts can work independently on each other. Only necessary part is device low level libraries, represented as HAL (hardware abstraction layer). Operating system is written with microkernel architecture, where kernel only creates and schedules threads. Other functions are implemented as optional libraries.

In the following text, we briefly describe OS structure. The priority scheduling algorithm compared with common round robin is described in more details.

### A. Booting process

After microcontroller reset, HAL is initialized first, especially clock configuration, GPIO initialization, UART timers and ADC setup. All parts are initialized only if they are linked in the binary. In other case, initialization of missing parts is skipped. Absolute minimum requirement for OS running is main clock initialization. For common problems, UART and timers are necessary.

978-83-60810-66-8/$25.00©2015, IEEE

Operating system libraries such as STDIO, software timers, messages subsystem and mutexes are initialized next. After this, kernel is initialized and user main thread is started.

### B. User application and libraries

Users main loop is discussed in this section. The main function is called $void\ main\_thread()$. This main thread can create other threads, by calling $create\_thread$ function. Following code shows how another thread can be created. When $void\ main\_thread()$ is running, user can initialize it's own libraries, usually sensors, displays or communication module. Boot up and four running threads screenshot is displayed in the Fig. 2.

Listing 1. Thread creating

```
thread_stack_t thread_01_stack
[THREAD_STACK_SIZE];

void thread_01(){
}

void main_thread(){
    create_thread(
        thread_01,
        thread_01_stack,
        sizeof(thread_01_stack),
        PRIORITY_MAX);

    while (1)
    {
    }
}
```

## III. Scheduling algorithm

Main part of OS is the microkernel core. Preemptive multitasking with two options, round robin scheduling or time decrease priority scheduling is implemented. To compare different schedule algorithms (especially real-time processing), we first need to define error function. Consider set of threads as

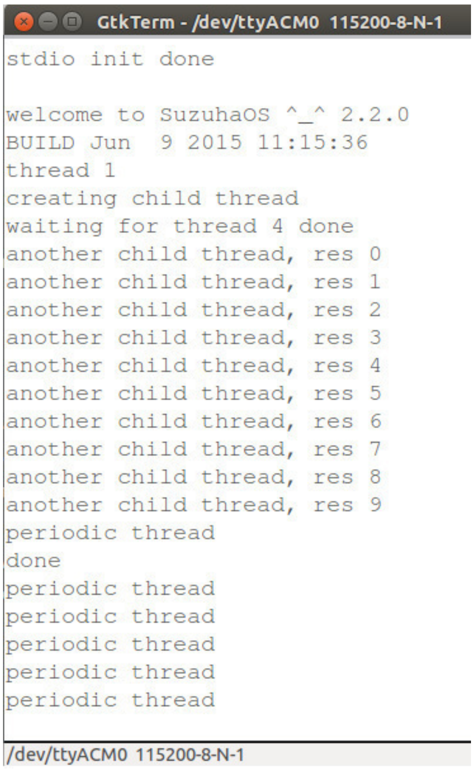
$$t_i \in T(p, k, s, d, c), \tag{1}$$

where $p$ represents thread priority (lower number - higher priority), $k$ is the counter of thread priority current value, $s$ stands for thread state (running, waiting, created), $d$ states thread deadline time (set by user, usually in ms), $c$ is thread running code (represented as Turing machine).

Let us define thread execution time function as $g(t_i)$ and error function as

$$e = \sum_{i=1}^{Tc} |d_i - g(t_i)|, \tag{2}$$

where $Tc$ is threads count. This function represents the error, which corresponds with the difference between required deadline time and measured time of running thread. Using priorities we can define error as



```
stdio init done

welcome to SuzuhaOS ^_^ 2.2.0
BUILD Jun  9 2015 11:15:36
thread 1
creating child thread
waiting for thread 4 done

periodic thread
periodic thread
```

GtkTerm - /dev/ttyACM0 115200-8-N-1
/dev/ttyACM0 115200-8-N-1

Fig. 2. OS terminal screenshot

$$e = \sum_{i=1}^{Tc} |d_i - g(t_i)| \frac{1}{p_i}, \tag{3}$$

where lower $p_i$ means higher priority.

Consider that the faster execution of the thread is not an issue. This fact means that CPU spends remaining time waiting (executing other threads or sleeping). We can write this as (4) and (5).

$$e_i = \begin{cases} d_i - g(t_i) & if\ d_i < g(t_i) \\ 0 & else \end{cases} \tag{4}$$

$$e = \sum_{i=1}^{Tc} |e(t_i)| \frac{1}{p_i} \tag{5}$$

Threads with higher priority (smaller $p_i$) have bigger influence on the total error. To implement priorities, we define following structure for each thread:

Listing 2. thread structure

```
struct sThread{
    u16 cnt, icnt;
    u32 flag;
    u32 *sp;
};
```

where $cnt$ and $icnt$ are counters used for priority scheduling, corresponding with $p$ and $k$ respectively in (1). When thread is created, $p$ and $k$ are set to $priority$ value and remain constant (variability during execution is also possible, but not tested yet). Each nonzero $k$ is decremented after each timer interrupt. Thread with smaller $k$ is chosen for the next execution and its $k$ is loaded back to $p$. Realization in C code is presented on following code listings.

Listing 3. priority scheduler

```
u32 i, min_i = 0;

/*find thread with minimum cnt*/
for (i = 0; i < THREADS_MAX_COUNT; i++)
{
    if (__thread__[i].cnt <
      __thread__[min_i].cnt)
        min_i=i;

    /*decrement counters*/
    if (__thread__[i].cnt != 0)
        __thread__[i].cnt--;
}

__thread__[min_i].cnt =
        __thread__[min_i].icnt;
__current_thread__ = min_i;
```

For full function, other common functions like thread creating, waiting or setting into waiting state are implemented.

Listing 4. kernel functions

```

void sched_off();
void sched_on();

void yield();

u32 get_thread_id();

void kernel_init();
void kernel_start();

u32 create_thread(
    void (*thread_ptr)(),
    thread_stack_t *s_ptr,
    u32 stack_size,
    u16 priority);

void kernel_panic();

void set_wait_state();
void wake_up_threads();
void wake_up_threads_int();

void join(u32 thread_id);
```

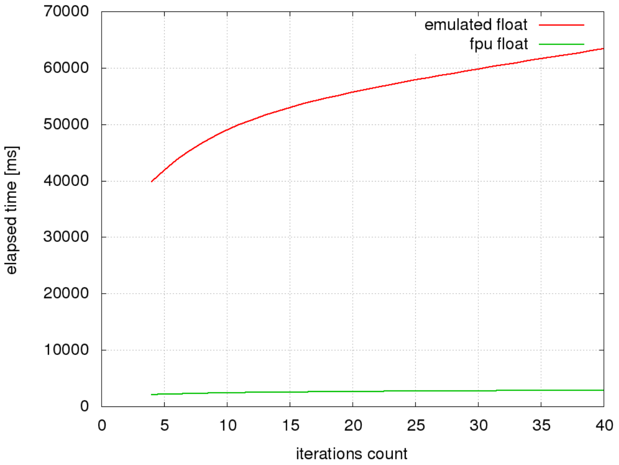

Fig. 3. FPU and CPU calculation times

## IV. Experimental results

For testing OS, few experiments were performed. First one was aimed for the basic multitasking test and comparison of performance using hardware and software emulated float performance. There were four running threads in this experiment. One thread was calculating Julia set fractal and results were displayed on LCD. Total number of calculating points was set to 96x96. Quantity of algorithm iterations was changing from interval $\langle 4, 40\rangle$. Performance result is represented in the Fig. 3. In this test, basic functionality has been tested, especially preemptive multitasking, timers and terminal interface.

Next testing was focused on the real-time processing ability. There were two main and six child threads (only first three are shown in figures). Each thread was waiting specified time (required waiting time) and this time was measured. Difference between required and measured time was used to compare round robin and priority scheduler scheduling algorithms. We

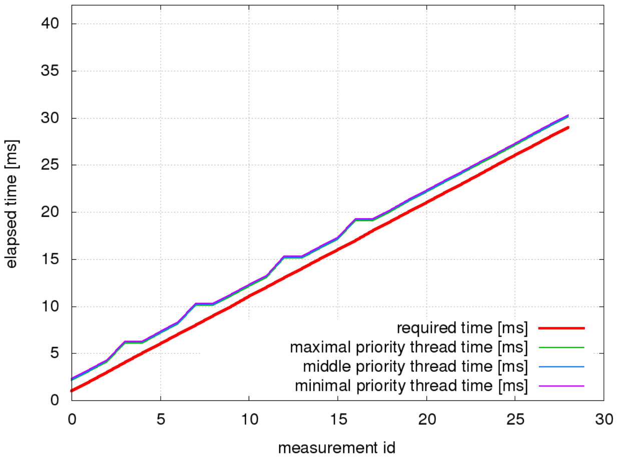

Fig. 4. Round robin real-time test

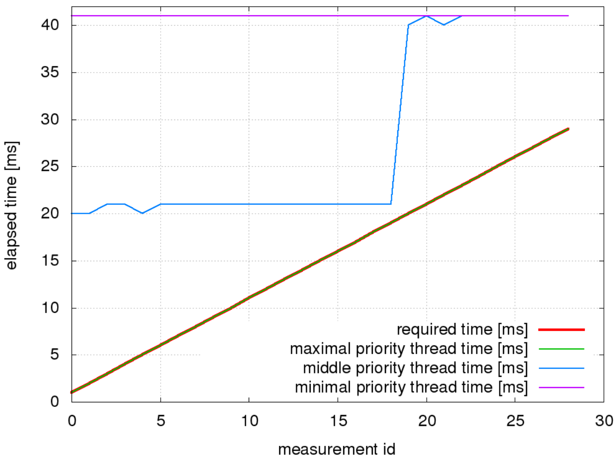

Fig. 5. Priority scheduler real-time test

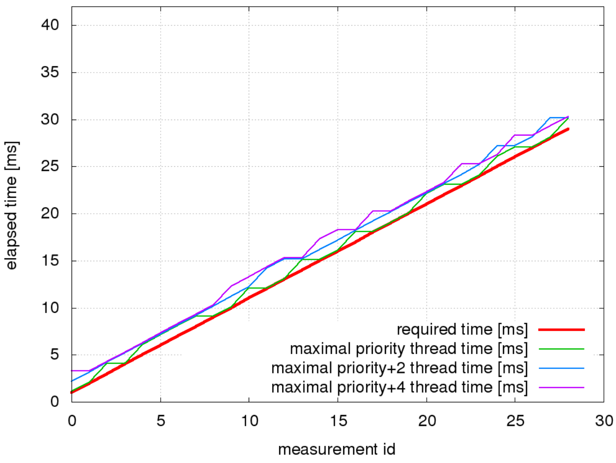

Fig. 7. Priority scheduler real-time test with similar priorities

can see round robin results in the Fig. 4 (all threads have same results). It can be seen, that required value is bellow measured lines and the time difference is around 1ms. Little peaks are consequence of timer resolution, which is 1ms. Situation with priority scheduler can be seen in the Fig. 5.

Threads with the maximum priority perfectly meet the conditions. Threads with lower priorities were executing for much longer time. Following priority values $p_i$ have been used:

- PRIORITY_MAX = 8
- PRIORITY_MID = 128
- PRIORITY_MIN = 255

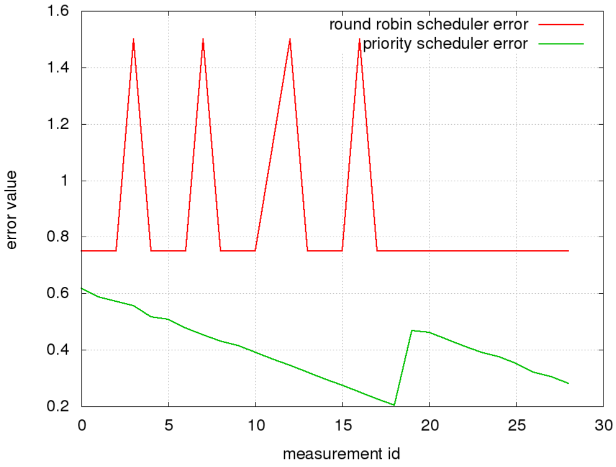

Fig. 6. Schedulers error comparison

We can use (5) to compute total error from meassured times. Result is shown in the Fig. 6. From priority scheduling algorithm, it can be seen that it converges into round robin when priorities are equal. This experiment was accomplished and results are presented in the Fig. 7.

## V. Conclusion

In this paper, priority scheduler has been explained and OS was briefly introduced. From experimental results, we can see that priority scheduler has better results, when considering error function definition (5). Of course, if we consider maximal deadline time without looking for priorities, round robin has better results. For applications, where same priority is necessary, round robin (or priority scheduler with same priorities represented in the Fig. 7) provides better solution. For applications, where it is needed to prioritize some processes, priority scheduler is of course better choice.

# Trust Security Mechanism for Marine Wireless Sensor Networks

Walid Elgenaidi, Thomas Newe
University of Limerick,
Optical Fibre Sensors Research Centre
Department of Electronic and Computer Engineering
Limerick, Ireland
Email: {walid.elgenaidi, thomas.newe }@ ul.ie }

*Abstract*—**To provide a strong security service in Wireless Sensor Networks (WSNs), cryptographic mechanisms are required. Generally these security mechanisms demand intensive use of limited resource, such as memory, and energy to provide a defense against attacks. Monitoring the behavior of nodes and detecting risks according to these behaviors, and then taking decisions based on these measurements generally requires the use of a trusted Key Management scheme. In this paper we compare two existing security key management schemes that were designed for use in mobile ad hoc networks: "An overlay approach to data security in ad-hoc networks" authored by Jorg Liebeherr, Guangyu Dong, and "A hierarchical key management scheme for secure group communications in mobile ad hoc networks" authored by Nen-Chung Wang, Shian-Zhang Fang. Then a Hybrid Security Key Management Mechanism designed for use in the marine environment is proposed. This scheme focuses on reducing the memory storage of keys, using a leader node that is responsible for both the node joining and the node revoke processes. This security mechanism is implementing in real time on the Waspmote sensor platform.**

## I. Introduction

Design of smart security solutions for wireless sensor networks for specific fields such as marine environments is a big challenge. Since smart security protocols must be designed to have efficient and flexible key distribution systems to prevent attacks while conserving energy [1], [5]. This work aims to provide a secure technique using both Symmetric and Asymmetric key algorithms. Our designed scheme seeks protection against attacks by providing the standard security services such as confidentiality and authentication in addition to addressing the re-keying process between adjacent nodes, as well as reducing the number of stored keys. Therefore the sensor nodes are configured in a point-to-point topology which is suitable for marine coastal WSN systems.

The system proposed in [2] uses public/private keys, pre-message keys and requires that offline signed certificates are stored in each node. Authentication between nodes is performing without coordination with other nodes; this makes trust revocation difficult for 'bad' nodes. Each node maintains a single symmetric key that it shares with its current neighbours in the network topology. Furthermore, a public key is required in the authentication of new neighbours, and every node requires its neighbour's public key for use with the RSA public key algorithm.

The system proposed in [3] offers key management for secure group communications using a two-layer structure. The selected cluster head constructs and transmits a group key to all nodes. This scheme uses symmetric keys for subgroup keys and communication keys. The Diffie–Hellman "DH" key exchange scheme is utilized to achieve secure key transmission between subgroups. These schemes are discussed in section II below.

Section III presents a comparison between the neighbourhood key and hierarchical key management schemes for secure group communications. Section IV proposes a new hybrid key management scheme and section V concludes.

## II. Trust Key Management Techniques for Wireless Sensor Networks

There are essential practices for developing a good trust management system for WSNs and for the management of the necessary cryptographic keys [3]. In [2] Jorg Liebeherr, Guangyu Dong presented a key management and encryption scheme, called the neighbourhood key method, that ensures integrity and confidentiality of application data in overlay networks. The neighbourhood key method avoids network wide re-keying operations and payload data re-encrypting at each hop.

### A. Updating and Exchanging Neighbourhood Keys

The solutions presented in this scheme [2] are orthogonal to the problem of secure routing, which seeks protection against attacks to routing protocols. Each node has its own certificate and this certificate has been signed by a trusted third party using X.509 Version 3. These certificates, which include secret keys are exchanged between neighbours to use in encrypting or signing messages of

authenticated nodes. Encryption of data and the signing of hashes in each node are done with a single symmetric key called a"neighbourhood key". The neighbourhood key is shared with its current authenticated neighbours in network.

A joining node must generate a new neighbourhood key and send it to all of its authenticated neighbours in order to maintain confidentiality in the network.

Therefore every node must use a public key algorithm to encrypt the new neighbourhood key with the public keys of all the authenticated neighbours that are stored in the node during the authentication process as shown in "Fig. 1,". In this phase, nodes update keys only with current neighbours. However updating and exchanging a new neighbourhood key is executed whenever the set of authenticated neighbours are changed or the specified maximum lifetime of the current neighbourhood key is expired. The security issues are exacerbated during failures in reconstruction of the network topology when one or more nodes join and leave the network at the same time.

The neighbourhood Scheme prevents nodes against a DoS attack from a malicious adversary by implementing an integrity test, and also the allowed frequency of transmitted Key Request messages is limited.

### *B. Constructing and Transmitting Keys Using Cluster Head*

Nen-Chung Wang, and Shian-Zhang Fang [3] introduced a hierarchical key management scheme for secure group communications in a mobile ad hoc network. They proposed a new approach with a two-layer structure whereby a cluster head manages information between nodes in the layers as shown in "Fig. 2". Node with the largest weight value in each level is selected to be a cluster head [4]. The key transmission operation between nodes in the same level subgroup and with nodes in other level subgroups is coordinated by the cluster head.

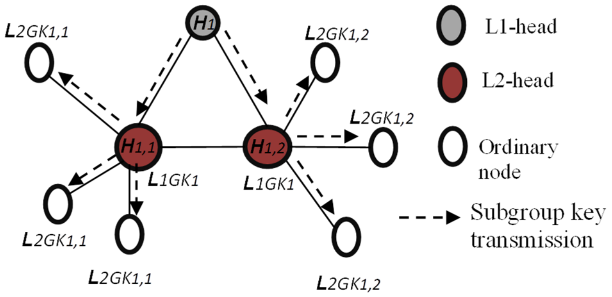

Fig.2. Subgroup key transmission operation between nodes

Level 1 subgroup "L1-subgroup" contains all of the nodes in the subgroup and the level 2 subgroups "L2-subgroup" are selected based on their positions. The node with the largest weight value in every L2-subgroup will be selected as the level 2 cluster head "L2-head" to manage the other nodes of the L2-subgroup.

The Diffie–Hellman "DH" scheme is used for secure transmission between nodes in subgroups, and each subgroup has its own subgroup key. L1-head generates the communication keys that are used between the different subgroups. The encryption and decryption operation during data transmission in different subgroups is only through subgroup keys, which means that packets are transmitted through the cluster heads.

The level 2 cluster head "L2-head" is responsible for a new node joining its subgroup. It initiates the generation of a new subgroup key "$K_{LXGK_S}$" after a new node joins a subgroup.

A node leaving of subgroup [4] falls under three cases: the leaving of ordinary nodes, the leaving of L2-heads and the leaving of L1-heads. These cases for each scheme are explained in the section III.

## III. Security Analysis and Comparison between Neighbourhood and Hierarchical Key Management Schemes

In this section, the neighbourhood key and hierarchical key management scheme for secure group communications are compared under the headings; Security Keys, Node joining process, and Node leaving process.

### *A. Security Keys*

In both schemes the packet during data transmission is encrypted using different cryptographic algorithms depending on the packet function; AES for symmetric encryption, RSA for public key encryption, and Diffie-Hellman scheme to generate keys. Two symmetric keys "128 bits" in the neighbourhood scheme are generated in every node, one is shared with all authenticated neighbours and the other is used to encrypt the payload of the message.

$$\left(\{M\}_{k_s}, \{k_s\}_{k_{nj}}\right) \qquad (1)$$

Where "$M$" is message, "$k_s$" is source key, and "$k_{nj}$" is neighbourhood key of node $j$.

In order to reduce the delay that is incurred by decrypting and re-encrypting the message between forwarded nodes, a node only needs to re-encrypt the source key "$k_s$" with its own neighborhood key before transmission. However the hierarchical key management scheme uses three security keys to deliver data between nodes in a network. Symmetric subgroup keys "$K_{LXGK_S}$" are used for transmission between all nodes that fall under the L1-head subgroup. Additionally, secure data delivery in different subgroups is achieved through symmetric communication keys "$k_c$" and "$k_{DH}$" which only belongs to the source node and the destination node. "$k_{DH}$" is used for the first encrypted packet transmitted.

*Example*: Assume node A in subgroup X would like to send data to node C in subgroup Y:
In node A:

$$\{\mathrm{M}\}_{\mathrm{K_{DH}}} \tag{2}$$

Packet will encrypt and decrypt with "$K_{LXGK_S}$" when transmitted through nodes in the same subgroup. At the first forwarding node in the subgroup Y:

$$\{\{\mathrm{M}\}_{\mathrm{K_{DH}}}\}_{\mathrm{K_C}} \tag{3}$$

After receiving the packet, the first forwarding node in the subgroup Y will decrypt the packet with "$k_C$", then encrypt the decrypted packet with "$K_{LYGK_S}$" and then send the packet to node C

$$\{\{\mathrm{M}\}_{\mathrm{K_{DH}}}\}_{\mathrm{K_{LYGK_S}}} \tag{4}$$

Where $M$ is message, "$k_{DH}$" is the Diffie-Hellman generated key, and "$K_{LYGK_S}$" is the symmetric, Y subgroup key.

The decryption and encryption steps are repeated until the destination node receives this packet.

All nodes in a subgroup have their own public and private keys. In case of any change in subgroup members, the L1-head will encrypt the regenerated Symmetric subgroup keys "$K_{LXGK_S}$" with the public key of each node before sending it to the nodes via the L2-heads in its subgroup.

### B. Node Joining Process

In the neighbourhood key method the authentication process relies on public key certificate that are signed by an offline trusted third party [7][8]. Also nodes can perform authentication with new nodes independently without any coordinate from any other nodes. A new node sends a join request including its own signed certificate to existing nodes. Certificates between nodes will be exchanged after the received node has verified the certificate of the new node. Once the certificates are exchanged, the nodes will exchange symmetric neighbourhood keys using the RSA algorithm. Whenever a node receives request messages from a node for the first time it must update its neighbourhood key store.

Since rebuilding and redistributing of a new neighbourhood key to all nodes is required each time a node joins or leaves the network, the network may take a long time to stabilise. This issue will worsen when many nodes join and leave the network at the same time.

The benefit of the hierarchical key management scheme is mainly based on its hierarchical structure. When a new node joins a subgroup, rekeying is not a global operation. The L2-subgroup head just regenerates the L2-subgroup key "$K_{LXGK_S}$" for this subgroup, which can be relatively few nodes.

### C. Node leaving process

When an authenticated neighbour has not sent a message for a long time in the neighbourhood key scheme it is assumed to have left the network and a new neighbourhood key must be generated and transmitted to its authenticated neighbours. Whereas in the hierarchical key management scheme the leaving of a node falls under three scenarios;

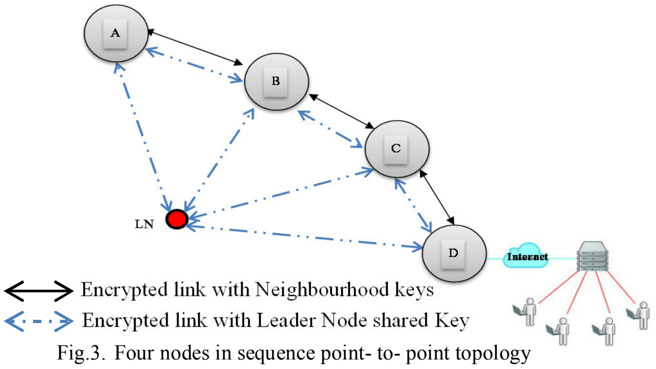
- For the leaving of an ordinary node, the level 2 cluster head regenerates the L2-subgroup key.
- In the case of the L2-head leaving the subgroup. The node with the largest weight value of the remaining ordinary nodes in the subgroup will be selected to be the new L2-head.
- The third case is the leaving of L1-heads; L2-head with the largest weight value of the L2-heads in the subgroup will selected to be the new L1-head.

## IV. Proposed Trust Security Mechanism for Marine Wireless Sensor Networks

This section outlines the proposed smart security technique for Wireless Sensor Network nodes suitable for use in marine coastal environments. The scheme addresses issues highlighted above in [2] and [3] such as the rekeying process and the number of stored keys required in each node. This scheme uses the advanced encryption standard "AES-128" and the public key cryptosystems "RSA-1024" to allow the secure transmission of data between nodes in the network. The pre-distribution of keys is currently been used is the scheme, whereby keys are allocated to all sensor nodes before deployment and securely transferred between nodes using a master key.

### A. General Outline of the Scheme

Each node keeps its own symmetric key, called an adjacent key "$k_{ni}$" that it shares only with its two neighbours in the network "Fig. 3". Also each node must have



A
B
C
D
LN
Internet
Encrypted link with Neighbourhood keys
Encrypted link with Leader Node shared Key

Fig.3. Four nodes in sequence point- to- point topology

a symmetric master key called the leader node key“$k_{LN}$” that is generated by the master node called Leader Node. The RSA algorithm is used for key management in updating the leader node key.

Each node performs authentication and revocation in coordination with a leader node. In the authentication process a new joining node simply sends a request-to-joint command to any ordinary node included with its Identification. Then the ordinary node sends the received Identification to the leader node. The leader node will verify the Identification based on stored certificates in a trust database of its network members. Once a new node is authenticated from the leader node, adjacent keys are securely exchanged between nodes. These keys are encrypted with the leader node key“$k_{LN}$”.

One of the most important aspects of our security mechanism is the process of revocation and rebuilding the network topology when a node leaves. The leader node monitors the behaviour of all nodes in the network through broadcasting a ‘hello’ message, and all nodes must reply with a response message. If any node does not respond to the ‘hello’ message, the leader will revoke this node and rebuild the network via one of its authenticated neighbours.

As already mentioned, the leader node uses the public key of the authenticated neighbours to securely share a new symmetric leader node key and the identification of the revoked node.

### B. *Key Maintenance and Revocation Process in Proposed Technique*

When a node leaves the network, it should not be able to decrypt the future encrypted traffic [6]. The leader node monitors all nodes’ activities continuously in the network and every node maintains contact with the leader node. In case of any node not responding the leader node will remove this node from its member list and reconnect its neighbours to keeps the network functioning as shows in “Fig. 4”.

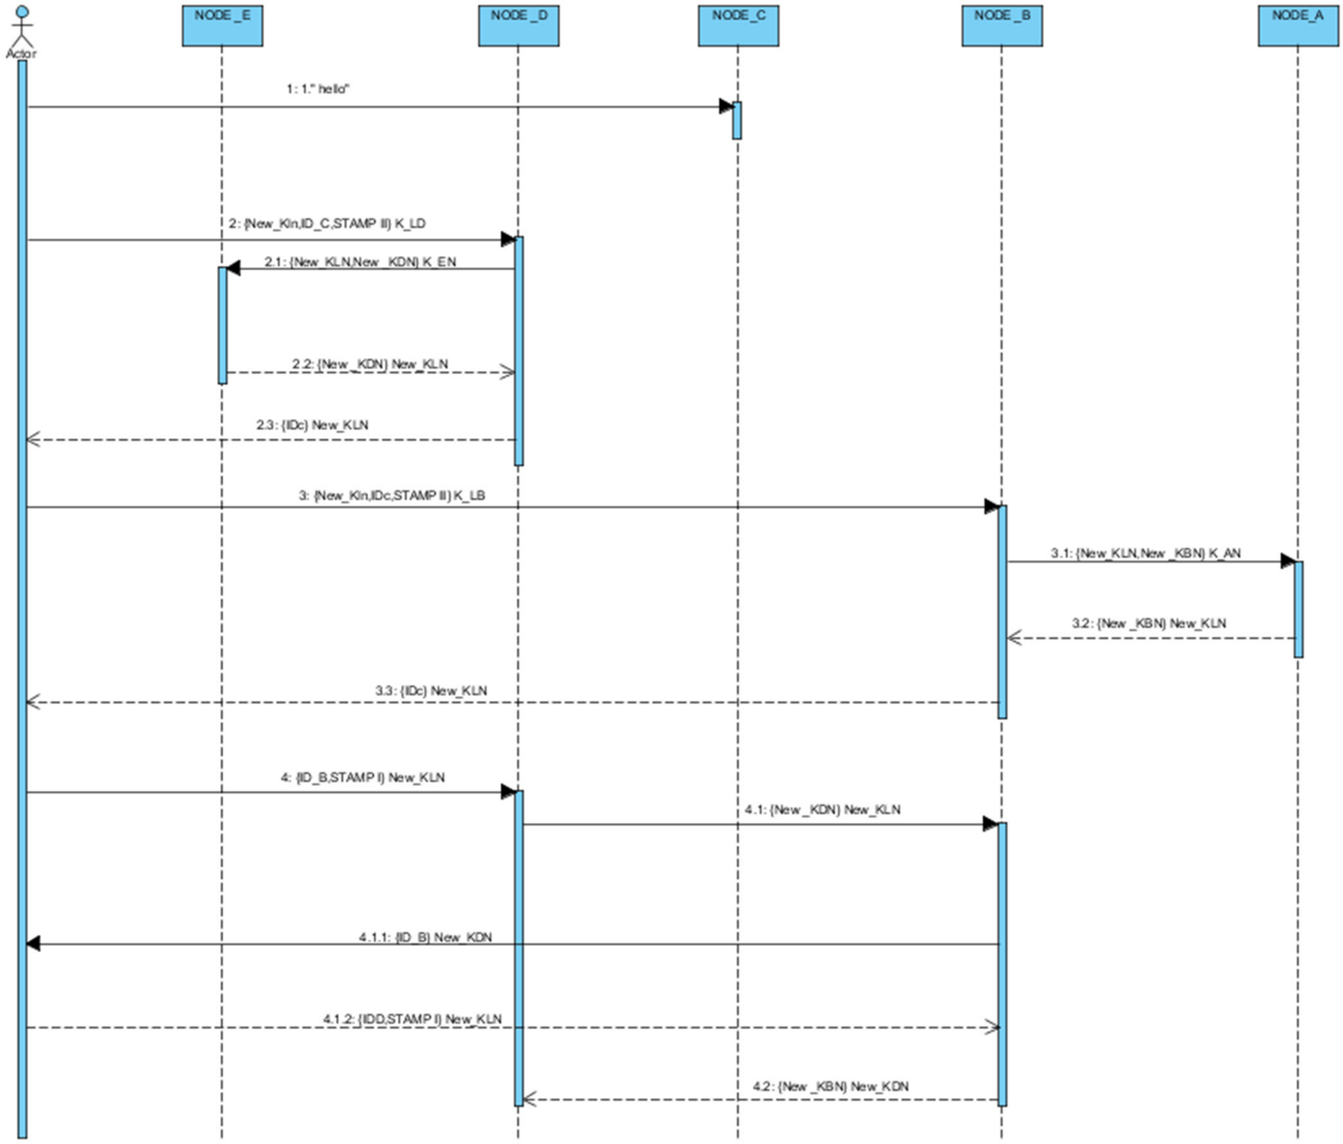


Fig.4. Key maintenance and revocation process: sequence diagram

In "Fig. 4" assume that node C does not response to the 'hello' message and nodes B and D are its two neighbouring nodes.

Notation Used:

New_$K_{LN}$: New shared secret key between Leader and nodes "128bits".
ID*x*: A unique Identification of node x.
$STAMP_{II}$: Part of message means the included ID is revoked.

New_$K_{DN}$: New shared secret key between D and its neighbours "128bits".

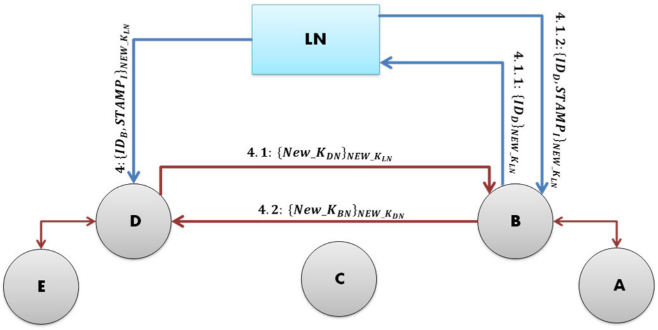
New_$K_{BN}$: New shared secret key between B and its neighbours "128bits".
$STAMP_I$: Part of message means the included ID is authenticated.
$K_D$: Public Key of D.
$K_B$: Public Key of B.

Messages Exchanged:
1: "Hello"
2: $\{New\_K_{LN}, ID_C, \mathrm{STAMP}_{II}\}_{K_D}$.
2.1: $\{New\_K_{LN}, New\_K_{DN}\}_{K_{EN}}$.
2.2: $\{New\_K_{LN}\}_{NEW\_K_{DN}}$.
2.3: $\{ID_C\}_{NEW\_K_{LN}}$.
3: $\{New\_K_{LN}, ID_C, \mathrm{STAMP}_{II}\}_{K_B}$.
3.1: $\{New\_K_{LN}, New\_K_{BN}\}_{K_{AN}}$.
3.2: $\{New\_K_{LN}\}_{NEW\_K_{BN}}$.
3.3: $\{ID_C\}_{NEW\_K_{LN}}$.
4: $\{ID_B, \mathrm{STAMP}_I\}_{NEW\_K_{LN}}$.
4.1: $\{New\_K_{DN}\}_{NEW\_K_{LN}}$.
4.1.1: $\{ID_D\}_{NEW\_K_{LN}}$.
4.1.2: $\{ID_D, \mathrm{STAMP}_I\}_{NEW\_K_{LN}}$
4.2: $\{New\_K_{BN}\}_{NEW\_K_{DN}}$.

### C. Description of key maintenance:

After the relationships among the nodes are re-established, all nodes must send a response to the 'hello' message to the leader node. The leader node knows the certificates of all the nodes in the network. Assuming that node C does not response to the 'hello' message, then the LN must remove it from the network. Due to the point-to-point topology the nodes that are positioned before and after the revoked node C must be securely reconnected. The scenario for the revocation of node C "Fig. 4" is described below.

Step 1: Node C does not response to 'hello' message.
Step 2: After the LN has verified all node responses, the leader node will send an encrypted message to node D. This message includes a new leader node master key "$New\_K_{LN}$" and the Identification of the revoked node C. Node D will update and share its adjacent key "New_$K_{DN}$" and new leader node key "$New\_K_{LN}$" with authenticated node E, its neighbour. Node D will confirm this step by sending Identification of the revoked node "C" encrypted with" $New\_K_{LN}$" to leader node.



LN
4: $\{ID_B, STAMP_I\}_{NEW\_K_{LN}}$
4.1.1: $\{ID_D\}_{NEW\_K_{LN}}$
4.1.2: $\{ID_D, STAMP_I\}_{NEW\_K_{LN}}$
4.1: $\{New\_K_{DN}\}_{NEW\_K_{LN}}$
4.2: $\{New\_K_{BN}\}_{NEW\_K_{DN}}$
D
B
E
C
A

Fig.5. Rebuilding the network topology after node C revocation

Step 3: After receiving the revoked message of node C, node B will update its adjacent key and share both "$New\_K_{BN}$" and" $New\_K_{LN}$" with its authenticated node A.
Step 4: leader node will coordinate the authentication process between B and D as shown in "Fig. 5". Initially, leader node will send the Identification of B and $STAMP_I$ to node D in order to reconfigure the network. Then nodes D and B will mutually exchange their shared keys using the master key" $New\_K_{LN}$".

### D. Advantages

This approach provides a number of advantages in comparison with [2] and [3]. Firstly, each node in [2] performs authentication independent of and without coordination with other nodes. An exchange and verification of certificates between neighbours in the network occurs only when needed. However management of the authentication process in [3] is occurring via the L2-head and the L1-head.

In our scheme the authentication process is coordinated by the leader node LN. Ordinary nodes store only information of their neighbours which leads to reducing the number of keys stored in every node and also the security risks involved in storing large number of network keys. Furthermore, when a new node joins the network, authenticated nodes do not need to regenerate their keys if they are not a neighbour of the new node. After the new node is verified by LN, it will exchange adjacent keys with its neighbours "Fig. 5". This increases the life of the node as well as lifespan of the entire WSN as it only communicates with its closest nodes. The second advantage is that the encryption and decryption operation during data transmission in [3] is occurring through" $K_{DH}$", subgroup keys and communication keys. Therefore, it has a longer transmission time than our scheme, which encrypts and decrypts only the part of the source key when a message is forwarded. The third and important advantage of this security mechanism is updating the shared key, where only current neighbours of a revoked node will regenerate their symmetric keys. The leader node will distribute a new master key through the trustworthy nodes. In the network, ordinary nodes are deployed in a line topology, and the distance between every two neighbours is around 1500m. In order to cover a range of up to 7000m, in this scheme, we have used XBee-802.15.4-Pro/2.4GHz integrated with Waspmote. This advantage will lead network to securely reconnect in case of three neighbour nodes are revoked.

## V.CONCLUSION

The overall objective of this work is to design a smart security technique for Wireless Sensor Network nodes that can successfully operate in marine coastal environments. We address some potential drawbacks of two existing key management schemes that would be considered suitable and combine their advantages. These protocols used symmetric-key and public-key based key transport protocols for the provision of authentication between nodes. However, both schemes require updating all shared keys whenever the membership in the network changes. The time required to build and distribute new keys will lengthen the time it takes to establish a stable topology in comparison with our proposed scheme which restricts key update to the neighbours of the leaving node. An implementation of the technique is currently being performed on the Waspmote sensor platform and it is hoped that some measurements will be available for the conference presentation.

***Abstract*—In Wireless Sensor Networks (WSNs), clustering techniques are usually used as a key effective solution to prolong the network lifetime by reducing energy consumption among the sensor nodes . Despite many works on clustering in WSNs this issue is still outstanding. However, the most existing solutions suffer from long and iterative clustering cycles. In an attempt to fill in this gap, we propose a new cluster-based protocol, referred to as Load-balancing Cluster Based Protocol (LCP) that introduces a new inter-cluster approach to increase network lifetime. This new protocol rotates continuously the election of the Cluster Head (CH) election in each cluster, and selects the node with the highest residual energy in each round. Extensive simulation experiments show that our proposed approach effectively balances the energy consumes among all sensor nodes and increases network lifetime compared to other clustering protocols.**

***Keywords*—*WSNs; Distributed clustering; lifetime; Routing; Network*.**

## I. Introduction

THE Wireless Sensor Network (WSN) technology has been one of the major avenues of networking and Internet of Things (IoT) due to their potential role in digitising smart physical environments [1]. WSNs composed of a large number of sensor nodes with limited battery power, which can be either densely or sparsely deployed in harsh and extreme environments, such as wild remote areas, natural habitats, and regions with access risk. On one hand, sensor nodes are usually battery-powered with limited operating time, and therefore they are highly sensitive to failure [2] [3]. On the other hand, the design an energy efficient WSNs protocol to prolonging the network lifetime is a challenging task due to the unique nature and strong networking constraints of wireless sensor networks [4].

The research community proposed different routing protocols to optimise the routing process in WSNs. Typically, the routing protocols for WSNs can be classified into three categories: flat, location and hierarchical based routing [5]. In flat routing, all nodes have identical functionality and they work together to sense and route [6]. Location based routing protocols rely on the position information of each node to discover and build optimal routing paths [7]. Compared to the two previous categories, in hierarchical routing approaches, the sensing field is subdivided into a set of administrative domains called clusters [8]. Each cluster has an organised leader or a root node called the ClusterHead (CH). The primary aim of the CH is to collect data from attached and associated downstream nodes and forward it to the best next well-known hierarchical upper level upstream neighbour node. The data is forwarded in a hop-by-hop manner until it reaches the Base Station (BS). The BS can then send the data, using a wired or wireless Internet connection, to an end user located outside the sensing field [9][10].

A number of cluster protocols based on energy efficient have been proposed in the literature [11]. These approaches attempt to minimise energy consumption by reducing the transmission of redundant data. Clustering approaches focus primarily on the communication process during cluster organisation and CH election and neglect the effect of information processing on energy consumption. Hybrid Energy-Efficient Distributed (HEED) is one of the clustering protocols that uses both energy and communication costs to select CHs in a probabilistic manner. This protocol uses different inter-cluster approach in order to reduce energy consumption and to prolong the network lifetime [12].

In this paper, we present a new energy-aware distributed and dynamic clustering protocol, namely A Load-balancing Cluster Based Protocol (LCP). LCP addresses load balancing issues in cluster-based routing approaches. Given that cluster-based protocols require regular re-clustering for balancing energy consumption. However, re-clustering process in interval time for entire network increases the network overhead and consequently decreases the network operation time. The proposed model provides a pre-defined interval of time at the beginning of every round to select the CH. This delays the frequency of the re-clustering messages received from the BS. If the sensor nodes do not receive the BS message, the CHs continues rotating the leadership among them within the same members of cluster by electing the node with the highest residual energy each round. The performance evaluation of LCP is examined in depth and compared to HEED [12], LEACH [13] and R-HEED [14]. Obtained results demonstrate that LCP enhances the network lifetime by 15%.

The rest of the paper is organised as follows. In Section II, we review a set of up-to-date clustering algorithms proposed for WSNs. Section III presents the features of the new LCP protocol. Section IV presents a detailed description of the simulation environment and the simulation results. Finally, section V reviews the entire study and offers conclusions and recommendations for future work.

## II. Related Work

Different cluster-based approaches have been proposed by the research community to address the challenging issues of WSNs. Some of these approaches are as follows:

### A. Low Energy Adaptive Clustering Hierarchy (LEACH)

Heinzelman, et al. proposed the first well-known clustering LEACH protocol [13]. This protocol was targeted at prolonging the lifetime of WSNs and reducing the energy consumption of sensor nodes. From an algorithmic point of view, LEACH is hierarchical, probabilistic, distributed and single-hop protocol. It forms clusters based on the strength of received signal, while CH nodes act as default gateways to the BS, as illustrated in Fig. 1. In LEACH protocol, nodes make autonomous decisions without relying on a centralised third party entity. In addition, all nodes have an equal opportunity to become CHs. Initially, a node generating a random number between (0-1) to be a CH by comparing it with a threshold value T (n), calculated using Equation (1).

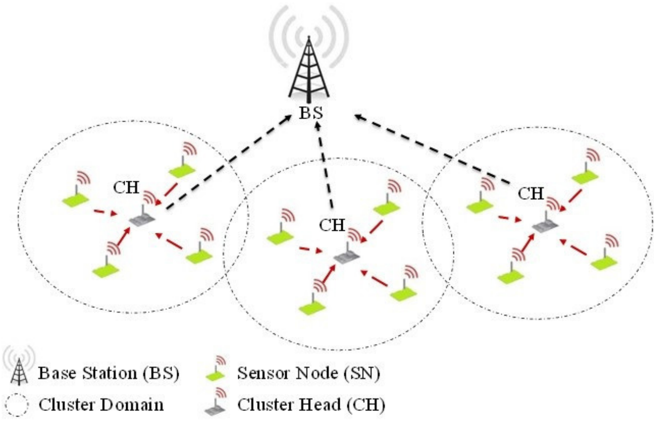

Fig. 1. Basic LEACH topology [11]

Nodes with a random number lower than T (n) then become CHs. Each elected CH broadcasts an advertisement to non-CHs to form a cluster.A non-CH node selects a CH that expending the least energy for communication.

$$T\left(n\right)=\begin{cases}\frac{p}{1-p\left(rmod\frac{1}{p}\right)} & ifn\in G\\ 0 & \end{cases} \quad (1)$$

Where p is the desired percentage of nodes to be CH; r is the current round; G is the set of nodes that have not been cluster heads during the last 1/P rounds.

Generally, LEACH provides a good model for energy consumption while providing an equal probability for node to be elected CHs. Once chosen as a CH, a sensor node cannot be reselected in a subsequent round. Moreover, LEACH avoids unnecessary collisions between CHs because it uses the Time Division Multiple Access (TDMA) protocol. Despite its generally good performance, LEACH also has some clear limitations. It uses single-hop communication which limits its scalability. In addition, the probabilistic election mechanism of CHs may lead to either high concentrations of CHs in one part of the network, or to orphan nodes (nodes without CHs in their neighbourhood.

### B. LEACH-Centralised (LEACH-C)

To address the shortcomings of LEACH with respect to determining each CHs location and number rounds,a new version of LEACH, named LEACH Centralised (LEACH-C) proposed [15]. In the new version, the BS decides which sensor nodes are eligible to become CHs and form a cluster. Each node transmits its location and energy level to the BS, which in return calculates the average energy level for the network and eliminates the nodes with remaining energy levels below this average, to form the set of CHs for that round. In the centralised algorithm the energy load is distributed among all nodes equally, where the numbers of CHs are specified and the network is divided into optimum and equal sized clusters. However, the construction of clusters with an equal number of nodes in each cluster is not guaranteed in this protocol, and it is not always possible for nodes distant from the BS to send information about their status.

### C. CHybrid Energy-Efficient Distributed (HEED)

O. Younis et al. [12] Introduced HEED clustering protocol. In this protocol, the authors enhanced LEACH protocol by introducing two basic parameters to elect the CHs. The first main parameter concerns the remaining energy of each node, and the second parameter is the intra-cluster "communication cost". For example, the cost can be a function of neighbour proximity or cluster density, that can calculated using Equation (2). Unlike LEACH, HEED protocol the CH nodes are not randomly selected. Only nodes with high levels of remaining energy can become CH nodes. In addition, when two nodes are within each other's cluster range, the probability of both becoming cluster heads is negligible. In comparison to LEACH, in HEED, the CHs are well distributed throughout the network. However, this protocol cannot fix the cluster count in each round. In addition, the energy consumption is not balanced, because more CHs could be generated more than expected, which creates massive overheads due to multiple election rounds.

$$CH_{prob}=C_{prob}\times\frac{E_{residual}}{E_{max}} \quad (2)$$

Where: $C_{prob}$ is an initial percentage of cluster heads among all n nodes, $E_{residual}$ is the estimated current energy of the node, $E_{max}$ is the referenced maximum energy (corresponding to a fully charged battery).

### D. Distributed Energy-Efficient Clustering (DEEC)

Li Qing et al. [16] proposed the DEEC algorithm for WSN to improve HEED performances. In DEEC, the CHs are selected with a probability based on the residual energy of each node and the average energy of the network. The authors of this algorithm assumed that nodes would have different amounts of energy. With the adaptive values, the sensor nodes determine their role probabilistically in each round. The main drawback of DEEC is that each node demands global knowledge from the network, which increases the overheads.

### *E. Rotated Hybrid, Energy-Efficient and Distributed (R-HEED)*

W. Mardini et al. [14] introduced R-HEED. With this protocol, the authors improved the performance of HEED by applying a different inter-cluster approach. The new approach conducts the cluster reformation based on certain rules. At the start of setup phase on every round, the CHs node must delay for period of time waiting for a cluster reformation message from the sink .if the cluster reformation message not received, each cluster persevere with rotating the cluster head task in the same cluster. However, randomly rotating the CH does not take into account energy consumption.

### *F. Distributed weight based energy efficient hierarchical clustering protocol (DWEHC)*

P Ding et al. [18] proposed a new protocol called DWEHC that improves HEED performances. Their primary aim was to to improve energy consumption by forming balanced cluster sizes and improving intra-cluster routing. Each sensor node begins broadcasting its (x, y) coordinates to search for its neighbour. After finding neighbouring nodes in its area, each node calculates its weight. Weight is the only parameter calculated locally and used for CH election; it is represented by weight in DWEHC as defined by Equation 3.The node with the largest weight is selected as a CH. The ordinary nodes become child nodes by joining CH. The nodes at this stage, are considered first level members because they have a direct link to the CH. As the child nodes are further divided into levels (level 1, level 2, etc.) the total number of levels is seen to depend on the cluster range and the minimum CH energy. Like HEED, DWEHC is a fully distributed clustering protocol with a more balanced CH distribution. In addition, its clustering process does not rely on network size. However, this protocol cannot increase its energy efficiency give its inter-cluster communication function and the large control message overheads.

$$W_{weight(s)} = \left( \sum_{u \in N\alpha, c(s)} \right) \frac{(R-d)}{6R} \times \frac{Eresidual\,(s)}{Einitial\,(s)} \tag{3}$$

Where: R is the cluster range, d is the distance from node s to neighbouring node; $E_{residual(s)}$ is the residual energy in the nodes; $E_{initial(s)}$ is the initial energy in the nodes.

### *G. Power-Efficient and Adaptive Clustering Hierarchy (PEACH)*

The majority of existing clustering protocols consume large amounts of energy, incurred by cluster formation overheads and fixed-level clustering. This is especially true when sensor nodes are densely deployed. To address this problem, Sangho Yi et al. [17] proposed PEACH protocol to reduce energy consumption, that improve the network lifetime.In PEACH protocol, a node selected as CH when the packet received was for the that node . When the packet is received by a different node and is not the destination for the packet, the node will join the destination of that packet. Simulation results showed that PEACH consumes lower energy and prolonges the network lifetime comparative to the LEACH, and HEED protocols. However, the network is not very scalable, because all the nodes must have global knowledge of the network.

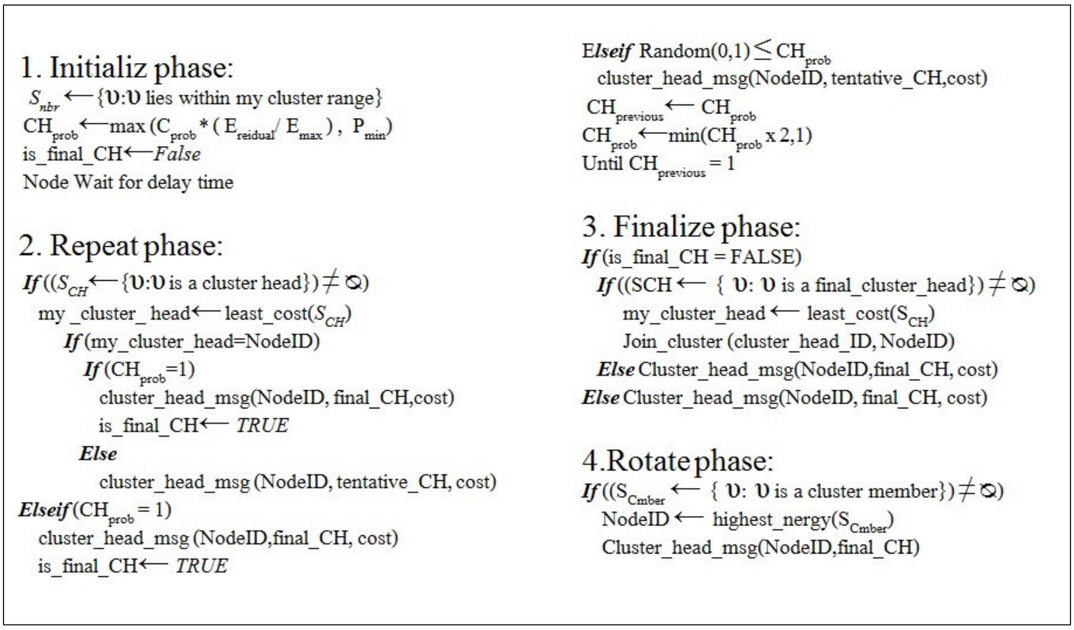
## III. THE LCP CLUSTERING PROTOCOL

The proposed scheme builds on the success of the HEED protocol. The clustering phase of the HEED protocol has been modified to make it more energy-efficient. The modified version is named A Load-balancing Cluster Based Protocol (LCP). In LCP, the clustering operation is divided into several rounds, each round has two phases: the setup and the steady-state phase. LCP is similar to HEED in terms of the following features:

- The elected CHs sent advertisement message within cluster range.
- The cluster formation "setup phase" finish in O(1) iterations.
- Each node become member only to one cluster and communicates directly with its CH.
- Through the cluster formation process, Nodes can become either a tentative_CH or a final_CH, or it can be covered.
- At the end of the clustering procedure, CHs node forms a network backbone. Thus, the data is forwarded in hop-by-hop through CHs until it reaches the BS.
- The steady state phase for LCP protocol is alike HEED, and CH election is done as part of an iterative process.

The setup phase is divided into four phases: 1) Initialise phase, 2) Repeat phase, 3) Finalise phase and, 4) Rotation phase. The following steps describe the proposed phases, which are illustrated in Fig. 2.

1) Initialise phase: At the beginning of this phase, nodes exchange their information with neighbours in order to computes its cost. Unlike HEED, the costs are exchanged through the cluster head message. The LCP algorithm sets an initial percentage of node become Cluster head $C_{prob}$. Thus, each sensor node establishes its probability of becoming a CH based on the reaming energy $CH_{prob}$ according to HEED.
2) Repeat phase "Main Processing": Each node in this phase is subject to a delay time, in which it can decide whether the node will be elected as candidate CH node "tentative_CH". If the node not elected as tentative_CH, it will declare itself a cluster head node "final_CH". The final_CH node broadcast a cluster_head_msg (Node ID, tentative, cost) within cluster range.
3) Finalize phase: During this phase, most sensor nodes declare itself either a cluster head node or a member node. If node received a cluster head advertise message, it will join the final_CH with the lowest cost. The node neither final_CH or has not received cluster head advertise message, it will declare itself a final_CH node.



```
1. Initializ phase:
  $S_{nbr} \leftarrow \{\upsilon : \upsilon$ lies within my cluster range$\}$
  $CH_{prob} \leftarrow \max(C_{prob} * (E_{reidual} / E_{max}),\ P_{min})$
  is_final_CH ← False
  Node Wait for delay time

2. Repeat phase:
  If (($S_{CH} \leftarrow \{\upsilon : \upsilon$ is a cluster head$\}) \neq \emptyset$)
    my _cluster_ head ← least_cost($S_{CH}$)
      If (my_cluster_head=NodeID)
        If ($CH_{prob}$=1)
          cluster_head_msg(NodeID, final_CH,cost)
          is_final_CH ← TRUE
        Else
          cluster_head_msg (NodeID, tentative_CH, cost)
  Elseif ($CH_{prob}$ = 1)
    cluster_head_msg (NodeID,final_CH, cost)
    is_final_CH ← TRUE
  Elseif Random(0,1) ≤ $CH_{prob}$
    cluster_head_msg(NodeID, tentative_CH,cost)
  $CH_{previous} \leftarrow CH_{prob}$
  $CH_{prob} \leftarrow \min(CH_{prob} \times 2, 1)$
  Until $CH_{previous}$ = 1

3. Finalize phase:
  If (is_final_CH = FALSE)
    If ((SCH ← { $\upsilon$: $\upsilon$ is a final_cluster_head}) $\neq \emptyset$)
      my_cluster_head ← least_cost($S_{CH}$)
      Join_cluster (cluster_head_ID, NodeID)
    Else Cluster_head_msg(NodeID,final_CH, cost)
  Else Cluster_head_msg(NodeID, final_CH, cost)

4.Rotate phase:
  If (($S_{Cmber} \leftarrow \{\upsilon : \upsilon$ is a cluster member$\}) \neq \emptyset$)
    NodeID ← highest_nergy($S_{Cmber}$)
    Cluster_head_msg(NodeID,final_CH)
```

Fig. 2. A Load-balancing Cluster Based algorithm.

4) Rotate phase: After elect the CHs node and form clusters in the first round, each CH constructs a turning schedule for its member when it becomes a CH. The turns are sorted based on residual energy in the sensor node. Node with the highest residual energy will be the first candidate to become a CH for next round. Therefore, at begging of the next round unlike HEED protocol is not necessary to re-cluster the network. Node within the same cluster in subsequent rounds continues rotating the CH role between them, by selecting the node with the highest residual energy every round. When first cluster finishes the rotating process,it inform the BS by sending re-form cluster message via multi-hop route. BS re-broadcast the message among the nodes inform them to start a new cluster process, See Rotate phase in Fig. 3.

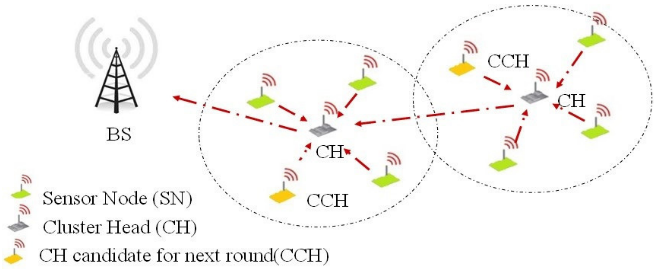


Fig. 3. A Load-balancing Cluster Based Protocol Rotate phase.

## IV. PERFORMANCE EVALUATION

In this section, we evaluate the performance of the LCP mechanism by using open source Castalia simulator [19]. We consider a sensor network, composed of (100-350) sensor nodes, which are randomly deployed in a playground of 200mX200m square region. All sensor nodes are fixed and homogeneous and with limited stored energy. Nodes are not equipped with GPS-capable antennae. The BS is placed at the center of the sensor field. The energy consumption for each sensor node is calculated by data transmission and aggregation per round. The energy efficiency of LCP is compared against LEACH, HEED, R-HEED. Simulation parameters are given in Table I.

TABLE I
PARAMETER SETTINGS

| Parameter | Value |
|---|---|
| Deployment field | 200 X 200 m |
| Data packet size | 200 bytes |
| Control packet | 25 bytes |
| Number of node | 100-350 |
| Initial cluster radius (RC) | 25m |
| Sink position | (0,0) |
| Initial energy | 25J |
| Threshold distance ($d_0$) | 75m |
| Deployment method | Uniform, Random |
| Rotated time ($T_r$) | 20 Sec |
| Radio model | CC4220 |

We use in this paper the residual energy matric,and the network lifetime metric to evaluate the performance of our protocol. The residual energy metric is computed by the average energy remaining in all nodes at a specific round. The network lifetime metric is based on WSN applications require.For example , applications require that all node must work to ensure the network has good coverage. Thus, the network lifetime metric for these applications should be measured according to the lifetime of the shortest-living node. Some Other applications they only need a specific percentage of nodes have to remain alive to achieve the applications requirement [17]. Therefore, the network lifetime in our protocol ,is measured by following three different metrics.

1) First Node Die (FND): is defined as time elapsed in rounds until the first node has consumed all available energy.
2) Half Nodes Die (HND): is defined as time elapsed in rounds until half of the nodes have consumed all available energy stores.
3) Last Node Dies (LND): is defined as time elapsed in rounds until all the nodes have exhausted their entire energy supply.

The "round" definition in our paper refer to the time interval in seconds befor the network statr a new cluster process.Therfore , no difference between the round concepts in LCP ,and HEED in terms of time.In LCP protcol we specified a round time of 20 seconds.

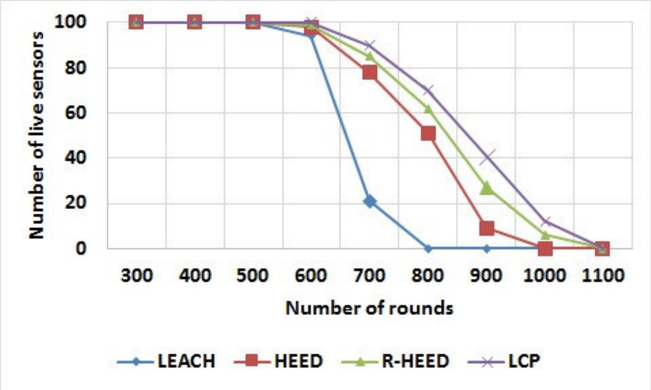

Fig. 4. Number of alive sensors Vs numbers of rounds for LEACH, HEED, R-HEED and LCP.

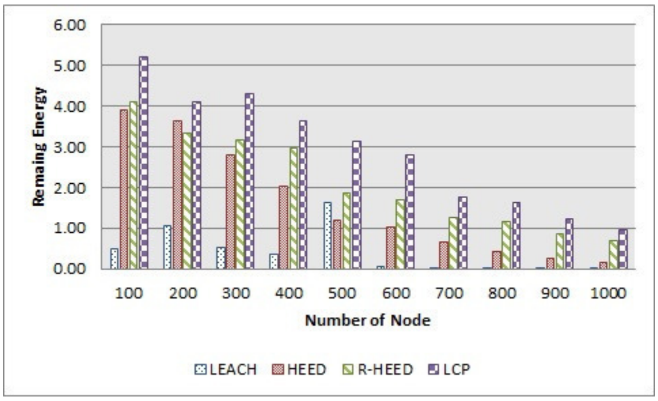

Fig. 5. Total remaining energy in LCP in comparison with HEED, R-HEED.

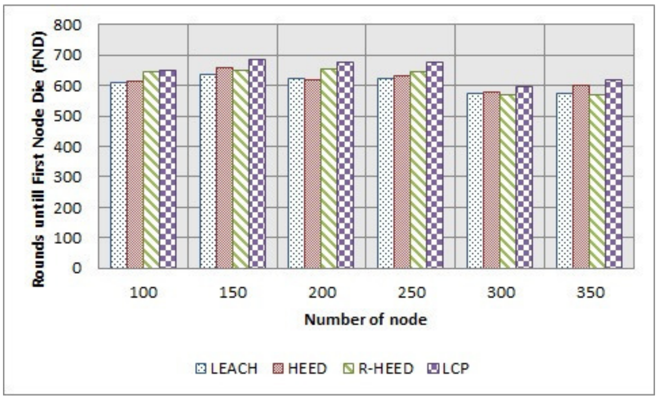

Fig. 6. Comparing LEACH, HEED, R-HEED and LCP using different number of node for FND metric.

Fig. 4 . demonstrates the total number of nodes remaining alive following the simulation round. LCP increases the network lifetime compared to its peers. Fig. 5. demonstrates the relationship between the remaining energy and the number of nodes. It is evident that LCP consumes the least amount of energy. Furthermore, how the increasing number of the nodes affects the lifetime of each protocol has been evaluated. . Fig.6 demonstrates the network lifetime until the first node dies, when the number of nodes varies between (150- 350).

Figure.7 and 8 also reveals the same comparisons to define the network lifetime.In Fig.7 shows the number of rounds until half of the nodes die, while Fig.8 show the number of rounds until the last node dies. It is evident that the network lifetime improves when the number of nodes increases in all protocols. Figs 6, 7 and 8 show that in all three cases LCP protocol performs better than the rest of the protocols. This advancement is caused by the rotating process of the cluster heads within the same cluster.

Consequently, the rotating process leads to reduc the energy consumption among the nodes, and increasing the network lifetime. It can be easily observed from the simulation results that when the number of the nodes increases the percentage improvement also increases. Therefore, it can be reasoned that when Increase the amount of nodes it reduce the energy consumed during the setup phase.Thus, the energy saved as a result of this new clustering scheme will be maximised, which will improve the networkâĂŹs lifetime.

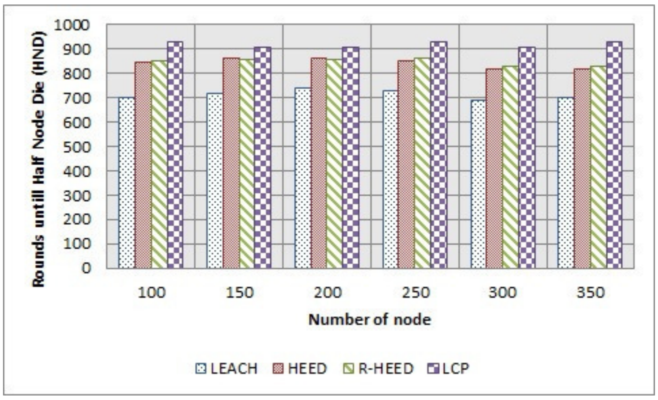

Fig. 7. Comparing LEACH, HEED, R-HEED and LCP using different number of node for HND metric.

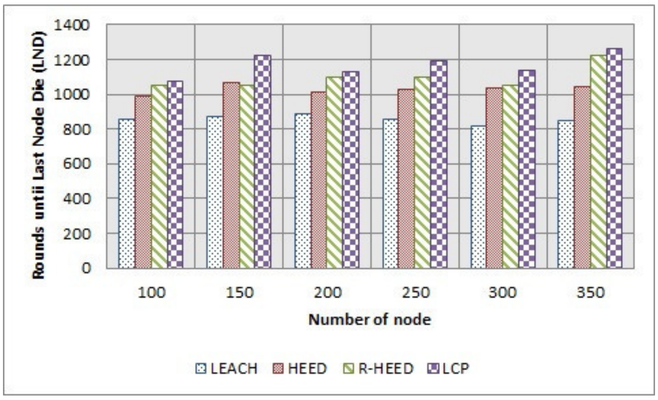

Fig. 8. Comparing LEACH, HEED, R-HEED and LCP using different number of node for LND metric.

## V. Conclusions and Future Work

In this paper, the clustering scheme Load-balancing Cluster Based Protocol (LCP) for wireless sensor networks was proposed as a more energy-efficient protocol. The main contribution of the LCP protocol is its ability to continue rotating the cluster head (CH) role between nodes within the same cluster, by selecting the node with the highest residual energy to become a CH for the next round. We compared and evaluated the LCP protocol performance with well-known Energy Efficient clustering protocols, which is have the same aim increase the network lifetime. The simulation results showed that LCP protocol significant balance the energy consumption among the entire node and achieves an obvious improvement to the network's lifetime by 15%.

Finally, we evaluated our protocol performance in term of energy consumption. Hence our future work we plane to investigate the performance of LCP according to other networking metrics, such as packet delivery ratio and end-to-end delay.

***Abstract* — Application scenarios of WSN implementations are really broad. Due to their typical characteristics, such advantageous power consumption, wide communication coverage and relatively broad sensing possibilities, many application fields can be covered. In this paper, the problematic of power metering is targeted. Places with shared power sources, where electricity usage is calculated equally according to the number of users, are often misused by single users for illegitimate power usage. Special WSN was developed and implemented in a scenario of multi-store parking garage to solve this problem.**

## I. Introduction

Wireless sensor networks (WSNs), as the front-end representative of Internet-of-Things framework, are still more and more implemented in real applications of our present life. When considering the typical WSNs implementation advantages, as their scalability, capability, integration simplicity or operability easiness, their application usage is really broad. The typical applications cover mainly the problematic of environment monitoring [1], [2], [3], e.g. with particular focus on the specific parameters of the nature [4], [5], [6], [7]. Other typical abundant application field is the area of Intelligent Transportation systems, where WSNs already got used to the climate, see [8], [9], [10], [11]. Secondary areas, with no such a high WSN implementation capabilities, are military [12] and eHealth [13], where some strict security/safety rules make the accommodation of central applications difficult. However, by implementation of specific approaches, as [14], [15], [16], [17] and [18], the application fields covered by WSNs could be wider, e.g. agriculture, industry, home automation… Especially the last two areas offer interesting opportunities of WSN indoor implementations, the application problematic on which this paper is geared to.

Real applications of WSNs indoors are the challenging tasks, which due to the certain specific conditions - stronger multipath, blocked line-of-sight, interference,..- attract not so many realizations. The possibility of energetic self-sufficiency - as of the WSN biggest asset - omission, due to the unlimited energy sources indoors, makes utilization of WSNs indoors a lot ineffective. However, there exist some indoor applications, where utilization of application-specific WSNs can be advantageous.

In [19], authors introduced a smart home system which could supervise household appliances remotely and realize real-time monitoring of home security status through mobile phone offering the possibilities of real-time monitor of the house status. In [20], the paper described a practical design and implementation of WSN for controlling and monitoring system in multi-storey building implemented in the university building. Authors in [21] proposed a service oriented architecture for development of an enterprise networking environment that was used for integrating facilities management applications and building management systems for the purpose of the enterprise environment control. The application of WSN brought in this case significant benefits due to the lack of wiring installations allowing flexible positioning of the sensors, especially when building retrofitting was concerned. In [22], the paper presented a WSN-based smart monitoring and control system for building automation. The system was developed with focus on significant reduction of energy consumption of the building under control. The data gathered by WSN were used in order to calculate and estimate the requirements for heat corrections, with respect to ventilation and weather predictions. Non-traditional usage of Facebook as a platform for such kind of indoor sensor network monitoring system was examined in [23]. For the purposes of building emergency-management system, an indoor emergence guidance algorithm based on WSN to guide people to a building exit gate while helping them avoid a hazardous area was introduced in [24]. WSN was responsible for real-time monitoring of the environment, when emergency event was detected the proposed algorithm was applied. The proposed guiding mechanism was successfully examined and verified through the real test bed implementation.

978-83-60810-66-8/$25.00©2015, IEEE

Developments in the field of WSNs, coming out from the MEMS system designs advancements, allow realizing special WSN-based-systems for smart grids too. Smart grid technology is one of the recent developments in the area of electric power systems that aid the use of non-conventional sources of energy in parallel with the conventional sources of energy [25]. By realizing the two-way communication between the utility and the smart meters in the houses, smart grid enables a time-of-use tariff to reduce peak load through incenting residents to adopt a more efficient usage of domestic appliances [26]. However, by application of specific WSN-based smart grids, implementation of local networks, allowing bidirectional communication of local distribution grid with related electric meter. Reliable and, especially, more efficient power metering could be in this case reached. Some applications of WSN-based smart grids can be seen in [25], [26], [27] or [28], where different application scenarios were discussed: e.g. the designs of power sensing nodes to calculate the power for any kind of loads; the designs of special energy management schemes connecting non-urgent appliances to the smart meter through the wireless sensor networks; the architecture of reliable communication protocol for the harsh WSN-based smart grids environment; the architecture of WSN as a platform to enable detailed household monitoring interfaced with smart-grid through a single input to the building control system.

## II. Shared-Power sources Metering

In this paper, the problematic of local power metering at special places with the shared power meters and, therefore, shared bills for power sources, is targeted. Places with shared power sources, where electricity usage is calculated equally according to the number of users, are often misused by single users for illegitimate power usage. The creativity of the individuals is unlimited. The people are able to risk their health to spare a little amount of money modifying the installations to provide the possibilities of power feeding for their gadgets. The most common case is to extend the pure lighting installations with sockets, where their rarely used devices, which have to run permanently, are attached, e.g. freezers, wine coolers, servers, battery chargers, heaters(!)... These devices do not require such a high power, so the circuit breakers can cope with this load. In the Fig. 1 can be seen the typical "cheating" scenario.

The problem, which was described above, was bother the users of public garages in Slovakia, housing estate "Vlčince" in Žilina (Fig. 2), where people paid exceptional amount of money for their garages "taking advantage" of shared power metering. The particular garages were equipped just with garage door openers - power consumption under load around 400W, in standby only 1W - and with neon-tube lamps - 20W - but the average daily power consumption was after re-counting on each user 3kWh$^{-1}$/year, what means 830Wh$^{-1}$/day per common user which opens and closes the garage doors in 30s two times a day.

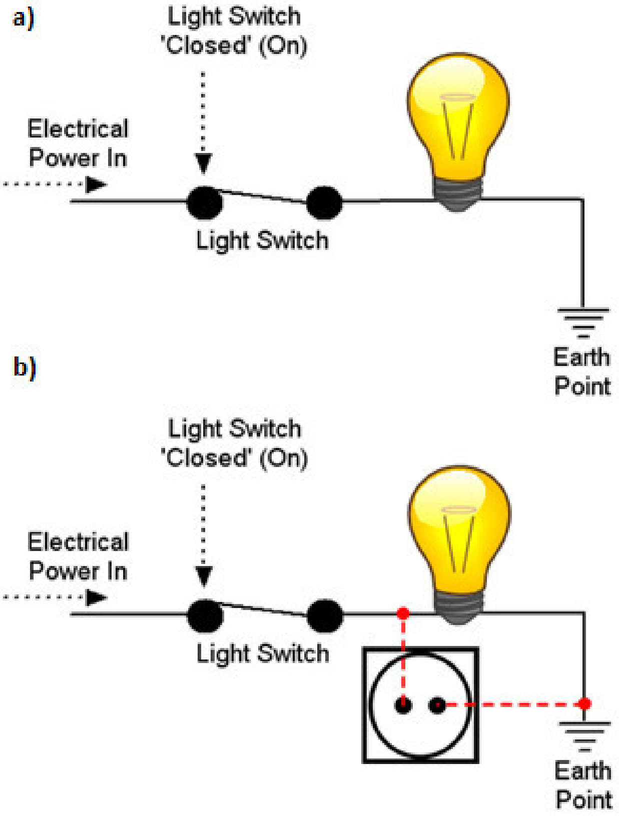

Fig. 1 a) normal lighting installation b) modification of normal lighting installation extended by power socket for "black" power consumption

Therefore the inspection of particular garages was performed to investigate the quality of electrical installations - not every user wanted to make the garage accessible.

Fig. 2 Investigated garage house

The reason was trivial, "black" power sockets were presented in some garages. The garage owners modified the installations and used the power sockets for illegitimate power usage. In the figures below can be seen the installation modifications.

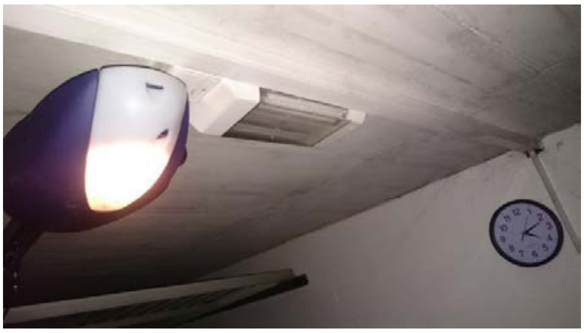

Fig. 3 Lighting installation as the source of shared power

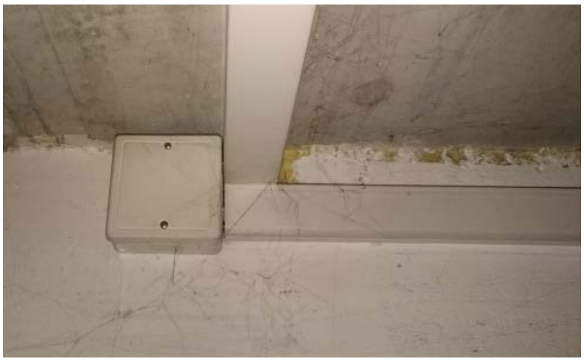

Fig. 4 Modification of lighting installation by screw terminal

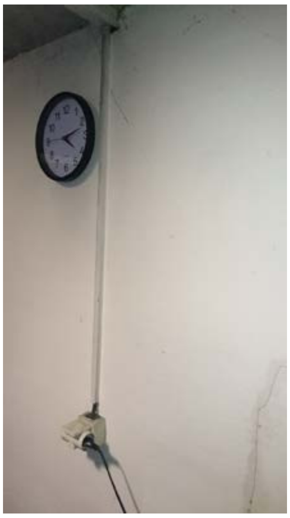

Fig. 5 Illegal socket as a “black” extension of lighting installation

To help people to overcome this problem, the special WSN-based power grid monitor was introduced. The power grid monitor is a system for energy consumption monitoring in the electricity grid. It consists of a measuring device in the form of the outlet adapter and the display device. The outlet adapter task is to measure the mains voltage and current that passes through it. The measured data are sent wirelessly to the display device. The outlet adapter consumes no more than 30mW during the measurement and it is able to measure with 15 kHz sampling rate (it means 300 samples per period (20 ms)). The outlet adapter is able to turn on / off the output which allow controlling remote devices, e.g. external lighting, or black power consumption characterized by increased power consumption. Moreover, switching can be automated on the time basis, power consumption or the outlet adapter temperature. So it can be used as a fuse.

As a display device with API, there is currently used a personal PC with its own wireless module in the form of a USB key. Wireless module communicates with the outlet adapter in unlicensed bands at frequencies around 868 MHz. Wireless range is 200m in ideal conditions, in real about half. The outlet adapter can be upgraded to have wired data connection, but currently does not have this opinion. USB acts in this case as an interconnection gateway providing connection to the other users (admin) with particular nodes employing the star architecture.

### *A. The outlet adapter*

The outlet adapter device is capable of measuring mains voltage and current drawn from the output of the outlet adapter. This output can be turned on / off via the communication interface. The device has a wireless communication interface for unlicensed bands around 868MHz. Wired interface is not implemented yet, but there is this option. Also "Power-line" communication can be added, it means to transfer data directly via the electricity grid.

Possible use of the outlet adapter:

- Electricity meter - The device can measure the power consumption and report it to the remote computer. The graphical application on the computer evaluates the power consumption of multiple outlet adapters.
- Electronic fuse - The device can monitor current limit and turn off output when the limit is exceeded. Turn off limit can be set in application. The device should be turn on again after a time period so no manual turn on is needed.
- Remote device switching - User can through a computer with a wireless module freely turn on / off the device plugged into the outlet adapter. This is an advantage especially for the inaccessible devices e.g. Christmas lights in an exterior or on the roof.
- Power inverter management - Modern household equipped with a solar panel and power inverter can use consumption information so that the inverter will only supply the power that the household consummates (and charge the batteries with the rest power). So the household wouldn´t become energy producer and could be resistant to short power dropout. During the power dropout the device will separate the household and the rest of the electricity grid. The inverter would then supply the household or a part of it.

Present version of the socket, which will be in our case installed at each garage doors power input is shown in a Fig. 5. To secure the socket, the socket cover is connected to the I/O pins of the socket, so the operator knows when the cover was removed. Therefore, if the cheater would like to somehow manipulate with the particular socket, it could be easily identified, since each socket will be accessible only from particular garage interior. A newer version of the device could be in a DIN rail housing thus could be put between circuit breakers.

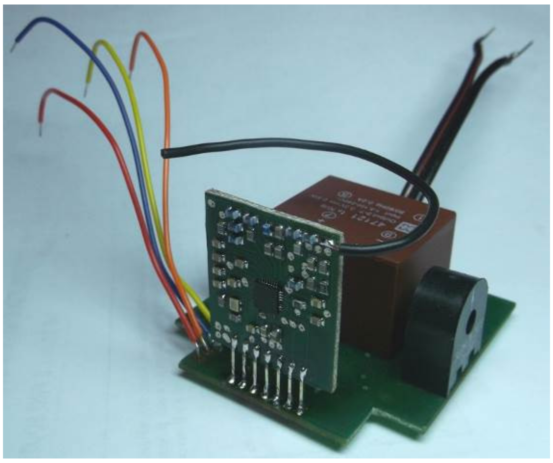

Fig. 6 The outlet adapter, system socket

*B. Wireless Module for PC*

Small module as a USB key contains a wireless transceiver with built-in antenna. The module transmits in the unlicensed bands, the same as the outlet adapter. Communication radius is approximately 200 meters in ideal conditions; in the building it is a bit less (depending on the particular location). The primary usage of the module is for receiving measured data from the individual outlet adapters. User application installed on a computer can interpret this data (e.g. consumption graph plotted for each outlet adapter for a certain period, displaying current / average consumption…). The USB module is shown in the Fig. 6.

The modules are able to communicate well with each other, allowing the interconnection of computers over a greater distance as Wi-Fi network. The transmitter can be improved in order to reach the communication radius near to 1km. The disadvantage is the low communication speed - only 12kbps. Other possible applications could be for warehouses or logistics centers where computers are far apart and need to transfer only a small amount of data.

## III. Description of the System HW Designs

Outlet adapter is using MSP430AFE252 microcontroller, which has a differential 24-bit sigma-delta converter with two input channels (there are also versions with more channels). Input voltage range for the converter is +-0,5V. One channel measures the electric grid voltage on the voltage divider adapted for its input range. The second channel measures the voltage at the current transformer "AX-1000" from the manufacturer "Talema". Mains conductor passes through the transformer to the device connected to the outlet adapter. The voltage at the transformer is thus proportional to the current flowing through the device (current includes also its own consumption). The maximum operating current which can microcontroller converter measure is 10A. Output from the power latching relay flows "JSL-D5N-K" manufacturer "Fujitsu". The relay is used to control the output of the two coils, which are activated by a voltage of 5V. The maximum power that can load the component part was set by the manufacturer to 2000W.

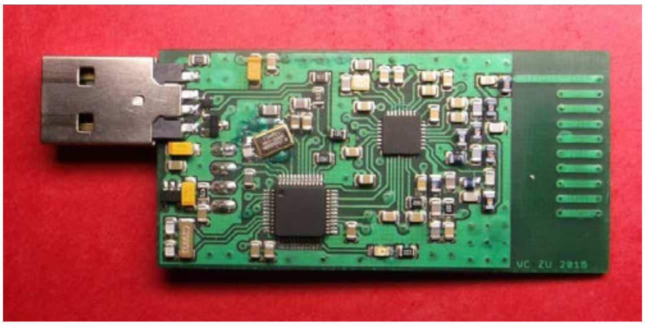

Fig. 7 USB wireless module for PC, interconnection gateway

Outlet adapter electronics is powered from the switching power supply from "Myrra" producer. The switching power supply changes the AC mains to stabilised operating voltage 3,3V with a maximum current consumption 750 mA. Producer guaranteed that average efficiency is 65% for this switching power supply. We did not observe any malfunctioning during its working. The outlet adapter includes a charge pump "TPS60401" manufacturer "Texas Instruments". The charge pump is connected as a voltage inverter and serves as a power supply for the bistable relay.

Changing the voltage using the charge pump is advantageous for this application. The main reason is its high efficiency and low circuit complexity. Low output current may seem like a disadvantage because of the higher current necessary to change the relay status. Usage of the bistable relay however means that the control current in the coils may not stay for the conservation of the relay. Its switch requires only short pulse. Since the relay is the only component that uses a negative potential, it does not matter if it is this tension fluctuate. To switch the relay is sufficient to have a negative voltage branch of a sufficiently large capacity of which short pulse will pass.

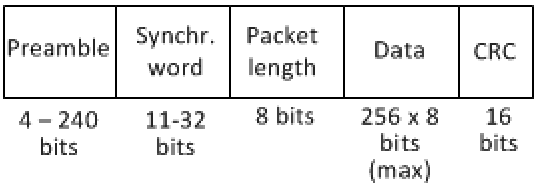
The wireless transmitting and receiving is provided through "CC1120" device from "Texas Instruments". The module combines transmitter with maximum output of 16dBm and receiver sensitivity of -123dBm at a 1,2kbps. Important features are summarized in the following points:

- Operating voltage is from 2V to 3.6V.

- 4-wire communication SPI bus and an interrupt signal.
- Special FIFO memory for transmitting and for receiving, both 128 bytes.
- Maximum transmission power to 50 Ohm antenna varies depending on the supply voltage. For 2V power supply is 12dBm and for 3.6V is 16dBm
- Power consumption when in max+imum power transmitting mode (+ 15dBm) is 50 mA. Power consumption for receiving mode is approximately 22,6 mA.
- The transmission frequency rate can be 164-192MHz, 274-320MHz, 410-480MHz or 820-960MHz
- Width of the transmission channel can range from 7812 Hz to 200 kHz.
- Circuit supports the following modulation: FSK-2, 2-GFSK, 4-FSK, 4-GFSK, ASK, OOK, DSSS and analog FM
- The maximum bit rate is half of the width of the transmission channel. For the two-state frequency modulation is the highest bit rate of 100ksps. When four state modulation it can be equal to the width of the channel - thus maximum 200kbps.

Wireless module offers the useful function "Enhanced Wake on Radio" (eWOR). This is a power-saving mode of receiving when the module turns on and off wireless module at regular intervals to detect the presence of the transmitter. This process reduces the average current consumption during receiving. It is possible to make the communication protocol in order to use this function by simply increasing the preamble size before the data packet so the receiver had more opportunities to capture the packet.

Wireless module CC1120 supports hardware processing of the packet that is shown in the figure below.



| Preamble | Synchr. word | Packet length | Data | CRC |
|---|---|---|---|---|
| 4 – 240 bits | 11-32 bits | 8 bits | 256 x 8 bits (max) | 16 bits |

Fig. 8 Hardware packaging data into packets

The preamble does not contain any valuable data, usually only alternation of ones and zeros. The task of the preamble is to give remote devices possibility to capture the presence of a transmitted signal to wake up from standby. The data transfer can be realized even without the preamble. Next important part is the synchronization word. Its purpose is to indicate the start of transmission of important data. If the receiver does not receive proper synchronization word transmission failed. Next part is the length of the packet. Length of the packet means only the size of user data that follow this part. This part may be omitted and sets the protocol for constant packet length. The last addition is the CRC code through which the correctness of the transferred data can be checked. Wireless module calculates its own CRC code from the received data and compares it with the received CRC code. If during transmission, there are some interference sources, which caused data defection, data are automatically declared non-conformity and will be erased.

The transmitted data encapsulates also two bytes for addressing devices and two bytes for the security key. The current implementation of the key can be understood as a password by which the system will or will not respond to the packet.

Smart metering units have their own standardized protocol that ensures compatibility among devices from different manufacturers. It is described in the standard "EN 13757", developed by "CENELEC". Wired communication protocol is commonly referred to as "Mbus" and wireless version as "WMbus". Standard "EN 13757" contains six documents. The latest ones are from 2013. [29], [30], [31], [32], [33]

The current weaknesses of the system are mainly related to the crisis cases. As an example, a power failure in the electric grid can be considered. Power failure causes loss of measured data which have not been sent to headquarters. The biggest problem is the loss of measured consumption. There are two ways to prevent it. The first is to use the backup battery, which provides data transmitting after power failure. This case assumes that the central has its own backup battery. The advantage of this method is the possibility of error detection in electrical distribution. If the mains voltage re-starting, headquarter can detect the status of the measuring devices. If the device reports the absence of voltage, it is situated in the faulty branch. The second way how to deal with data loss in case of power failure is using of non-volatile memory in which can the node hold the regularly stored data. In case of failure by using of such equipment, only a small part of data record will not be recorded.

Headquarter for the measuring device presents a personal computer. Ability to communicate in the ISM band at a frequency below 1 GHz gives the USB device. For proper operation of the device to a computer it is necessary to add a custom driver. Subsequently, the device appears as a virtual serial link. The easiest way is through the usage of direct communication from serial line.

The main scope of the WSN implementation was to distinguish the difference between authorized and unauthorized power consumption. An analysis of power characteristic waveforms will help with this problem, since it provides the information about the load type.

## IV. Power Factor Estimation

The definition of the power factor (PF) in AC circuits is well-known as the ratio of the real power ***P*** that is used to do work and the apparent power ***S*** that is supplied to the circuit:

$$PF = \frac{P}{|S|}\,, \qquad (1)$$

where ***PF*** is power factor, ***P*** is real power in watts [W] and |***S***| is apparent power - the magnitude of the complex power in volt·amps [VA].

The power factor can get values in the range from 0 to 1. When all the power is reactive power with no real power (usually inductive load) - the power factor is 0. When all the power is real power with no reactive power (resistive load) - the power factor is 1.

For **sinusoidal current**, the power factor ***PF*** is equal to the absolute value of the cosine of the apparent power phase angle φ:

$$PF = |\cos\varphi|, \qquad (2)$$

where **φ** is the apparent power phase angle.

In order to estimate power factor, we can compute real energy ***E<sub>PP</sub>*** consumed during one period by formula:

$$E_{pp} = \left(\sum_{i=0}^{n-1} U_i \,.\, I_i.T_s\right), \qquad (3)$$

where $\boldsymbol{U_i}$ in [V] and $\boldsymbol{I_i}$ in [A] are sampled values during one period of mains voltage, $\boldsymbol{T_s}$ is the sampling period in [s] and n is number of samples sampled during one period of mains voltage.

Now we can estimate apparent energy $\boldsymbol{E_{SP}}$ as:

$$E_{sp} = U_{RMS} \cdot I_{RMS} \cdot T_s\,, \qquad (4)$$

We can get $\boldsymbol{U_{RMS}}$ and $\boldsymbol{I_{RMS}}$ as the maximal sampled value divided by the square root of two:

$$U_{RMS} = \frac{|U_{MAX}|}{\sqrt{2}}\,, \qquad (5)$$

$$I_{RMS} = \frac{|I_{MAX}|}{\sqrt{2}}\,, \qquad (6)$$

where $\boldsymbol{U_{MAX}}$ and $\boldsymbol{I_{MAX}}$ are absolute maximums of sampled waveforms.

When we have all this values we can compute power factor ***PF*** by the formula:

$$PF = \frac{E_{pp}}{E_{sp}}\,, \qquad (7)$$

In normal case the light bulb has resistive character. Therefor the power factor is very close to 1. In case of inductive (or capacitive) load the power factor is lower. This indicates that the lessee uses forbidden type of appliance. Differences between reactive and resistant power waveforms can be seen in the figures below.

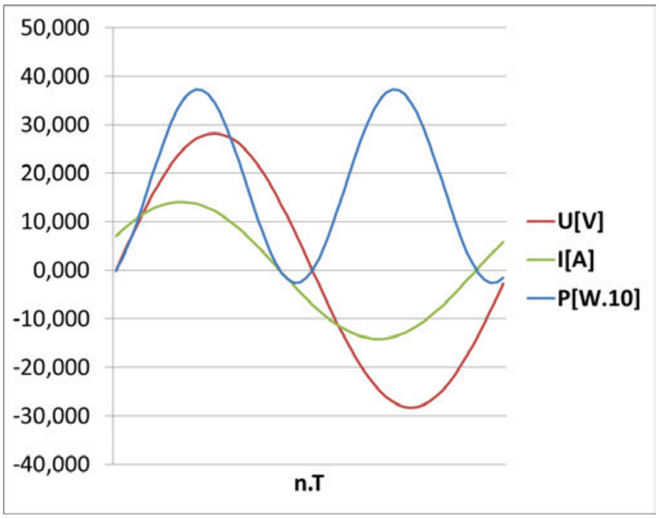


Fig. 9 Waveform of reactive power characteristics

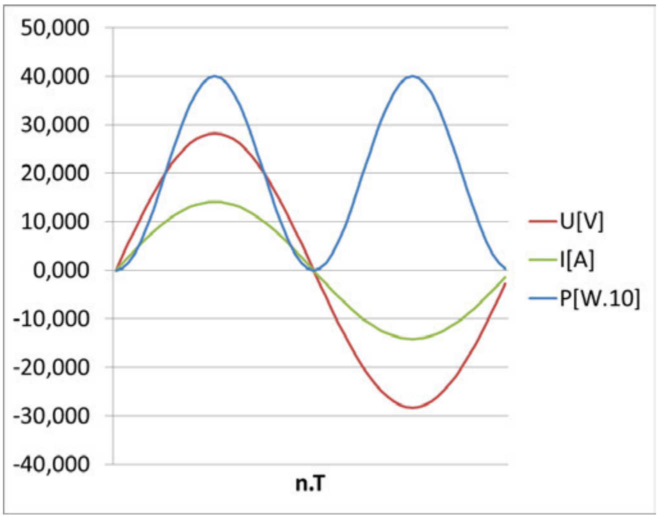

Fig. 10 Waveform of resistant power characteristics

## V. Conclusion

The paper described the first try to implement the application-specific indoor WSN for power metering at places with shared power sources. Practical measurement shows, that the network is ready to be finally applied. However, approval of all garage owners is necessary, what is at the moment an irresolvable problem. Other concrete application scenario has therefore to be found.

***Abstract*—The energy consumption in Wireless Sensor Networks, WSN, need to be balanced in order to avoid early depletion of nodes. In this paper we use a common context to analyze a broad range of the energy balancing algorithms suggested in literature. In addition we suggest three new algorithms to complete the range. Altogether, nine different balancing techniques are analyzed. We focuses on networks running the IPv6 Routing Protocol for Low-Power and Lossy Networks (RPL) routing protocol. Our simple change in RPL's parent selection procedure can give a significant balancing effect without any increase in management cost. However, the best balancing algorithm is when the nodes exchange residual-energy information to ensure forwarding through the highest residual-energy next-hop node. The increased information exchange implies increased management cost due to the amount of information transmitted and added computational load.**

## I. Introduction

WIRELESS sensor networks (WSN) generally consist of wireless nodes with a collective objective of gathering measured information at the sink [1]. The monitored area may be large compared to the nodes' transmission range. Hence, the information needs to be relayed to reach the sink. The topology of the relaying paths may create imbalance in the traffic share, and therefore the energy consumption, between the nodes. Energy imbalance results in lifespan variation between the nodes. Observations of real networks in [2] and [3] show that some nodes relay a substantial portion of the traffic, thus they become hot-spot-nodes having a high energy consumption rate.

Depleted or dead nodes make the gathered data incomplete and, more important they may cause network partitioning. Applying energy balancing routing algorithms levels the traffic load, hence lifetime, between the nodes. The ideal situation is long living WSNs where all nodes have equal lifetime. However, this ideal situation not feasible due to the increased traffic density toward the sink in multihop networks. The goal in multihop networks is instead to balance the energy consumption between nodes at equal hop distance from the sink. Network management will be simplified if the nodes at each rank have similar lifetime. Balancing algorithms are the topic of this paper.

Our contribution is threefold. First we present a methodical review of a broad range of energy balancing algorithms. The algorithms range from approaches requiring simple changes of the applied routing algorithms, to approaches that require complex add-ons. Second we use a common context to compare these algorithms. Third, we suggest three new balancing algorithms to complete the collection of balancing algorithms found in the literature. The tree suggested algorithms are random selection of preferred-parent, conserving of Single Point of Failure (SPOF) parent and energy balancing based on eavesdropping.

To get a good estimate of the energy pattern in the network we use the nodes residual-energy. The residual-energy gives the true picture of the energy variation that appears between the nodes. In addition, residual-energy is directly related to the nodes lifetime.

To evaluate the impact of different energy balancing techniques, we use the routing protocol suggested by Internet Engineering Task Force (IETF) for use in WSN, IPv6 Routing Protocol for Low-Power and Lossy Networks (RPL) [4]. RPL creates routing entries in the nodes which forms an overall destination oriented directed acyclic graph (DODAG) rooted at the sink. The graph is created by broadcasting of DODAG Information Object (DIO) messages. The sink initiates the transmission, and the messages are further broadcasted throughout the whole network. The DIO includes the senders' rank information. The rank indicates a node's distance to the sink. The rank increases as the distance to the sink increases. The sink is at rank 0 and the sink's one-hop neighbor defines the rank-one nodes and so forth. Each node caches a parent-list containing all neighbors that report a rank equal to the lowest rank heard. A preferred-parent is selected among the nodes in the parent-list. The preferred-parent is used as the current next-hop node on the path toward the sink. To maintain the DODAG, the nodes transmit DIO messages periodically at intervals decided by a trickle timer [5].

The rest of the paper is structured as follows. In Section 2 we present related work, in Section 3 introduces the different energy balancing approaches to be analyzed, the

978-83-60810-66-8/$25.00©2015, IEEE

simulation is presented in Section 4, and Section 5 comprises the conclusion.

## II. Related work

Several energy balancing approaches are suggested in the literature. Energy balancing based on selecting the most energy optimal path is suggested in [6] - [13]. In all but the two latter of these algorithms are energy information exchanged through DIO messages. Applying DIO messages to exchange energy information means the energy balancing depends on the number of data packet transmitted per transmitted DIO message. Thus, increased energy balance is paid by increased DIO transmission frequency, which means increased average energy consumption. Further, the trickle timer [5] decides the DIO emission frequency such that the emission frequency decreases exponentially with time in converged networks. Hence, the balancing effect of the algorithms discussed in the next paragraph will decline with time.

The object function (OF) for RPL suggested in [6] defines the path cost as the energy level of the node on the path with lowest residual-energy. The node that advertises the highest path cost is preferred as selected parent, and the lower energy nodes are spared. The authors of [8] suggest that the node with the highest remaining energy among the nodes with the lowest expected transmission count (ETX) is chosen as the preferred-parent in network running RPL. Both ETX and node energy is used to select between parent nodes of equal hop-count in [9]. The residual-energy is included as a denominator in the additive distance metric in [10]. Using it as in the denominator makes the cost of a node increase toward infinity as energy approaches zero. Hence, the paths including low energy nodes is avoided due to their high cost. A routing metric that calculate the expected lifetime of the nodes is defined in [11]. The expected lifetime is calculated as the ratio of the node's residual-energy over the total energy spent to transmit data. The paths including the most constrained nodes are avoided by defining the path weight as the minimum expected lifetime along the path. An approach similar to RPL is used to create paths for networks with multiple sinks in [7]. Several equal-rank nodes are cached as potential parent based primary on hop-count metric, secondary the nodes energy metric and third on the highest link-quality-indication. Algorithms where the highest residual-energy path is selected or the lowest residual-energy paths are avoided are part of our analysis.

Energy information is exchange through the ACK packet in the approach presented in [13]. The network run RPL, and the nodes perform a weighted selection to choose among its available next-hop nodes. The selection is weighted between distributing the traffic through the lowest delay path and distributing the traffic to nodes with higher remaining energy. In the routing protocol suggested in [12], the energy information is both piggybacked on data packets and included in the ACK packets. Hop-count is used as the metric to generate parent-list. Data packets are transmitted to the highest energy member of the parent-list. If there is no parent node available, the packet is transmitted to the sibling node with the highest amount of energy. Our analysis includes an algorithm where the ACK message exchange the energy information.

Energy consumption can be balanced by continuously spreading the transmitted data over multiple paths, and such methods are also part of our analysis. Approaches using multiple paths are suggested in [14] [15]. RPL is used as the routing protocol in [14] where the forwarding load is weighted between the members of the parent-list. The weighting is based on the members' residual-energy. The transmission range dynamically adjusted to maintain k parents. Energy information is exchanged between the nodes through ACK and DIO packet. In addition is also hello packets mentioned as possible information carriers. The approach in [15] enables multipath data forwarding through energy-sufficient paths, as opposed to minimum-energy-cost paths. They propose a routing algorithm which makes a hierarchical routing graph similar to RPL. The nodes forward packets through alternate paths to extend the network lifetime. The conditions of the paths are monitored by the sink which re-initiate path search if the number of working paths gets lower than two. Multiple paths are also discussed in the surveys presented in [16] [17]. Survey [16] cites an algorithm presented in [18], which takes both the energy level and hop distance into account to allocate different data rates to multiple disjoint paths. The sink decides the rate of the different paths and assign messages are sent form the sink to the source nodes to inform about the path rates. The top-down survey paper [17] cites an interesting improved cost function used to balance the energy consumption among the nodes [19]. The improved cost calculation algorithm makes the cost increase rapidly with decrease in the nodes remaining energy. Hence, traffic is directed away from hot-spot nodes. The approach requires that the nodes cache several states for each neighbor and that energy information is exchanged periodically. The survey paper [17] also discusses energy balancing by using a few relay nodes with enhanced capabilities. In addition they discuss use of mobile sinks. These algorithms increase the start-up management cost of the networks, and increases the network cost.

Clustering is among the energy efficient algorithm discussed the survey presented in [20] and suggested to improve energy utilization in [26]. The basic idea of energy efficient clustering is to perform energy efficient rotation of the clusterhead assignment and let the clusterhead perform energy efficient management of the local cluster traffic. Clustering is not part of our analysis as it is not very well fitted for RPL running network.

Balancing the energy consumption by making the nodes alternate between direct transmissions to the sink and using multi-hop transmissions is suggested in [21].

The protocol is used as an extension to RPL in [22] which presents a smart/green test-bed of nodes spanning across several smart offices. The findings of [22] shows that the protocol suggested in [21] balances the network energy consumption compared to classic RPL. However, it is more energy expensive giving an overall increased energy dissipation. This algorithm is only considered for one-hop networks, while we are considering multihop networks.

## III. Balancing network energy consumption

In this section we present the different energy balancing algorithms that are analyzed. Our hypothesis is that introducing small changes in the parent selection procedure improves the WSN energy balance, while substantial enhancements come at a cost of increased management complexity and information exchange between nodes. Further, efficient energy balance is achieved when focusing on reducing the load of the hot-spot nodes.

The following text lists nine algorithms. The tree new algorithms that we suggest are A: Randomize parent selection, D: Weighting round-robin based on SPOF-parent energy level and H: weighting round-robin based on eavesdropping.

### *A. Randomize parent selection*

As a first approach to enhance the energy balance in WSN, we suggest a simple change in the preferred-parent selection algorithm. The aim of the suggested algorithm is to reduce the probability of creating hot-spot nodes. The probability is reduced by preventing that several child nodes select the same preferred-parent if other potential parents exist. According to the RPL algorithm, all nodes cache a parent-list containing all candidate parent nodes. A preferred-parent are selected among the parent-list nodes, using a specific parameter as tiebreaker. Hence, nodes with globally good tiebreaker value will be selected by all potential child nodes and may therefore become hot-spot nodes.

Our suggested algorithm creates a small change in the preferred-parent selection procedure to reduce the probability of creating such hot-spot nodes. The nodes randomly select a preferred-parent among the nodes in the parent-list instead of using a preordain tiebreaker parameter value. Hence, the probability that several potential child nodes select the same node as preferred-parent is reduced. The forwarding load is therefore more balanced. The weakness of the algorithm is that it can give energy consumption imbalance if selected parents are located such that they represent single paths for other nodes.

### *B. Round-robin through multiple paths*

Selecting a single preferred-parent may overload some potential parents while leaving some potential parents unused. Thus, our analysis comprises an approach where this imbalance is alleviated by making the nodes transmit data packets to all nodes in their parent-list in a round-robin fashion. The approach shares the forwarding load equally between all members of the nodes' parent-lists. The main weakness of the approach is the load imbalance that is created between nodes with different number of child nodes.

### *C. Weighted round-robin based on energy information in DIO messages*

To level the energy imbalance that may appear using the round-robin approach we implement algorithms in which the nodes exchange energy information during DIO transmission. The information is used to perform a weighted-fair-sharing between the parent nodes. Thus, the nodes share the traffic load among the nodes in the parent-list according to their relative residual-energy level. The energy-balancing effect of the weighted algorithms depends on the freshness of the energy information cached for the nodes in the parent-list. Hence, increased DIO exchange frequency means improved energy balance. However, increased DIO exchange frequency increases the energy consumption in the network. Thus, there is a tradeoff between energy balance and average energy consumption.

Weighted round-robin ensures that the energy depletion rate of the low energy parents is reduced, hence the energy balance is improved. However, the algorithm preserves the existing energy imbalance relationship between parent nodes.

### *D. Weighting round-robin based on SPOF-parent energy level*

The goal of our single point of failure (SPOF) algorithm is to prevent early depletion of SPOF nodes. We define SPOF nodes as nodes that are part of one or more parent-lists containing only one member. In other words, a child that has a SPOF parent is disconnected from the routing graph if the parent node dies. Child of SPOF parent forwards all data through the SPOF parent. Even when the SPOF parent has a very low energy level, the child has no other option than continue forwarding through the SPOF parent. Hence, depleting of the SPOF node is continued.

To reduce the depletion rate of the SPOF nodes we suggest to direct traffic originating from higher rank nodes away from the SPOF nodes. In order to do so, we let nodes with a SPOF parent advertise the energy level that is the lowest of its own and its SPOF-parent's residual-energy level. Thus, traffic is directed away from the paths including the SPOF node.

Directing the traffic away from the SPOF nodes may come at an expense of other low energy nodes on the same rank as the SPOF node. However, child with SPOF parent continue to transmit their own generated data to their SPOF parent, while other nodes only get a weighted amount of traffic from their respective child nodes.

The DIO is used to exchange energy information.

### *E. Weighted round-robin based on prediction parents energy consumption*

The energy information gained through received DIO can be used to predict the energy consumption pattern in between DIO updates. To test such energy prediction algorithms, we implement an algorithm that estimate parents current energy level based on statistics of former energy consumption. The algorithm is as follows. The residual-energy a node advertises in consecutive transmitted DIOs is cached at the receiving nodes. The timespan between the consecutive DIO is further used to estimate the depletion rate of the transmitting node. The current energy level is estimated using the individual parents' energy drain rate and last advertised energy level. The estimated energy level is used to perform weighted-fair-sharing between the parent nodes.

### *F. Weighted round-robin while avoid lowest energy parent*

In order to focus on the hot-spot nodes we suggest a partly weighted algorithm. The data is weighted between the parent nodes. However, no data is transmitted to the parent with the lowest residual-energy. Hence, the load on the hot-spot nodes is reduced. This algorithm requires that the nodes exchange residual-energy information through the DIO message.

### *G. Use the highest energy parent node*

In the multiple path approaches, although weighted, each parent receives data for forwarding from their child nodes. This applies even if the residual-energy level of the parent is low. Hence, if all nodes transmit approximately equal amount of traffic, the nodes that are members of several paths are depleted faster than other nodes.

The depletion pace of low energy nodes is reduced in approaches where the lowest energy parent is avoided such as the approach presented in subsection III.F. However, nodes forces parents with second lowest energy level to forward traffic. Hence, the lowest energy nodes alternates their states with next lowest energy nodes.

A simple solution is to use only the highest energy parent node as the next-hop node. This algorithm is similar to the algorithm used in [8]. We implemented this algorithm and used DIO to exchange energy information.

### *H. Weighting round-robin based on eavesdropping*

Utilizing information conveyed in DIOs may give an incomplete view of the current energy levels of the nodes in the parent-list. The reason is that traffic imbalance, and associated energy consumption imbalance that occurs between DIO transmissions are not taken into account.

In order to predict parents' energy consumption between DIO updates, we suggest that nodes eavesdrop on the traffic transmitted in the area. The algorithm operates as follows. Nodes read the source and destination address information in the eavesdropped traffic. The address is matched against the content in the parent-list of the eavesdropping nodes. When a match is found, the energy level of the associated parent-list entry is reduced according to the eavesdropped information. The energy level of the nodes in the parent-list is then used to perform weighted-fair-sharing.

Eavesdropping does not significantly influence on the nodes energy consumption. The reason is that overheard packets destination address has to be read anyway to determine the intended receiver of the packet. The energy consumption due to overhearing is not taken into account when comparing the different balancing techniques. The reason is that the extent of overhearing energy consumption is mainly decided by the energy saving approach chosen at the MAC layer, while we are concentrating on the routing layer algorithms' impact on energy consumption.

The eavesdropped traffic may not give a complete overview of the parent nodes traffic load. For instance, child nodes of a common parent may not receive each other's packets due to hidden node. Thus, the calculations of the energy consumption of the parent-list nodes may be imprecise.

### *I. Weighting round-robin based on energy information conveyed in ACK packets*

Lastly, we implement an algorithm in which information about the nodes' energy variation in between DIO transmissions is exchanged through ACK packets. ACK packets are sent as a response of received data packet. Hence, the nodes achieve a complete overview of the diverse energy levels of the nodes in their parent-list as each parent relays a packet.

However, the energy information of parents with low residual-energy is less current. The reason is that low energy nodes seldom forward data as they have low weight. In addition, nodes that rarely transmit data can have stale energy information for the nodes in their parent-lists. This may give temporary screwed forwarding load among parent nodes. However, the energy levels are continuously

balanced as energy information is updated, smoothing the discrepancy over time.

Weighted-fair-sharing is performed based on the energy information.

## IV. Simulations

We perform simulations to evaluate the different discussed algorithms. The energy consumption in WSN increases toward the sink as the inner nodes are obligated to relay traffic for outer nodes. Thus, we mainly present simulations segregated on the node's rank. Applying an energy balancing algorithm will not change the average energy consumption for the nodes at the different rank since the total number of packet transmitted through each rank is unchanged.

We concentrate on transmitting and receiving energy consumption. Overhearing energy is not taken into account. The reason for omitting the overhearing energy consumption is that we concentrate on energy balancing at the network layer, and overhearing energy consumption is strongly dependent on the energy saving approach applied at the MAC layer. Overhearing may give a small variation in the average energy due to the chosen path. However, the difference between the energy consumed due to overhearing become negligible because the algorithms are compared at given average node density.

As discussed above, the average energy consumption at each rank is consistent regardless of applied balancing algorithm. However, an efficient energy balancing algorithm makes the residual-energy of the most depleted node approach the average residual-energy at the given rank. Hence, we present the average and minimum residual-energy after each node has generated 100 data packets.

Energy information is used to tune the traffic load between parent nodes in some of the evaluated algorithms. In networks running these algorithms, each node caches residual-energy information of its parents. The accuracy of the cached information depends on the update interval. For the algorithms that exchange energy information through DIO messages, the accuracy is improved by reducing the number data packets exchanged per DIO transmitted. The residual-energy information accuracy approaches the accuracy of the ACK algorithms if the DIO emission frequency approaches the data rate. However, increased DIO exchange frequency increases average energy consumption. Further, the DIO exchange frequency is decided by the trickle timer such that the exchange frequency is strongly reduced in converged stable networks. Thus, the energy balance is declining over time when the balance depends on DIO exchanged information.

In our initial simulations, 100 data packets create sufficient network traffic to discriminate the balancing effect of the different category of balancing algorithms. However, each node transmit a total of 16 DIO messages during the simulation runs, hence the number of data packets transmitted for each DIO transmission is low. Thus, to improve the basis of comparison we present additional simulation results for the weighting algorithms. Only two DIO messages are transmitted during the simulation run in these additional simulations, and the number of transmitted data packets is increased to 300. This gives a more fair comparison between the algorithms relying on DIO to exchange energy information, relative to the algorithms that use additional means to exchange energy information.

We evaluate the different energy balancing approaches by performing simulations in OMNET++ [23], using the MiXiM module for wireless communication. The nodes' energy consumption is calculated based on traffic load. Based on the observations and references in [24], we assume that receiving and transmission of data packets consume the same amount of energy. The different types of packets have different packet sizes. Management packets are assumed to be half the size of data packets, while ACK packets are one tenth of the size of the data packets. These relative values are chosen based on an assumption that data packets never need the maximum allowed packet sizes as they are mainly limited to carry only measured data, while management packets only carries strictly needed information. Maximum data frame sizes and ACK frame sizes information extracted from 802.15.4 datasheet [25].

The nodes are randomly distributed in an 800m times 800m area. The nodes transmission range is 141m. The number of nodes is varied such that the node density changes from 8 to 20. The node density is defined as the number on nodes inside a circle with radius equal to the nodes transmission range. Every simulation point presented represents the average value of 30 simulation runs with different seeds for random deployment of nodes.

As discussed above, the average energy consumption is equal for each rank over all energy balancing algorithms. However, the residual- energy values of the most depleted nodes change with the applied balancing algorithm. The most optimal energy balancing algorithm is the algorithm in which the residual-energy of the most depleted nodes converges to the average value. Therefore, we compare the algorithms with respect to their ability to make the nodes with lowest residual-energy approach the average value of their associated rank. Figure 1 shows simulation results that demonstrate to what extent the different algorithms make the lowest and average values converge. All the algorithms discussed in Section 3 are presented in the figure.

The nodes' average residual-energy, as well as the residual-energy of the most depleted nodes are presented in Figure 1. This is the residual-energy level of the nodes after each node has generated and transmitted 100 data packets. In addition to data, management traffic has been exchanged to make the network converge. Further has periodic DIO updates been transmitted. The circled shaped

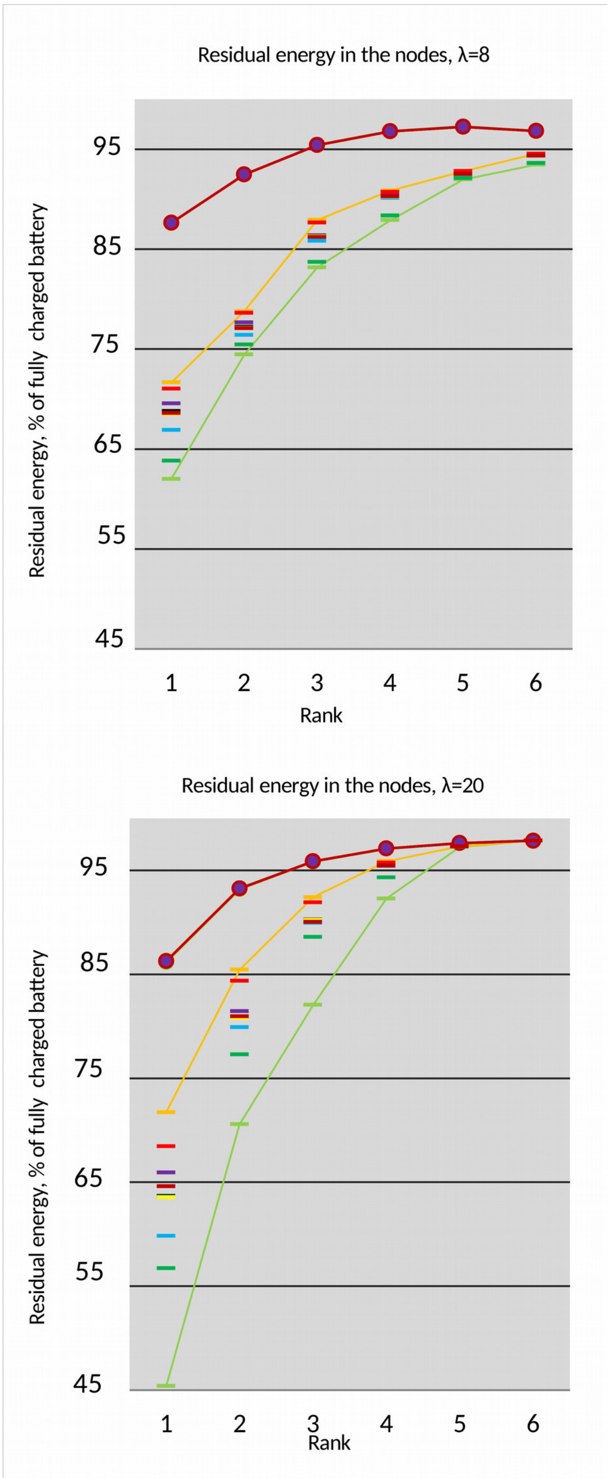

Fig 1. Residual-energy in the nodes after each node has generated 100 data packets.

markers with the corresponding lines show the average residual-energy values. The energy levels for the most depleted nodes are shown as short horizontal markers. In order to clarify the information displayed in the figure, the best and the worst of the residual-energy levels are displayed with solid curves through their associated markers. Hence, the orange curve cut through the markers representing the highest residual-energy level and light green curve cut through the markers representing the lowest residual-energy. The colors of the markers and lines indicate the corresponding energy-balancing algorithm as defined in Table 1. To prevent that the important information gets hidden in an overloaded display, the 95% confidence interval is not shown in the figures. However, the 95% confidence interval is always within 7% of the average values. Simulations performed for node densities of λ = 10 and λ = 15 show the same trends as shown for λ = 8 and λ=20 in Figure 1.

The simulation results displayed in Figure 1 shows that native RPL creates energy imbalanced networks. The native RPL simulation results are represented by the light green marks and the light green curve. Native RPL gives the overall lowest residual-energy for all ranks and all node densities. The reason is that a fixed parent is used throughout the whole simulation scenario, further is lowest node-id used as a tiebreaker when choosing between potential parent nodes. The latter means that several nodes choose the same preferred-parent node.

The difference between the lowest residual-energy node and the average value increases toward the sink. The reason is the increased traffic density. A given imbalance in traffic share causes an increase in the real traffic load difference as the total traffic increases.

The energy imbalance increases rapidly with node density for approaches where the parent node is fixed. This is observed in Figure 1 where the light green native RPL line rapidly moves away from the average line as the node density increases. The reason is the increased number of neighbors. Increased number of neighbors increases the number of child nodes for the fixed parent.

Based on the discussion above it is clear that some kind of energy balancing techniques should be added to networks running native RPL. Our suggested random preferred-parent selection algorithm presented in subsection III.A, demands a minor change in the RPL implementation. Nevertheless, the residual-energy of the most depleted node is reduce by over 10% compared to native RPL for high density networks. This is seen in the Figure 1 comparing the light green native RPL marks with the dark green marks.

However, the most efficient energy balancing algorithm is the one presented in subsection III.G, in which the parent with the highest residual-energy is selected as the next-hop node. The algorithm is represented by the orange marks in the Figure 1. Using highest energy parent increases the residual-energy of the most depleted node more than 25% compared to the native RPL. The merit of the algorithm is that the residual-energy nodes are avoided. This result corresponds to the results presented in [8] and [6] where ETX is used as a metric to populate the parent-list. However, using the parent with the highest residual-energy means that energy information has to be exchanged between the nodes. Randomizing parent selection, presented in subsection III.A, does not add any overhead.

The weighted share algorithms increase the residual-energy of the most depleted nodes with 15 to 20% compared to native RPL in high density networks. The weighted share algorithms are presented in subsection III.C-F and III.H-I. The improved performance complies with the studies performed in in [14] [15]. However, the poorer performance of these algorithms compared to the highest energy parent algorithm, III.G, is due to the fact that the lowest energy parent is still used, although rarely.

In subsection III.F we suggest the improved weighting algorithm, where the most depleted node is avoided while the traffic is weighted between the other parents. The improved algorithm is represented by the red marks in Figure 1, and shows that the residual-energy of the most depleted node is always distinguishable higher than the general weighting algorithms.

The round-robin approach, represented by the light blue marks, contributes less to balance the energy than the weighting algorithms. The reason is that parent with low residual-energy are loaded with the same amount of traffic as the other parents.

The simulated weighted-fair-sharing algorithms exchange energy information through DIO messages as well as through the algorithm-specific energy information exchange technique. Thus, the energy information update intervals between the different algorithms converge if the DIO exchange frequency is high compared to the packet exchange frequency. This phenomenon is demonstrated in Figure 1 as it is difficult to discern between the simulation results for the algorithms that use weighting as balancing technique. To better illustrate the difference between the weighting algorithms we performed simulations where each node generated 300 data packets. The DIO exchange is limited such that each node only generates two DIOs during the whole simulation. The simulation result is shown in Figure 2.

As expected, when the DIO exchange frequency is reduced, the ACK method has an improved balancing performance relative to weighting based on DIO information. The ACK method is presented in subsection III.I and weighting based on DIO information is presented in subsection III.C. The improved balancing performance is seen in Figure 2 where the blue marker of the ACK method is closer to the average values than the yellow DIO information markers. In Figure 1, the blue ACK markers are actually hidden by the yellow markers. Hence, the ACK and the DIO information performed equally well when the number of data packets per DIO packet is low.

The eavesdrop-algorithm described in subsection III.H and represented with the black marks and line in the Figure 2, has the worst balancing capabilities. This applies especially for the one-hop nodes. The reason is increased traffic density in these areas of the network. High traffic density means that nodes often become hidden terminals preventing them from eavesdropping neighbors' traffic.

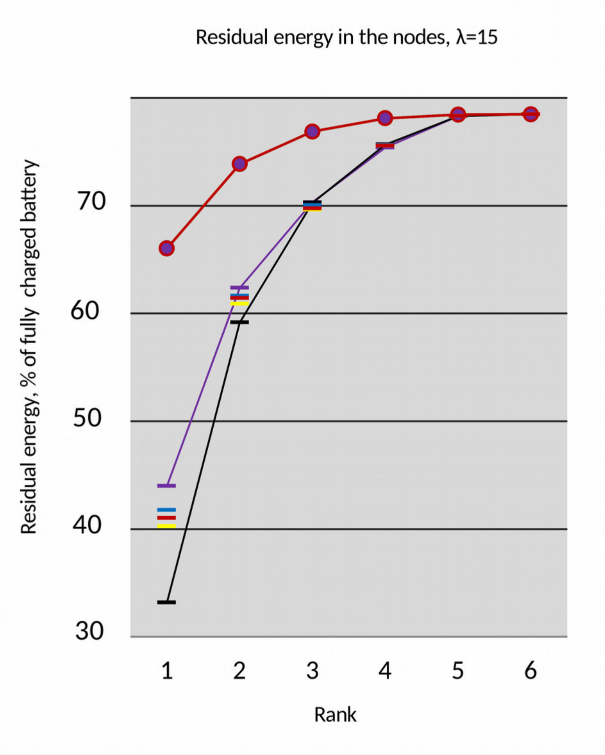

Fig 2. Residual-energy in the nodes after each node has transmitted 300 data packets

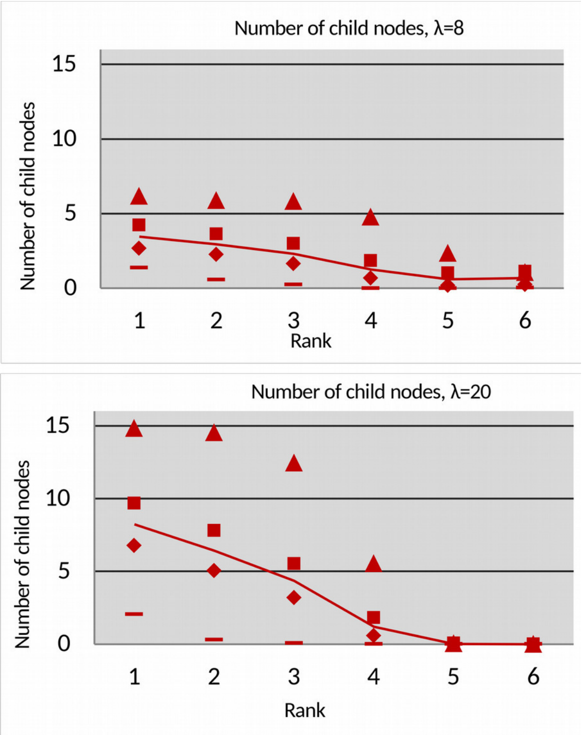

Fig 3. Number of child nodes versus rank for different node densities

Our SPOF-algorithm described in subsection III.D and presented with purple line and marks in Figure 2, gives the best balancing effect. The reason is that higher-rank nodes are encouraged to choose paths that does not include the nodes that act as SPOF. However, SPOF nodes are not completely unloaded from forwarding data since child nodes have to forward all traffic through their SPOF parent nodes.

At higher rank nodes the SPOF-algorithm gives equal or marginally less balance compared to all other weighted-fair-sharing algorithms. However, the most efficient energy-balancing algorithm is the algorithm that focuses on energy balance among the lowest rank nodes, although this may give reduced balancing effect at the higher-rank nodes. The reason is that the lowest rank nodes always consumes the highest average amount of energy.

Increased number of child nodes enlarges energy imbalance between nodes, in particular for algorithms that uses fixed preferred-parent nodes. The number of child nodes increases with increased node density and reduced rank. This is demonstrated in Figure 3 which shows the number of child nodes versus rank for two different node densities, λ=8 and λ=20. This figure supports the findings in Figure 1 related to the rapidly increase in energy imbalance for increased node density. The circled shaped markers in Figure 3 with the corresponding lines show the average values. The square shaped and the diamond shaped markers shows the 95% confidence interval. In addition, the highest values, averaged over all different-seeds simulations are shown as triangular markers. The lowest values, averaged over all different-seeds simulations are shown as short horizontal lines.

## V. CONCLUSION

Simulations presented in this paper show that the energy imbalance is substantial in network running the native RPL routing protocol. Thus, some kind of energy balancing algorithm should be used to prevent premature node depletion.

A total of nine energy balancing algorithms applicable for RPL running networks are analyzed in this paper. Six of the algorithms are based on various approaches suggested in literature. In addition, we suggest three new energy balancing approaches to complement the selection of algorithms. A common context is used to simulate and compare the performance of all the algorithms.

The simplest of our suggested approach is just a tiny adjustment of RPL's parent selection algorithm. Instead of using a preordain tiebreaker parameter, the preferred-parent (next-hop node) is randomly selected among the nodes in the parent-list. The adjustment gives a significant balancing effect. Especially in high density networks, where the residual-energy of the most depleted node is increased more than 10% compared to running native RPL.

The second and the third suggested algorithm use the nodes' residual-energy to weight-balance the transmitted traffic between all available parent nodes. In the second algorithm, a node with a single point of failure (SPOF) parent advertises a residual-energy level equal to the lowest of its own and its parent energy level. The algorithm requires residual-energy information to be exchanged between the nodes during RPL management packet exchange.

In the third algorithm, the nodes eavesdrop on the traffic in their vicinity to estimate neighboring nodes residual-energy level. Increased traffic density degrades the eavesdropping algorithm in the proximity of the sink.

Simulations shows that the SPOF algorithm performs best of all the weighting algorithms. Compared to native RPL is the SPOF algorithm increasing the residual-energy of the most depleted node with over 20%.

However, the best energy balancing is achieved when nodes choose the preferred-parent as the member of the parents list that has the highest residual-energy level. Simulations of the algorithm show that, compared to native RPL, the residual-energy of the most depleted nodes increases by 25%. The merit of this algorithm is that the lowest residual-energy paths are always avoided. On the contrary, weighting the traffic between all potential parent nodes means that also the lowest energy nodes are used, although rarely. However, to select the node with highest residual-energy, the nodes must exchange energy information. Randomly selecting the preferred-parent requires no extra information exchange.

Although the energy consumption is balanced, it is always the nodes closest to the sink that consumed the highest amount of energy. However, balancing the energy consumption of equal rank nodes can give reduced network management cost.

*Abstract*—**The paper is focused on the use of methods of compressed sensing (CS) in energy efficient monitoring of signals. CS allows to minimize the number of data that need to be transmitted to the sink node in the WSN environment. As a case study, we use compressed sensing for monitoring of mains voltage deformation. In this case we can assume that the measured signal is sparse in frequency domain and using of methods of compressed sensing is meaningful. Computational complexity imposed on the sensor node is minimized. On the other hand, reconstruction of the original signal in the sink node requires relatively high computing power.**

## I. Introduction

INTERNET is undergoing a third stage of development nowadays. Since 1995, the Internet has evolved from interconnecting desktops and later mobile devices (tablets, smart phones), via networking of all devices (Internet of Things) to the Internet of Everything - IoE (networking of things, people, data and processes). According to estimate of Cisco [1] there are about 200 things for every one person on the Earth that can be connected to the data network. It follows that in the near future we can see the network containing up to 1.5 x $10^{12}$ elements. Meaningful use of such a network is a huge challenge for the visionaries and theorists, but also for programmers, workers in the field of transmission technology and developers and technical resources. According to [2] we expect that in the next five years, the number of connected devices will increase from the current value of 12 x $10^{10}$ to about 35 x $10^{10}$, Fig.1.

In the IoE raises huge space for development and implementation of new applications of Wireless Sensor Netvorks (WSN). Recall that WSN consists of spatially distributed autonomous sensing elements that work together. They are distributed in the monitoring area and continuously evaluate the status of the monitored object. The term object here is understood in its broadest sense and may represent guarded area, production line or living being. Based on this definition the WSN represents a natural part of a global network IoE. The above projections indicate that in the near future we will see the growing number of WSN applications.

It is natural that during development of successful applications of WSN we are facing many constraints. Some of these constraints arise from the relationship of the society to the new information technologies (fear of loss of privacy, inability to effectively utilize the benefits of the system and many others). These limits are not analyzed in this paper. Let us mention technical limitations that determine the extent and success of WSN applications:

- limited energy resources of WSN elements,
- limited processing power, storage capacity, communication speed and range of broadcast modules of network elements,
- limited size of individual elements,
- limited (or even excluded) maintenance of the network elements during their lifetime,
- constraints imposed by the requirements for working conditions of WSN components,
- price limits for a single network element and the like.

Many of these limits are becoming less important with the continuous development of new electronic components and technologies. Others, however, will permanently restrict the

This work was supported by the Research & Development Operational Programme funded by the ERDF.

development of new applications. One of such limitations that must be respected in the development of applications is the limited capacity of energy resources. Note that limited energy consumption of WSN node affects other technical parameters - computing power, communication speed and range, and so on.

The problem of efficient powering of network elements can be addressed in the following ways:

- consistent use of energy harvesting (EH) exploiting resources that are available in the application [3],
- appropriate design of network topology with minimal demands on communication, optimal distribution of network tasks, dynamic reconfiguration of the network with respect to the current state of energy resources of individual elements, etc.,
- reducing consumption of sensor nodes that can be achieved by combining two approaches:
    - using only low-power elements in the process of sensor node development,
    - choosing of such a mode of operation of sensor node that minimizes energy consumption.

Energy harvesting systems used for powering of network elements are usually designed so that they can ensure continued operation of the nodes. The term Zero Power Wireless Sensor [4] indicate precisely those solutions that do not need a power source for their operation, but are able to drain the necessary energy from the environment. The construction of sensor nodes is based on modern circuit with reduced consumption. During the operation the sensor nodes use sleep modes with reduced consumption and the sensor wakes up to the active state only when it is necessary. The wake up event is usually based on external conditions. Such systems are referred to as "event-driven". The node is brought into active mode only under specified conditions (e.g. change of the observed variables by defined amount, the achievement of pre-defined state of the object, etc.). In many cases (e.g. by monitoring of non-stationary processes) is such system more energy efficient when compared to conventional "Time-driven" systems.

However, there is a group of systems that strictly speaking cannot be classified into any of the above mentioned classes. It is a class of systems that use for collection, transmission and processing of information methods known under the name compressed sensing. The next section describes the basic theoretical background of compressed sensing.

## II. Compressed Sensing

The basis of the theory of digital processing of continuous signals is Shannon's theorem, which says that a perfect reconstruction of the sampled signal is only possible if the sampling frequency is at least twice the maximum frequency component contained in the original signal. The theorem is universally applicable, however, in some cases the strict requirement for the sampling rate can be substantially released. Recent research [5], [6] has shown that this is possible particularly in the case if the sampled signal is in some domain sparse. Sparse means that relatively few coefficients describing the signal in the domain are non-zero.

Let $y$ be a one-dimensional discrete signal comprising of $n$ elements. Next, let $x$ be the representation of the signal $y$ in some domain (e.g. Fourier or wavelet). For linear transformation it holds that $x = \Phi y$ and $y = \Psi x$ where $\Phi$ and $\Psi$ and are square $n$ $x$ $n$ matrices representing the direct and inverse transformation and are composed from linearly independent base vectors (usually orthonormal).

We say that the signal $x$ is $s$-sparse (for $1 \leq s \leq n$) if it has at most $s$ non-zero coefficients. Intuitively, if the signal is $s$-sparse, it should have only $s$ degrees of freedom. In that case one needs substantially only $s$ measurements for the reconstruction of the original signal. This is the basic idea of the compressed sensing - the number of measurements that is required for the perfect reconstruction of the original signal is directly proportional to its sparsity.

Let's show how it is possible to reconstruct the original signal $y$, if we have only $m$-dimensional vector of measurements $b$, while $s \leq m < n$. The challenge is to find a solution to the equation $Ax = b$, where $A$ has dimensions $m$ $x$ $n$ and is referred to as a measurement matrix. If $m < n$, the problem is underdetermined and generally it has infinitely many solutions. Provided that any subset of $2s$ columns of the matrix $A$ are linearly independent, the solution of the defined problem is the sparsest vector $x$:

$$min_x \|x\|_0 \quad \text{subject to} \quad Ax = b \qquad (1)$$

where

$$\|x\|_0 = \sum_{i=1}^{n} |x_i|^0 \qquad \{1 \leqslant i \leqslant n, x_i \neq 0\}$$

denotes the sparsity of the vector $x$.

Unfortunately, $l_0$ minimization is, in general, NP hard problem as it requires a search of all $\binom{n}{s}$ possible solutions. The problem is that the $l_0$ minimization is not a convex optimization problem, and therefore one cannot use the appropriate optimization algorithms. Replacing $l_0$ minimization by $l_2$ minimization (least squares problem) yields not satisfactory results. A more accurate estimate of the solution $x^e$ can be obtained by $l_0$ minimization:

$$x^e = min_x \|x\|_1 \quad \text{subject to} \quad Ax = b \qquad (2)$$

where

$$\|x\|_1 = \sum_{i=1}^{n} |x_i|$$

$l_1$ norm as a means of finding the most sparse solution has been used already in 1973 in reflection seismology [7]. The problem (2) is a convex optimization problem, which can be effectively solved using methods of linear programming. It is often referred to as basis pursuit (BP). Equivalence of $l_0$ and $l_1$ minimization is guaranteed if either of the following sufficient conditions is met. The first condition is a requirement that the matrix $A$ approximately maintains the Euclidean length of the $s$-sparse signals. This characteristic of the matrix $A$ is called the restricted isometry property (RIP) [9]. RIP is related to the isometric constant $\delta_s$ defined as the smallest number such that

$$(1-d_s)\|x\|_2^2 \leqslant \|Ax\|_2^2 \leqslant (1+d_s)\|x\|_2^2 \qquad (3)$$

holds for all $s$-sparse vectors $x$.

We can say that $A$ obeys the RIP of order $s$ if $\delta_S$ is not very close to one. It is met if all the subsets of $s$ columns of the matrix $A$ are approximately orthogonal. However, checking whether the matrix $A$ obeys the RIP is generally NP hard problem. Some matrices are known to obey the RIP with overwhelming probability (e.g. Random Gaussian Matrices, Bernoulli matrices, partial Fourier matrices). There is a prove in [12] that Gaussian and Bernoulli random matrices probably obey the RIP when the number of measurements satisfies the condition $m \geq Cs\ ln(n/s)$, where $C$ is some constant dependent on $\delta_S$.

It is much easier to verify the second sufficient condition based on mutual coherence $\mu(A)$. Mutual coherence is defined as the cosine of the smallest angle between any two columns of matrix $A$. Mutual coherence has to be as small as possible (cosine is close to zero for angles close to 90 °, which means that the columns are independent). Incoherence of the matrix $A$ indicates that if the signal is sparse in one domain, it has to be spread out in the other domain (the one in which it is sampled). In practice, this means that columns of the matrix $A$ are roughly uniform in magnitude.

Both sufficient conditions essentially require independence of columns of the matrix $A$. Interconnection of RIP and mutual coherence has been shown in [11]. For an orthogonal square matrix it holds that both $\delta_S$ and $\mu(A)$ equal to zero. However, for $m\ x\ n$ matrix ($m < n$) it is not possible to ensure the complete independence of columns, we just require them to be roughly orthogonal.

Simulation experiments in [18] have shown that there is rather universal dependence between the ratios $m/n$ and $s/m$. This dependence can be used for selection of appropriate number of samples $m$ if the sparsity $s$ of the signal is known. Practical experiments indicate that most $s$-sparse signals can be perfectly reconstructed if $m$ is in range from $3s$ to $5s$ [13].

We have shown that CS is applicable for the reconstruction of sparse undersampled signals. However, to be useful in practice, it is necessary for CS to cope with both nearly sparse signals and with noise. In other words, CS must be robust. Most real signals are not strictly sparse and measurements are corrupted with at least quantization noise, as the sensors do not have infinite precision. In this case, it is necessary to find solution to the equation:

$$b = Ax + e \qquad (4)$$

where $e$ is a random variable.

If the sensed signal is not strictly $s$-sparse, we require it to be at least $s$-compressible. $S$-compressible signal has at most $s$ significant coefficients and all the other coefficients are close to zero. In other words, if the coefficients are sorted by value, all coefficients, except for the first $s$, are smaller than some small nonzero constant. Thus, the majority of the signal's information content is concentrated in only a few coefficients. Typical examples of the compressible objects are images when expressed in appropriate base (e.g. wavelet). This feature of natural images has been used in compression algorithms such as JPEG2000 for years. We can say that many images are efficiently sparse in wavelet base.

To reconstruct the original signal in case of noisy measurements one can use $l_1$ minimization with relaxed conditions:

$$min_x \|x\|_1 \quad \text{subject to} \quad \|Ax-b\|_2^2 \leqslant \epsilon \qquad (5)$$

This is a linear programming optimization problem with quadratic conditions (Basis Pursuit Denoising - BPDN). The problem can be reformulated as quadratic programming problem with linear conditions (known as LASSO):

$$min_x \|Ax-b\|_2^2 \quad \text{subject to} \quad \|x\|_1 \leqslant \epsilon \qquad (6)$$

For appropriately selected parameter $\lambda$ the problem (5) can be expressed without conditions:

$$min_x \frac{1}{2}\|Ax-b\|_2^2 + \lambda\|x\|_1 \qquad (7)$$

Several types of algorithms can be used to reconstruct the original signals. Methods based on a convex optimization are computationally demanding. This category includes Basis Pursuit (BP), Basis Pursuit Denoising (BPDN), interior point methods [17] and projected gradient methods. This category is sometimes supplemented by Iterative Shrinkage algorithms such as Iterative Hard Thresholding (IHT).

The second group of algorithms consists of greedy algorithms that are looking for non-zero coefficients incrementally, starting with the most significant. Among greedy algorithms belong mainly Matching Pursuit (MP) [14] and its variations: Orthogonal Matching Pursuit (OMP) [8], regularized OMP (ROMP), Stagewise OMP (StOMP), OMP with Replacement (OMPR) and also the first sub-linear algorithm OMPR-Hash. This category includes also Subspace Pursuit (SP) [16] and Least Angle Regression(LARS) [15]. Some of greedy algorithms are capable of providing similar guarantees of stability as BPDN while they are faster. Also they have the advantage of being easier to understand.

There are also combinatorial algorithms (e.g. HHS pursuit), which are very fast, but they require a lot of measurements.

Special types of algorithms are Total Variation (TV) algorithms. These are used mainly in the reconstruction of images where one may require sparsity of the gradient of the image. TV algorithms are particularly suitable for images composed from smooth areas separated by curves (objects without complex textures). Such images are common in medicine (MRI, angiogram, and the like).

Compressed sensing can be used if:

- the signal is sparse in any known base,
- measurements or calculations at the sensor are expensive in some sense,
- calculations at the receiver are cheap.

The application area of compressed sensing is very broad: MRI, astronomy, WSN, communication [10] and so on. The use of CS in wireless sensor networks is particularly useful. Compressed sensing allows to substantially simplify sensor nodes. The use of compressed sensing saves limited energy resources at several levels:

- Signal sampling - the number of AD conversions required is a fraction compared to the conventional sampling using Nyquist frequency.
- Preprocessing of the signal - transfer of all acquired samples is usually undesirable. It is necessary to reduce the amount of data to be transmitted by a communication channel. Signal preprocessing algorithms often involve computationally intensive transformations such as Discrete Fourier transformation. Compressed sensing does not require pre-processing at all.
- Data transfer - energy is saved especially if we need to transfer the whole measured signal to the central node. Transmission of data is typically the most energy intensive operation in the processing of distributed data. Transmission of a smaller number of data has a positive effect on energy balance of the node and also on the throughput of the entire network.

From the perspective of information processing the block structure of the node only consist of two parts: sensing and transmission. Simplification of the node and a reduction of its consumption significantly increases its reliability and extends its lifetime.

Note that the sampling process can be done in several ways. We can use random sampling, but then we must transmit pairs of numbers (sample-time). The major advantage of the compressed sensing is then deteriorated. The second possibility is to use a pseudo-random sampling when the signal is sampled according to a predetermined scheme, which, of course, has to be known in the central node, in which the original signal is recovered.

Pseudo-random sampling is advantageous also because it is possible to fit it for a specific application. The sensing matrix can be defined in order to meet all the prerequisites needed for perfect signal reconstruction. The compressed sensing can be realized also in such a way that the signal is captured at a Nyquist rate and then a subset of the samples corresponding to the sensing matrix is picked out. In this case there is no energy saving during sampling but only in blocks of preprocessing and transmission. The development of sensors that allow sensing of physical quantities using the principles of compressed sensing is one of intensively researched areas. Successful penetration of CS into WSN depends mainly on the availability of suitable (cheap and energy-efficient) sensing elements.

## III. Example of using CS in WSN

One of the cases where it is possible to effectively use the compressed sensing is the monitoring of power quality. To provide high quality electric power service, it is essential to monitor number of parameters at different places in the network. Among the monitored parameters belong current and voltage RMS, phase relationship between waveforms of a multi-phase signal, power factor, frequency, total harmonic distortion, different kinds of power and many more. In this example we will focus on measuring of total harmonic distortion (THD).

THD can be calculated using following equation:

$$THD = \frac{\sqrt{\sum_{i=2}^{N} V_i^2}}{V_1} \tag{8}$$

where $V_i$ is the RMS voltage of *i*-th harmonic and $i = 1$ is index of the fundamental frequency component.

As indicated by (8), we need to know the frequency spectrum of the measured signal in order to calculate the THD. The second option is to use filters to obtain the fundamental component and all other components [19]. In both cases it is necessary to make quite a number of calculations on the sensor side.

THD monitoring is now more important than ever, given the increasing use of switching power supplies to power consumer electronics. Switching power supplies are causing clipping of supply voltage. Fig. 2 shows a clipped sine wave and its spectrum. The frequency of the sine wave is 50 Hz and the amplitude is clipped to 0.9.

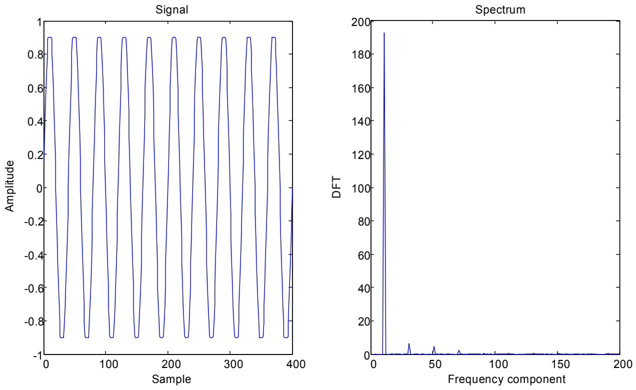

Fig 2. *Clipped sine wave and its spectrum*

The more clipped is the sine wave, the more energy is concentrated in the higher harmonics and the greater is the value of THD. If both half-waves are clipped, non-zero coefficients correspond to odd order harmonics. Clipping only one half of the sinusoid causes a doubling of the number of harmonics (all the harmonics are non-zero). However, this case is not common in practice. The number of non-zero coefficients in the spectrum of clipped sinusoid is theoretically infinite and must be reduced to make calculation feasible. This truncation causes some error, but it is relatively small and it can be neglected. For example, the THD of the example signal is 4.6416 % taking into account only the first ten non-zero coefficients or it is 4.6444 % if the number of non-zero coefficients is one hundred.

Since the representation of the clipped sine wave is sparse in the frequency domain, it is possible to engage principles of the compressed sensing. Compressed sensing allows reducing the cost of the sensor element but, on the other hand, increases the demand for the computing power of the central network node.

To verify the possibility of using compressed sensing in this case we conducted simulation experiments. For the calculation of THD we used first 20 higher harmonics (i.e. first 10 non-zero coefficients). The fundamental frequency equals to line frequency: 50 Hz. The 20-th harmonic then corresponds to 1 000 Hz. According to the Shanon theorem, the signal must be sampled by frequency of at least 2 000 Hz. Suppose that the mains voltage is stationary within an interval of 200 ms (i.e. the statistical properties of the voltage are constant for a short period of time). In this example, we monitor the mains voltage within time windows of a length of 200 ms, which corresponds to the number of samples *n = 400*. Random sampling was realized by random selection of *m*-samples such that the mean period between two samples equals to *n/m*. Input signal is a sine wave with a frequency of 50 Hz and amplitude clipped to 0.9:

$$x(t)=\begin{array}{ll} 0.9, & \sin(2\pi ft)\geqslant 0.9 \\ \sin(2\pi ft), & |\sin(2\pi ft)|<0.9 \\ -0.9, & \sin(2\pi ft)\leqslant -0.9 \end{array} \qquad (9)$$

Using Monte Carlo method, we performed simulations for different values of *m* and different values of signal to noise ratio (SNR). For each pair {m, SNR} we conducted 100 simulations. The simulation consists of a reconstruction of the original signal in the frequency domain and the subsequent calculation of THD using (8). For the reconstruction of signal we used collection of MATLAB routines l1-magic [20]. The resulting THD value is calculated as the arithmetic average of the 100 values. Fig. 3 shows the result of simulations. The THD of the original noise-free signal is 4.32 %.

Reconstruction of the original signal took from 1 to 5 seconds on dual core 2.6 GHz Athlon 64 processor. The duration of simulation depends on the length of the original signal *n,* the number of samples *m* as well as their distribution.

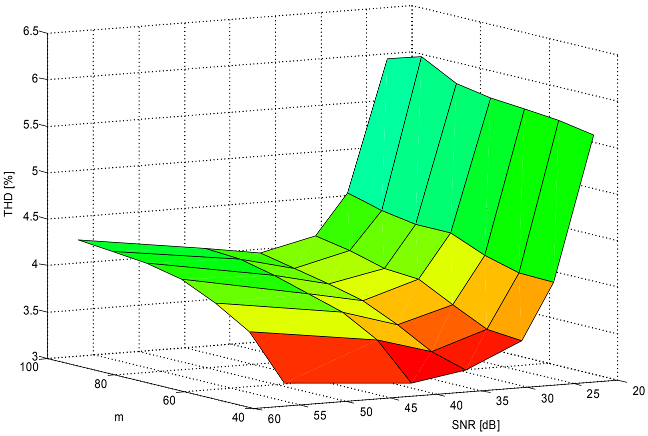

Fig 3. *THD as a function of m and SNR*

The results show that decreasing the number of samples and/or increasing the SNR deteriorate the accuracy of the reconstruction of the signal and thus the accuracy of the calculated THD. The simulations suggest that good results can be obtained when the number of samples *m* is at least 80 and the SNR is greater than 30 dB. In that case the compression ratio would be 1:5. If the mains voltage is stationary over longer periods, it is possible to achieve even higher compression ratios. If we increase the length of the time window to 400 ms (n = 800), it is possible to achieve even better results using the same compression ratio *m/n*. The effect of increasing the number of samples *n* is shown in table 1. The simmulation was done with noise-free sinusoid.

TABLE I.
EFFECT OF DIFFERENT WINDOW LENGTHS ON ACCURACY OF THD ESTIMATE

| **m/n** | **THD [%]** | | |
|---|---|---|---|
| | **n = 400** | **n = 600** | **n = 800** |
| 0.1 | 3.19 | 3.8 | 4.13 |
| 0.125 | 3.7 | 4.12 | 4.25 |
| 0.15 | 3.99 | 4.24 | 4.29 |
| 0.175 | 4.19 | 4.29 | 4.3 |
| 0.2 | 4.28 | 4.3 | 4.3 |

We see that doubling the length of the window allows to reduce the ratio *m/n* from 0.2 to 0.15. Knowledge of the parameters of measured signal is therefore essential in optimal design of compressed sensing parameters.

## IV. CONCLUSION

Simulation experiments demonstrate a possibility to use compressed sensing in appropriately selected applications of WSN. Energy savings due to the use of compressed sampling can be maximized if we know parameters of the measured signals.

In the future, we will focus on design of deterministic sensing matrices suitable for compressed sensing of selected signal classes. It is also necessary to develop fast algorithms for reconstruction of the original signals so they can be used even in less powerful network nodes.

***Abstract*—This paper addresses analysis of the principle of a bi-directional electric energy charge pump and describes circuit solution for control unit of a wireless sensor node power subsystem. This power and control unit, as the power subsystem of the wireless node, comprises two supercapacitors. Bi-directional energy flow between these two supercapacitors takes place in order to optimally satisfy the sensor node energy requirements. At the same time, the bi-directional energy flow enables optimal energy harvesting from the selected energy scavenging (harvesting) subsystem. The mentioned Power Unit Control System has been successfully verified in the process of energy harvesting from a solar module.**

## I. Introduction

IN RECENT years, we encounter with many new unconventional applications of wireless sensor networks (WSNs). Related to the expected rapid expansion of so called *Internet of Everything* (IoE) applications [1], [2], [3], the problem of WSN is about to stand in the center of scientists community interest as well as of the public.

Basic limiting factors of WSN expansion are price and unattended operation time [4]. Both mentioned limitations are closely related to the energy requirements of essential nodes of a sensor network. The issue of effective sensor node power supply is being solved by two basic methods [5], [6]:

- Reducing a sensor node (SN) energy requirements,
- Consistent utilization of energy harvesting (EH) options from sources that are available in given application.

Both methods are used these days. Modern low power components are used for construction of present SNs, which help to reduce the energy requirements. In running mode, the SN uses modes with reduced power consumption and their combinations [7]. This approach turns MCU into active mode only in case the application or (external) conditions of monitored environment require it. Second option is the utilization of EH systems that are designed so that they would be able to ensure SN operation [8]. Today, there is a popular term *Zero Power Wireless Sensor* [9], which represents just solutions that do not need power supply for continuous operation, but they are able to harvest required energy from the environment. However, until recently, the lifetime of such solutions was limited to finite battery life or the number of charging cycles [10]. These limitations have been overcome by supercapacitors since they are characterized by high number of charging cycles (up to 1 million) [21]. Combination of low-power integrated circuits, effective systems of energy transformation from environment to electric energy and advanced tools for electric energy accumulation enables pushing the boundaries of WSN applications to the areas (mostly applications of information and communication means), where no one would have imagined their effective operation few years ago.

## II. Sensor Node

Sensor networks consist of large number of sensor nodes (SNs). The SNs are deployed in a sensor field, where each of these sensor nodes has the capabilities to collect and route data to the sink and the end users [12]. In order the basic characteristics of a sensor network could be satisfied, each SN has to perform the following functions [13]:

- Data collection,
- Data preprocessing,
- Communication.

It is obvious that except the mentioned basic functions of each network node, there are also other important SN parameters, such as [14]:

- Computing performance of the sensor node,
- Low power consumption/long lifetime,
- Production cost,
- Security,
- Fault tolerance.

Many of mentioned requirements are contradicting each other [12]. Increasing computing performance increases energy requirements as well as sensor price. Enhancing transmission security involves higher computing performance. Higher fault tolerance usually negatively influences production cost. Therefore, it is impossible to develop appropriately universal node, which would be optimal in terms of all mentioned requirements. Moreover, it should be noted that different applications of SNs set different weight for the mentioned requirements. Problem of sensing elements designing is described in

[15]. The authors propose to use class of universally usable modules for development and application-oriented carriers and, thus, reach high degree of universality with possibilities to use the developed systems in the widest set of various applications. Data collection is performed by the data collection subsystem of a sensor node. This subsystem is extremely dependent on the requirements of the particular application and consist of sensing elements observing parameters that are relevant for solving the desired task. It is clear that different sensing elements are required for road traffic monitoring, other for patient telemonitoring and absolutely another for environment monitoring.

Because the energy requirements for data transmission are very high [5], it is suitable to perform significant part of data processing process directly at place of acquisition - in the sensor node. Then, the other network nodes will transfer only data that contain substantial information for solving the given problem.

It is clear, that in each sensor node data compression is executed. Then, the fundamental processes of data pre-processing relate to extraction methods of information content. Not in all WSN applications is the sensor node's task relegated only to the operations related to signal compression, increasingly there are used *Collaborative Signal Processing Algorithms* [16], that use suitable distribution of partial task among each nodes in order to increase the computing performance of network while minimizing of whole energy consumption. Today there is a wide range of various methods that can be successfully implemented onto WSN platform (Kalman filtering, neural networks, Bayesian inference etc.) [17].

Wireless communication ability is one of the basic features of a sensor node [5]. Communication abilities of WSN nodes are in most cases limited by communication range and transmission speed. It should be reminded that with increasing communication range the transmission power/sensitivity raises. This always leads to increased requirements on energy consumption.

Based on the mentioned functions and parameters of the SN, it is possible to create a generalized schematic block of a sensor node, which is depicted on Fig. 1. Each WSN node contains four basic units [4]:

- Sensing unit,
- Processor unit,
- Communication unit,
- Power unit.

In terms of WSN utilization properties, operating time of the network without need of operator intervention is important. The critical point is just the power supply of the SN. As mentioned earlier, the unit that takes care of power supply for a sensor node is called power unit. This part of sensor node can be simply represented by a power system with use of primary (battery) cells, or it may be constructed of a complex power supply system with energy harvesting (EH) features with effective energy accumulation. The following section describes the power unit developed at our department.

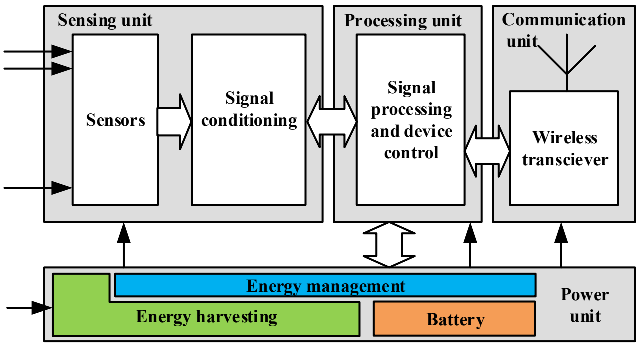

Fig. 1. Wireless node

## III. Energy Management System

Ensuring the continuous effective operation of a sensor node, which has limited energy sources is a difficult problem. Solving this consists of:

- Right choice of EH type,
- Right choice of energy storage capacity,
- Designing such sensor node operation mode that minimizes energy consumption.

Subsystem that covers energy requirements of a sensor node is *power unit*. The power unit can be implemented in several ways. Today we encounter very simple power supply systems using primary (battery) cells that are designed so that the energy requirements and desired SN lifetime are met.

### *A. Power Unit*

Power supply of a SN is realized through the subsystem, which is often referred as power unit. This supply subsystem can be based on one of the following options [18]:

- Supply from primary (battery) cells,
- Supply from rechargeable batteries,
- Energy harvesting (EH) features,
- Near Field Charging (NFC).

Today one can often meet complex solutions for power units that satisfy energy management in such way that all WSN energy requirements are compressed down to zero (zero power systems) [19]. Such unit consists of three main parts, Fig. 2:

- Energy harvesting system,
- Energy processor,
- Energy storage.

Functions of each subsystem of power unit result from their names. EH is used to temporary preserve energy and energy management controls the operation of the whole power unit in the way that it is possible to ensure all requirements of a sensor node with reaching the maximal energy effectiveness.

Unless the application permits performing basic maintenance during sensor node lifetime - battery exchange, then rechargeable batteries are often used. In those simple cases is energy consumption control (transitions to energy saving modes of individual subsystems) often performed by the SN processing unit. In case more complex power units are used

TABLE I
SELECTED PARAMETERS OF ENERGY STORAGE SYSTEMS ( 1KWH=3,6 MJ)

| Type | | Specific energy [MJ/kg] | Number of cycles N | Self discharge rate [%] | Charge/discharge Efficiency [%] |
|---|---|---|---|---|---|
| Primary batteries | Alkaline | 0.6 | - | 3 per year | - |
| | Lithium | 2 | - | 2 per year | - |
| Rechargeable (liquid electrolyte) | Lead Acid | 0.14 | 500-800 | 3-20 per month | 50-90 |
| | NiMH | 0.36 | 500-1800 | 8 per month | 66 |
| | Li-Ion | 0.9 | 400-1200 | 5 per month | 80-90 |
| | Li-Poly | 0.95 | 500-1000 | 8 per month | 80-90 |
| Rechargeable (solid electrolyte) | ss-battery EnerChip | 1.8 | 5000 | 2 per year | 90 |
| Supercapacitors | Twolayers | 0.01-0.02 | 500 000 | 50 per week | 95 |
| Pseudosuper capacitors | Li-Ion | 0.055 | 10 000 | 10 per month | 90 |

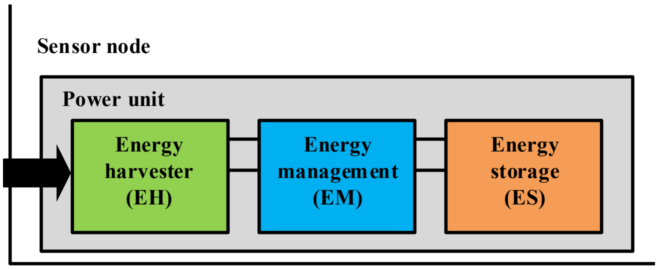

Fig. 2. Power unit

(combined energy storage and energy harvesting, etc.) the control of individual subsystems is often performed by a specialized unit - energy processor. When designing the energy management (EM) system, it is possible to use some of commercially available solutions. As an example, it is possible to mention energy processor CBC915 [20]. Other possibility is to create the Power management unit based on Low power MCU. That solution is universal enough and usable for wide range of applications with low-power energy consumption.

### B. Energy Storages

Energy storage (ES) is one of the basic parts of power unit. It is used for energy storage that is used for SN supply. ES accumulates the electric energy and delivers it to the powered device. In case the EH systems is used and that is not able to generate sufficient amount of energy from its environment, the ES temporarily helps EH subsystem with delivering enough power. It is clear, that either case (using EH or not) there is always need for energy to be accumulated and preserved in some way. In present, there are usually used the following "media" for energy accumulation:

- Primary batteries,
- Rechargeable batteries,
- Solid state batteries,
- Supercapacitors.

Selected parameters of above listed options of energy storages are described in Table I for comparison. Note, that in terms of long-term node operation, particularly the number of charge/discharge cycles is important, partially also a self-discharge rate, but in terms of continuous operation of node with EH system utilization energy efficiency is important. Therefore, it is clear that there is no commonly valid criterion, which recommends specific type of energy storage. Selection is always dependent on specific conditions and nature of the application.

One of the parameters of modern energy storage systems is specific energy (energy density), which moves from 2 $MJ/kg$ with high-end primary lithium batteries up to 0.01 $MJ/kg$ with supercapacitors [18]. Specific energy of primary lithium batteries is up to 100-times higher then current supercapacitors can reach. But specific energy is not the only parameter for choosing suitable type of energy storage. Not the less important parameters are number of charging cycles, self discharge rate, operating conditions, etc.

Because the parameters and limitations of each battery type vary quite much, there are often combinations of various types of elements for energy storage. In many applications it is possible to preferably use the combination of supercapacitor and rechargeable battery. For example, this combination benefits from high number of charge/discharge cycles of a supercapacitor and high specific energy of a battery. Especially, this combination appears a lot in power units based on EH.

### C. Energy Harvesting

EH represents ability to obtain the energy from natural resources in environment and transforms it to the electric energy [6]. Ambient energy, that can be used for power supply of low-power electronic systems is in various forms. It depends on the specific application, which takes the available energy in a suitable form. Common types of ambient energy sources, which is possible to use in EH systems for WSN are [21]:

- Biochemical energy,
- Mechanical energy,
- Acoustic noise energy,
- Wind energy,
- Thermal energy,
- Photovoltaic energy,
- Wireless energy.

It is obvious that it is quite impossible to define generally applicable rule, which type of energy is optimal for utilization in WSN. Choice of power source type depends on specific requirements of the SN and environment possibilities, which the node operates in. Basic comparison of possibilities that can be used when designing EH system are summarized in Table **??**.

TABLE II
POWER DENSITY OF EH TECHNIQUE

| **Energy harvesting technique** | **Power density** |
|---|---|
| Photovoltaic | Outdoors (sunny day) $15\mathrm{mW/cm^2}$<br>Indoors $10\mu\mathrm{W/cm^2}$ |
| Thermal energy - Thermoelectric | Human $30\mu\mathrm{W/cm^2}$<br>Industrial $110\mathrm{mW/cm^2}$ |
| Mechanical energy - Piezoelectric | $250\mu\mathrm{W/cm^3}$ |
| Mechanical energy - Electromagnetic | Human $1-4\mu\mathrm{W/cm^3}$<br>Industrial $800\mu\mathrm{W/cm^3}$ |
| Mechanical energy - Electrostatic | $50100\mu\mathrm{W/cm^3}$ |
| Wireless energy - RF radiation | GSM $0.1\mu\mathrm{W/cm^2}$<br>WiFi $0.01\mu\mathrm{W/cm^2}$ |
| Wind energy | $380\mu\mathrm{W/cm^3@5m/s}$ |
| Acoustic noise | $0.96\mu\mathrm{W/cm^3@100dB}$<br>$0.003\mu\mathrm{W/cm^3@75dB}$ |

In WSN applications with EH systems photovoltaic energy, thermal energy and mechanical energy are most frequently used. In present, there are appearing always new systems of effective energy conversion from environment to electric energy, which encourages the development of new, unconventional solutions.

## IV. Principled Design of Proposed Power Unit Management System

In the context of increasing of capacity elements for storing electric energy (supercapacitors) new applications arise, in which traditional solutions that use rechargeable or primary sources are replaced by supercapacitors. A solution for efficient energy flow between supercapacitors $C1$ and $C2$ or rechargeable cells is shown in schematic Figure 5. First, let's have a look at the principle of the energy flow and then the technical solution will be presented.

### *A. Energy flow from C1 to C2 (direct mode)*

The description of the basic function comes out from the assumption that the voltage on the capacitor $C1$ is within the range of permissible working voltage of the used control circuit (CC).

CC is capable of $C1$ capacitor voltage monitoring via $ADC1$ and $ADC2$, and similarly on the secondary capacitor $C2$. In case it is necessary to transfer energy from the capacitor $C1$ to the capacitor $C2$, CC closes the switch $S1$ through $DO1$ for time $T11$. Immediately after the time $T11$ switch $S1$ closes and opens switch $S2$ for time $T21$. The energy stored in the inductance $L$ at the time $T21$ is transferred to the capacitor $C2$. Waveforms of control signals of switches $S1$ and $S2$ are shown in Figure 3.

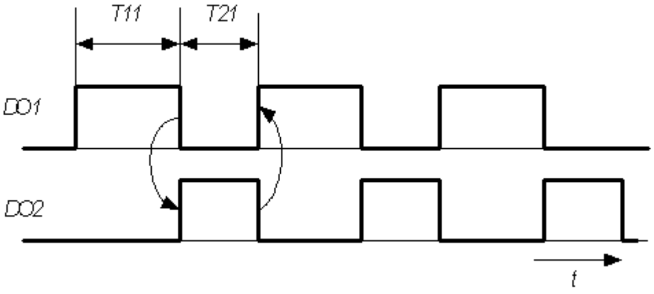

Fig. 3. Control signals in direct mode

Time $T11$ can be calculated with the following assumptions:

- Assume that the inductance coil $L$ is used. Let the $I_{L_{max}}$ be the maximum current that is the inductance coil able to handle;
- The voltage $U1$ denotes voltage at capacitor $C1$ and the voltage on the capacitor $C2$ is labeled $U2$.

Then for time $T11$ applies:

$$T11 \leq \frac{L \cdot I_{L_{max}}}{U_1}. \tag{1}$$

For time $T21$ applies the following:

$$T21 \leq \frac{U_1}{U_2} \cdot T11. \tag{2}$$

Please note that from (1) arises the fact that for times higher than $T11$ there is a current overload of inductance $L$. At higher times than the switch-on time $T21$ there is a discharge of supercapacitor $C2$, which results from (2), and thereby reduces the efficiency of the device.

Further, the CC has up-to-date information about the $U1$ and $U2$ voltages through an integrated ADC peripheral. On the basis of equations (1) and (2) switching times $T11$ and $T21$ can be optimally calculated by CC.

Essential amount of energy transferred in one cycle can be expressed by the following formula:

$$\Delta E = \frac{1}{2} C1 \cdot U_1^2 \left(1 - cos\left(\frac{T11}{\sqrt{L \cdot C1}}\right)\right). \tag{3}$$

Eventually, in simplified form where $T11 << \sqrt{LC1}$ applies, equation (3) turns into:

$$\Delta E = \frac{1}{4} \frac{U_1^2 \cdot T11^2}{L}. \tag{4}$$

*Remark 4.1:* Simultaneous opening of switches $S1$ and $S2$ leads to the destruction of the circuit, therefore, it should be strictly taken to comply with equations 1 and 2. These equations are approximate relations, while assuming that the opening time $T11 << \sqrt{LC1}$ and $T21 << \sqrt{LC2}$ with sufficient accuracy to satisfy the requirements of practical implementation.

### *B. Energy flow from C2 to C1 (inverse mode)*

In case it is necessary to transfer the energy in the opposite direction than described in the previous subsection - from capacitor $C2$ to the capacitor $C1$ - the switching mode of switches $S1$ and $S2$ is similar to the previous mode, except that the order of switching is reversed. In this case, CC through $DO2$ closes at first switch $S2$ for time $T22$ and after that the switch $S2$ is closed and switch $S1$ opens for time $T12$. The energy stored in the inductance $L$ is during time $T12$ transfered to capacitor $C1$. Waveforms of control signals of switches $S1$ and $S2$ are shown in Figure 4.

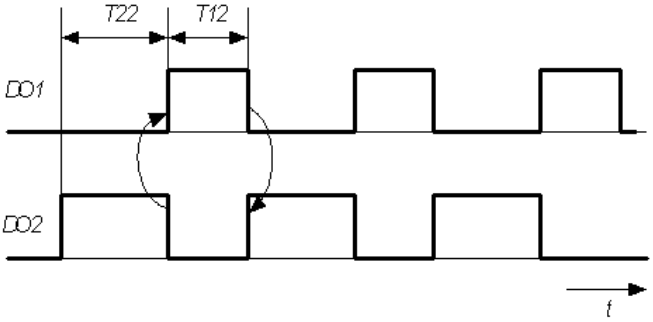

Fig. 4. Control signals in inverse mode

Similarly to the previous case, the conditions for calculating time $T22$ are as follows:

- Assume that the inductance coil $L$ is used. Let the $I_{L_{max}}$ be the maximum current that is the inductance coil able to handle;
- The voltage $U1$ denotes voltage at capacitor $C1$ and the voltage on the capacitor $C2$ is labeled $U2$.

Then for time $T22$ applies:

$$T22 \leq \frac{L \cdot I_{L_{max}}}{U_2}. \tag{5}$$

For time $T12$ applies the following:

$$T12 \leq \frac{U_2}{U_1} \cdot T22. \tag{6}$$

Even in inverse mode, the similar restrictions. Therefore, please note that from (5) arises the fact that for times higher than $T22$ there is a current overload of inductance $L$. At higher times than the switch-on time $T12$ there is a discharge of supercapacitor $C1$, which results from (6), and thus reduces the efficiency of the device.

Further, the CC has up-to-date information about the $U1$ and $U2$ voltages through an integrated ADC peripheral. On the basis of equations (5) and (6) switching times $T22$ and $T12$ can be optimally calculated by CC.

*Remark 4.2:* Simultaneous opening of switches $S1$ and $S2$ leads to the destruction of the circuit, therefore, it should be strictly taken to comply with figures 5 and 6. These equations are approximate relations, while assuming that the opening time $T22 << \sqrt{LC2}$ and $T12 << \sqrt{LC1}$ with sufficient accuracy to satisfy the requirements of practical implementation.

## V. Technical Solution of Proposed Power Unit Management System

The previous section describes the proposed power unit principle of operation - energy flow. This device controls power transmission with EH system, supercapacitor and rechargeable battery or supercapacitor, its principle schematic is depicted in Fig. 5. Please note that some parts that are not substantial in terms of function are not mentioned in the figure.

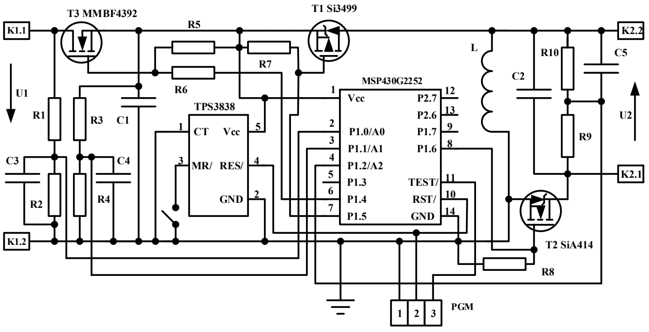

Fig. 5. Energy management system schematic

Output from EH system (photovoltaic cell, thermo generator, vibration generator) is connected to connector $K1$, which has voltage $U1$. The supplied device - a sensor node - is connected to connector $K2$. The energy is stored in supercapacitor $C1$, alternatively in rechargeable battery. Control unit, which is based on MCU MSP430G2252 enables by energy flow between primary supercapacitor $C1$ and secondary supercapacitor $C2$ in both directions by properly switched transistors $T1$ and $T2$. The control unit (the MCU) is able to measure:

- Voltage on generator output with no load or with load according to state $T3$ (input $A0$),
- Voltage $U1$ on supercapacitor $C1$ (input $A1$),
- Voltage $U2$ on supercapacitor $C2$ (input $A2$).

Based on measured voltages and character of EH energy processor, the energy can be moved between energy storages $C1$ and $C2$ to obtain maximal efficiency of the whole system and to operate at maximal point of efficiency. It is clear that in such simple electronic circuit solution (Fig. 5) the system is able to work correctly only if voltage on supercapacitor $C1$ is in range $2.5V - 3.6V$ (supply voltage of the MCU) that imposes relatively serious restriction. Though, this problem is able to be solved quite easily - control MCU power supply is separated, alternatively has its own supercapacitor with charge pump from $C2$.

The Fig. 6 shows voltage behavior at the output of a capacitor $C1$ ($1000uF/16V$). The start of the energy pumping is colored white, the voltage at the gate of the upper transistor is colored in cyan and the voltage at lower transistor is colored in purple. The upper transistor is a P-channel so that it is closed at high voltage and open at low. Lower transistor is N-channel so it opens at high voltage and closes at low. Input source is a constant voltage of $3.6V$, which is able to deliver up to $500mA$ average current. The process of energy flow starts with opening of the upper transistor for $800us$. Immediately, lower transistor opens the same time. During testing, the interval between such "open-closes" was $9.6ms$ and the whole period took $10.4ms$.

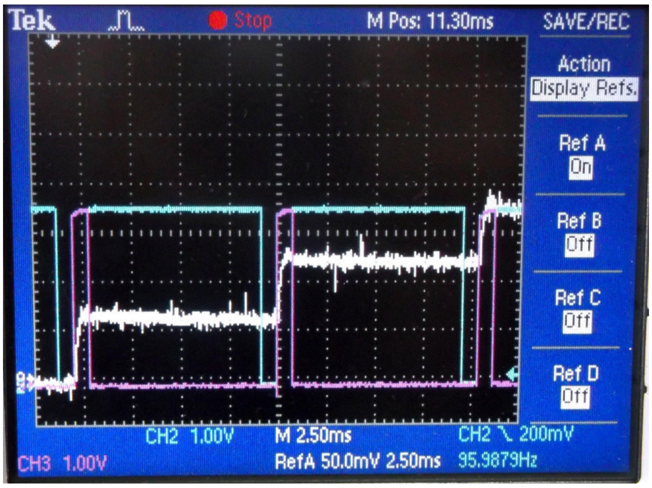

Fig. 6. Voltage behavior of the capacitor $C1$ on the testbed

The Fig. 7 shows a scenario with $C2$ capacitor and its alternating charges and discharges. Charging starts with opening of the upper output transistor for $800us$ following with opening of the lower transistor for $8us$. After a short pause $4.1ms$ inverse energy flow takes place ($C2$ to $C1$).

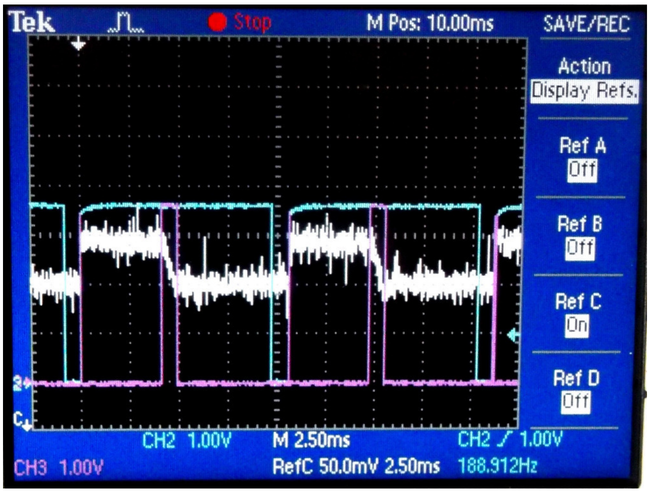

Fig. 7. Voltage behavior at $C2$ with alternating charges and discharges

The whole cycle takes $10.412ms$. The figure shows steady state of the oscillation and its lower voltage level is $360mV$ and its top level reaches $406mV$.

It is possible to achieve interesting solutions by connecting this systems from Fig. 2 in series. Alternatively, modifying the mentioned scheme for various EH systems that load power to a joint primary supercapacitor $C1$. In the latter case the voltage value has to be kept in order to ensure each system to operate in the point of maximal power. As an example, we can speak about more solar panels with various characteristics, alternatively with different exposure, whose energy is stored in a single accumulator cell.

## VI. Case Study

In this section we propose one simple example of the proposed system utilization. Let's imagine the proposed device to be used for energy harvesting purposes from a photovoltaic (PV) module. PV generators have two basic drawbacks - i) conversion efficiency of the incident radiation to electric energy is low (10 - 20%), especially at low light intensities; ii) and the amount of the obtained energy depends on the weather. Other disadvantage of solar cells is nonlinear V-I characteristic that is changing with the radiation intensity and the temperature. At particular, having the value of light exposure and the temperature on V-I characteristic, it is possible to find just one point, in which PV system works with maximal efficiency. This point is called Maximum Power Point (MPP). For the illustration, the V-I characteristic of a solar module is depicted in Fig. 8.

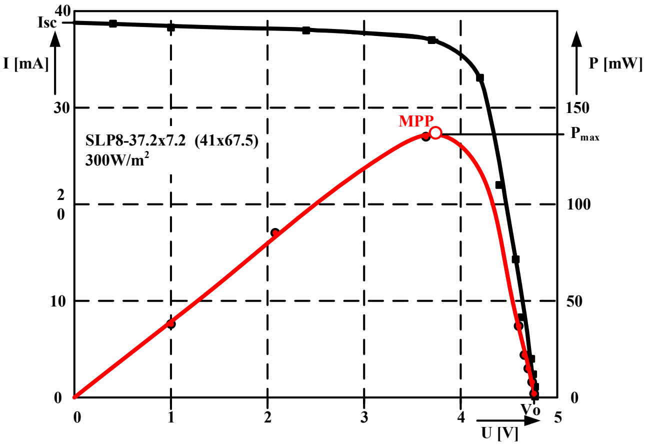

Fig. 8. V-I characterisitcs of solar module

It is clear that during active photovoltaic EH system operation there are various outer conditions. The intensity and angle of incident radiation changes as well as the temperature of solar cells, etc. These conditions considerably influence the parameters of the solar panel as well as the electric energy generator. The aim of the user is a system capable of utilize/accumulate solar energy at the MPP, while changing conditions apply. For this purpose, there are techniques called Maximum Power Point Tracking (MPPT) ensuring that in changes of working conditions, the photovoltaic system (PVS) is able to monitor Maximum Power Point (MPP) and then to ensure the effective operation of the whole system. Problem of designing and evaluation of MPPT methods was dedicated in many papers in specialized journals [22], [23], [24]. At present, there is a large number of used methods. In Table **??** there are most often used methods listed and at the same time there is listed its effectiveness as percentage of theoretical reachable value to obtained energy. It is obvious, that listed values are dependent on character of changes in outer conditions, so the table gives average values obtained in 14 different modes. Further information can be found in [22]. Note, that several methods was in [22] tested with various modifications, so Table **??** summarizes the best achieved results in that cases.

TABLE III
MPPT MEHODS AND THEIR EFFECTIVENESS

| **MPPT technique** | **Effectiveness [%]** |
|---|---|
| Constant Voltage Method (CV) | 79.5 |
| Short Current Pulse Method (SC) | 90.7 |
| Open Voltage Method (OV) | 94.6 |
| Perturb and Observe Method (P&O) | 99.3 |
| Incremental Conductance Method (IC) | 99.5 |
| Temperature Method (TP) | 97.1 |

For the implementation purposes into the proposed system, OV method is used. This method is easy to implement without other demands on the technical equipment. Average effectiveness of solar system with use of this method is sufficient enough. Note, that it is possible to use also other of the above methods, but implementation of MPPT techniques is not the matter of this contribution.

Algorithm of PV system control is the following:

1) Switch off the $T3$.
2) Delay $10\mu$s
3) Voltage with no load measurement $U1$.
4) Switch on $T3$.
5) Voltage calculation $U_p = 0.76 * U1$.
6) Voltage measurement $U_{C1}$.
7) Comparison with $U_p$, if $\mathrm{U_{C1} > U_p} + \varepsilon$ is true, then $\mathtt{pumpU_{C1}}()$ if $U_{C1} < U_p$ is true, then $\mathtt{pumpU_{C2}}()$
8) Delay $100ms$
9) Go to 1

$\mathtt{pumpU_{C1}}()$ is a function that pumps the energy from supercapacitor $C1$ to $C2$ unless the condition is true $\mathrm{U_{C1} > U_p} + \varepsilon$ (opens and closes $T1$ for the time according to (1) and opens and closes $T2$ for the time in accordance with (2)), then measures $U_{C1}$ and compares it with $\mathrm{U_p} + \varepsilon$ and if the condition is met then ends, otherwise repeats the whole "main loop".

$\mathtt{pumpU_{C2}}()$ is a function that pumps the energy from supercapacitor $C2$ to $C1$ unless the condition is true $\mathrm{U_{C1} > U_p}$ (opens and closes $T2$ for the time in accordance with (5) and opens and closes $T1$ for the time in accordance with (6), then measures $U_{C1}$ and compares it with $U_p$ and if the condition is met then ends, otherwise repeats the whole "main loop".

$\varepsilon$ is the constant, which value depends on values of supercapacitor $C1$, it constrains oscillation and often pumping of the energy.

In described algorithm, as the source of the energy was used the solar module SLP8-37,2x7,2 with dimensions 41x67,5 mm. Solar module consists of 8 solar cells that are connected in series. In good working conditions it can generate voltage $U1$ (with no load) that exceeds allowed operating voltage of the MCU. For this reason it is necessary to ensure that $\mathrm{U_{C1} < 3.6V}$.

The described example demonstrates applicability of the proposed control unit in EH WSN applications with utilization of solar energy. It is obvious that effectiveness of the solution, as the proportion of obtained energy to theoretical maximum is dependent on specific conditions. Because self-energy consumption of the control unit is constant, it does not depend upon amount of generated energy by the solar module. But this effectiveness also depends upon the size of the solar module and the light exposure.

## VII. Conclusion

The control unit of EH system that was developed at our department is designed for controlling the power unit with low power. That fact predetermines it for use in WSN applications, where we expect, that individual nodes are supplied through EH systems and contain energy storages based on supercapacitors, alternatively rechargeable batteries. Control unit, thanks to its versatility and simple parametrization with use of programmable resources, can find its enforcement in all cases, where the realization of effective energetic management with low cost is needed. Despite the fact, that experiments were made only with solar module, it is possible to use the proposed system also in many another applications, where it is needed to implement the bi-directional flow of electric energy.

***Abstract*—Many wireless sensor networks operating outdoors are exposed to changing weather conditions, which may cause severe degradation in system performance. Therefore, it is essential to explore the factors affecting radio link quality in order to mitigate their impact and to adapt to varying conditions. In this paper, we study the effects of temperature and humidity on radio signal strength in outdoor wireless sensor networks. Experimental measurements were performed using Atmel ZigBit 2.4GHz wireless modules, both in summer and wintertime. We employed all the radio channels specified by IEEE 802.15.4 for 2.4GHz ISM frequency band with two transmit power levels. The results show that changes in weather conditions affect received signal strength. Of the studied weather variables, variation in signal strength can be best explained by the variation in temperature. We also show that frequency diversity can reduce the effects of channel-specific variation, and the difference between the transmit power levels.**

## I. Introduction

MANY wireless sensor networks (WSNs) and their applications are in use outdoors exposed to changing environmental conditions. Weather conditions particularly can have a significant impact on the performance of WSNs and therefore cannot be ignored [1], [2], [3]. While the location of nodes may be fixed and their surroundings might remain almost static, the weather will not remain stable. The ambient temperature and humidity will change and fluctuate temporally, having both diurnal and seasonal variation. In addition, there can be spatial variation in weather, which affects WSN due to microclimates. While changes in weather conditions are inevitable and may have significant effects, they are usually measurable and could be mitigated based on experimental measurements. Hence, it is essential to explore weather-related factors affecting radio link quality in order to mitigate their impact and to adapt to varying conditions.

The effects of weather conditions on link quality (e.g., signal strength) in WSNs have been explored in quite a few studies (e.g., [2], [4], [3], [1], [5], [6], [7], [8], [9]). However, no clear consensus has been achieved so far. Some studies report that temperature is the dominating factor affecting signal strength while others claim that humidity is the main reason. Some suggest also other reasons. Furthermore, research methods, radios and platforms employed and a number of explored weather variables vary between studies, occasionally resulting in contradictory results and conclusions. Hence, there definitively seems to be a need for further studies.

This paper sets out to find out the effects of temperature and humidity on radio signal strength in outdoor WSNs. Experimental measurements were carried out using Atmel ZigBit 2.4GHz wireless modules [10] with AT86RF230 radios [11] in a university campus area during December 2013 and July 2014. Unlike most previous studies, we employed all the 16 radio channels specified by IEEE 802.15.4 for 2.4GHz ISM frequency band (channels $11-26$) using two different transmit power levels. For the purpose of measuring local weather conditions, each node was integrated with a sensor (SHT75) [12] to measure the ambient temperature and relative humidity. To begin with, we show the temporal variation of signal strength. To find out the role of temperature and humidity on this variation, we study how signal strength correlates with temperature, relative humidity, and absolute humidity. Furthermore, we apply linear regression to explore the magnitude of these effects. We also highlight the differences between channels, the utility of frequency diversity, and the difference between the transmit power levels used. Our findings may be useful for designing algorithms and protocols which are adaptive and robust against the effects of weather. In particular, RSSI-based ranging and localization could benefit from these results.

In summary, our study has the following main contributions:

- We show that changes in weather conditions affect radio signal strength. Temperature seems to be the best explanatory variable for signal strength variation and has a negative, linear effect on signal strength in general, while high relative humidity may have some effect, particularly when temperature is below 0°C.
- We show that correlation between signal strength and the studied weather variables vary depending on radio channel and link. Applying frequency diversity will alleviate these effects.
- We show that smaller transmit power results in smaller unexplained variation in received signal strength (in most cases) and thus stronger correlation with the studied weather variables.

The rest of this paper is organized as follows. In Section II,

978-83-60810-66-8/$25.00©2015, IEEE

some related studies in the field are shortly presented. In Section III, we briefly take a closer look at the central variables used in this paper. Experimental measurements performed are described in Section IV. Thereafter, experimental results are presented and analyzed in Section V, followed by a short discussion in Section VI. Finally, we conclude our work in Section VII.

## II. Related Works

Temperature has been the main focus in many recent studies dealing with the effects of weather conditions on link quality. For example, Bannister et al. [1] found a linear decrease of $8\mathrm{dB}$ in signal strength when temperature rose from $25°\mathrm{C}$ to $65°\mathrm{C}$ when they used TI CC2420 radio on a Tmote Sky node, both in their outdoor experiment in the Sonoran Desert and in the lab experiment. They also showed the implications this has for communication range, network connectivity, multi-hop data collection, and RSS-based localization. Based on both outdoor and indoor experiments, Boano et al. [5] showed that the increase in temperature decreases both RSSI (Received Signal Strength Indicator) and LQI (Link Quality Indicator). In the outdoor experiment in a wheat field in Govone, Italy, Boano et al. used Tmote Sky nodes. In their indoor experiment, they used both Tmote Sky (CC2420 radio) and MSB430 nodes (CC1020 radio). They also found that the noise floor readings of both platforms decrease with the increase in temperature. Based on their over 10-day deployment of TelosB nodes in a forest garden, Luo et al. [7] showed that both temperature and relative humidity correlate with RSSI. However, based on linear regression, only the effect of temperature on RSSI can be regarded as relatively significant. Wennerström et al. [8] in their half-year experiment near Uppsala, Sweden, showed how variations in meteorological conditions affect IEEE 802.15.4 link performance when using TelosB nodes with CC2420 radio. Particularly, they studied how variations in PRR (Packet Reception Ratio) and RSSI correlate with temperature, absolute humidity, precipitation, and sunlight. Their results show that PRR and RSSI correlate mostly with temperature, while the correlation with other factors is not so clear. They also observed both diurnal and seasonal variation in PRR. In their recent work, Boano et al. [9] studied the impact of temperature on various WSN platforms and radios (CC2420, CC2520) and showed the different effects of temperature on transmitter and receiver nodes. They also showed that the relation between temperature and RSSI is similar with different platforms and can be approximated as a linear function when using platform-specific parameters. Also, Lin et al. [13] found a temporal variation of RSSI (with MICAz nodes) during their 3-day outdoor experiment, in which different transmit power levels were used, but they did not analyze the cause.

Humidity-related issues have also received a lot of attention in the research community. Anastasi et al. [2] found that the transmission range of mica2 sensor nodes (using RFM ChipCon radios) decreases substantially during rain or fog. Contrary to this, based on their measurements conducted in a potato field with the help of Mica2Dot nodes equipped with Chipcon CC1000 radios, Thelen et al. [4] showed that radio waves propagate better under high humidity conditions, in the presence of rain and at night for example. They attributed this positive impact to changes in the reflection coefficient of the top of the canopy of the potato field. They showed that RSSI values were positively correlated with RH and negatively with temperature, but they focused only on humidity in their analysis. Capsuto and Frolik [3] demonstrated how rain and snowfall, freezing rain and fog, and humidity can significantly affect RSSI, causing large fades or even complete loss of connectivity. They used Chipcon CC2420DK nodes at three different frequencies of 2.4GHz ISM band in the experiment. Boano et al. [5] also showed that the effect of both thin and thick fog, and rainfall on RSSI is almost negligible. However, the impact of a very heavy rainfall on wireless communication may be significant. Markham et al. [6] conducted a 26-day measurement in the forest of Wytham Woods, near Oxford and a lab experiment, using T-mote Sky nodes with CC2420 radios. They showed that variations in RSSI are due to the presence of water on a node's casing rather than fading caused by rain. They justified their finding by stating that water is capacitively loading the antenna, thereby changing its radiation pattern.

In contrast to previous studies, our experiment was conducted with AT86RF230 radio transceivers. Further, we utilized all the specified 16 radio channels for 2.4GHz ISM frequency band with two different transmit power levels and used sensors to measure the ambient temperature and relative humidity in each node.

## III. Background

In the following, the related variables used to measure radio signal strength, temperature and humidity are defined.

### A. Received Signal Strength Indicator, RSSI

The well-known basic metrics used to link quality estimation in WSNs are RSSI (Received Signal Strength Indicator), PRR (Packet Reception Ratio), SNR (Signal to Noise Ratio), and LQI (Link Quality Indicator) [14]. Received Signal Strength Indicator (RSSI) is a standard feature built in most radio transceivers typically employed in WSN nodes and indicates the received radio signal power in a particular radio channel. As specified in the IEEE 802.15.4 standard [15], RSSI is computed by averaging RSSI values over 8 symbol periods ($128\mu\mathrm{s}$). The IEEE 802.15.4 standard refers to this (average) RSSI as Energy Detection (ED), as also does the AT86RF230 radio transceiver [11].

The ED value of the AT86RF230 radio used [11] is computed by averaging RSSI values over 8 symbol periods ($128\mu\mathrm{s}$). In AT86RF230, RSSI is a 5-bit register value with $3\mathrm{dB}$ resolution, and ED value is an 8-bit register value with $1\mathrm{dB}$ resolution. The ED value has $84\mathrm{dB}$ range and absolute accuracy of $\pm5\mathrm{dB}$. The RF input power in AT86RF230 can be computed as follows:

$$\mathrm{P_{RF}} = \mathrm{RSSI\_BASE\_VAL} + (\mathrm{ED\_LEVEL} - 1)\ \ [\mathrm{dBm}],$$

where $\mathrm{RSSI\_BASE\_VAL} = -91\mathrm{dBm}$ (RSSI sensitivity) and $\mathrm{ED\_LEVEL} = 1..84$. The minimum ED value $(\mathrm{ED\_LEVEL} = 0)$ indicates receiver power less than $\mathrm{RSSI\_BASE\_VAL}$. The formula used to express RSSI as RF input power [dBm] is radio-specific and usually can be found in the data sheet of the particular manufacturer.

Throughout this paper, the terms RSSI and signal strength will be used to refer to RF input power $\mathrm{P_{RF}}$ $[\mathrm{dBm}]$, unless otherwise stated.

### *B. Relation between temperature and humidity*

The relationship between different weather variables, such as temperature and humidity, can be quite confusing. As it is well known, temperature and humidity are connected to each other either directly or indirectly. For the purpose of analyzing the results, it is of the essence to know their mutual dependence. In the following, we try to emphasize the differences between various humidity definitions and how they are related to temperature and to each other. For clarification, their relationship is also illustrated in Fig. 1.

Humidity is the amount of water vapor, the gaseous state of water, in the air, and is usually invisible. The maximum amount of water vapor in the air depends on air temperature. *Absolute humidity (AH)* is the water content in the air, i.e., the mass of water vapor included in a particular volume of air, expressed in $\mathrm{g/m^3}$. *Saturated humidity (SH)* is the maximum amount of water vapor in the air at particular temperature (the blue line in Fig. 1). *Relative humidity (RH)* defines, in a percent, how much water vapor (AH) is in the air relative to the maximum amount of water vapor (SH) at the same temperature and pressure. Relative humidity of saturated air is $100\%$. *Dew point (temperature)* is the temperature to which air must be cooled down in order that water vapor starts to condense into liquid water or ice $(RH = 100\%)$. [16]

Of particular interest is the point wherein water vapor is changing from gaseous state into liquid (condensation) or solid (deposition, $\mathrm{T} < 0°\mathrm{C}$) state. Condensation/deposition starts when humidity increases or temperature falls, reaching the saturation point $(RH = 100\%)$. The condensed water vapor is called either dew (frost when $\mathrm{T} < 0°\mathrm{C}$) or fog (or clouds), depending on whether formed on a solid surface or in the air. [16]

Absolute humidity $AH$ $(\mathrm{g/m^3})$ can be defined, e.g., as a function of temperature and relative humidity as [17]:

$$AH(t, RH) = 216.7 \cdot \left[ \frac{\frac{RH}{100\%} \cdot A \cdot \exp\left(\frac{m \cdot t}{T_n + t}\right)}{273.15 + t} \right], \qquad (1)$$

where $t$ is the actual temperature $(°\mathrm{C})$, $RH$ the actual relative humidity $(\%)$, $m = 17.62$, $T_n = 243.12°\mathrm{C}$, and $A = 6.112\mathrm{hPa}$.

## IV. Experiment Overview

In the experiment, we set up a wireless sensor network operating in 2.4GHz ISM frequency band in a university campus area in western Finland. The WSN measured and collected data related to weather and radio link quality, both in summer and wintertime. This raw data was sent to a server to be further processed and analyzed. In the following, the experiment is described in more detail.

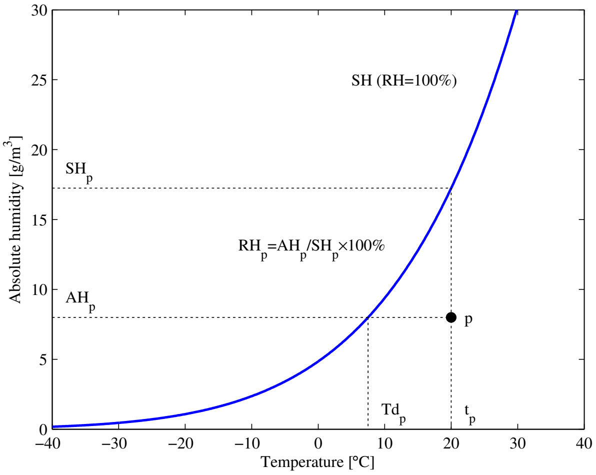

Fig. 1. Relationship between the following weather variables: temperature (t), relative humidity (RH), absolute humidity (AH), saturated humidity (SH), and dew point (Td) (at constant barometric pressure).

### *A. WSN Configuration and Deployment*

We used a wireless sensor network operating in 2.4GHz ISM frequency band in our experiment. The WSN consisted of Atmel ZigBit 2.4GHz wireless modules (ATZB-24-B0) [10] containing Atmel's ATmega1281V microcontroller [18] and AT86RF230 RF transceiver [11]. Furthermore, the sensor nodes were integrated with a Sensirion's humidity and temperature sensor (SHT75) [12] to measure the ambient temperature and relative humidity. The sensor nodes were powered with two AA-size $3.6\mathrm{V}$ primary lithium batteries. The nodes were enclosed with a weatherproof plastic casing, leaving the external antennas and SHT75 sensors outside the casing. A drain valve was added into the bottom of the casing to remove possible moisture or water. The sink node was similar to sensor nodes, without an SHT75 sensor and protective casing, and connected wired to a Raspberry PI. The Raspberry PI had LAN connection for sending raw data from the sink to the server/database.

The equipment used in the experiment consisted of five sensor nodes, one sink node and one Raspberry PI. In addition, there was one server/database. The sensor nodes were attached to five lamp posts with the help of mounting racks. There was one 2.4GHz node in a single rack. The nodes were at the height of approximately $3\mathrm{m}$ (top of the antenna). The sink node and Raspberry PI were inside the university campus, and they were powered by mains current. The network setup can be seen in Fig. 2.

### *B. Data Collection and Processing*

The sink node broadcasted a link-measurement packet twice in every minute using two different transmit power levels,

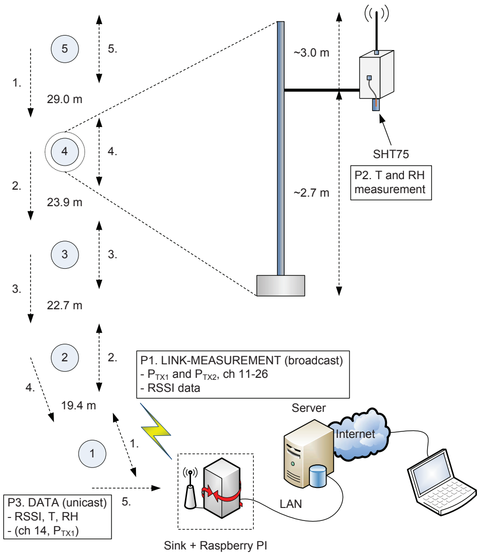

Fig. 2. Measurement network setup (not in scale).

first the maximum transmit power of $+3.0\mathrm{dBm}$ ($\mathrm{P_{TX1}}$) and thereafter $-7.2\mathrm{dBm}$ ($\mathrm{P_{TX2}}$). Radio channel was changed every minute, thus all the 16 channels $(11-26)$ were rotated in 15 minutes. Sensor nodes receiving the link-measurement packets updated their neighbortables for the particular links (RSSI, etc.), and forwarded the packets in their scheduled time frames. After the link-measurement phase, the nodes measured temperature (T) and relative humidity (RH) readings by using the SHT75 sensor. Thereafter, the sensor nodes sent (unicast) neighbortable and sensor data (T, RH) to the sink by using predefined static routing (see Fig. 2). The sink forwarded the collected raw data to Raspberry PI, which in turn sent it to the server/database via LAN. Temperature sensor readings (ADC) were converted to temperature values according to [12] and calibrated with each other by using offset values, before saving to the database. Also, RH sensor readings (ADC) were linearized and temperature-compensated according to [12] before saving to the database.

The collected raw data was downloaded from the server to be further processed and analyzed. We used MATLAB [19] for processing, analyzing and presenting data. Both RSSI data (of each channel) and weather data (T, RH) were averaged over one hour. There were 60 RSSI samples in an hour for each link, i.e., on average $3-4$ samples (for both TX power) for each radio channel. Weather data was measured once in a minute; thus there were 60 samples in an hour for each node. Absolute humidity was also computed; it was based on average temperature and relative humidity values for each node, according to (1).

To mitigate the effects of changes in environmental conditions, effects such as multipath fading, on different radio frequencies, we utilized frequency diversity and computed link RSSI by averaging the RSSI samples collected at different radio channels. The $1\mathrm{h}$ average RSSI for each link $k$, $\overline{RSSI}^{k}_{1\mathrm{h}}$, was computed as

$$\overline{RSSI}^{k}_{1\mathrm{h}} = \frac{1}{n}\sum_{i=1}^{n} RSSI^{k,i}_{1\mathrm{h}} \text{ [dBm]}, \tag{2}$$

where $i = 1..16$ (channels $11-26$ specified by IEEE 802.15.4 for 2.4GHz ISM frequency band). Bardella et al. [20] have shown that exploiting frequency diversity will mitigate the multipath fading effects, which could help us in analyzing the effects of weather conditions.

To calculate statistics (TABLE I), we used the $1\mathrm{h}$ average RSSI change of the analyzed links, $\overline{\Delta RSSI}_{1\mathrm{h}}$, as follows:

$$\overline{\Delta RSSI}_{1\mathrm{h}} = \frac{1}{8}\sum_{k=1}^{8} \underbrace{\overline{RSSI}^{k}_{1\mathrm{h}} - \overline{RSSI}^{k}}_{=\Delta RSSI^{k}_{1\mathrm{h}}} \text{ [dB]}, \tag{3}$$

where $k$ is the link number, $\overline{RSSI}^{k}$ the average RSSI for link $k$ over the measurement period, and $\Delta RSSI^{k}_{1\mathrm{h}}$ the $1\mathrm{h}$ RSSI change for link $k$. The links chosen to be analyzed were the ones between the closest neighboring nodes, i.e., the links $1 \leftarrow 2$, $2 \leftarrow 1$, $2 \leftarrow 3$, $3 \leftarrow 2$, $3 \leftarrow 4$, $4 \leftarrow 3$, $4 \leftarrow 5$, $5 \leftarrow 4$.

As for weather data, we also used $1\mathrm{h}$ average temperature and relative humidity of the analyzed links. Absolute humidity was computed based on these average values, applying (1).

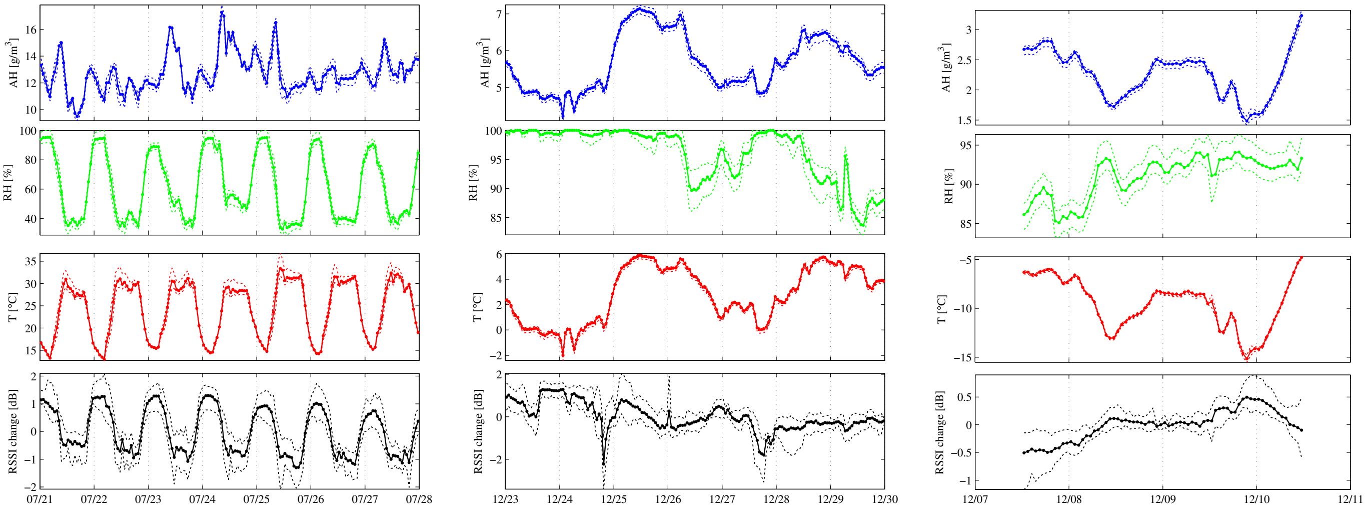
## V. Experimental Results

We performed experiments and gathered data by using our WSN in different seasons. Data from three different periods was chosen, one set in summer and two in winter, to be analyzed here. The representative periods are 1 week in July 2014 (temperature $> 0°\mathrm{C}$), 1 week in December 2013 (temperature $<> 0°\mathrm{C}$), and 3 days in December 2013 (temperature $< 0°\mathrm{C}$). Our aim is to find out how temperature and humidity affect radio signal strength.

### A. *Temporal Variation of Signal Strength*

When exploring the results from our experiments in both summer and winter, it is evident that signal strength has both short-term (diurnal) and long-term (seasonal/weekly) variation. Interestingly, the variation is notably different in each period. Diurnal variation (day/night) is clearly apparent in summer, whereas seasonal variation is easier to detect in winter and between different seasons (summer/winter). These variations are not random but mainly cyclic, following a certain distinct pattern. For example, in summer, as can be seen in Fig. 3 (a), signal strength falls in the daytime and rises in the nighttime.

Comparing the variation of signal strength with the variation of weather variables in Fig. 3, it is easy to find similarity between them, especially in summer. This suggests that there is a relation between signal strength and particular weather variables. However, the relation in summer seems to be different from that in winter. For example, in summer there is hardly any relation between absolute humidity and signal strength, but in winter below $0°\mathrm{C}$ the correlation is quite clear. In contrast, when temperature fluctuates near $0°\mathrm{C}$, the relation between weather variables and signal strength is unclear.



(a) July 2014 (above 0°C).

(b) December 2013 (around 0°C).

(c) December 2013 (below 0°C).

Fig. 3. RSSI change, temperature (T), relative humidity (RH), and absolute humidity (AH) of the analyzed links (mean, min, max) during three different periods ($\mathrm{P_{TX}} = 3.0\mathrm{dBm}$). RH data of node 3 is excluded from all computations for December 2013 (around 0°C) due to humidity sensor malfunction.

The behavior of individual links is quite similar, as shown in Fig. 3. This indicates that RSSI variation is mainly caused by changes in weather affecting all the links, rather than by some site-specific reason. However, between individual channels there can be quite large variations in RSSI behavior, both within and between individual links. Probably this results from other factors, such as multipath propagation. By averaging the RSSI samples of different radio channels, we can thus smooth the random and channel-specific variation to better discover the effects of weather conditions.

Nevertheless, our observations confirm the findings reported in the literature (e.g., [1], [8]), which states that signal strength has temporal variation. Probably these variations are mostly due to changes in weather conditions. In the following, we will focus on temperature and humidity to find out their effects on RSSI variation.

### B. *Effects of Temperature on Signal Strength*

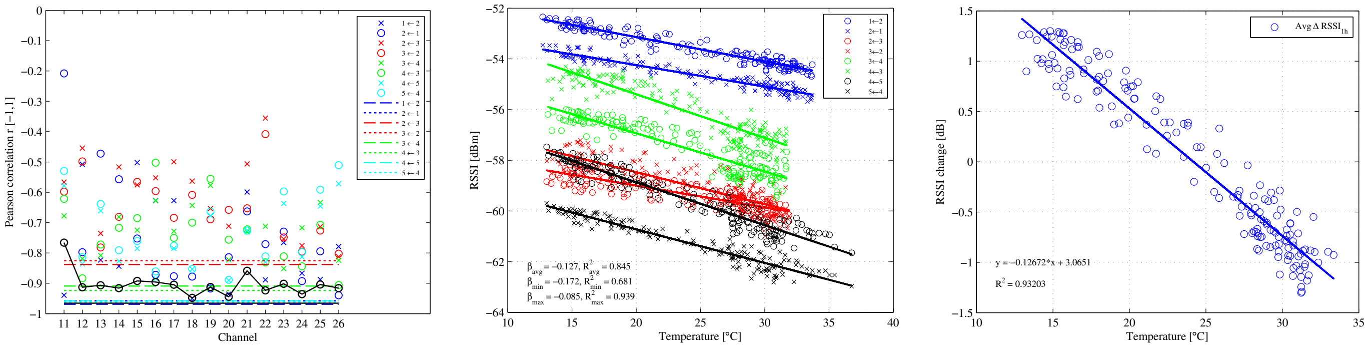
As could already be seen in Fig. 3, there is an obvious relationship between temperature and signal strength. In general, when temperature rises signal strength (RSSI) falls, and vice versa. This indicates negative correlation (dependence) between temperature and signal strength. To get a better understanding of the matter, we computed Pearson correlation coefficient to measure the degree of linear dependence between temperature and RSSI. The results from July are presented in Fig. 4 (a). As can be seen, the correlation varies depending on channel and link. Some link-channel combinations have a very strong correlation, while in some others the correlation is less significant. The difference between the correlation of average RSSI change with temperature (straight black line) and the individual link-channel correlations with temperature is quite clear, indicating the benefits of exploiting frequency diversity. The correlation of the average RSSI change (also channel-specific) is strong, confirming the hypothesis that RSSI correlates negatively with temperature.

The correlation of average RSSI change with temperature is high also while below 0°C in December. However, when temperature fluctuates near 0°C, there is a substantial degradation in correlation. Nevertheless, the negative correlation still holds. The correlation between temperature and RSSI is statistically significant ($p < 0.001$) in each measurement period.

When comparing how RSSI correlates with temperature with two different transmit power levels, we can find some differences. On average, RSSI correlation with temperature is slightly stronger (negatively) when using smaller transmit power ($\mathrm{P_{TX}} = -7.2\mathrm{dBm}$) compared to when using the maximum transmit power ($\mathrm{P_{TX}} = 3.0\mathrm{dBm}$). This holds true for all the three periods, being emphasized in winter when the deviation is bigger.

To quantify the effect of temperature on RSSI, we plotted both RSSI of individual links and average RSSI change versus temperature and applied simple linear regression, where we used temperature as an explanatory variable for RSSI variation. The results from July are presented in Fig. 4 (b) and 4 (c). As can be seen, temperature has quite a considerable effect on signal strength. A linear, negative trend can be observed for all the links, but there is some variation regarding magnitude of the impact (regression coefficient). As for RSSI change, regression coefficient is $-0.127$, i.e., the rise of temperature by $10°\mathrm{C}$ decreases RSSI approximately by $1.3\mathrm{dB}$. The coefficient of determination ($\mathrm{R}^2$) is very high ($0.93$), which implies that in this model RSSI variation can be explained to a high degree by the variation in temperature.

There are no great differences between the different periods regarding the magnitude of the impact. The regression coefficient varies between $-0.09$ and $-0.13$. However, $\mathrm{R}^2$ decreases during frost, and practically plunges while temperature is



(a) (b) (c)

Fig. 4. Relationship between RSSI/RSSI change and temperature (T) during one week in July 2014 ($P_{TX} = 3.0$dBm). (a) Pearson correlation between RSSI/RSSI change and T, (b) Linear regression of RSSI on T (all links), (c) Linear regression of average RSSI change on T.

around 0°C. This indicates that when temperature fluctuates around 0°C, there are some other factors causing large deviations, thus reducing correlation and $R^2$. The regression coefficients are statistically significant ($p < 0.001$) in each measurement period.

As for the magnitude of the effect, the differences between two power levels are not significant. $R^2$ values are somewhat higher with the smaller transmit power ($P_{TX2}$), indicating that the smaller transmit power results in smaller unexplained RSSI variation.

The summary of the relationship between temperature and RSSI is presented in TABLE I.

### *C. Effects of Humidity on Signal Strength*

Another potential factor affecting signal strength is humidity. As can be seen in Fig. 3, there is also a clear relation between both relative (RH) and absolute (AH) humidity and signal strength in particular times. Relative humidity rises and falls together with RSSI (above 0°C), indicating positive correlation, while the trend of absolute humidity indicates negative correlation (below 0°C). As previously, we computed the Pearson correlation coefficients and simple linear regression for both RH and AH. The summary of the relationship between RH/AH and RSSI is presented in TABLE I. The correlation and regression coefficients of RH to be discussed below are statistically significant ($p < 0.01$) in each measurement period, while those of AH are statistically significant only for winter periods.

In July, RH has a very high positive correlation (0.95) with RSSI while AH and RSSI are uncorrelated. $R^2$ in the regression model is also very high for RH, which means that in this model RSSI variation could be explained to a high degree by the variation in RH. As for RSSI change, the regression coefficient of RH is about 0.03, which means that the rise of RH by 10% increases RSSI approximately by 0.3dB.

In December, at the temperature below 0°C, both RH and AH have high, almost equally strong but opposite correlation with RSSI. Interestingly, the regression coefficients of both RH and AH are about $2 - 3$ times higher compared to the other period(s). Also $R^2$ is quite significant ($\approx 0.6$) for both RH and AH, although for RH it is smaller when compared to July.

In the near 0°C period, correlation is quite low for both RH and AH. However, it is still consistent with the other period(s). Due to decreased correlation, it is obvious that $R^2$ in the regression model is also low for both RH and AH. Therefore, the explanatory powers of the linear regression models are not sufficient.

On average, RSSI correlation with AH is slightly stronger (negatively) with smaller transmit power in both winter periods, as are the regression coefficients and $R^2$ values. In the case of RH, the differences between the power levels are relatively minor.

### *D. Temperature vs. Humidity*

While correlation is a good predictor of a potential causal relationship, it does not imply causation and could be caused by some other factor. The high correlation between the studied weather variables and RSSI both in July (T, RH) and below zero (T, RH, AH) could be partly explained by the high mutual dependence of temperature and humidity, as illustrated in Fig. 5. As can be seen, RH correlates strongly with temperature in July, while AH does so in December. This close relationship between the studied weather variables complicated our attempts to distinguish between the actual impact of temperature and humidity on RSSI. Therefore, we applied multiple linear regression with two explanatory variables to find out both the combined effect and the effect of a particular weather variable while the other variable is taken into account. As previously, to analyze the effects of temperature and humidity on RSSI, we used the average RSSI change, T, RH and AH of the analyzed links.

As expected, some of the results show high collinearity between temperature and humidity. In July, temperature and RH are highly collinear (*variance inflation factor*, *VIF* is high), while in December below 0°C, temperature and AH are collinear. Therefore, it is questionable to use them together in the regression model. Contrary to this, temperature and AH are not collinear (VIF = 1.01) in July, nor are temperature and RH (VIF = 1.38) in December when temperature is below 0°C.

TABLE I
AVERAGE RSSI CHANGE VS. TEMPERATURE (T) / RELATIVE HUMIDITY (RH) / ABSOLUTE HUMIDITY (AH).

The results from July show that temperature is the dominating factor affecting RSSI. Using AH as the other explanatory variable together with temperature in the model does not improve the adjusted $R^2$ ($\bar{R}^2$) in practice. Further, the weight of temperature in the model is significantly higher than that of AH. Therefore, it is sufficient to include only temperature in the regression model.

The situation is different in December below 0°C. While temperature is the most significant variable ($\bar{R}^2 = 0.72$ for $P_{TX1}$), using of RH as the other explanatory variable does improve the $\bar{R}^2$ to a relatively large extent ($\bar{R}^2 = 0.87$). This means that both temperature and RH seem to have effect on RSSI. However, the proportion of temperature in RSSI variation is somewhat higher than that of RH. It is thus reasonable to consider the inclusion of both temperature and RH in the regression model.

When temperature is around 0°C in December, there are other factors apart from temperature or humidity (although probably related to them) causing sudden RSSI variations, as can be seen in Fig. 3. RSSI can experience large variations when temperature fluctuates near 0°C and RH is close to 100%, resulting in low $R^2$ for all the variables. RSSI variation thus cannot be explained with the help of any linear model in this case.

In conclusion, temperature generally seems to be the most significant variable affecting RSSI and could be used in a linear model to explain RSSI change, except in the above-mentioned special case. Relative humidity may have some effect on RSSI, particularly in high humidity conditions below 0°C, where it may be useful to include both temperature and RH in the model.

## VI. DISCUSSION

Our findings confirm the previous results in the literature of the effects of temperature on link quality. Moreover, some RF transceiver manufacturers mention the temperature dependency in their data sheets [21], [22], [11], thus supporting the results. It has been reported that both output power and receiver sensitivity [21], as well as crystal frequency accuracy (drift) and characteristics of the VCO (Voltage Controlled Oscillator) [21], [22] vary with temperature.

As it was shown, the effect of humidity is more complicated. Additionally, the accuracy of SHT75 sensor decreases substantially during high humidity conditions (RH $> 90\%$). It decreases linearly from typical $\pm 1.8\%$RH to $\pm 4.0\%$RH when RH increases from $90\%$ to $100\%$ [12]. Furthermore, [12] states that long term exposure to conditions outside the sensor's normal operating range may temporally offset the RH signal ($+3\%$RH after 60h). During both our winter periods, relative humidity is high and mostly over $90\%$. According to [12], RH can drop drastically due to heavy condensation of water on the sensor surface, which was also observed in our experiment. The foregoing aspects may affect the accuracy of the results in winter.

Particularly problematic is the case when near-zero temperature is combined with high humidity (RH close to $100\%$). RSSI fluctuation in that period could be due to ice/snow on top of the nodes and antennas melting into liquid water and/or liquid water (due to condensation or rain) freezing into ice. The same kinds of effects of water/ice on link quality are reported, e.g., in [6] and [3]. This indicates that water in liquid or solid state on top of the nodes or antennas may cause unpredictable changes in signal strength. Therefore, temperature and humidity may have indirect effects on RSSI variation through condensation (RH $\approx 100\%$) and freezing of water or melting of ice/snow (T $\approx$ 0°C).

Regardless, the effects of temperature and humidity on signal strength can have severe implications on different sensor network protocols. Particularly, the accuracy of RSSI-based ranging and localization decreases significantly if the effects of temperature and humidity are ignored. Therefore, temperature and humidity conditions should be taken into account in RSSI-based ranging in order to adapt to prevailing weather conditions. Our results could be used to compensate RSSI variation caused by temperature and humidity, and thus to improve ranging accuracy. Based on the experiment, it could be advisable to use frequency diversity in RSSI-based ranging and localization instead of a single channel. Further, the effects of temperature and humidity have implications on many other

protocols besides localization. These include protocols related to network connectivity and management, routing, etc.

Weather conditions are not the only reason for RSSI variation. Also HW-related issues and other environmental conditions, such as changes in surroundings (especially in winter), interference, etc. may affect signal strength. The effect of RSSI resolution on the results is also unknown. Furthermore, the measurement period we used was relatively sparse. By using a more dense measurement period as well as applying some filtering method to RSSI readings, it could be possible to achieve more accurate results.

In our future studies, we intend to carry out more experiments and lab measurements to study the effects of temperature and humidity on radio link quality in a controlled environment.

## VII. Conclusion

In this paper, the effects of ambient temperature and humidity on radio signal strength of Atmel ZigBit 2.4GHz wireless modules in outdoor WSNs were explored. Experimental results show that changes in weather conditions affect received signal strength. Temperature seems to have a significant negative influence on signal strength in general, while high relative humidity may have some effect on it, particularly below 0°C. Further, it was shown that use of frequency diversity can reduce the effects of channel-specific variation, and the difference between the transmit power levels used. Our findings could be useful when designing adaptive, robust algorithms and protocols, such as those related to RSSI-based localization.

***Abstract*—Global warming is big issue of this time. It is caused by producing emissions, mainly carbon dioxide. Many organizations tries to establish restrictions to limit $CO_2$ emissions. Our aim is to monitor underground parking lots and detect level of carbon dioxide using wireless sensor network. Gained results are drawn in the map of pollution of monitored area.**

***Index Terms*—WSN, $CO_2$ monitoring, global warming**

## I. Introduction

CARBON dioxide is a chemical compound, formed by two atoms of oxide and one atom of carbon connected by two double bonds. Carbon dioxide is a natural part of chemical compounds and atmosphere in certain amount, which is produced by fauna and flora. After the industrialization, carbon dioxide concentration in the air dramatically arose. This fact was caused by gas and oil combustion.

Recently, $CO_2$ concentration is at such level that population health is at risk. Some animal species can even face extinction because of climatic changes. Carbon dioxide is one of the most typical greenhouse gases and it causes that the heat reflected by Earth surface is kept in the atmosphere. This phenomenon results in increase of Earth temperature, which affects our ecosystem.

According to Kyoto protocol, 141 countries agreed to lower their emissions of greenhouse gases, including carbon dioxide. The aim is to reach 5.2% lower level than concentration of greenhouse gases in the 1990. To control $CO_2$ level in underground parking lot, its monitoring has to be performed. Nowadays there is a lot of underground parking lots in cities, which are not sufficiently air ventilated. For this purpose wireless sensor network (WSN) should serve [1]. This paper deals with $CO_2$ detection at the bases of its level monitoring by WSN.

## II. Consequences of $CO_2$ accumulation

In the garages, monitoring of air pollution is provided by measuring the $CO_2$ level using appropriate sensors which are deployed in whole area, based on the zone division. It is important to deploy sensor all over the building because of different gas concentration in given zones.

Measured values fall in range from 0 to 2 000 ppm (particles per million) $CO_2$. Minimal carbon dioxide concentration is around 400 ppm which is adequate to clean air. $CO_2$ is well mixed in the atmosphere, so observations of concentrations from a single site are an adequate indicator of world trends for atmospheric $CO_2$ [2]. For better imagination, concentration of $CO_2$ is shown in relative values, where 0% is equivalent to outside air (cca 400 ppm), 100% is adequate to maximal acceptable concentration, usually 2 000 ppm. The air pollution may be divided into several levels. First level is up to 40% which means 800 + 400 ppm, second level is in range up to 65 % which is 13000 + 400 ppm and the third level can get values up to 85% (1700 + 400 ppm). Level of carbon dioxide has a significant influence to the people:

- 1 % concentration of carbon dioxide in the air can cause sleepiness,
- 2 % causes human to be slightly dopey, increases blood pressure and heartbeat and decreases hearing ability,
- 5 % usually stimulate breath center, causes dizziness and confusion and troubles with breathing accompanied by headache and anhelation. This concentration can also result in access of panic.

There are two approaches to detect $CO_2$ using sensors. The first one is measurement using method of wavelength absorption, which is one of the properties of chemical compound. This method is called NDIR (not dispersive infrared) [3]. The second method is based on changes of electrical charge of chemical reaction measuring. This reaction is a result of air contact ($CO_2$ particles) with particles in the sensor.

If we want to control and decrease the level of $CO_2$, at first we need to know its concentration in give area. The most used detection method is using NDIR sensors [4], but the price of sensors is quite high (between 100 and 1000 euro). For that reason we decided to use sensor with technology of measuring chemical reactions. We selected MQ-135 sensor, which provides monitoring of air quality and with suitable settings it can be used as sensor for $CO_2$ detection.

## III. Sensor description

The sensor is designed for the use in air quality control equipments for buildings / offices. It is suitable for detection of $NH_3$, $NO_x$, alcohol, Benzene, smoke and $CO_2$ [5]. The sensitivity characteristic of the MQ-135 sensor can be seen at Fig. 1. This characteristic is used for the conversion of sensors output to the related *ppm* characteristic for the gas under test.

As the graph shows, the $CO_2$ curve can be described by the equation in the form

978-83-60810-66-8/$25.00©2015, IEEE

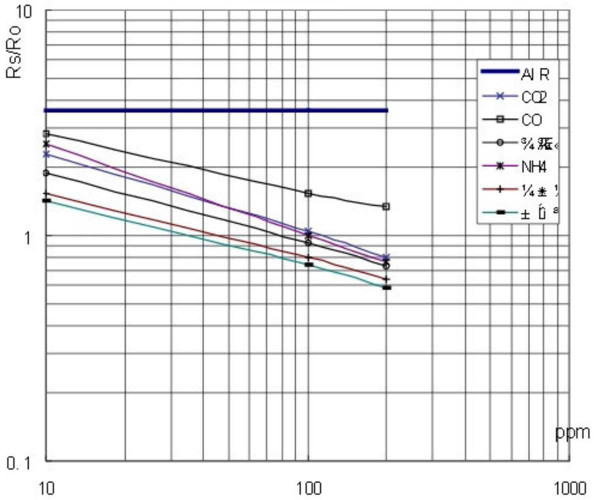

Fig. 1. Characteristics of MQ-135 sensor

$$y = a \cdot x^b, \tag{1}$$

where *y* corresponds to *ppm* and *x* corresponds to $R_s/R_o$.

Since the characteristic is defined graphically, we determine two points that can be described with the minimum deviation. Substituting these points and then solving the set of two equations

$$\begin{aligned} 200 &= a \cdot 0,8^b \\ 10 &= a \cdot 2,1^b, \end{aligned} \tag{2}$$

we obtain coefficients *a* a *b* which represent scaling factor and exponent respectively.

To obtain the calibration constant $R_o$, known current average value of $CO_2$ in the atmosphere and the equation 3 is used, where $R_s$ is the measured value, *a = 100.0482*, *b = -3.1041* and current *ppm = 401.52*.

$$R_o = R_s \cdot \sqrt[b]{\frac{a}{ppm}} \tag{3}$$

On this basis, we can conclude that the ppm value can be determined by the equation

$$ppm = 100.0482(R_s/R_o)^{-3.1041}. \tag{4}$$

Using the above calculation, it is possible to obtain values of $CO_2$ levels in the air of monitored environment. This theory was applied via a wireless network, where each nodes computational part is microcontroller SAM4S.

## IV. Description of printed circuit board - processing and communication

The basis of the board is a microcontroller ATSAM4S. This model contains a Cortex-M4 core and it is equipped with RISC architecture. It works at 120MHz frequency, it is equipped with 12-bit AD Converter with Programmable Gain Amplifier and its consumption is 180uA/1MHz-max [6]. The input of the AD converter is a signal obtained from the $CO_2$ sensor (module with the sensor MQ-135). RF module is also connected to the PCB. Communication between MCU and RFM70 module is provided via SPI communication interface. The sensor node is also equipped with an SD card slot with which the MCU communicates via HSMC interface. The archtecture of WSN node is described at Fig. 2. Sensor, processing and communicational modules are interconnected, so real $CO_2$ monitoring device can be seen at Fig. 3.

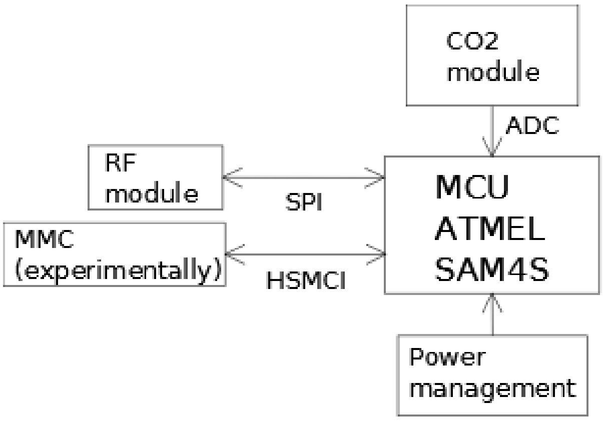

Fig. 2. Architecture of WSN node

### A. Collecting the results (processing)

To be able to determine the level of $CO_2$, it is important to apply mathematical relationship at the output of $CO_2$ sensor. MQ-135 changes the analog output voltage value with respect to the $CO_2$ level.

To define this value in digital domain, we use an integrated 12-bit AD converter. After the timer interrupt is set, method $ADCRead()$ is implemented. In this method, a single conversion is performed. When the end of the transfer is reached, the obtained data are stored to the variable and are ready for further processing.

To work with the proper amount of $CO_2$ level values, it is important to apply the normalization function (4), where we got a correction constant $R_o = 0.869565$, which represents $15\%$ more than measured value. The acquired data are then written to the microSD card (or sent through the RF module) and the MCU waits for the next interrupt from the timer.

WSN node functionality can be divided into several working modes:

- data gathering - sampling, converting signal from analog to digital form (A/D converter), processing, data storage
- data transmission - data encoding, data encapsulation, broadcast
- data receive - filtering, decoding, data extraction, error checking

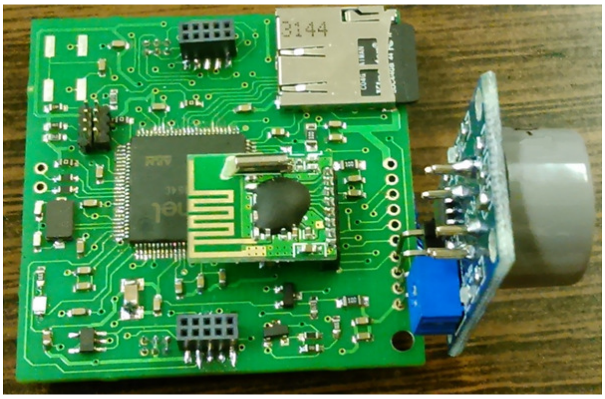

Fig. 3. $CO_2$ detection module

### B. Communication method

When we were creating the network topology, we had to take into consideration some basic information about WSN.

Network designs are based on three types of topologies:

- Bus Topology - This topology consists of a Backbone cable connecting all nodes on a network without intervening connectivity devices.
- Star Topology - In the computer networking world the most commonly used topology in local area networking is the star topology.
- Ring Topology - In ring network, each node is connected to the two nearest nodes so that the entire network forms a circle.

We chose a star topology, which we have expanded to the tree topology. This topology was enough for our purpose of use. Properties of tree topology are:

1) resistance of the network against downtime of the individual stations and lines
2) sensitive to downtime of nodes
3) easy expandability
4) two-point connections

Our next challenge was WSN synchronization. We were deciding between known synchronization methods which are:

- Reference Broadcast Synchronization (RBS), [7]
- Timing-sync Protocol for Sensor Network (TPSN), [8]
- Flooding Time Synchronization Protocol (FTSP), [9]
- Universal synchronization algorithm for wireless sensor networks - "FUSA algorithm", [10]

From these methods, we decided to use the algorithm FUSA, especially because it can be easily implemented and it is not suitable only for hierarchical networks, it is universal and scalable. After resolving these problems, we managed to submit data to the central node and ensure proper network functionality. In the central node, these data are saved on the microSD card. These data are then evaluated in the offline mode, so they can be processed and map of air pollution of the monitored area can be created.

An inexpensive wireless module that meets our requirements is used for communication between nodes. Wireless module RFM70 is a transmitter / receiver that operates at a frequency of 2.4GHz. The module has low power consumption, which is 23 mA when it is used as a transmitter and 18 mA as a receiver. It can be powered by supply from 1.9V to 3.6V, but its inputs withstand the voltage up to 5V. Consumption in standby mode of the module is only 50$\mu$A. The speed of wireless transmission of this module is 1Mbps or 2Mbps. The module supports 126 channels. It communicates with the microcontroller via SPI serial interface [11].

Individual nodes are synchronized by FUSA algorithm [10]. Nodes send data via RF module to the central node, where these data are saved on the SD card. These data are then evaluated in the offline mode, so they can be processed and map of air pollution of the monitored area can be created.

## V. The deployment of WSN and visualization of results

For testing purposes, WSN was deployed in the basement of the shopping centre [12]. Deployment of the nodes can be seen at Fig. 5, nodes are drawn as black bullets. There was an effort to place the sensors effectively for purposes of measurement. Some of the sensors are placed nearby the doors. Entrances and exits are marked in the figure. Other sensors were placed far from entrance / exit and in the corners where we expected the pollution to reach the highest values. One floor of the underground garage has been diagnosed for the period of one week. The collected data are graphically represented in the Fig. 4, where we can observe the dependence of emissions from the time for the sensor S1, so it is possible to monitor the time trend of the pollution.

Occurrence of emissions in the object during the night and early morning is insignificant (very small) [13]. The rate of pollution increases with active use of the parking lot [14]. This fact is the most visible in the early loading and afternoon emptying of these areas. We noted that the level of emissions for various days is very similar. Friday differs from other days significantly, because parking services are used by most drivers.

Fig. 5 shows the map of the environment with an adequate level of emissions at given time. To create such map, measured emissions from all the sensors that are valid for a given time should be collected. We expected the worst air in the corner areas but on the contrary the most polluted spots were nearby southern exit. We analysed the situation and found out that the cars entering and leaving the parking lot use more often this exit than the eastern exit. It means that on this way, there is often traffic jam while waiting for opening the barrier because each car has to stop and check the parking ticket in the machine and all cars have its engine turned on. Reason for choosing this exit is logistical - this entrance / exit has better connection towards the city centre, other shopping centres and also it is a direction to some apartment settlements. The corner parts are quite good ventilated, what outreached our expectation. That is thanks to effective ventilation system. Thus we can recommend to increase ventilation only in the area of southern exit.

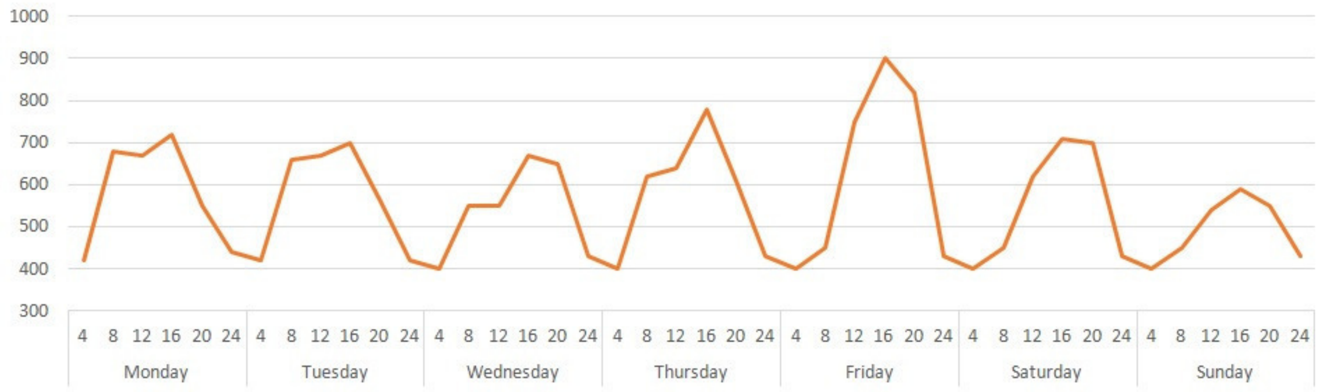

Fig. 4. $CO_2$ concentration recorded at sensor S1 during the week

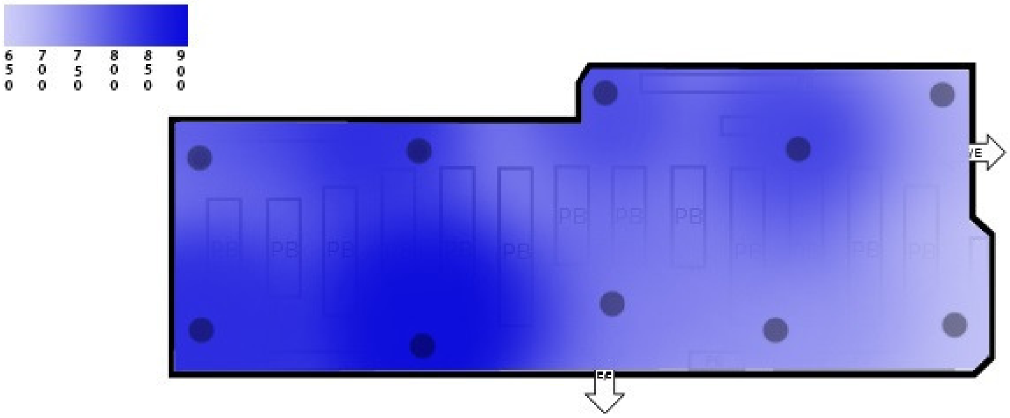

Fig. 5. Map of $CO_2$ concentration

## VI. Conclusion

Underground parking lot monitored during the testing week did not reach the first level of air pollution. This fact is caused by a good ventilation system (air conditioning) deployed in these areas. Nevertheless, it can be said that in the time of rapid usage of these spaces by drivers, the pollution level of parking lot has increased from an average to almost double.

System for the detection of $CO_2$ proposed and designed by us may be used not only in the underground parking lots but also in industrial zones. In the future, the system could be extended by the microphone and thus it might also serve for measuring acoustic emission eg. at road administration (control of the traffic flow, noise and $CO_2$ emissions).

***Abstract*—With WSN deployments increasing in popularity, securing those deployments becomes a necessity. This can be achieved by encrypting inter-node communications and/or using message authentication codes. AES is a well studied symmetric cipher, with no known practical vulnerabilities, that can be used to solve both problems. We provide an optimized implementation of AES, with four modes of operation (ECB, CBC, CFB and CTR), that uses the hardware accelerator available on the ATmega128RFA1 microcontroller, and compare it with the best known software implementation. We show that our hardware AES implementation is both faster and more energy efficient than a software implementation. This is not the case for previous sensor nodes and implementations, which show an improved execution speed, but with a higher energy consumption.**

## I. Introduction

As a general definition, a wireless sensor network is composed of a set of nodes which communicate through a wireless medium in order to perform certain tasks. A couple of examples where WSNs can be deployed, as stated in [1], are: fire extension detection, earthquake detection, environment surveillance for pollution tracking, intelligent building management, access restriction, detection of free spaces in parking lots and so on. Advantages brought by WSNs are enhanced flexibility and mobility, mainly because nodes are generally powered from an on-board battery and thus do not depend on their surroundings. This, however, is also their biggest weakness. The lifetime expectancy of a node depends on its usage. The constraints mainly come from the limited energy source, as data processing and transmission can be energy intensive.

The particular characteristics of these types of networks make the direct implementation of conventional security mechanisms difficult. The imposed limitations on minimizing data processing and storage space and reducing bandwidth need to be addressed. The major constraints for WSNs, as presented in [2], [3] and [4], are: energy consumption (which can lead to premature exhaustion of the energy source and to the denial of service), memory limitations (flash, where the application source code is stored, and RAM, where sensed data and intermediary computing results are stored), unreliable communication (the routing protocols used, collisions), latency (which can lead to synchronization issues and algorithms that cannot act correctly) and unattended nodes (an attacker could have physical access to the nodes).

The concept behind WSNs and their applications presents an increased risk to a series of attacks which can affect the network's functionality. In this paper we analyze algorithms that provide confidentiality for WSNs. We focus our analysis on AES-128, as it is a well studied cipher with no known practical vulnerabilities, has a speed comparable with other symmetrical encryption algorithms and is supported on multiple WSN platforms through a hardware acceleration module.

In section II we discuss some of the related work. Sections III and IV present the algorithm design and modes of operation and the implementation with two methods, software and hardware. Then, in section V, we make a comparative analysis of the solutions, based on execution time and energy consumption, and select the encryption methods suitable for ATmega128RFA1-based platforms, taking also into consideration the provided security. Finally, we present the conclusions of our work.

## II. Related Work

The problem of measuring the cost of encryption on wireless sensor node hardware has been addressed previously. In [5] Lee et al. analyze a range of symmetric-key algorithms and message authentication algorithms in the context of WSNs. They use the MicaZ and TelosB sensor nodes and measure the execution time and energy consumption of different algorithms. For AES they provide measurements for a hardware assisted implementation and conclude that it is the cheapest when either time or energy is considered. They do not however study this implementation on different plaintext lengths and instead rely on datasheets to extend to lengths longer than one block. However, this conclusion is not backed by Zhang et al. in [6] which compares different AES implementations on the MicaZ nodes. They conclude that hardware assisted encryption is faster, but also consumes more energy due to the external chip which handles the computation in hardware.

Compared to their work, we study only AES-128 which is a well known cipher also adopted by the National Institute of Standards and Technology (NIST) and which has been proposed as a viable alternative ([7]) to other less studied ciphers in WSN applications. This choice is also supported by the fact that multiple 802.15.4 transceivers offer a hardware accelerator for AES operations. We study the newer Sparrow v3.2 sensor nodes based on the ATmega128RFA1, which integrates the microcontroller with the radio transceiver and hardware encryption module, and show that AES-128 can be efficiently implemented reducing both execution time and energy consumption. We also provide hybrid implementations for modes of operation that are not natively supported by the

978-83-60810-66-8/$25.00©2015, IEEE

hardware and show that they can still be efficiently implemented with the available primitives.

In [7] Law et al. conduct a thorough survey of the costs of different block ciphers, when implemented on sensor node hardware. They conclude that Rijndael (AES) is the second most efficient cipher, being surpassed only by Skipjack. However, their analysis is based on older hardware and does not consider any hardware accelerated implementations.

In [8] de Meulenaer et al. study the problem of key exchange and measure the cost of two key agreement protocols: Kerberos and Elliptic Curve Diffie-Hellman. They measure the energy consumption of the two protocols on MicaZ and TelosB sensor nodes and conclude that the listening mode is the principal factor in the energy efficiency of key exchange protocols, with Kerberos being the more efficient protocol. Compared to their work, we concentrate on encryption algorithms, and more specifically on AES, with key distribution left for future work.

## III. Design

AES is a block cipher encryption algorithm that uses symmetrical keys for encrypting a block of plaintext and decrypting a block of ciphertext [9]. The algorithm uses a series of rounds consisting of one or more of the following operations: byte-level substitution, permutation, arithmetical operations on a finite field and XOR-ing with a given or calculated key [10]. As a general rule, the operations are handled bytewise.

AES receives as input a plaintext of 16 bytes and the encryption key, which has a variable dimension of 16, 24 or 32 bytes. The input text is processed into the output text (ciphertext) by using the given key and applying a number of transformations. Encryption and decryption are similar, except for the fact that decryption needs an extra step —it first runs a full encryption in order to obtain the modified key needed for decrypting data.

In [11], Schneier divides symmetrical encryption algorithms in two basic categories: block ciphers and stream ciphers. A block cipher encrypts a block of plaintext producing a block of encrypted data, whilst a stream cipher can encrypt plaintexts of varying sizes. This makes block ciphers prone to security issues, if used to encrypt plaintexts longer than the block size, in a naïve way, mainly because patterns in the plaintext can appear in the ciphertext.

A more secure way to encrypt data with a block cipher can be achieved by combining the encryption algorithm with a few basic operations, in a *mode of operation*. It is worth mentioning that the operations are not directly securing data. This is the responsibility of the block cipher. Still, they should not compromise the security provided by the cipher.

### A. Electronic Code Book (ECB)

The ECB mode of operation receives blocks of plaintext, respectively ciphertext, and a key and produces corresponding blocks of ciphertext, respectively plaintext. One property of this mode of operation is that two blocks of plaintext, encrypted with the same key, will result in two identical blocks of ciphertext. ECB is the most simple mode of operation. However, one major drawback is that it does not hide data patterns, meaning that identical ciphertext blocks imply the existence of identical plaintext blocks.

### B. Cipher Block Chaining (CBC)

The CBC mode of operation takes as input parameters the plaintext, respectively the ciphertext, the key and an initialization vector (IV). One property of CBC is that two encrypted blocks are identical only if their respective plaintexts have been encrypted using the same key and the same IV. Unlike ECB, CBC has link dependencies, as its basic chaining mechanism makes the ciphertext blocks dependent on previously encrypted data. This, coupled with a randomly chosen IV, ensures that identical plaintext blocks will be encrypted to different ciphertext blocks.

### C. Cipher Feedback (CFB)

The CFB mode of operation is very similar to CBC regarding its input parameters and the operations it performs. The main difference between them lies in the fact that CBC works as a block cipher, while CFB can be used as a stream cipher. Unlike CBC, CFB can encrypt variable-length blocks (which are not restricted to 16 bytes). The properties of this mode of operation are similar with the ones of CBC. One key difference between the two can be observed at the implementation level: CFB uses only the encryption primitive of the underlying block cipher, both for encrypting and for decrypting data.

### D. Counter (CTR)

The CTR mode of operation also produces a stream cipher. The IV used in CBC and CFB is now associated with the starting value of a counter, which is incremented and used to encrypt each block. In this mode, the output from a previous block is not used for obtaining the input to the current block. In order for the described system to work, a generator is needed on both sides of the communication. The generators have to remain synchronized in order to produce the same stream of data on both sides. A disadvantage of this mode of operation is the possible desynchronization of the communicating entities. This results in the incorrect decryption of all subsequently received data.

## IV. Implementation

A practical example would be a wireless sensor network, which transmits data gathered from three types of sensors: temperature, humidity and luminosity. Because of privacy and integrity concerns all data must be encrypted during transmission. The working platform for this scenario is based on the Sparrow v3.2 node [12]. Its technical specifications are:

- CPU: ATmega128RFA1, 16MHz
- Memory: 128KB flash, 16KB RAM
- Bandwidth: up to 2Mbps
- Programming: C/C++

The ATmega128RFA1 microcontroller is actually a SoC (System on Chip) which incorporates a radio transceiver compatible with the IEEE 802.15.4 standard [13]. It offers, among other things, a relatively low energy consumption (mostly in sleep states), a FIFO buffer of 128 bytes for receiving and transmitting data, a partial hardware implementation of the MAC protocol and support for AES-128.

This microcontroller facilitates secured data transmissions by incorporating a hardware acceleration module which implements the AES algorithm. The module is capable of encrypting and decrypting data in a fast track way, as most of the functions are implemented directly in hardware. It is compatible with the AES-128 standard (the key is 128 bits long) and supports encryption and decryption for ECB mode, but only encryption for CBC mode. The input to these operations consists of the plaintext/ciphertext block and the encryption key. Note that for decryption, the extra round needed by AES to compute the decryption key is performed automatically. Other modes of operation are not supported by the hardware.

As we already stated in the previous sections, energy consumption is the main issue and challenge for WSNs. In order to obtain the best approach for ensuring confidentiality with a minimum energy use, we implemented and compared AES-128, coupled with the ECB, CBC, CFB and CTR modes of operation. All four modes have both a hardware and a pure software implementation. Since only ECB has a full hardware implementation, for the other modes we used a hybrid approach, combining the hardware part from ECB with software implementations for the remaining operations. We also refer to these hybrids as hardware implementations. For the pure software implementation we used an optimized version of AES, called TableLookupAES [6].

## V. Evaluation

### A. Experimental setup

To measure the energy consumption of our implementation, we perform two kinds of measurements: the time required ($t$) and the current drawn by the node ($I$) while encrypting/decrypting. Using the formula $E = P \cdot t$, where $P = U \cdot I$ is the power required by the node, we can compute the energy consumed by the algorithm, be it implemented in software, in hardware or using a hybrid approach. We ensure a constant voltage $U$ using a voltage regulator, as explained in the next subsection.

In certain applications, the latency of encrypting/decrypting a given payload might be more important than the energy consumed. For this reason, this section also presents the timing results of the different solutions, independent of the energy measurements. As we later show, the current drawn by the node using both software and hardware security approaches is practically the same. Thus, the time taken is a sufficient metric for relative comparisons between the different solutions.

*1) Current measurement:* For the purpose of measuring the energy consumption of the Sparrow sensor node during our experiments, we built a current sensing circuit based on the INA 193 current shunt monitor.

Fig. 1 presents the circuit we designed. Power is provided by a $3.3V$ voltage regulator, which ensures a constant voltage regardless of the current drawn by the circuit. A shunt resistor connected in series with the Sparrow node acts as a current sensor. The voltage drop on the resistor is directly proportional with the current drawn by the circuit. This has two implications. On the one hand, the chosen resistor value must be small enough not to disturb the rest of the circuit (e.g. by incurring a big voltage drop). On the other hand, the same value has to be big enough so that the expected currents register a voltage drop that can be sensed with enough precision. In order to improve the measurement precision and sensitivity, without the drawbacks of a big resistor value, we employ a INA 193 current shunt monitor, which provides a constant gain of $20V/V$ on the input voltage drop, and a $4.99\Omega$ precision resistor with a tolerance of $0.01\%$. The output of the current sensing circuit is connected to a Metrix OX 5042 oscilloscope which we used to monitor the current drawn by the node during the different encryption/decryption operations. Determining the current is as simple as dividing the voltage shown on the oscilloscope by the current shunt monitor gain $(20V/V)$ and the shunt resistor value $(4.99\Omega)$.

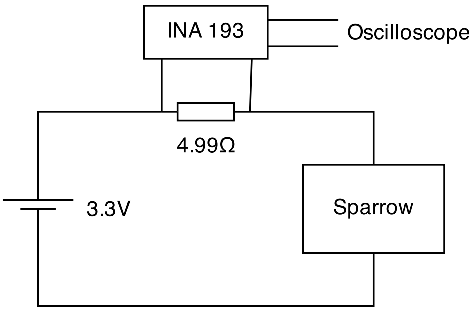

Fig. 1. Current measurement setup

*2) Time measurement:* Using the oscilloscope, we also measure the time required for each encryption/decryption operation. The oscilloscope has a function that accurately measures pulse duration. We create a pulse lasting for the duration of the operation by setting a GPIO pin before the start of the operation and clearing it after it ends. Using this method, we can measure the duration of an operation with minimal overhead: 1 bit set instruction and 1 bit clear instruction, each taking 2 cycles.

Although the proposed measurement scheme is precise, it has the disadvantage of requiring manual intervention. The available oscilloscope cannot be interfaced with a PC, so a measurement point is obtained by uploading a program which encrypts a hardcoded message length in a loop, reading the information from the oscilloscope and repeating the process for all message lengths.

In order to automate the time measurements, we resorted to a software implementation running along side the encryption/decryption operation, that measures the time required. To keep overhead to a minimum, our solution employs the hardware timer module available on the ATmega128RFA1 to count the number of cycles taken by the operation. Each operation is measured by sampling a counter before and after the operation and taking the difference of the two values. The count is then converted to a time value given that the microcontroller operates at $16MHz$.

This time measurement solution allowed us to automate the whole process of evaluating the algorithms for different message sizes. A small overhead can be observed between the software based time measurement and the oscilloscope based one, but the relative difference between the algorithms is unaffected. If absolute numbers are required, the software-based measurements can be corrected by noticing that the overhead increases linearly with the message size when compared with the oscilloscope measurements.

### *B. Results*

We conducted multiple experiments, to evaluate both the time taken and the energy consumed by AES encryption/decryption operations. We measured our hardware assisted implementation against the pure software implementation based on look-up tables.

*1) Time experiments:* We started of with measuring the difference between the optimized software implementation and our hardware assisted implementation for each of the 4 studied modes of operation. For each type of implementation and operation mode, we measured the time taken by an encryption operation and a decryption operation on varying message lengths. We used message lengths from 1 byte to 127 bytes, which is the maximum packet size allowed by the transceiver and the 802.15.4 standard.

As can be seen in figure 2, the hardware assisted implementation easily outperforms the optimized software implementation. The staircase shape of the graph is easily explained by the requirement of every block cipher, including AES, to operate on multiples of the block size. Plaintext sizes that are not a multiple of the block size need to be padded, thus still incurring the cost of an entire block.

The difference in performance varies between ∼6.5x for the ECB mode, which is fully supported in hardware, down to ∼3.8x for the CFB and CTR modes, which are only partially supported in hardware through the AES single block encryption primitive. The difference in performance between the optimized software implementation and our hardware assisted implementation is summarized in table I.

For the ECB and CBC modes we can also observe (figures 2a and 2b) the extra preparation step needed by the single block decryption primitive, which makes decryption slightly

(b) CBC mode

(c) CFB mode

(d) CTR mode

Fig. 2. Comparison between software and hardware AES implementations

| | encryption | decryption |
|---|---|---|
| ECB | 4.61x - 6.49x | 5.59x - 6.02x |
| CBC | 5.51x - 6.28x | 4.86x - 5.28x |
| CFB | 3.87x - 5.29x | 3.86x - 5.34x |
| CTR | 3.87x - 5.17x | 3.85x - 5.17x |

TABLE I. EXECUTION SPEED-UP HARDWARE VS. SOFTWARE

more time consuming than encryption. No difference can be observed (figures 2c and 2d) between encryption and decryption for the CFB and CTR modes, because they only use the encrypt primitive of AES for both encryption and decryption, albeit with some extra software processing.

Figure 3 compares the hardware assisted implementations of the 4 modes against each other during encryption and decryption. For encryption, ECB has the lowest runtime for all sizes, which was to be expected, as it does no extra operations on the output of the encrypt primitive to mask patterns in the plaintext. CBC is slightly worse, as it adds a XOR operation, which is implemented by the hardware accelerator, but better than CFB and CTR, which have no hardware support, except for the encryption primitive. For decryption, CFB and CTR have a slight advantage over ECB and CBC for small sizes, as they only use the encrypt primitive, which has a smaller setup time than the decrypt primitive. This advantage is lost at around 32 bytes with respect to ECB and at around 64 bytes with respect to CBC. From the plots we can also observe that the extra software processing done on top of the AES encrypt primitive by CFB and CTR is similar in overhead, for both encryption and decryption.

If we look at the cumulated time of both encryption and decryption, CFB and CTR still hold an advantage up to 32 bytes with respect to CBC. Thus, for small message sizes, as it usually happens in WSNs, it might be more efficient to use the CFB or CTR modes even if they are not completely accelerated in hardware.

*2) Energy experiments:* For energy consumption we concentrated our efforts on determining the cost of using AES in CFB mode. We chose this mode based on the fact that the timing measurements showed it to be the best encryption/decryption mode for small message sizes, similar to those that are commonly found in WSNs. We only performed measurements for message encryption, as decryption is identical in terms of the code which is ran. We measured the cost of doing the encryption in software as well as the cost of using our hardware accelerated implementation. For completeness, we also measured the cost of an empty processing loop to compare against the two encryption implementations.

In our experiments, we used the measurement circuit described in subsection V-A1 to measure the base and peak currents during encryption, as well as the voltage and duration of the operation, as reported by the oscilloscope. As with the timing measurements, we performed the experiment for different message size, from 1 byte to 127 bytes. The oscilloscope was configured to report the mean over 16 samples in order to obtain the average energy consumption of the device. An instantaneous energy consumption is hard to obtain and is irrelevant when considering the long time operation of the node.

Using the raw current and voltage measurements, we plot the average power drawn with respect to the encryption size. As can be seen in figure 4a, the software and the hardware solutions draw equal amounts of power. Furthermore, this average power is independent of the plaintext size and is only slightly higher than the average power drawn by the empty processing loop.

If we plot the average energy consumed by the encryption operation (figure 4b), we see a linear increase in energy consumption with increasing plaintext size. Using the timing measurements performed in the previous subsection and the average power values from figure 4a, we can also derive the average energy consumption for every mode, operation and plaintext size, not just for encryption in CFB mode. This can be done by adjusting for the overhead induced by the software timer, using a correction factor deduced from correlating the oscilloscope timings with the internal timer timings.

## VI. Conclusion

In this paper an evaluation of the cost of adding AES-128 encryption to WSN communications has been presented. Both the time penalty as well as the more important (from the point of view of a WSN) energy penalty have been analyzed, for multiple modes of operation: ECB, CBC, CFB and CTR and for two implementations: a pure software implementation, based on the optimized table lookup AES and a hardware accelerated implementation, that uses the AES hardware module of the ATmega128RFA1 microcontroller.

We showed how the AES hardware module in the ATmega128RFA1 microcontroller can be used to implement other modes of operation than the ones supported natively. Our solution uses a hybrid approach that runs some operations in hardware and emulates the missing ones in software. Using this approach, we implemented CBC decryption, as well as two full modes of operation for AES, CFB and CTR, which do not have direct hardware support.

We presented a methodology of accurately measuring the power consumption using low cost components and a way of determining the encryption/decryption duration using only the wireless node itself. We compared the different modes of operation and concluded that except for the unsecure ECB mode, CFB and CTR are better overall alternatives for the small message sizes (below 32 bytes) usually exchanged in WSNs. This is true even though the hardware accelerator has native support for the CBC mode and it relates to the way decryption works for CBC.

We also built on the work of Zhan [6] and showed that the newer ATmega128RFA1 microcontroller with an integrated transceiver, used in the Sparrow v3.2 node, can reduce both the duration and the energy consumption of AES operations. This is in contrast to work done on previous sensor nodes, that used a separated microcontroller and transceiver and which had a higher energy cost when running the encryption in hardware as opposed to using a pure software implementation.

***Abstract*—In Wireless Sensor Networks (WSN$_s$), energy conservation is one of the main concerns challenging the cutting-edge standards and protocols. Most existing studies focus on the design of WSN energy efficient algorithms and standards. The standard IEEE 802.15.4 has emerged for WSN$_s$ in which the legacy operations are based on the principle that the power-operated battery is ideal and linear. However, the diffusion principle in batteries shows the nonlinear process when it releases a charge. Hence, we can prolong the network lifetime by designing optimized algorithms that reflect the battery characteristics. Within this context, this paper proposes a cross-layer algorithm to improve the performance of beacon enabled IEEE 802.15.4 network by allowing a Personal Area Network Coordinator (PANc) to tune its MAC behavior adaptively according to both the current remaining battery capacity and the network status. The performance of the new algorithm has been examined and compared against that of the legacy IEEE 802.15.4 MAC algorithm through extensive simulation experiments. The results show that the new technique reduces significantly the energy consumption and the average end-to-end delay.**

***Index Terms*—WSN; IEEE 802.15.4, MAC; analytical model; battery aware; delay.**

## I. Introduction

RECENTLY, most wired sensors are now being replaced with wireless ones creating the emerging era of Wireless Sensor Networks (WSNs). WSNs consist of sensing devices that can communicate with each other and with the surrounding environment via the wireless communication medium [1] [2]. Yet, a huge number of sensor nodes are often scattered in unreachable areas, and WSNs are often battery powered and cannot be easily recharged. Thus, energy conservation is one of the main concerns in the area of WSN. Many studies that focus on designing WSN energy efficient algorithms and standards, based on IEEE 802.15.4, have emerged recently [3]. The IEEE 802.15.4 standard supports both physical and Media Access Control (MAC) layers. IEEE 802.15.4 MAC supports two types of devices, namely, *Full Functional Devices (FFDs)* and *Reduced Functional Devices (RFDs).* FFDs act as a regular coordinator and/or as a sink node. If both features are taken, the node is typically referred to as Personal Area Network Coordinator (PANc). In contrast, RFDs act as an ordinary end device [4]. Despite these differences, both FFDs and RFDs communicate with each other, forming two types of topologies, *star* and *peer to peer* topologies. All of the supported topologies must have one PANc. In the star topology, all network nodes can only communicate with the PANc in their active period. On the other hand, in mesh network topologies, all devices can talk to each other directly sending broadcast messages.

The IEEE 802.15.4 MAC layer operates either in beacon enabled or beaconless modes. In the beacon enabled mode, the FFD broadcasts regular beacon frames that synchronise nodes when they need to access the channel [4]. The time between two successive beacons is referred to as the *Beacon Interval (BI),* which is divided virtually into 16 equal sized slots. BI duration is specified by the Beacon Order parameter (BO) according to the following formula [4].

$$BI = aBaseSuperframeDuration * 2^{BO} \qquad (1)$$

Nodes can use the channel during the whole BI period or can sleep for some time portions depending on Superframe Order (SO) parameter. This parameter decides the Superframe Duration (SD) active session according to the following formula [4].

$$SD = aBaseSuperframeDuration * 2^{SO} \qquad (2)$$

where $0 \leq SO \leq BO \leq 14$

The aBaseSuperframeDuration value depends on the slot duration according to the following formula.

$$aBaseSuperframeDuration= aBaseslotDuration * total\ slots \quad (3)$$

All these concepts can actually be indicated through one concept: the duty cycle (D). This is the percentage of time the node is awake from the whole time between the two successive beacons. D is mathematically expressed as [5][6]:

$$D=SD/BI * 100\% \qquad (4)$$

When a node needs to access the medium, it has to locate the beginning of the next time slot in order to compete for the channel based on the Carrier Sense Multiple Access/Collision Avoidance algorithm (CSMA/CA). This time portion is referred to as the Contention Access Period (CAP) [4-6].

The lengths of the discussed periods are assigned through the beacon frame, which is transmitted in the first time slot (slot 0) [5][6]. Due to the complicated issues of the inactive period, most beacon enabled IEEE 802.15.4 studies are limited to star one-hop topology. Similarly, this paper considers the same assumption.

BO and SO values controls the performance of beacon enabled IEEE 802.15.4. Small BO values lead to frequent beacon frames and consequently increase beacon overhead, which, in return, drains more power in a short period of time. Small SO values, on the other hand, decrease nodes active time, while increasing the sleep time period. However, while small SO values might save energy, they increase delay and adversely affect throughput. This is because nodes which do not have enough time to send their data frames during the current superframe, will differ in their activity to the next superframe and therefore attempt to send their data packets in one go causing collision. Clearly, this situation becomes worse as the number of nodes increases [5][6]. Beacon overhead, collision and packets retransmission are all reasons for early battery charge depletion. In order to maximize node lifetime, we

978-83-60810-66-8/$25.00©2015, IEEE

need to increase battery lifetime. To achieve that we need to analyse the battery behaviour and study how it cope with IEEE 802.15.4 operations. Most of the studies found in literature are based on the fact that the IEEE 802.15.4 battery operations are ideal and linear. Batteries deliver power based on the electro-chemical reactions that occur between the electrodes and the active material around the electrodes. Continuous electro-chemical reactions deplete active mass near the electrode. Active material is able to diffuse towards the electrodes when the battery is idle allowing battery to heal and gain some of its charge [7]. This is called *battery recovery effect,* which occurs in the idle recovery time. Accordingly, in order to provide energy, real battery behaviour is governed by complex non-linear internal chemical reactions which occur due to the nonlinear behaviour when it gains charge in the recovery time [7].

To conclude, we can prolong network lifetime through adaptive techniques designed according to the battery's behaviour. For instance, we can exploit battery recovery effect by adding a relaxation time artificially between two packets in order to gain more capacity charge. Through this way, the performance of IEEE 802.15.4 could be improved by adopting IEEE 802.15.4 battery-friendly algorithm for the packets transmission.

Nevertheless, improving battery performance should not be at the expense of the standard reliability. Packets average end to end delay can be estimated at higher layers of the protocol stack, while energy consumption and battery behaviour are evaluated at the lower layers with respect to the OSI model. Therefore, the overall IEEE 802.15.4 protocol stack needs to be revisited so that the MAC layer can adaptively tune its parameters according to the actual needs in terms of the available battery capacity and the current delay. In other words, friendly battery management technique should be able to adapt to the actual network operating status; according to average end to end delay for example. This could be achieved for example by exploiting information provided by the different layers of the protocol stack. By following a cross-layer approach we do believe that we can minimize the energy expenditure.

In this paper, we propose an adaptive and cross layer approach that improves the beacon enabled IEEE 802.15.4 performance by allowing the MAC layer to tune its parameters according to the battery behaviour of the coordinator as well as the network status in a star topology. To summarize, the contribution of this paper is fourfold:

- The real behaviour of the battery in a beacon enabled IEEE 802.15.4 MAC is investigated by considering battery nonlinearity by analysing the diffusion of chemical reactions in the battery following *Rakhmatov model*.
- The gain of the battery recovery effect according to what sleep period can increase battery life time of the beacon enabled IEEE 802.15.4 is analysed.
- A cross-layer and adaptive battery aware beacon enabled IEEE 802.15.4 MAC that tunes synchronization time according to current battery status is proposed.
- The network reliability is considered by checking network delay and tune nodes active period accordingly.

This paper is organized as follows. Section II summarizes some of the literature work which is closely related to the paper topic, while Section III illustrates the battery models and our followed methodology. In Section IV we evaluate and discuss the performance of our proposed protocol. Section V concludes the paper and outlines future work.

## II. Related Work

Recently, there has been significant amount of studies that addressed the electro-chemical behaviour of batteries. Li et al. [8] proposed an analytical model that computes the life time of a low duty cycled star sensor network. In their model they considered nonlinearities of lithium-ion battery following Rakhmatov model [15] and they aimed to minimize the total energy consumption of the lithium-ion battery by finding the optimal idle and sleep period while guaranteeing energy efficiency, reliability and reasonable latency. In their proposal, they considered the trade-off between energy that is dissipated in sending frequent preambles and the period thereby sensors stay idle waiting for the preamble. Experimental results show that the proposed method can provide the optimal sleep or channel check intervals that maximize the lifetime of the network while guaranteeing a little latency and high reliability. However, this model target only a simplified work mechanism of MAC protocol, without giving details of battery nonlinearity effects on the proposed protocol on their network.

Li et al. [9] presented three battery aware algorithms that reduce power consumption and extend battery lifetime. Each one of the proposed schemes is targeted towards a specific application type, which are the hard real-time applications, the soft real-time applications, and the periodic applications. For hard real-time applications, Battery-friendly lazy packet algorithm is proposed to minimize battery charge consumption by allowing it drew lower current. A battery-friendly local optimization algorithm with slack time is targeted towards the soft real-time applications. For the periodic applications, a battery-aware task-scheduling algorithm is developed, which performs task rescheduling to achieve the battery friendly discharge profile. Li et al. [9] follows Rakhmatov model to depict both battery and recovery effect and nonlinearity. Simulation results demonstrated that the three battery-friendly algorithms perform better in extending lifetime of battery-operated sensor nodes as they reduce battery charge consumption.

Chau et al. [10] attempted to exploit the battery recovery effect in WSN. They empirically studied the gain at which the battery recovery effect prolongs commercial sensors lifetime. This effect has also been studied analytically corroborated by simulation. The outcome of [10] revealed that there is a saturation threshold at which the battery recovery resulted from idle listening will contribute less in improving the behaviour of the battery. Authors in [10] proposed a distributed battery aware duty cycle protocol and measure the battery runtime under both deterministic and randomized schedules. The authors in [10] studied also the trade-off between both delay and harnessing the recovery effect and suggested that we can perfectly harness battery recovery without increasing delay if we carefully adjust the sleep time period before reaching the saturation threshold. The authors in [11] derived upper bounds of battery lifetime and proposed a more energy-efficient algorithm that is aware of battery recovery effect and this is by extending the pseudo-random duty cycling scheme proposed in [11] by a *forced sleep*. In addition, the authors in [11] achieved analytical results that predict the average delay in sensor networks by setting the sleep duration of the RF transceiver as the saturation threshold of the battery, which can take the maximal advantage of the duration-dependent battery recovery effect. The authors in [11] presented also a useful tool to compromise the trade-off between increasing battery lifetime of sensor networks and the average delay of delivered packets.

Casilari et al. [12] proposed an analytical model that forecasts the minimum, mean and maximum battery lifetime of a WSN by allowing it to work under different traffic load, data rate and probability of packet loss. This is done by an experimental characterization of activity cycles battery consumption in commercial motes that follows the 802.15.4/ZigBee stack and also by measuring the current that is drained from the power source under different 802.15.4 communication operations [12]. The characterization considers the different operations required by 802.15.4 protocol and takes into consideration the delay introduced by the CSMA/CA algorithm applied by the 802.15.4 MAC layer. The model has also been extended to cope with the extra consumption that the node re-association requires when a packet loss occurs. Mario et al. [13] proposed an adaptive and cross-layer energy-aware module for energy-efficient and reliable data collection targeted towards IEEE 802.15.4/ZigBee WSNs. The proposed module captures the packet delivery ratio at the application and configures the MAC layer parameters, which are backoff window size and the number of (re)transmissions, according to the traffic conditions in order to minimize the power consumption.

## III. Battery Model & Protocol Description

Battery is a repository of electrical charges which provides voltage and current for the components attached to it, such as radio transceiver, microprocessor, memory, sensor, etc. A battery losses charge when a load draws current from it, where the loss rate is a function of the load [7]. It is common that the Radio Frequency (RF) transceiver operations are the most energy consumable resources (even in listening mode), as compared to the processing and sensing activities [8]. As it shown in (5), the total energy ($E_{total}$) consumed by RF energy model is the total sum of energies consumed by sensor in performing the four operations, which are: transmitting ($E_{tx}$,), in receiving ($E_{rx}$), being idle ($E_{idle}$) and in sleeping ($E_{sleep}$).

$$E_{total}= E_{tx}+E_{rx}+E_{idle}+E_{sleep}. \quad (5)$$

IEEE 802.15.4 standard, as many of other previous studies, consider ideal behavior of the battery, that is, voltage stays constant over time until the moment it is completely discharged, then the voltage drops to zero, whereas the capacity is the same for all loads that the battery generates [7]. The total energy E in the ideal case can be calculated as follows.

$$E = V \text{ x } C, \text{ and } C= I \text{ x } L \quad (6)$$

where E (Watt-hour) is the provided energy, V is the voltage (volt), C is the total capacity of the battery (Ampere-hour), I is the provided load (Ampere) and L is the lifetime of the battery (hour) [14].

In order to exploit battery characteristics in our protocol, we need to study its electro-chemical behaviour, which can be analysed empirically or through models [7]. Empirical analysis is time consuming and requires expensive prototyping and measurement for each alternative. Therefore, battery behaviour under various conditions of charge/discharge can be predicted through models [7-10].

Models for energy consumption and performance estimation of each system component are described in the following sub-section.

### *A.* Battery Models

There are different models that describe the battery discharge processes. Each model type has a varying degree of accuracy and complexity [7][8]. Those models can be classified as low level electro chemical models and high level mathematical models. Electro chemical models are the least flexible and the most computation intensive, so they are sophisticated models to use for battery modeling and they are the most accurate ones. On the other hand, electrical circuit models, analytical models and the stochastic models can be easily configured for different types of batteries. Electrical circuit models are highly efficient when used for simulation but they ignore the effects of charge recovery during idle periods. The stochastic models are highly efficient for simulation and are capable of modeling rate capacity and recovery effects. Analytical models are computationally efficient, but limited in the discharge effects they model. One of these models is Sarma and Rakhmatov model which is an abstraction of a real battery [15] that we used in this work. Rakhmatov model is chosen for estimating the real residual battery capacity at a specific time, because it is the simplest accurate analytical model. Other models require solving complex Partial Differential Equations (PDEs) which are difficult to optimize [7][15]. For the model to adequately mimic real behaviour of the batteries, one can utilize this formula:

$$\alpha = \mathrm{I}\left[L+2\sum^{\infty}\frac{1-e^{-\beta^{2}m^{2}L}}{\beta^{2}m^{2}}\right] \quad (7)$$

Where I is the applied load and L is battery lifetime, α is the capacity of the battery when it is fully charged, β refers to battery materials diffusion around the electrolyte and measures the nonlinearity of the battery as it tells us how fast the diffusion process can keep up with the rate of discharge. The value of α is a battery related parameter and its value is decided by manufacture of battery designer [15]. Formula (7) indicates that the total capacity of the battery is the sum of two terms, the linear ideal behaviour plus the nonlinear behaviour. As long as β value is large, the battery behaviour becomes closer to battery ideal effect. When β goes to infinity, the battery works in its ideal situation. This means that the higher the value of β, the better the battery performs. The value of β is estimated from the data sheet of the battery. For example, the data sheet of a battery might model rated capacity (in Ahr) vs. discharge current (in hour) [15]. Thus, before one can use the proposed model, the parameters need to be estimated from experimental data for the modeled battery. Simple experiments with constant loads are sufficient for estimation purposes. However, choosing the optimized values for both α and β is beyond the scope of this paper.

It is important to note that the load generated from the battery is discharged according to different transceiver activities (transmission, receive and idle), each has its own time duration. Thus, the load can be depicted in the form of consecutive N constant current values $I_1$, $I_2$, $I_3$, …., $I_N$ , where $I_k$ is the current of activity k which took place at time $t_k$ in the duration of $\Delta k = t_{k+1} - t_k$ [15]. Accordingly, battery capacity when it is fully charged can be depicted as follows:

$$\alpha=\sum_{k=1}^{N} I_K \Delta_k+\sum_{k=1}^{N} 2I_k \sum_{m=1}^{\infty} \frac{e^{-\beta^2 m^2 (L-t_k-\Delta k)} e^{-\beta^2 m^2 (L-t_k)}}{\beta^2 m^2} \tag{8}$$

In order to calculate the remaining capacity at a specific time unit, we need first to calculate the amount of charge consumed after performing M activities (charge lost from the battery) which is denoted by σ as follows:

$$\sigma(t)=\sum_{k=1}^{M} I_k \Delta_k+\sum_{K=1}^{M} 2I_k \sum_{m=1}^{\infty} \frac{e^{-\beta^2 m^2 t}\left(e^{\beta^2 m^2 \Delta_k}-1\right)}{\beta^2 m^2} e^{-\beta^2 m^2 t_k} \tag{9}$$

According to (8) and (9), the residual capacity at a specific time t (the available charge) is presented here:

$$\alpha(t)=\alpha-\sigma(t) \tag{10}$$

### B. *Battery Recovery Threshold*

Duty cycling is a technique adopted to regulate the on/off periods of the RF transceiver, while keeping the rest of sensor module on. It is important to design proper duty cycling and buffering strategies that can maximize the battery recovery effect when a transmitter moves to an inactive state during which the battery load becomes low, allowing the battery to recover. This results in extending the battery lifetime.

Before injecting this factor in order to improve the IEEE 802.15.4 performance, we need to analyse the rate at which sleep period can maximize battery lifetime. To achieve that, we followed Rakhmatov model and studied different active periods with different sleep time portions allowing the duty cycle to decrease gradually and we analysed the residual capacity in a star topology with 7 clients. Simulation parameters are depicted in Table 1 and the achieved results are depicted in Fig. 1. It can be noticed from Fig. 1 that, for all the tested active periods other than 61.44 ms, increasing the sleep time portion by 50%, and thus decreasing the duty cycle, increases the total residual capacity. On the other hand, allowing node sleep more than 50% decreases the total residual capacity. That is because the sleep time portion allows the chemical charge diffuses around the electrode which enables the battery heal and regain some of its charges because of the battery recovery effect principle. Moreover, it can be noticed that the effect of battery recovery increases as the active period increases, because for in a longer active time, node have enough time to do its activities and thus avoid other unnecessary operations such as, retransmission, which will save battery energy due to the increased residual capacity. This explains why for 61.44 ms active period, as the sleep time increases, total battery capacity increases for the three tested duty cycles. For this short period, a node does not have adequate time to perform its activities at all. Instead, it will keep differing its activity to the next superframe. Consequently, as all nodes will try to transmit together, this will cause frequent collision and retransmission which adversely affect network performance. It is therefore better for the node to sleep than to stay active. To conclude, in order to exploit battery recovery effect, BO is needed to be increased only by one as this will allow the node to operate within 50% duty cycle. BO can be incremented according to the current battery status. The algorithm description is presented in the following subsection.

### C. *The Proposed Technique:*

Achieved results motivate us to propose a more energy-efficient duty cycling scheme by setting the sleep duration of the coordinator RF transceiver at the saturation threshold of the battery, which can take the maximal advantage of the duration-dependent battery recovery effect.

Nevertheless, improving battery performance should not be at the expense of other performance metrics. Packets end to end delay can be estimated at higher layers of the protocol stack, while energy consumption and battery behavior are evaluated at the lower layers. Therefore, the overall IEEE 802.15.4 protocol stack is needed to be considered for the MAC layer to adaptively tune its parameters according to the actual needs. In other words, friendly battery technique should be able to adapt to the actual network operating status. Through this approach, both physical and application layers cooperate with MAC layer in order to prolong network lifetime by preserving energy battery charge at the physical layer, while considering average end to end delay delay status at the application layer.

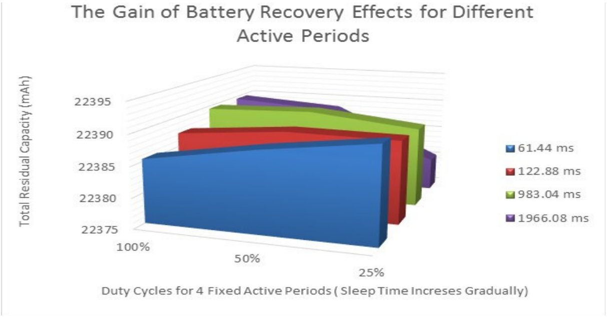

Fig. 1: Residual battery capacity for different duty cycles with different active periods.

This works as follows, before sending a new beacon frame, PANc asks the physical layer for its total residual capacity. If the new residual capacity is worse than the previous one, then it increments the value of BO, otherwise it does nothing. At the same time, PANc also checks the number of received packets at the application layer, for example, if the number is five, and if the new average end-to-end delay is worse than the previous one, then it increments the value of SO, otherwise it does nothing. The new battery aware IEEE 802.15.4 MAC algorithm is summarized in Fig. 2.

## IV. Performance Evaluation

Using QualNet 5.2 Simulator, the performance of the new proposed approach is evaluated by conducting a comparison against the legacy IEEE 802.15.4 performance in terms of total energy consumption, total battery residual capacity, average end-to-end delay and throughput. Evaluation process is applied on a star topology of seven RFDs with 7 Constant Bit Rate (CBR) traffic applications working over 1000 s simulation period.

**Algorithm:** Battery Aware and Reliable Beacon Enabled IEEE 802.15.4 (BARBEI)

**Objective:** Tune MAC superframe structure parameters according to battery nonlinear behavior and network status.
**Input:** FFD node *f*, seven RFD nodes $r_1$-$r_7$
**Output:** New superframe structure with updated BO and SO values

**Phase 1:** Tune BO value according to *f* residual capacity.

```
if f send BEACON
  if f. check RESIDUAL_CAPACITY (t (BEACON)) <
  RESIDUAL_CAPACITY (t (BEACON-1)) = true
    if BEACON. BO! = 8
      BO+=1
    endif
  endif
```

**Phase 2:** Tune SO value according to $r_1$-$r_7$ average end to end delay

```
for r1 to r7
  If r check DATA_PACKETS.num %5=true
    r. calculate (DELAY)
  endif
endfor
if f.check AVERAGE_DELAY.new > AVERAGE_DE-
  LAY.prevouis= true
    if BEACON.SO! = BEACON.BO
      SO+=1
    endif
  endif
```

Fig. 2: Battery Aware and Reliable Beacon Enabled IEEE 802.15.4 (BARBEI)

Table 1**: QualNet 5.2 SIMULATIONPARAMETERS**

| **Parameter** | **Value** |
|---|---|
| Physical and MAC | IEEE 802.15.4 |
| Area | 50 m *50 m |
| Energy Model | MICAZ |
| Number of nodes | 8 |
| Transmission range | 10 m |
| Simulation time | 1000 s |
| Battery type | Duracell AA |
| Battery model | Rhakhmatov |
| Traffic | CBR (1s arrival rate) |
| Payload size | 50 byte |
| BO values | 2,3,6,7 |
| SO Values | 2,3,4,6,7,8,9 |

Data rate is fixed for all nodes and the chosen packet interval is 1s for a 50 bytes packet size. 16 scenarios are tested, each one with different BO: SO combination to cover different duty cycles behaviour. Each time the new algorithm performance is compared against the original IEEE 802.15.4 MAC algorithm. Each case is repeated 10 times. Simulation parameters are the same as those presented in Table 1 but with more BO values considered.

The following subsections illustrate the results achieved for the four metrics:

### *D. Total Energy Consumption (mWh):*

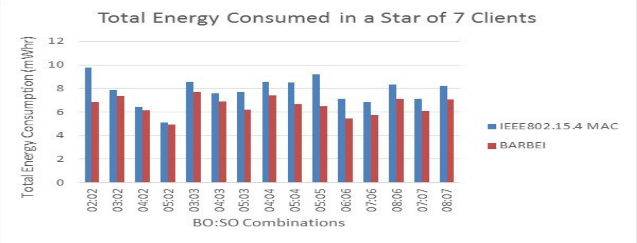

Fig. 3: Total energy consumption for a 7 RFDs in a star topology.

According to Fig. 3, it is apparent that the new algorithm decreases energy consumption regardless of the values in BO:SO combination. This is because the new algorithm tunes the MAC BO parameter according to battery residual charge. BO value is incremented if the current residual capacity is less than the previous one allowing the inactive period to increase. This offers node more time to sleep, which in turn allows PANc battery gain some of charge according to battery recovery effect. Consequently, battery capacity increases providing more energy according to (6). Moreover, increasing BO decreases beacon overhead which will decrease energy consumption, this effect is obviously noticed in BO: SO combination with small BO values, such as BO=2. In addition, energy is saved because the new algorithm avoids packets collision and retransmissions as it increases SO according to the application layer status. This gives nodes more time to transmit packets in the increased active period.

### *E. Residual Battery Capacity (mAh):*

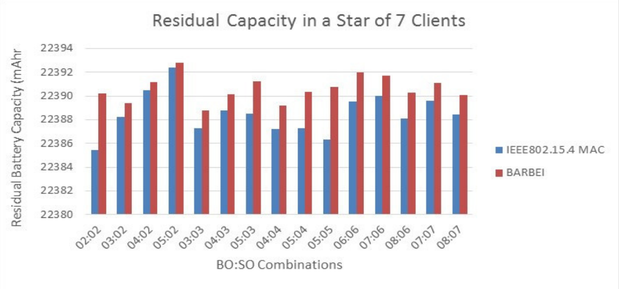

Fig. 4: Residual battery capacity for a 7 RFDs in a star topology

Fig. 4 reveals that despite the duty cycle or BO: SO values, the residual capacity in a network that follows our algorithm is higher than for the network that follows the legacy IEEE 802.15.4 MAC. This is because PANc exploits battery recovery effect by incrementing BO value according to battery status. This allows PANc battery to heal and gain some of its charge which will increase battery residual capacity. Network nodes are also given more time to sleep as BO increases. This saves residual battery capacity for all network nodes. Fig. 5 depicts that the new algorithm increases the throughput at most of BO:SO values. This is mostly obvious in combinations with small BO: SO values, such as 3:2, 4:2, and 5:2. In these scenarios, following the legacy MAC algorithm, the active period is two short causing a node to differ packet transmission to the next superfrme which will cause collision and hence adversely affecting network throughput.

### F. *Throughput (bits/s):*

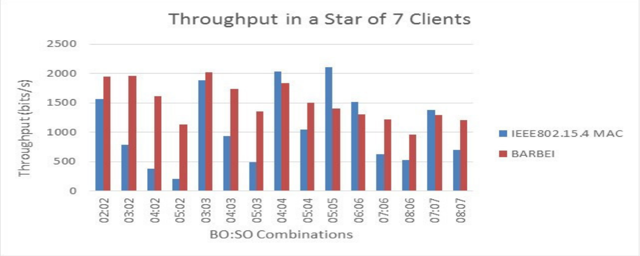

Fig. 5: Throughput for a 7 RFDs in a star topology

However, as the new algorithm allows the SO values to increase according to network performance, this will give more time for RFDs to complete their packet transmissions successfully, and consequently will improve network throughput. For combinations with 100% duty cycle, such as 4:4, 5:5 6:6 and 7:7, the legacy MAC outperforms our algorithm. This is because a node in these situations will have full active period to perform its activities and therefore which increase the throughput. However, increasing the inactive period according to battery status lowers the duty cycle which consequently will decrease the throughput.

### G. *Average End To End Delay (s):*

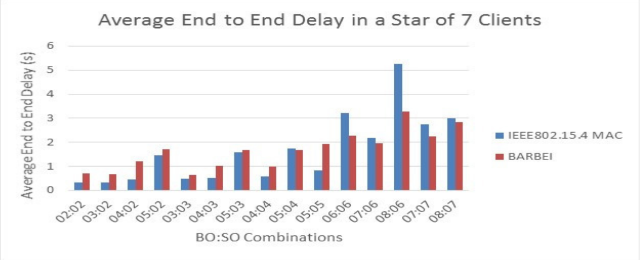

Fig. 6: Average End to End Delay for a 7 RFDs in a star topology

Fig. 6 shows that the average end-to-end delay for our algorithm performs better only for combinations with large BO values, such as BO=6, 7 or 8, because nodes have enough time to do their work and there is no need to increase SO value which avoids the increase of delay. Unfortunately, average end-to-end delay performs worse for the new algorithm for BO: SO combinations with small values such as SO=2, 3, 4 and 5. For small BO:SO values, the delay is always bad, and there will be frequent increments in BO and SO values allowing node to operate in consequent 50% duty cycles which will increase delay.

## V. Conclusion

The IEEE 802.15.4 standard is designed for different types of low-power and low-rate wireless Personal Area Networks. The performance of the standard can be improved by adopting battery-friendly algorithms for packets transmission. This can be achieved by designing battery aware approaches that exploit battery nonlinearity of recovery effects. However, there is a threshold at which battery recovery effect can be exploited. The proposed adaptive cross-layer and battery aware approach improves energy efficiency and power consumption for all possible duty cycle applications that the beacon enabled IEEE 802.15.4 standard offers. As a future work, not only the PANc is allowed to be aware of its battery behaviour, but also all network nodes will tune their activities according to their residual capacity. This can be achieved by taking the priority as criteria for packets transmission. Node priority will be determined according to its residual capacity.

***Abstract*—Machine-to-Machine Communication (M2M) enables communication between heterogeneous devices without human intervention. It is considered to be a key enabler technology for the concept of Internet of Things (IoT) and Cyber Physical Systems (CPS). With M2M's integration with Wireless Sensor Networks (WSN), information from different kinds sensors can be obtained. In order to discover useful knowledge from sensor data, various data mining techniques need to be applied. Due to the development of microprocessors on end devices in M2M system which collect data from sensors, data processing can also be executed on those devices. However, since end devices are often battery powered, energy consumption when running those algorithms needs to be taken into account. In this paper we implement an algorithm in M2M system, on Libelium Waspmote devices, which detects temperature plummeting in an indoor space. Afterwards, energy consumption of Waspmote devices is analyzed for two cases: when algorithm is executed on-device and when algorithm is executed on gateway or on back-end system.**

## I. Introduction

MACHINE-to-Machine Communication (M2M), a concept which enables connection of heterogeneous devices with limited human intervention, is considered to be one of the enablers for the process of provisioning advanced applications and services, such as smart cities and hospitals, automated vehicular and industrial operation, along with others [1]. Through integration with Wireless Sensor Networks (WSN), M2M systems can obtain wide range of information [2]. By analyzing that information, useful knowledge can be discovered, and appropriate actions can be initiated. M2M is considered to be one of the fundamental technologies for enabling the concept of Internet-of-Things (IoT) and Cyber Physical Systems (CPS) [3]. The IoT concept includes connecting sensors and other devices to the broader Internet by using general Internet technologies [4]. CPS is considered as evolution of M2M which supports more intelligent and interactive operations, under the architecture of IoT [3]. Although interlaced with the aforementioned areas, in this paper we use the term of M2M systems for a sensing systems in which end devices collect measurements from sensors, and send them via gateway to the back-end system.

M2M systems generate massive data sets which are considered to be of high business value [5]. To extract hidden knowledge from data, data mining algorithms can be applied. For instance, by analyzing sensor measurements collected within a smart home, the system can detect actions of the inhabitants and predict their future behavior. Additionally, it can recognize outliers, events which are not within usual patterns, and indicate towards a potential problem [6].

Most of the existing M2M solutions incorporate a central point for collecting and analyzing information [7]. However, with the development of hardware technologies which enabled miniaturizing wireless devices, smart sensors or actuators and micro-controllers, and enhancing their processing power, new schemes for refining software for embedded systems started to evolve [6]. The example of those new schemes is the possibility for certain algorithms to be executed on end devices or on gateways, instead of only on back-end system [8].

In this paper we analyze data mining techniques in M2M networks. Furthermore, we want to disclose how the functionalities of nodes within M2M system architecture influence energy efficiency of the system with limited energy resources. Particularly, we compare energy consumption of the battery-powered end devices when end device has measurement analysis functionality (i.e. analysis is performed on-device) and when measurement analysis functionality is performed elsewhere (i.e. when analysis is performed on gateway or on back-end system).

Section 2 presents research activities within the area of interest of this paper. Section 3 describes the network architecture compliant with existing M2M standards in which we conduct our measurements. In section 4 we introduce an algorithm which was deployed on end devices of our system and which monitors temperature fluctuations in an indoor space. Section 5 presents energy consumption comparison of end devices for two cases - when algorithm was executed on end devices, and when it was executed elsewhere. Section 6 concludes the paper and gives an outline for future work.

## II. Related work

This section presents current research efforts in the area of applying data processing techniques within M2M network. Stojmenovic [7] considers M2M as a key enabling technology for the CPSs. The author identifies the problem that existing work in the area of M2M communication is based on small-scale M2M models and centralized solutions, while a few existing distributed solutions do not scale well. A paradigm

978-83-60810-66-8/$25.00©2015, IEEE

shift is suggested where end nodes should also make decisions based on local knowledge, instead of only forwarding collected messages to back-end system. By using this new paradigm, M2M solutions could scale to a significantly larger number of M2M devices. In the use-case example, the author considers a smart building control application in which sensors and actuators exchange information directly, without communication with servers, and coordinate by using distributed decision making to react to data. This reactions include opening of windows or injecting fresh air when needed.

Chen et al. [5] introduce an overview of data mining techniques in the area of Internet of Things. They present five data mining functionalities: classification, clustering, association analysis, time series analysis, and outlier analysis. The application areas of data mining are also presented: e-commerce, banking, retail, health care, and city governance. The main research issues are identified in the area of finding erroneous data, analysis of data streams and developing a framework to support big data mining. As for the nodes where data processing is performed, the authors suggest servers in the cloud where open source solutions like Hadoop, HDFS, Storm or Oozie can be used. According to their perception, end devices are used only for data gathering and forwarding towards cloud.

Bruns et al. [9] state that in traditional M2M systems, data processing is usually hard-coded and scattered all over source code, which makes it difficult to maintain. Therefore, they propose a complex event processing system (CEP) which separates event processing from source code. In CEP, event processing is capsulated in rules which can be efficiently adapted and maintained. The authors discuss the application of the proposed system in solar power plants and printer supply and maintenance service. CEP is implemented on M2M server, it processes data streams just as new data arrives to the server.

M2M systems where end devices are serving as nodes which collect measurements from sensors are referred to as Wireless Sensor Networks (WSN). Analytics in WSN is also an ongoing research topic closely connected with the concept of M2M systems. Mahmood et al. [10] propose a taxonomy of data mining techniques for WSN. First level of classification is connected with general data mining classes: frequent pattern mining, sequential pattern mining, clustering and classification. Second level of classification is based upon the ability of the approach to process data in a centralized or distributed way. The third level of classification is determined according to the focus on two different aspects - WSN performance issues and application issues. The approaches which focus on WSN performance issues try to take into account resource constraints like energy, memory, and communication bandwidth. On the other hand, approaches which focus on application issues try to satisfy application requirements without much consideration for WSN performance. The authors group existing data mining techniques for WSN according to the presented taxonomy. Moreover, they also discuss what is the focus of this paper - on which nodes to execute different data mining techniques. Sensor nodes, referred to as M2M devices in M2M system architecture, perform single pass algorithms and forward only the required and partially processed data to the network. In network, referred to as M2M gateway, data from various end devices is collected, and activities as network pattern identification are carried out. On sinks, reffered to as M2M servers, computationally demanding tasks are executed.

Alsheikh et al. [11] present an overview of existing machine learning techniques used in WSNs. They group them into the categories of supervised, unsupervised and reinforcement learning. As important aspects which need to be taken into account when deploying machine learning techniques in WSNs, the authors emphasize power and memory constraints of sensor nodes, topology changes, communication link failures and decentralized management. The main functional challenges for which machine learning techniques were adopted include routing in WSN, clustering and data aggregation, event detection and query processing, localization and objects targeting, and medium access control. As for the nodes where processing is taking place, the authors also consider in-network processing of data since it enables the nodes to rapidly adapt their future behavior and predictions in correspondence with current environmental conditions. However, when executing learning algorithms on-device, special attention needs to be payed not to exhaust the nodes with complex and resource demanding computational tasks.

Suryadevara et al. [6] developed a smart home solution which enables identification of the Activities of Daily Living (ADL) in order to determine the wellness of elderly people. This was done by processing time series of data collected by the sensors deployed at users' homes. Among other things, the authors discuss different storage mechanisms for WSN data. They identify two approaches for storing data in WSNs - centralized and decentralized way. In centralized approach, data is stored and can be analyzed on a node which generates it. In decentralized approach, data is stored on different nodes. The most common decentralized storage approach is data centric storage, where data is stored on a node called sink. Centralized approach is identified as not appropriate for a setup with recurrent bursts of activities since it quickly overfills memory resource. Moreover, when sequences gathered from different sensors need to be processed, as is the case in the solution developed by the authors, data-centric storage appears to be a better solution. Therefore, the authors developed a system which stores sensor data in the form of event activities on a central system which then analyses that data and makes assumptions of ADLs.

Research efforts analyzed within this section focus on presenting current trends in the area of data processing in M2M/IoT/WSN domain. However, we have not identified solutions which would take into consideration optimal position in the network to perform data processing with regard to energy efficiency of the system with limited energy resources.

## III. M2M Architecture

The architecture of our M2M system is shown in Figure 1, and is compliant with functional M2M specification from oneM2M[1] [12] and high-level M2M system architecture by ETSI[2] [13].

Application Dedicated Node (ADN) contains sensors which collect measurements from their physical environment. It contains at least one Application Entity (AE), which is an entity in the application layer that implements M2M application service logic. Examples of these application entities are power metering application or remote blood sugar monitoring application. ADN does not contain Common Services Entity (CSE) which is situated on Middle Node (MN) or Infrastructure Node (IN). CSE is a set of common service functions of the M2M environment, like data management, device management, subscription management and location services. Middle node contains CSEs and can contain one or more AEs. When ADN contains CSE, it is called Application Service Node (ASN). ADN/ASN can communicate directly with IN, or can communicate with IN via MN. In our case scenarios, ADN and ASN communicate via MN. ADN/ASN, MN, IN, defined in oneM2M standard [12], can be referred to as M2M Device, M2M Gateway and M2M Server respectively in previous standards by ETSI [13].

In this paper we focus on M2M communication within smart homes which can include following sensors: temperature, humidity, luminosity, presence, hall effect, electricity consumption or water metering. Based on the data collected by these sensors, various events can be detected, for instance if residences are present in the house, if temperature fluctuates unnecessarily (e.g. a window is opened too long during cold winter or hot summer days) and should be controlled, if power is more affordable in certain times of day and when should specific consumers with variable operating times like washing machine be turned on etc. Moreover, the system can detect outliers and report them to the interested users, like water leakage, extreme temperatures or unusual power consumption. Our system is composed of ADNs/ASNs which monitor temperature fluctuations and an MN through which the devices communicate with IN.

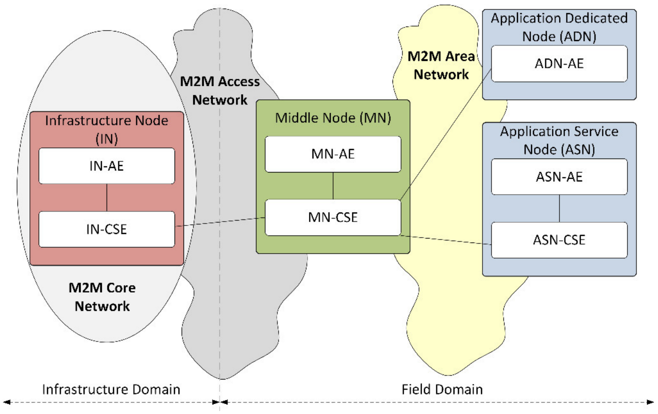

Fig. 1: M2M Architecture

The easiest way to perform the analysis of data collected by sensors is to transfer it to infrastructure domain where servers have plenty of memory and processing power [14]. However, due to rapid development of embedded devices which have more and more processing power and due to application needs for faster response, processing can also take place in field domain, on MNs and ADNs/ASNs [11], [15]. When executing in-network data processing, special attention needs to be paid not to exhaust the nodes with complex computational tasks. By analyzing data in networks, valuable information instead of raw data is delivered to infrastructure domain, from where it can be easily accessed by user applications.

In the first case scenario of our energy consumption measurement process, explained in detail in Section V, end device is according to oneM2M specification an ASN because it contains both AE and partially CSE - data management. In the same scenario, gateway is MN with only CSE functionality. In the second case scenario, end device is an ADN since it contains only AE, while CSE - data management and other functionalities, as well as a part of Application Entities (AE) is executed on MN (gateway).

## IV. Outlier Detection Algorithm

Temperature function shown in Figure 2 recorded temperature values at our laboratory during one week in winter from February $23^{rd}$ until March $1^{st}$. Vertical dotted lines separate measurements belonging to a certain day of the week. The measurements were obtained from sensors and forwarded to back-end system every 10 seconds. Three peaks can be identified, which are marked on Figure 2 and which occurred when the window was opened, and no-one was present in the room. In these cases, temperature fell to around 12°C. The algorithm that we propose has its main goal to raise the alarm when temperature plummets like in those 3 cases. The reason for that is because in such occasions the temperature in the room was too low to reside there. By raising the alarm, window could be closed sooner to prevent those unpleasant conditions.

In order to determine the algorithm which could detect rapid temperature fall, which we define as an outlier from normal temperature fluctuation during the day, we monitored the derivative of the temperature function. Since the temperature function is discrete, its derivative, often referred to as backward difference, is calculated by using the following expression [16]:

$$\Delta_n f(n) = f(n) - f(n-1) \qquad (1)$$

where $f(n)$ is a current temperature value measured by end device, while $f(n-1)$ is the value measured in the last measurement. In our case, the difference between those two consecutive measurements is 10 seconds. By calculating the difference of the function, we wanted to analyze how does the difference of the function behave when the temperature plummets. When analyzing the difference between two consecutive

[2] ETSI (http://www.etsi.org/) - European Telecommunications Standards Institute

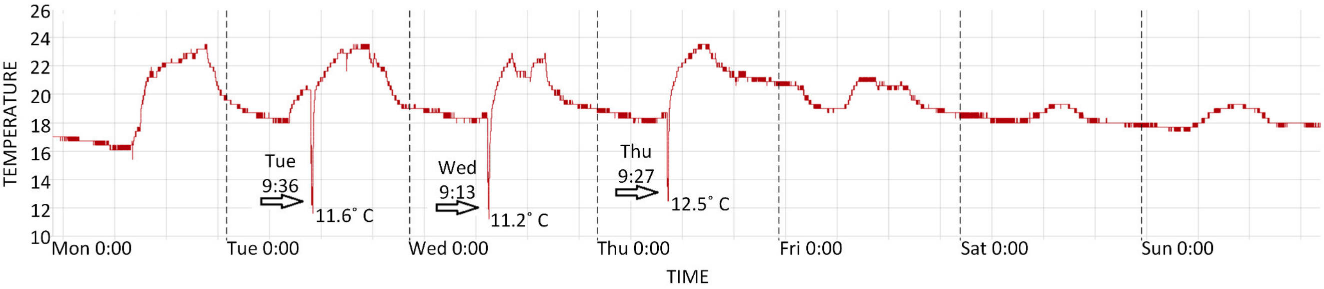

Fig. 2: Measurements from temperature sensor during 1 week in winter

values, extreme descends as the ones seen in Figure 2 cannot be detected since in those events the temperature does not fall in every interval. However, if we monitor the difference in larger time window, which is a good approach when dealing with data that arrives continuously in time [17], rapid decrease can be detected when comparing current measurement with the 5th historic measurement. The equation of such differences calculation is the following:

$$\Delta_n f(n) = f(n) - f(n-5) \qquad (2)$$

where $f(n)$ is current measured value, and $f(n-5)$ is 5th historical measurement, measured 50 seconds ago. We have tried to use more recent historic measurements (1st-4th), but in those cases certain temperature decreases were captured which were not so steep as the ones we wanted to identify. When running an algorithm which analyzes when difference values calculated as in Equation 2 are falling in 10 more than consecutive intervals, extreme descends in temperature like the ones marked in Figure 2 can be detected. The number of falling intervals was set according to empirical evaluation. Table I shows the number of falling intervals for the cases when temperature plummeted. The times of these events were 9:36 on Tuesday, 9:13 on Wednesday, and 9:23 and 9:27 on Thursday. The reason for two captured intervals on Thursday is because temperature was falling for a longer period on that day. The temperature for that case did not fall in every interval, in some intervals it remained unchanged or even slightly grew. Since the algorithm was analyzing constant falls of differences from Equation 2, this particular outlier was captured twice. If the number of intervals in which descend is monitored is between 7 and 10, those rapid falls can always be detected. However, if the number of falling intervals is smaller than 7, then some other events can be captured, which are not interesting to us, like the fall of temperature during night when the heating was off. Since the algorithm in which 10 consecutive falling intervals are detected fits to our needs (it identified rapid temperature fall caused by the opened window), it was implemented on our M2M system in order to monitor energy consumption of end devices in different case scenarios described in detail in the next section.

## V. Energy consumption analysis

The proposed algorithm described in Section IV was implemented on Libelium Waspmote devices v1.2 [18] with XBee communication modules to monitor energy consumption of end devices for two case scenarios: when the algorithm is executed on end devices and when algorithm is executed on gateway or on back-end system. Since device consumes different amounts of energy by executing different tasks during its operating cycle, it was necessary to identify those tasks, measure its duration and power consumed during the execution. Figure 3 shows the tasks and their order of execution for both scenarios.

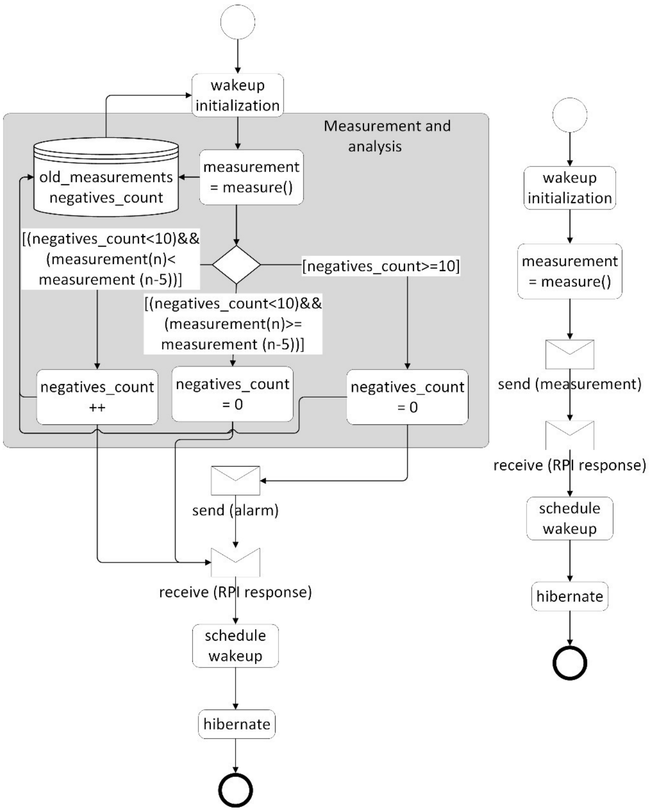

Fig. 3: Activity diagram of end device

In each operating cycle, device wakes up from hibernate mode, which is a state on Waspmote device where lowest amount of energy are consumed. Afterwards, it obtains measurements from sensors. In the first case scenario, shown on the left-hand side of Figure 3, that task is followed by executing the algorithm to detect rapid temperature decrease. When the overseen decrease is identified, the device reports it by sending a message to the gateway. After reporting the alarm message, it waits for a certain amount of time to receive a new message from gateway which contains information for a new task, e.g. if measurements are to be sent in a specified interval instead of forwarding only alarms. If no alarm needs to be raised, the device only waits for a message from the gateway. After the time for receiving message has expired, the device is ready to return to hibernate mode. The process of exchanging messages between end devices and gateway in order to reach an agreement about operating times is described in our previous work [19].

In the second case scenario, shown on the right-hand side of Figure 3, after wake up from hibernate mode and obtaining a measurement from sensor, the end device forwards that data to gateway. Since end device does not execute algorithm for detecting temperature decrease, acquired measurement needs to be sent to back-end system for further analysis. As in the first case scenario, the end device then waits for messages from gateway. After the eventual processing of the received message from gateway, end device goes back to hibernate mode.

Table II shows power consumption and duration of tasks executed on end devices when analysis is performed on-device (ASN functionality), while Table III shows power consumption and duration of tasks executed on end devices when analysis is performed on gateway or back-end system (ADN functionality of devices). Current consumption and voltage levels are measured by using Rigol DS1102D oscilloscope[3].

TABLE II: Power consumption and duration of tasks in the case of on-device analysis

| state/task | wake-up initialization | measure | analyze | send | receive | handle response |
|---|---|---|---|---|---|---|
| power consumption (mW) | 70,13 | 130,83 | | 258,95 | 262,68 | 141,12 |
| duration (ms) | 80 | 70 | | 255,3 | 208,8 | 1 |

TABLE III: Power consumption and duration of tasks when analysis is not performed on-device

| state/task | wake-up initialization | measure | send | receive | handle response |
|---|---|---|---|---|---|
| power consumption (mW) | 70,13 | 77,7 | 258,95 | 262,68 | 141,12 |
| duration (ms) | 80 | 10 | 255,3 | 208,8 | 1 |

Figure 4 shows the energy consumption for one operating cycle. The left-hand and central columns represent energy consumption for the first case scenario when analysis is performed on-device. Since the end device in that scenario needs to raise an alarm, it sends a message to the gateway only when temperature value plummets. The consumption of that operating cycle is shown in the left-hand column. When rapid temperature decrease is not detected, the device does not send any data to gateway. The consumption of such operating cycle is shown in the central column. The consumption of the operating cycle in second case scenario, when end device reads the value from sensor and forwards it to the gateway, is shown in the right-hand column of Figure 4.

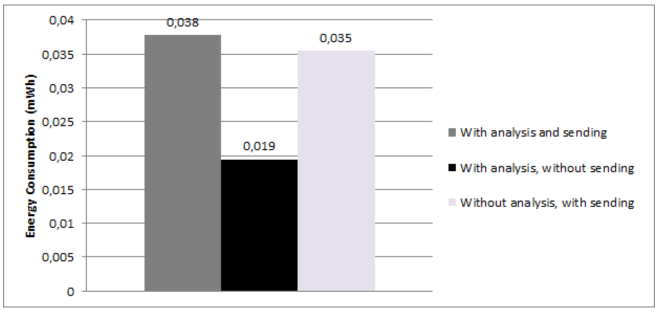

Fig. 4: Energy consumption of end devices during one operating cycle

It can be observed that energy consumption presented in the left-hand and right-hand columns is similar. It appears that on-device analysis does not add much to total energy consumption of the device in one operating cycle. However, when comparing the power consumption for measurement and analysis task in Table II - 130.8 mW and only measurement task in Table III - 77.7 mW, it can be observed that for the scenario when data is analyzed, the power consumption is around 70% higher. But since both actions last for quite a short time (0,07 s and 0,01 s), they do not have a large influence on the overall energy consumption. On the other hand, energy consumption shown in the central column is about 50% lower than in two aforementioned cases. The reason for that lies in the fact that sending data has a high influence on overall energy consumption. Although it consumes only twice as much power compared to measuring and processing, it lasts around 3.5 times longer.

Total energy consumption during one week for the two cases when analyzing data presented in Figure 2 is shown in Figure 5. Left-hand column shows consumption for the first case scenario when analysis is performed on-device. In that scenario, in most of the operating cycles the device was only performing measurements and analysis without sending alarm message to the gateway due to the fact that on the

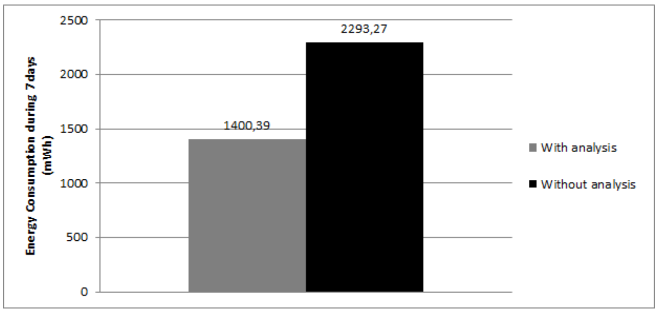

Fig. 5: Energy consumption of end devices during 1 week

[3] http://www.rigolna.com/products/digital-oscilloscopes/ds1000d/ds1102d/

analyzed data set alarms were needed to be raised only on four occasions. Since operating cycle which includes analysis without sending consumes around 45% less energy than the operating cycle in which the measurement data is forwarded to back-end system, the total consumption of the first case scenario is around 40% less than the consumption of the second case scenario which is shown in the right-hand column in Figure 5 and in which data was sent during each operating cycle.

As a power source for end devices used in this experiment we had at our disposal batteries with capacity of 6600 mAh. According to energy consumption shown in Figure 5, and by taking into account that the average voltage of the battery is 3.7 V, by using the first case scenario, device can operate for 17.4 weeks. By using the second case scenario, the device can remain operational for 10.6 weeks. For this particular application and data set, on-device analysis extends end-device lifetime for about 65%.

## VI. Conclusion

This work presented the analysis of the influence of data measurement analysis on energy efficiency in Machine-to-Machine system with Libelium Waspmote v1.2 devices. By implementing a specific outlier detection algorithm on end devices, it was shown that on-device data analysis when using this algorithm does not consume as much energy as communication. More energy can be saved by reducing communication. As a result, it can be advisable to perform local data analysis on end devices in those cases when the duration of the measurement and analysis tasks is shorter than the duration of communication tasks.

If the data set were different and temperature plummeting occurred more often, the difference in total energy consumption during one week would have been smaller. However, since temperature outliers do not occur often, the scenario in which the measurement analysis is performed on-device will usually spend less energy than the scenario where measurement analysis is performed on gateway or on back-end system.

In future work, we plan to compare energy efficiency for more sophisticated algorithms in smart home environment which would enable event detection. We also plan to extend this research to different types of applications, not only the applications which should raise alarms, but applications which require continuous or periodical streaming.

***Abstract*—In this work we present the results of design of smart dust sensor platform for combustible gas leakage monitoring. During the design process we took into account a lot of combustible gas sensor specific problems such as their huge power consumption, the necessity to work in explosive environment and sensor parameters degradation. To decrease power consumption we designed specific energy efficient algorithms for measurements. The resulting average power consumption of the node is low enough for one year autonomous lifetime. The methods and algorithms which was designed are very promising for catalytic combustible gas sensors.**

## I. Introduction

SMART dust is a term which was introduced in 2001 by Kristopher Pister and it is related to tiny devices for environmental monitoring with self-organization feature. Such devices should be able to measure different physical parameters, to process data and to send it to the end user through wireless data transmission channel. The main functional block of the "smart dust" is a sensor node which consists of microcontroller, memory, wireless transceiver, power source and one or several sensors (Fig. 1).

The power source of the sensor node is typically batteries. However, in the last time several platforms were designed which use supercapacitors, alternative power sources or their combination. Sensor node generally use microcontrollers which combine enough computational capability and performance and low power consumption. All these functions are very important for autonomous "smart dust". Wireless transceivers very often comply IEEE 802.15.4 standard and ZigBee specification. Such devices are low power and are able to transmit data for the distances up to 30-50 meters. The most popular sensors are temperature and humidity sensors and accelerometers. They are widely used for "smart dust" because of their low power consumption.

During design process of wireless sensor network for gas monitoring it is necessary to take into account that combustible gas sensors consume power up to several hundreds milliwatt. At the same time it is necessary for "smart dust" sensor nodes to have as long autonomous lifetime as it is possible. To increase sensor node autonomous lifetime, developers strive to select electronic components with low power consumption, to use energy harvesting technologies [1], [2], to equip sensor nodes with power sources with huge capacity [1], [3] or to use "smart" algorithms and methods [4], [3], [13] to decrease power consumption.

In this work we present the results of design of "smart dust" sensor node for combustible gas leakage monitoring as well as the results of design of energy efficient measurement algorithms for power consumption decrease.

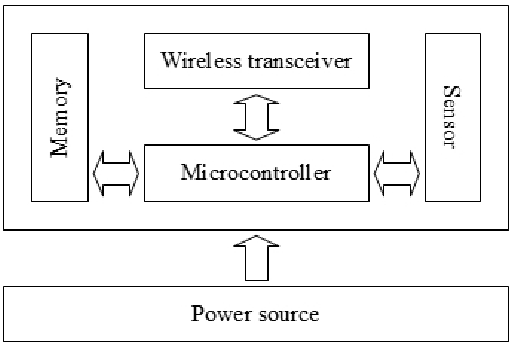

Fig 1. Typical structure of the "smart dust" sensor node.

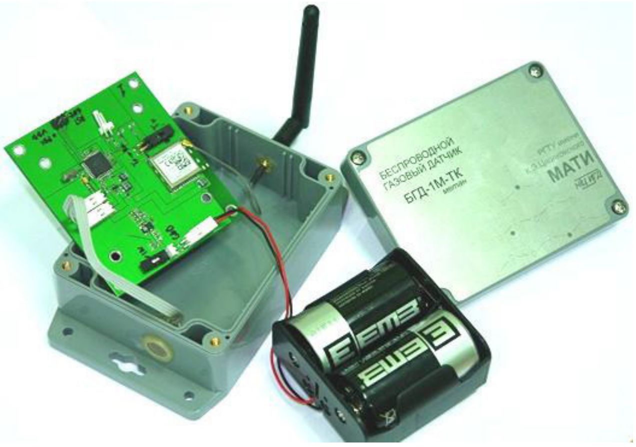

Fig 2. The smart dust gas sensor node prototype.

978-83-60810-66-8/$25.00©2015, IEEE

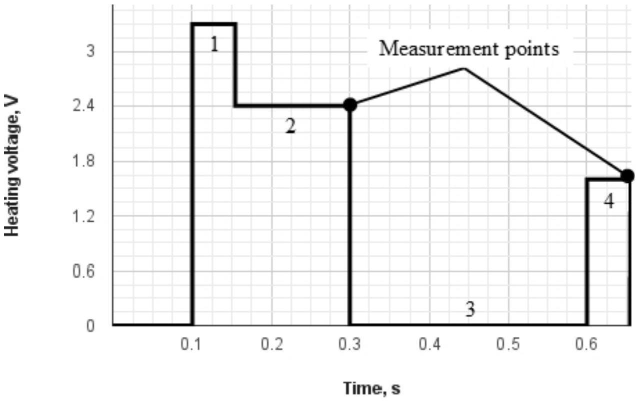

Fig 3. Multistage pulse heating profile.

At present time there are a lot of "smart dust" platforms. Ones of the firsts platforms are TelosB [5] and the family of modules MICA (MICA/MICA2/MICAz) [6], [7]. These platforms used light, temperature and humidity sensors, but end user was be able to add almost every kind of sensors through available connectors and interfaces.

After that commercial modules took their place [8], [9]. With that, typical sensor node became modular. The platform now is a motherboard and it is possible to connect other boards to it (with sensors, wireless transceivers and data processing modules). The main philosophy of these platforms is to provide every possible configuration of the sensor node to the end user, both from software and hardware points of view, using all platform possibilities.

However, all available sensor nodes do not take into account all problems which are related with using wireless sensor networks for combustible gas leakage monitoring. Particularly, such problems as huge power consumption of catalytic, semiconductor and optical sensors, the necessity to work in explosive environment and sensor parameters degradation.

The smart dust sensor node (Fig. 2) which we present in this work is able to work with catalytic combistible gas sensors.

Heating-up of the sensor to working temperature is performed using PWM-controlled voltage. With that, sensor temperature is controlled using complex algorithm. Sensor response measurements are performed in different temperature points. And these sensor response measurements are used to calculate combustible gas concentration.

## II. Experimental Details

In this paper we used the commercial catalytic sensors manufactured by NTC IGD, Russia. The sensor box height is 9.5 mm and diameter 9 mm, power consumption is 200 mW in the continuous measurement mode. Its relatively low power consumption (compare to Figaro, Nemoto and Hanwei) is achieved by applying a heater implemented as 10 µm platinum micro wire in glass insulation (2 µm). The active sensor has a platinum micro wire covered by porous gamma alumina oxide material that is used as catalyst support for catalytically active metals (mixture of Pd and Pt). In order to impregnate the catalyst support by the catalytic metal, salts of palladium chloride ($PdCl_2$) and platinum acid ($H_2PtCl_6$) are used. After annealing at 500 C, noble metal clusters are formed in the catalyst support.

Circuits for gases detection with catalytic sensors are commonly based on the Wheatstone bridge, which includes two resistors and two sensors, one active and one for reference. Most of the power goes into the sensor heating process (about 450 C for methane detection), required to perform the measurement. The power consumption is about 200 mW for Wheatstone bridge and that’s much higher than suitable for wireless application.

Excluding the reference sensor decreases power consumption. But at the same time it’s necessary to compensate atmosphere humidity and temperature which usually performed by reference sensor. This compensation was made by applying the specific multistage heating pulse. This method was offered and discussed in works [4], [3], [14].

Here we use four stages for every multistage pulse (1-4 regions in the diagram, Fig. 3).

The first and second stages provide the sensor heating to the external diffusion region of catalysis and the partial evaporation of surface water (~450 C). These stages are followed by a pause (third stage) during which the surface is

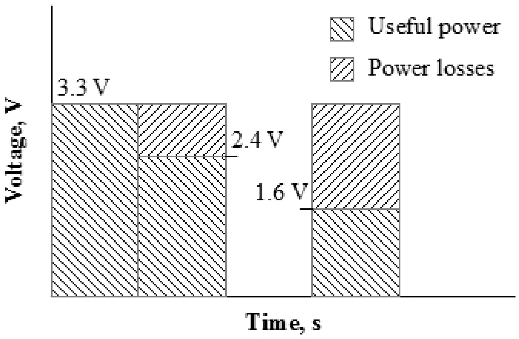

Fig 4. Useful and wasted power during multistage heating pulse in DAC circuit design.

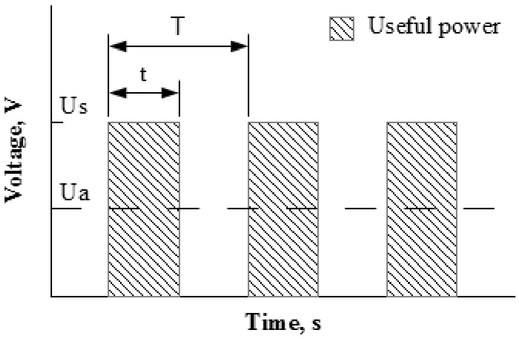

Fig 5. Pulse-width modulation parameters.

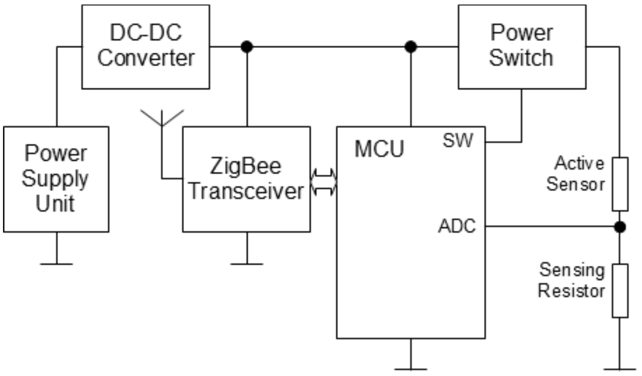

Fig 6. Block diagram of the wireless gas sensor node.

not heated. The final fourth stage heats the sensor to the beginning of the kinetic region of catalysis (~200 C). After this pulse, the element cools down to ambient temperature. Heating voltages for the stages are 3.3 V, 2.4 V, 0 V and 1.6 V respectively.

The measurement result is the difference between sensor voltages at two different temperatures (measurement points in the diagram).

Multistage heating pulse is formed by applying different levels of voltage to sensing circuit. Traditionally it can be done using DAC with buffer amplifier. But in this case relatively huge amount of power is wasted by means of power dissipation on buffer amplifier (Fig. 4). Another way is to generate these levels using pulse-width modulation.

Pulse-width modulation (PWM) is frequently used to heat the sensors for working temperature [10] because it allows one to change the average voltage with fixed voltage from power supply.

Pulse-width modulation is the method of regulation of average voltage value on the load by controlling pulse duty ratio.

The main parameters of PWM are its period (T) or frequency, pulse width (t), supply voltage ($U_S$) and average voltage ($U_A$) on the load. These parameters are illustrated in Fig. 5.

The average voltage of PWM can be solved using following equation

$$U_A=\frac{t}{T}U_S \tag{1}$$

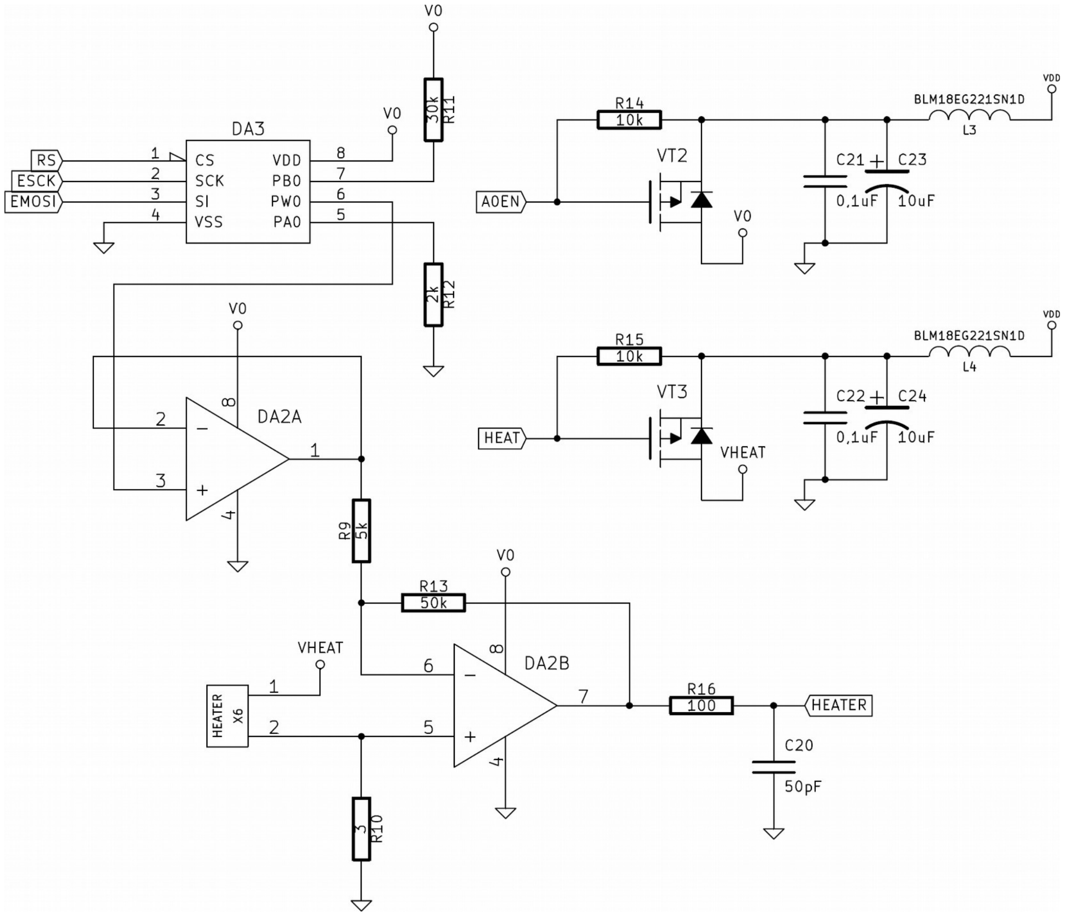

Fig 7. Sensing circuit for multistage pulse with PWM heating.

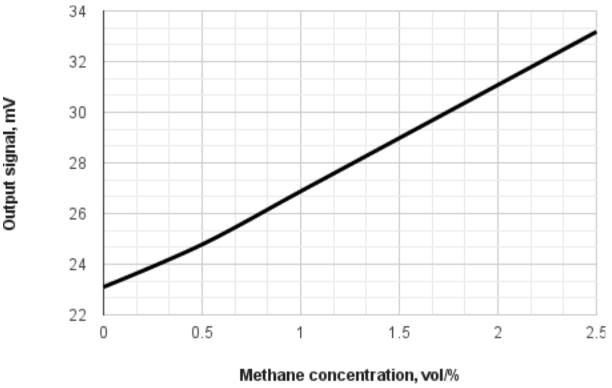

Fig 8. The dependence of the output signal of the sensor on the methane concentration.

As it follows from this equation, for the same PWM frequency and supply voltage changing pulse width it's possible to regulate average voltage on the load.

## III. Sensor Node Design

The full block diagram of the wireless gas sensor node is presented in Fig. 6. The sensor node is based on an AtXmega32A4 microcontroller and use an ETRX3 communication module. The selection of the MCU was mainly driven by the following requirements: low power consumption, on-chip temperature sensor, and good ADC integrated in MCU.

The wireless communication unit employs the low power ETRX3 wireless modem supporting IEEE 802.15.4 standard (ZigBee specification) and transmitting in unlicensed 2.4 GHz ISM band. The modem has an integrated chip antenna used in this design (up to 25 m) and a connector for an external antenna to enable a boost mode allowing data transmission for up to 350 m. Besides that, the modem has a number of self-x features enabling, for instance, WSN self-configuration and self-diagnostics which significantly reduce WSN debugging and deployment time.

Voltage conversion is performed by a DC-DC converter TPS63060 to provide maximum efficiency. The device generates stable output voltage of 3.3 V from 2.5 V to 12 V on its input.

Sensing circuit is presented in Fig. 7.

Since it is necessary to have long autonomous lifetime for wireless sensor node, all measurements are performed periodically. But at the same time, according to safety standards [11], [12], sensor node response time should be less than 20 seconds. Therefore, it is reasonable to perform two measurements every 20 seconds to assure this claim. To maintain low power consumption between measurements, the measurements circuit is turned off using power switch based on VT2 transistor.

As it was said before, sensor heating is performed using signal with pulse-width modulation. Here we use PWM frequency of 10 kHz. The average heating voltage is regulated by changing pulse duty rate with fixed power supply voltage. Therefore, with power supply voltage value of 3.3 V and voltage values for pulse stages of 3.3, 2.4, 0 and 1.6 V, duty rate values are 100, 73, 0 and 48 percent respectively. Voltage switching is performed using VT3 transistor. Since this switch also provides power supply for sensor itself, all measurements are performed with activated heating.

The sensor signal is the voltage from resistive divider which consists of sensor itself and reference resistor. The signal goes to the amplifier with gain value of 10.

Another input of the amplifier is connected to the output of voltage reference circuit. This circuit provides reference voltage for different stages of multistage pulse to exclude constant part of the signal from the output.

The circuit consists of resistive divider which is based on digital potentiometer. This potentiometer controls the reference voltage value. This voltage goes to the buffer amplifier. The output of this amplifier is the output of the circuit.

For all measurements built-in ADC of MCU with internal 1 V reference voltage source is used.

## IV. Sensor Response

As it was said before, the measurement result is the difference between sensor voltages at two different temperatures. The first value is the voltage at the end of the second stage of pulse heating (which heats the sensor up to 450 C and lasts for 190 ms). The second value is the voltage at the end of the fourth stage of pulse heating (which heats the sen-sor up to 200 C and lasts for 550 ms). This is done to compensate the absorption of moisture on the sensor surface that occurs between two cycles, and influences the quality of the measurement.

The dependence of the output signal of the sensor on the methane concentration is shown in Fig. 8. The value of the signal is changed from 23 mV for 0% of CH4 to 33 mV for 2.5% of CH4. Therefore, sensor sensitivity for this method is about 4 mV / %CH4.

The sensor node operates as a two-threshold device. Threshold values are 0.5 and 1 % vol. If the methane concentration is less than 0.5 % vol., there is no reaction from the sensor node. If the concentration is more than 0.5 % vol. methane, sensor node provides the light and sound alarm. This alarm is different for every threshold. At the same time, after every threshold is exceeds, node sends specific information to the data sink node.

## V. Power Consumption

The power consumption of the wireless sensor node is presented in Fig. 9.

As it was shown before, the advantages from PWM heating are in second and fourth stages of multistage pulse. For second stage the resulting power consumption is 150-160 mW. For fourth stage it is less than 80 mW. The average power consumption for overall multistage pulse is 81 mW. This value includes data transmission.

Measurements are performed periodically with period length of 10 seconds. The length of multistage pulse is about 0.6 seconds. The average power consumption, including data transmission, for overall period is about 4.9 mW.

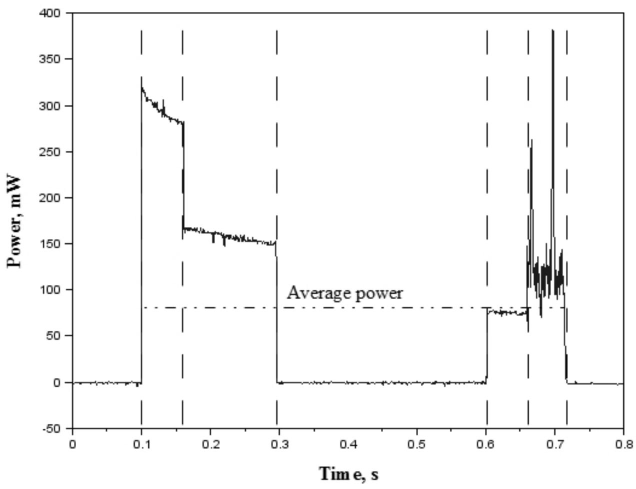

Fig 9. The power consumption of the wireless sensor node.

Since node power consumption is relatively low, the power consumption of data transmission is large enough part in overall power consumption.

The average power consumption of that data transmission cycle is about 125 mW. And its length is about 0.06 seconds. The average power consumption of multistage pulse including data transmission is about 81 mW. And its length is 0.6 seconds.

So the length of data transmission is about 10% of the pulse length. And during this time the power consumption is much higher than average values.

At the same time, usually it doesn't necessary to send data every time than measurements were made. It's much reasonable to transmit it only when gas concentration was changed or in other emergency situations.

The average power consumption excluding data transmission cycle is about 77 mW. The average power consumption for overall period in this case is 4.6 mW. These values are about 5% lower.

These power consumption values are relatively low. Since capacity of a single cell lithium battery of D type is typically 15000 mAh, its voltage is 3.6 V and there are 8760 hours a year, the average power consumption for one year sensor node lifetime is no more than 6 mW. Therefore, the average power consumption of the node is low enough for one year autonomous lifetime. This duration also complies with safety standards which claim to perform gas sensors calibration every year.

## VI. Conclusion

In this work the design of the "smart dust" sensor node for wireless sensor network for combustible gas concentration monitoring was presented.

The analog and digital circuits and energy efficient algorithms for sensor response measurements were designed. The parameters of designed sensor node was investigated.

The calculations of methane concentration were made using analysis of commercial catalytic methane sensor response in multistage pulse heating mode of operation which includes four heating stages. With that, sensor heating in every stage was performed using PWM voltage regulation unlike traditional heating with constant voltage.

It was shown that PWM regulation allows to save about 20% of power which sensor consume. Particularly the average power consumption for multistage pulse is 81 mW. And for 10 seconds measurement period the average power consumption value is about 4.9 mW.

The power consumption values provides the autonomous lifetime of the node more than one year. Therefore, the methods and algorithms which was designed are very promising for catalytic combustible gas sensors.

***Abstract*—For any wireless communications antenna system becomes indispensable. In this paper we analyzed linear array, planar array and three – dimensional (3D) array antennas. The array systems are simulated in Matlab based on uniform linear array antennas. Comparisons between planar array antenna and 3D array antenna are provided take into account different phases of currents injected in antenna elements. Also we propose to use the array antenna in WSN due to the advantages in signal to noise ratio and power consumption.**

## I. Introduction

A radio antenna, transmitting or receiving, is an independent and yet integral component of any wireless communication system. An antenna acts as a transducer that converts the current or voltage generated by the feeding-based circuit, such as a transmission line, a waveguide or coaxial cable, into energy field propagating through space and vice versa. Each radio signal can be represented as an electromagnetic wave that propagates along a given direction. The wave field strength, its polarization and the direction of propagation determine the main characteristics of an antenna operation [1].

Antennas can be divided in different categories, such as wire antennas, aperture antennas, reflector antennas, frequency independent antennas, horn antennas, printed and conformal antennas, and so forth. When applications require radiation characteristics that cannot be met by a single radiating antenna, multiple elements are employed forming “array antennas”. Arrays can produce the desired radiation characteristics by appropriately exciting each individual element with certain amplitudes and phases.

Over the last decade, wireless technology has grown at a formidable rate, thereby creating new and improved services at lower costs. This has resulted in an increase in airtime usage and in the number of subscribers. Recently, smart antenna systems have been widely considered to provide interference reduction and improve the performance of wireless mobile communication. The term “smart antenna” reflects the antenna’s ability to adapt to the communication channel environment in which it operates. Smart antenna arrays with adaptive beamforming capability are very effective in the suppression of interference and multipath signals. One practical solution to this problem is to use spatial processing. Spatial processing is the central idea of adaptive antennas or smart-antenna systems [2].

In this paper we are focused on changing of the phase of currents injected in antenna elements in order to conclude relating to position control of the radiation pattern characteristic and directivity.

## II. ANTENNA ARRAY RADIATION PATTERN

An antenna *radiation pattern* or *antenna pattern* is defined as “mathematical function or a graphical representation of the radiation properties of the antenna as a function of space coordinates. In most cases, the radiation pattern is determined in the far-field region and is represented as a function of the directional coordinates.” [3] The radiation property of most concern is the two- or three-dimensional spatial distribution of radiated energy as a function of the observer’s position along a path or surface of constant radius.

Antennas with a given radiation pattern may be arranged in a structure (line, plane, three – dimensional) to yield a different radiation pattern. Given an antenna array of identical elements, the radiation pattern of the antenna array may be found according to the pattern multiplication theorem [4]:

*Array pattern = Array element pattern x Array factor*

where *Array element pattern* is the pattern of the individual array element and *Array factor* is a function dependent only on the geometry of the array and the excitation (amplitude, phase) of the elements.

### A. Linear Array

The array factor (AF) is independent of the antenna type assuming all of the elements are identical. Thus, isotropic radiators may be utilized in the derivation of the array factor to simplify the algebra. The field of an isotropic radiator

□ Romanian Ministry of Education, CNCS – UEFISCDI

978-83-60810-66-8/$25.00©2015, IEEE

located at the origin may be written as (assuming $\theta$-polarization):

$$E_\theta = I_0 \frac{e^{-jkr}}{4\pi r} \tag{1}$$

where:

$I_0$ = the complex excitation of the isotropic radiator,

$k$ = the free space wave number,

$r$ = distance of the observation point from the origin.

In our approach, we assume that the elements of the array are uniformly – spaced with a separation distance $d$ (see Fig. 1).

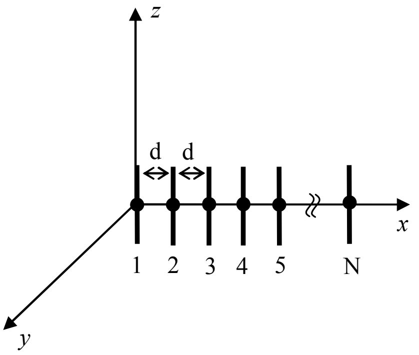

Fig. 1 The linear array antennas

The current magnitudes of the array elements are supposed to be equal and the current on the array element located at the origin is used as the phase reference (zero phase).

$$I_1 = I_0 \quad I_2 = I_0 e^{j\phi_2} \quad \cdots \quad I_N = I_0 e^{j\phi_N} \tag{2}$$

The far electromagnetic fields of the individual array elements are:

$$\begin{aligned} E_{\theta_1} &\approx I_0 \frac{e^{-jkr}}{4\pi r} = E_0 \\ E_{\theta_2} &\approx I_0 e^{j\phi_2} \frac{e^{-jk(r-d\cos\theta)}}{4\pi r} = E_0 e^{j(\phi_2 + kd\cos\theta)} \\ &\vdots \\ E_{\theta_N} &\approx I_0 e^{j\phi_N} \frac{e^{-jk[r-(N-1)d\cos\theta]}}{4\pi r} = E_0 e^{j\left[\phi_N + (N-1)kd\cos\theta\right]} \end{aligned} \tag{3}$$

The overall array far field is found using superposition and could be express as:

$$E_\theta = E_{\theta_1} + E_{\theta_2} + E_{\theta_3} + \ldots + E_{\theta_N} = E_0 * AF \tag{4}$$

The array factor for a uniformly – spaced $N$ – element linear array from (4) is:

$$AF = \left[1 + e^{j(\phi_2 + kd\cos\theta)} + \ldots + e^{j\left[\phi_N + (N-1)kd\cos\theta\right]}\right] \tag{5}$$

A uniform array is defined by uniformly – spaced identical elements of equal magnitude with a linearly progressive phase from element to element:

$$\phi_1 = 0 \quad \phi_2 = \alpha \quad \phi_3 = 2\alpha \cdots \phi_N = (N-1)\alpha \tag{6}$$

Inserting this linear phase progression into the formula for the general $N$ – element array, we obtain:

$$AF = \left[1 + e^{j(\alpha + kd\cos\theta)} + \ldots + e^{j(N-1)[\alpha + kd\cos\theta]}\right] = \sum_{n=1}^{N} e^{j(n-1)\psi} \tag{7}$$

The function $\psi$ ($\psi = \alpha + kd\cos\theta$) is defined as the array phase function and is a function of the element spacing, phase shift, frequency and elevation angle. If the array factor from (5) is multiplied by $e^{j\psi}$, the result is:

$$AF * e^{j\psi} = \left[e^{j\psi} + e^{2j\psi} + e^{3j\psi} + \ldots + e^{jN\psi}\right] \tag{8}$$

Substracting the array factor from the equation above, we obtain:

$$AF = e^{j(N-1)\frac{\psi}{2}} \frac{\sin\left(\frac{N\psi}{2}\right)}{\sin\left(\frac{\psi}{2}\right)} \tag{9}$$
