# Proceedings of the International Multiconference on Computer Science and Information Technology

October 20 – 22, 2008. Wisła, Poland

Volume 3 (2008)

DEAR Reader, it is our pleasure to present to you Proceedings of the 2008 International Multiconference on Computer Science and Information Technology (IMCSIT'08), which will take place in Wisła, Poland, on October 20-22, 2008. IMCSIT'2008 will be co-located with the XXIV Autumn Meeting of the Polish Information Processing Society (PIPS).

IMCSIT is a result of the evolutionary process. In 2005 a Scientific Session took place during the XXI Autumn Meeting of PIPS and consisted of 27 refereed presentations. After this relative success (we have advertised the Session very late in the year) we have decided to expand and extend it into a full-blown conference but continue cooperation (co-location) with the Autumn Meetings of PIPS. As a result of a steady growth, in 2008, IMCSIT will consists of the following events (and Proceedings are organized into sections that correspond to each of them):

- Workshop on Agent Based Computing (ABC V),
- 3rd International Symposium: Advances in Artificial Intelligence and Applications (AAIA'07),
- Workshop on Computer Aspects of Numerical Algorithms (CANA'08),
- Computational Linguistics—Applications (CLA'08),
- 8th International Multidisciplinary Conference on e-Commerce and e-Government (ECOM-08),
- 4th Workshop on Large Scale Computations on Grids (LaSCoG'08),
- First International Symposium Multimedia—Applications and Processing (MMAP'08),
- International Conference on Principles of Information Technology and Applications (PITA'08),
- International Workshop on Real-Time Software (RTS'08),
- 3rd International Workshop on Secure Information Systems (SIS'08),
- Workshop on Ad-Hoc Wireless Networks: Urban Legends and Reality (WAHOC'08),
- Workshop on Computational Optimization (WCO'08).

These conferences had their own Organizers and a Program Committees (listed in these Proceedings). We would like to express our warmest gratitude to all of them for their hard work in attracting and later refereeing 214 submissions.

IMCSIT'2008 was organized under patronage of Professor Barbara Kudrycka, Minister of Science and Higher Education and Waldemar Pawlak, Deputy Prime Minister and Minister of Economy. Furthermore, IMCSIT'2008 was organized in cooperation with the Poland Chapter of the IEEE Computer Society, Systems Research Institute Polish Academy of Sciences, Institute of Computer Science of the Polish Academy of Sciences, Institute of Innovation and Information Society, and Asociación de Técnicos de Informática.

Additionally, the 3rd International Symposium: Advances in Artificial Intelligence and Applications (AAIA'08) was devoted to the memory of Professor Ryszard S. Michalski, and organized in cooperation with:

- Poland Chapter of the IEEE Computational Intelligence Society,
- Polish Neural Network Society,
- World Federation of Soft Computing,
- European Society for Fuzzy Logic And Technology, and
- European Neural Network Society.

We would also like to mention that the 1st International Symposium: Advances in Artificial Intelligence and Applications (AAIA'2006) was devoted to the memory of Professor Zdzisław Pawlak. During this event a special awards carrying his name and recognizing "a general contribution" and "a contribution by a young researcher" were awarded. This year the Zdzislaw Pawlak Awards will be presented for the third time. They are sponsored by the Mazowsze Section and the Board of the Polish Information Processing Society.

Finally, we have utilized a unique opportunity brought about by co-location of a scientific/academic event (IMCSIT'2008) and a business IT oriented one (Autumn Meeting of PIPS) to address the inter-relations between the two. To this effect, in cooperation with the NESSI Technology Platform, we have organized a special joint session devoted to the IT Research and Development activities in Poland and in the European Union. During this session, for the first time, a Jan Łukasiewicz award will be given to the most innovative IT company in Poland.

During IMCSIT'2008 we plan three keynote presentations: Paolo Bresciani will talk about "Software and Services in the Future Internet; the 7th Framework Programme Perspective," Mike Hinchey will present a talk entitled "You Can't Get There from Here!Problems and Potential Solutions in Developing New Classes of Complex Computing Systems," finally, Zdravko Karakehayov, who is an IEEE Distinguished Visitor will present a talk devoted to "Wireless Ad-hoc Networks: Where Security, Real-Time and Lifetime Meet." Papers based on the latter two presentations can be found in these Proceedings.

We would like to express our gratitude to the Minister of Science and Higher Education for financial support in preparing and publishing this volume.

We hope that you will enjoy this volume and find it useful in your work. We would also like to invite you to participate in the next edition of IMCSIT as well Autumn Meeting of PIPS which will take place in Mrągowo in October of next year.

MEMBERS OF THE 2008 IMCSIT ORGANIZING COMMITTEE:

**Maria Ganzha,** Conference Chair, Systems Research Institute Polish Academy of Sciences, Warsaw and Elbląg University of Humanities and Economy, Elbląg.

**Marcin Paprzycki,** Systems Research Institute Polish Academy of Sciences, Warsaw and Management Academy, Warsaw.

**Tomasz Pełech-Pilichowski,** AGH University of Science and Technology, Kraków.

## TABLE OF CONTENTS

### Workshop on Agent Based Computing V:

### 3rd International Symposium Advances in Artificial Intelligence and Applications:

## Computer Aspects of Numerical Algorithms:

## Computational Linguistics–Applications:

## 8th International Multidisciplinary Conference on e-Commerce and e-Government:

## $4^{\text{th}}$ Workshop on Large Scale Computations on Grids:

## First International Symposium on Multimedia–Applications and Processing:

## International Conference on Principles of Information Technology and Applications:

## International Workshop on Real Time Software:

## 3$^{\text{rd}}$ International Workshop on Secure Information Systems:

## Workshop on Wireless and Unstructured Networking: Taming the Stray:

## Workshop on Computational Optimization:

# Workshop on Agent Based Computing V

ORGANIZED within the framework of the International Multiconference on Computer Science and Information Systems and co-located with the XXIV Autumn Meeting of the Polish Information Processing Society.

Agent-based computing has been hailed as the next significant breakthrough in software development, with the potential to affect many aspects of computer science, from artificial intelligence to the technologies and models of distributed computation. Agent-based systems are capable of autonomous action in open, dynamically-changing environments. Agents are currently being applied in domains as diverse as business information systems, computer games and interactive cinema, information retrieval and filtering, user interface design and industrial process control. The aim of the ABC'08 is to bring together researchers and developers from industry and academia in order to report on the latest scientific and technical advances, discuss and debate the major issues, and showcase the latest systems.

ABC Workshop welcomes submissions of original papers concerning all aspects of software agents. Submissions involving both implementation and theoretical issues are encouraged.

Topics include but are not limited to:

- Agent architectures
- Agent-oriented software engineering
- Agent-based simulations
- Agent benchmarking and performances
- Agent communication, coordination and cooperation
- Agent languages
- Agent learning and planning
- Agent mobility
- Agent modeling, calculi, and logics
- Agent security
- Agents and Service Oriented Computing
- Agents in the Semantic Web
- Applications and Experiences
- Simulating and verifying agent systems
- Multiagent Systems Product Lines
- Multi-Agent Systems in Applications
- Disaster Management
- E-commerce
- Workflow management and business processes
- Other areas

## Organizing Committee

**Maria Ganzha,** EUH-E and IBS PAN, Poland
**Marcin Paprzycki,** WSM and IBS PAN, Poland
**Shahram Rahimi,** Southern Illinois University, USA

## International Programme Committee

**Myriam Abramson,** Naval Research Laboratory, USA

**Stanislaw Ambroszkiewicz,** Institute of Computer Science, Polish Academy of Sciences, Poland

**Costin Badica,** University of Craiova, Romania

**Giacomo Cabri**, Università di Modena e Reggio Emilia, Italy

**Radovan Cervenka,** Whitestein Technologies AG, Slovakia

**Krzysztof Cetnarowicz,** AGH - University of Science and Technology, Poland

**Walter Binder,** University of Lugano, Switzerland

**Bengt Carlsson,** Blekinge Institute of Technology, Sweden

**Vladimir Gorodetsky,** SPII RAS, Russia

**Dominic Greenwood,** Whitestein Technologies AG, Switzerland

**Henry Hexmoor,** Southern Illinois University, USA

**Tomas Klos,** Delft University of Technology, The Netherlands

**Zofia Kruczkiewicz,** Wroclaw University of Technology, Poland

**Michele Loreti,** Università di Firenze, Italy

**Beniamino di Martino,** Seconda Università di Napoli, Italy

**Viorel Negru,** Western University of Timisoara, Romania

**Ngoc-Thanh Nguyen,** Wroclaw University of Technology, Poland

***Abstract*—Effective study of autonomous agents is a challenging activity, for researchers and programmers alike. In this paper we introduce a new agent environment built on top of the tank-simulation game Robocode. We consider this game a good choice for testing agent programming strategies and an excellent learning opportunity. We integrated SWI-Prolog into Robocode and built an architecture for writing agents with Prolog. Game generated events are translated by our framework into predicate invocations, allowing the agent to perceive the environment. An API to issue commands to the tank from Prolog acts as agent's effectors. We tested our architecture by implementing a simple autonomous agent that uses a static strategy.**

## I. Motivation

AGENT oriented programming is hailed to be the next paradigm shift in software engineering. Four key notions were identified that distinguish agents from arbitrary programs: reaction to the environment, autonomy, goal-orientation and persistence [4]. A lot of research goes in the areas connected to the field. Almost unquestionable goes the statement that the most important feature is autonomy, without which an agent can not be. A system is autonomous to the extent that its behavior is determined by its own experience [5].

The agent related ideas were around for some time and under different names. If we are to consider programming games like Robocode [3], we will see that these robots not only fulfill most if not all of the requirements to be named "agents", but the environment itself is well defined and complex enough to provide insight into harder real-life problems. We will describe with greater detail later on the characteristics of the game and the challenges it poses.

Logic programming, both as a field of science and as a practical tool, is old and new at the same time. Starting with the famous statement made by Kowalski, "algorithm = logic + control", made back in 1979 [6], the field knew ups and downs for the last 30 years. Although this may seem relatively old for the computer science field, there is still a lot of room for improvement. Software agents, especially, can benefit from a declarative logic programming language like Prolog and its dialects.

Last but not least, we strongly believe that research should be done as close to a practical field as possible, in order to benefit from a quick feedback loop. We chose the tank-simulation game Robocode to be our practical software virtual environment and Prolog our agent programming language. Thus we provide a new architecture for developing and experimenting agent programming techniques with ease.

## II. Robocode: the agent's environment

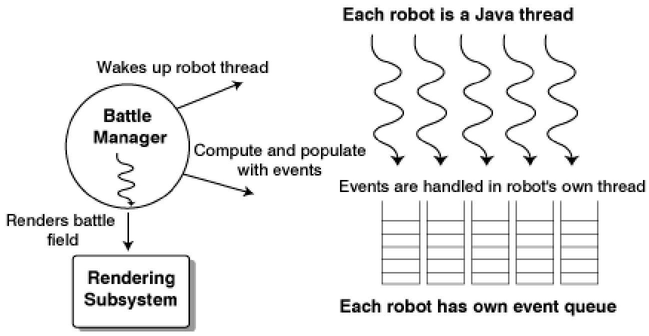
Robocode is a robotics battle simulator that runs across all platforms supporting any recent Java runtime (version 2 or more). It is an easy-to-use framework that was originally created to help teach object-oriented programming in Java [1]. The project was started by M. Nelson in late 2000 and was available through IBM's *alphaWorks* in July 2001. Now there is a strong open-source community around it with competitions runing all over the world [3].

The basic idea behind Robocode is letting autonomous software agents (robots) compete in a virtual closed environment against each other. Each robot is programmed in Java and has to implement a given base class. This code controls a virtual robot in arena by moving its body, steering, targetting and shooting other robots. The same base class provides handlers that the robot can implement to respond to external events. The whole system follows an event-driven architecture. Moreover, each robot runs in a security sandbox, allowing for easy and safe distribution of robot code throughout the community, protecting against harmful effects.

### A. Robocode simulation engine architecture

The Robocode game consists of several robots engaging in combat in a closed environment, a rectangular arena. The size of the arena and some other options can be configured just before a battle is started. As seen in figure 1, each robot runs on its own thread with its own event queue, responding to events generated by the game engine independently of the battle manager and the other robots [1]. In addition to this, each robot has a `run()` method where the main processing loop occurs. This is usually where the general strategy is implemented, i.e. what the robot does when no events occur.

Each robot is made up from three parts: the vehicle, the radar and the gun (figure 2). They can be moved both together and independent of each other. The vehicle can be moved ahead and back, in order to reposition the robot's body. Any of the parts can be turned left and right. Turning the vehicle changes the direction of further moves, turning the scanner



Each robot is a Java thread
Wakes up robot thread
Battle Manager
Compute and populate with events
Events are handled in robot's own thread
Renders battle field
Rendering Subsystem
Each robot has own event queue

Fig. 1. Robocode simulation engine architecture (see [1])

changes the area that the robot “senses” and turning the gun sets the direction where the bullet will be fired on.

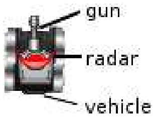


Fig. 2. Anatomy of a Robocode robot

## B. Robocode physics

Robocode *time* is measured in “ticks”, which are equivalent to frames displayed on the screen. Each robot gets one turn per tick. *Distance* measurement is done in pixels, with double precision, so a robot can actually move a fraction of a pixel. Robots *accelerate* at the rate of 1 pixel/tick and *decelerate* at the rate of 2 pixels/tick. Acceleration is automatically determined based on the distance the robot is trying to move. *Velocity* is calculated multiplying acceleration with time, and can never exceed 8. The direction is always the heading of the robot’s body.

Some limits are imposed for the rotation of a robot’s parts. Maximum rate of vehicle rotation is set such as it is limiting the ability to turn with speed. Maximum rate of gun rotation is 20 degrees per tick and is added to the current rate of rotation of the robot. Maximum rate of radar rotation is 45 degrees per tick and is added to the current rate of rotation of the gun.

Collisions cause damage, decreasing the energy level of the robot(s) involved. For example, hitting another robot damages both of them with 0.6, while a robot hitting a wall will take damage according to its speed.

# III. Logic programming agent architecture

The motivations behind our choice to implement a new logic programming agent architecture were already explained in section I. Still, we want to emphasize the practical need that drove our research effort. A strong community and momentum exists around Robocode both as an educational game and a tool for robot programming hobbists [3]. Agent oriented programming, on the other hand, is a field holding much promise not necessarily from a technological point of view, but mostly as a new design method. The shift in focus from designing parts (objects) that interact with each other in order to build a system that solves a problem to a more autonomous way of designing software poses new challanges. Artificial intelligence, and especially logics, play an important role in finding solutions to these problems. We believe that robot programming with Prolog is a field that was not explored enough. Our agent architecture is directed at making the entry into this field much easier for researchers and software engineers alike.

The architecture we propose is built around the natural event-driven nature of Robocode. We provide the means for a Prolog program to receive events from the game and to issue commands to it, thus implementing the basic requirements of an agent: “[it is] perceiving its environment through sensors and acting upon that environment through effectors” [5].

## A. Overall design

Any robot implementation in Robocode has to inherit from `robocode.Robot` class (or any subclass of it), and our design can not be an exception. We wrote a generic Java class `PrologRobotShared` that acts as an adaptor between the game environment and the concrete Prolog implementation of a robot. Its main responsability is to pass along events from the game engine, and to start the main strategy loop.

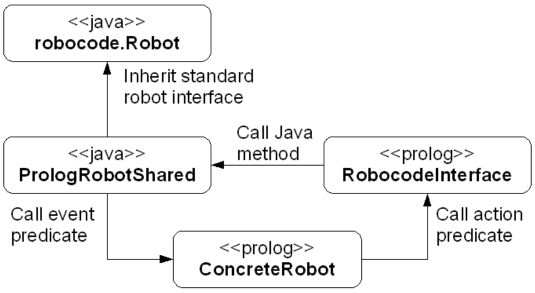

Fig. 3. Interaction model of a concrete Java-Prolog robot

By convention, the predicate that is being invoked when the game starts is `startStrategy`. Just as its Java counterpart, the `run` method, this predicate must not finish. Instead, this is where the overall strategy is specified. Acting upon the environment is possible using a collection of predicates that wrap the action calls from `robocode.Robot`. Calling any of these from the `startStrategy` predicate will freeze the robot thread while the game engine actually executes the command.

In order to improve the design and reusability of code between robot implementations, we separated any generic Prolog predicates to a different component (file), called `RobocodeInterface`. We also made sure that there is no Java code that needs to be changed if the robot’s logic is changed.

## B. Perceiving the environment

There are two ways of getting information regarding the environment. In the Robocode API there is a group of methods named `get*`. Most important ones are listed in table I. For all these wrapper predicates were implemented in `RobocodeInterface`, with exactly the same name. We can call this way of perceiving the environment *passive*, as these should be called from within the `startStrategy` predicate or any of the event handlers (see next section). The information they gather is always there, as it is the state of the game or of the robot.

The alternative way of perceiving the environment is by responding to events. A list of the most important events available is listed in table II. For all these a Java handler was written that calls the handler predicate with the same name from the concrete Prolog robot implementation, if it exists. We call this event-driven way *active*, as the environment interrupts the robot to inform it of a change in the environment or a sensory activity.

Maybe the most important of these methods is `onScannedRobot`. It is called when a robot's radar scan detects the presence of another robot. Responding to this event is usually a good strategy or at least a potentially strategy altering event.

### C. *Acting upon the environment*

A couple of "hardware" behavior properties can be altered using the `set*` methods listed in table III. These don't really count as effectors, but more like altering future behavior of effector methods. A couple more strictly cosmetic methods exist to set the appearance of the robot icon on the board. We did not implement these as Prolog predicates. If the user wants to change the default colors, they should do it directly in `PrologRobotShared`.

In table IV are listed the real effectors available to use for the robot's implementor. All these were implemented and are available in Prolog. Any call to these predicates will freeze the robot thread execution until the required action is completed, or an event occurs.

## IV. Reference implementation of an agent

Developing a framework can not be done without testing. We did a reference implementation of a robot in order to validate our approach, and provide an example of how to get started. We deliberately chose a simple robot, already present in the Robocode distribution as a sample. What we did was to start from the Java implementation and rewrite it using the framework. The end result is a functional Java-Prolog program implementing the same functional requirements as the original one.

### A. *Corners: a simple robot*

We chose a robot named "Corners" for our implementation. The strategy it applies is very simple: it chooses a corner, based on previous experiences, then proceeds to secure it. After it took the corner, it aims and shoots at the other robots using a fairly simple targetting algorithm.

### B. *Implementing the strategy in Prolog*

The strategy of a Robocode robot is made up, in general, of two parts: the main loop, triggered by the method `run()`, and the event handlers (see table II). Our implementation of the main loop initialises and customizes the robot, then calls the predicate `startStrategy` (listing 1). The first argument ($R$) of this predicate is received from Java and is a reference to the `PrologRobotShared` instance. It is necessary in order to issue commands back to the framework (actions, see table IV).

**Algorithm 1** Implementation of $startStrategy$ in Prolog

```
startStrategy(R) :-
        getOthers(R, Num),
        retractall(others),
        assert(others(Num)),
        goCorner(R),
        spinGunLoop(R, 3).

spinGunLoop(R, X) :-
        spinGun(R, X, 30),
        NewX is -X,
        spinGunLoop(R, NewX).
% ...
```

**Algorithm 2** Implementation of $onScannedRobot$ in Java and Prolog

```
public void
onScannedRobot(ScannedRobotEvent e) {
 executeQuery("onScannedRobot",
                new JRef(e));
}

onScannedRobot(R, E) :-
        stopWhenSeeRobot(Result),
        onScannedRobot(R, E, Result).

onScannedRobot(R, E, true) :-
        stop(R),
        getDistance(E, Distance),
        smartFire(R, Distance),
        scan(R),
        resume(R).

onScannedRobot(R, E, false) :-
        getDistance(E, Distance),
        smartFire(R, Distance).
%...
```

The event handlers are implemented in Java as delegators to Prolog, to predicates with similar names (listing 2). A ref-

TABLE I
ROBOCODE API: GATHERING INFORMATION ABOUT THE ENVIRONMENT AND SELF

| | | | |
|---|---|---|---|
| getBattleFieldHeight | the height of the current battlefield measured in pixels | getBattleFieldWidth | the width of the current battlefield measured in pixels |
| getGunCoolingRate | the rate at which the gun will cool down | getWidth | the width of the robot measured in pixels |
| getHeight | the height of the robot measured in pixels | getName | the robot's name |
| getNumRounds | the number of rounds in the current battle | getRoundNum | the current round number (0 to `getNumRounds` - 1) of the battle |
| getOthers | how many opponents are left in the current round | getTime | the game time of the current round |
| getGunHeading | the direction that the robot's gun is facing, in degrees | getGunHeat | the current heat of the gun |
| getEnergy | the robot's current energy | getHeading | the direction that the robot's body is facing, in degrees |
| getRadarHeading | the direction that the robot's radar is facing, in degrees | getVelocity | the velocity of the robot measured in pixels/turn |
| getX | the X position of the robot | getY | the Y position of the robot |

TABLE II
ROBOCODE API: EVENTS A ROBOT CAN RESPOND TO

| | | | |
|---|---|---|---|
| onScannedRobot | the robot sees another robot (i.e. the robot's radar scan "hits" another robot) | onStatus | called every turn in a battle round in order to provide the status to the robot |
| onBulletHit | called when one of robot's bullets hits another robot | onBulletHitBullet | called when one of robot's bullets hits another bullet |
| onBulletMissed | called when one of robot's bullets misses (i.e. hits a wall) | onHitByBullet | called when the robot is hit by a bullet |
| onHitRobot | called when the robot collides with another robot | onHitWall | called when the robot collides with a wall |
| onBattleEnded | called after end of the battle, even when the battle is aborted | onDeath | called if the robot dies |
| onRobotDeath | called when another robot dies | onWin | called if the robot wins a battle |

TABLE III
ROBOCODE API: BEHAVIORAL PROPERTIES THAT CAN BE SET

| | |
|---|---|
| setAdjustGunForRobotTurn | turn the gun independent from the robot's turn |
| setAdjustRadarForGunTurn | turn the radar independent from the gun's turn |
| setAdjustRadarForRobotTurn | turn the radar independent from the robot's turn. |

TABLE IV
ROBOCODE API: ACTIONS A ROBOT CAN TAKE

| | | | |
|---|---|---|---|
| ahead | immediately moves the robot forward | back | immediately moves the robot backward |
| doNothing | do nothing this turn (i.e. skip this turn) | stop | immediately stops all movement, and saves it for a call to `resume()` |
| resume | immediately resumes the movement you stopped by `stop()`, if any | turnLeft | immediately turns the robot's body to the left |
| turnRight | immediately turns the robot's body to the right | scan | scans for other robots |
| turnRadarLeft | immediately turns the robot's radar to the left | turnRadarRight | immediately turns the robot's radar to the right |
| fire/fireBullet | immediately fires a bullet | turnGunLeft | immediately turns the robot's gun to the left |
| turnGunRight | immediately turns the robot's gun to the right | | |

erence to the `PrologRobotShared` instance is passed to each predicate, to be able to call the action predicates.

## V. Related Work

Research on Agent architectures and frameworks is in progress for some time [9]. Even though, the field is still not developed enough and did not achieve the full embrace of industry yet. Logic programming is a good choice for implementing agents, as shown in several studies [10], [11].

The game Robocode was used in several studies before, including the creation of a team of robots [12] or a single robot's strategy [13]. Genetic programming was applied with some success, leading to generation of Robocode tank fighters [7], [8].

There is no study that we are aware of trying to implement Robocode fighters in Prolog.

## VI. Conclusion and Future Work

A new agent environment and framework for the creation of autonomous agents in Prolog was introduced. It is particularly interesting as it makes available the well known Robocode environment for programming in conjunction with the logic programming system SWI-Prolog. It also enables competitions with other agents built with different technologies, both created by humans and evolved [8]. It provides a good testing ground to validate different theories related to programming autonomous agents.

The framework can also be used to learn and experiment with agent-oriented programming, both in class and as a self-study tool. We plan to use it as learning environment for an undergraduate Logic programming course next year. The source code is released under an open-source GPL license and is available at http://www.info.uaic.ro/ alaiba/robocodepl/.

Several future directions can be followed. Our first priority is to extend the framework to support the full API of the latest version of Robocode (at the time of this writing 1.6.0). Tests will be done to determine the performance penalty, if it exists, that the framework adds on top of existing Java implementations of some common robots.

Programming teams of robots as multi-agent systems is another interesting area of research. Robocode supports the notion of teams and allows for collaborative combat [2]. Support in the framework should be added to enable inter-agent communicaton, both as point-to-point and as broadcast.

In the long term, we plan to add higher abstractions to the framework that will model concepts such as beliefs and goals, and support for different kinds of non-standard logics (such as temporal logic). Ideally this will lead to the development of design patterns for agent programming and their validation against a well defined, real environment.

***Abstract*—The development of distributed systems poses different issues that developers must carefully take into consideration. Web Services and (Mobile) Agents are two promising paradigms that are increasingly exploited in distributed systems design: they both try, albeit with very different conceptual abstractions, to govern unpredictability and complexity in wide-open distributed scenarios. In this paper, we compare the two approaches with regard to different aspects. Our aim is to provide developers with critical knowledge about the advantages of the two paradigms, stressing also the need for an intelligent integration of the two approaches.**

## I. Introduction

IN RECENT years, the interest in distributed computing has been ever-increasing both in industry and academia. Distributed computing offers advantages in its potential for improving availability and reliability through replication; performance through parallelism; sharing and interoperability through interconnection; flexibility and scalability through modularity. In order to gain these potential benefits, software engineers have been coping with new issues arising from distribution: components are scattered across network nodes and the control of the system is complicated by such a partitioned "system state", particularly challenging when dealing with failure and recovery; in addition, the interactions between the concurrent components give rise to issues of non-determinism, contention and synchronization. The key concept in distributed systems has been the *service*, implemented and provided by servers to clients that may dynamically join systems, locate and use required services and then depart. The last years' trend is toward the conception of services that can be globally accessible by remote clients over the Internet. Therefore, the technological and methodological background developed for conventional distributed systems often fail to scale up when applied to the design of large-scale systems. Languages for distributed programming were introduced so that each component could be described and used through an established *interface*, but language constructs turned out to be not enough. New paradigms were needed in order to tackle the growing *complexity* of software. Throughout this paper, we will discuss some of the critical aspects of modern distributed applications, showing where Agent-Oriented Programming (AOP) and Service-Oriented Computing (SOC) take different roads and how research efforts are being made to reconcile them.

## II. Background

The aim of distributed systems design is to identify the distributable components and their mutual interactions that together fulfil the system requirements. The client-server model is undoubtedly the most consolidated and applied paradigm in distributed computer system design. Pretty much every variation of application architecture that ever existed has an element of client-server interaction within it. Nevertheless, the last year trend has been in breaking up the monolithic client executable into object-oriented components (located part on the client, part on the server), trying to reduce the deployment headaches by centralizing a greater amount of logic on server-side components. The benefits, derived from the extensive use of the component-based approach, came at the cost of an increased complexity and ended up shifting ever more effort from deployment issues to maintenance and administration processes. The issues to tackle are not related only to how to partition the complex problem domain (i.e. the *problem space decomposition*) or where the identified components should reside (i.e. the *location awareness*), but an increasing emphasis is shifting on how these components should interact and should be maintained. As a consequence, researchers in software engineering are investigating the possibility to introduce paradigms born to deal with complexity even at the abstract model level. The two paradigms briefly discussed in the following subsections (i.e. *Service-Oriented Computing* and *Agent-Oriented Programming*) try to radically change the model entities upon which software designers use to build complex distributed systems. They introduced the powerful concepts of services and mobile software agents as the building blocks of the design, establishing then precise rules for their composition and interaction.

### A. Agent-Oriented Programming

An *agent* is basically defined as an entity that enjoys the properties of *autonomy*, *reactivity*, *proactivity*, *social abil-*

*ity* [27]. Software agents are significantly powerful when they live in communities made up of several interacting agents. Every agent is an active entity, situated in an environment, able to perceive and to react in a timely fashion to changes that occur in the environment. They are autonomous in the sense that they have the total control of their encapsulated state and are capable of taking decisions about what to do based on this state, without a third party intervention. In addition, agents exhibit goal-directed behaviour by proactively taking the initiative in pursuit of their design objectives.In an agent-oriented view, in order to represent the decentralized nature of many distributed systems, multiple agents are required and they will need to interact for the fundamental reason of achieving their individual objectives. Establishing collaborations with other partner agents, they obtain the provision of other services (i.e. social ability). An obvious problem is how to conceptualize systems that are capable of rational behavior. One of the most appreciated solutions to this problem involves viewing agents as *intentional entities*, whose behavior can be predicted and explained in terms of *attitudes* such as belief, desire, and intention (BDI) [20]. In AOP the idea is that, as in declarative programming, we state our goals, and let the built-in control mechanisms figure out what to do in order to achieve them. In BDI agents the computational model corresponds to the human intuitive understanding of beliefs and desires, and so the designer needs no special training to use it.

Another optional, but equally powerful, feature of software agents is *mobility* [10]. Conventional distributed systems assume that the various portions of the distributed application run on their own network node and are bound to it for their whole life. *Mobile Agents (MA)* reshape the logical structure of distributed systems, by providing a system in which components can dynamically change their location, migrating with them a part or the entire agent's state [4], [5].

### B. Service-Oriented Computing

*Service-Oriented Computing* (SOC) [23] proposes a logical view of a software system as a set of *services*, provided to end-users or other services. This recent paradigm proposes itself as the next evolutionary step of the client-server architecture applied to the modern highly distributed and dynamic business scenario.

SOC has the purpose of unifying business processes modularizing large applications into services. Any client, independently of its operating system, architecture or programming language, can access the services in the Service-Oriented Architecture (SOA) and compose them in more sophisticated business processes. *Reusability* has the benefit of lowering development costs and speeding time to market, but achieving high reusability is a hard task. SOC emphasizes the reuse of services, which have to be created *agnostic* to both the business and the automation solutions that utilize them; in addition they need to preserve the maximum degree of *statelessness* towards their current requestor. Moreover, one of the key concepts proposed by service-orientation is *loose-coupling* between the entities playing the role of client and server: limiting service dependencies to the *service contract* allows the underlying provider and requestor logic to remain loosely coupled. *Web Services* technology is, without any doubts, the most promising and industry-supported standard technology, adopted to implement all the service-orientation design principles, discussed more deeply throughout this paper.

## III. Two Approaches to Deal with Complexity

The evolution of distributed software development has been largely driven by the need to accommodate increasing degrees of dynamicity, decentralization and decoupling between distributed components. Software paradigms should take care of the new requirements of distribution and handle complexity from the early stages of the design. In the following subsections, we are going to analyze some aspects, related to the development of complex distributed systems [14], showing what design-level tools the two compared paradigms provide to the designer.

### A. Decomposing the Problem Space

Experience in software engineering taught that complex systems are inherently decomposable and many details can be ignored in the higher-level representations, thus limiting the scope of interest of the designer at a given time. Model entities can be grouped together and their relationships described trying to always provide the highest degree of autonomy between the components.

In the *Service-Oriented Computing* (SOC) paradigm, decomposition is based on the concept of services, which encapsulate units of logic that can be small or large. Service logic can encompass the logic provided by other services, when one or more services are composed into a collection. A typical automation solution is represented by a business process, whose logic is decomposed into a series of steps that execute in predefined sequences according to business rules and runtime conditions. Services can be designed to encapsulate a task performed by an individual step or a sub-process comprised of a set of steps.

*Agent-Oriented Programming* proposes an approach in which the problem space should be decomposed introducing multiple, autonomous components (i.e. agents) that can act and interact in a flexible way to achieve their set of goals. This sort of goal-driven decomposition has been even acknowledged by object-oriented community [16] as being more intuitive and easier than decomposition based on objects. It means that individual agents should localize and encapsulate their own control: in other words, they should be *active*, owning their thread of control, and *autonomous*, taking exclusive control over their own actions.

Although distributing automation logic is nothing new, the two approaches are both stressing the importance of *loose-coupling* when designing distributed components. The first inadequacy of previous paradigms derives from allowing components to form tight connections that result in constrictive inter-dependencies. By decomposing businesses into self-contained and loosely-coupled services, SOC helps achieving the key goal of being able to respond to unforeseen changes in an efficient manner: a service acquires knowledge of another one by means of *service contracts*; interactions take place only with predefined parameters, but the two services still remain independent of each other. In AOP, software agents are likewise self-governing entities, with well-defined boundaries and interfaces, situated in an environment over which they have partial control and observability; their encapsulated state is not accessible to other agents and mutual interactions occur by means of some kind of agent communication language (ACL).

Nevertheless, the strategies adopted by the two approaches make them inherently different. SOC keeps following the well-established *functional* philosophy, while Multi-Agent Systems (MASs) can be classified as *reactive* software systems. A service-oriented business process is started by the action of the end-user or by another client process; it performs its computations following a predefined execution flow (possibly invoking other services inside or outside the enterprise boundaries) and returns the results to the caller. In contrast, MASs are reactive because their components (i.e. agents) often do not terminate, but rather maintain ongoing interactions with their environment. Such interactions are also characterized by *proactiveness*, since an agent tries different ways to achieve its goals and is, consequently, able to influence its environment.

It is commonly agreed that the natural way to modularize most complex systems is in terms of multiple autonomous components, acting and interacting in flexible ways and exhibiting a goal-directed behaviour. This makes perhaps the agent-oriented approach the best fit to this ideal. Moreover, although the intrinsic complexity of the *functional* mapping may be great (e.g. in the case of very dynamic systems, such as air traffic control systems), functional programs are, in general, simpler to specify, design and implement than reactive ones.

### *B. Modelling Interactions*

It was argued that distributed applications are increasingly built out of highly decoupled components. Nevertheless, components need to interact to achieve the required behaviour. Interactions pose some demanding issues at design time, related mainly to the *nature of interactions*, the *degree of flexibility* to provide and the *location* of the interacting entities, which we are going to detail in the following subsections.

*1) Nature of Interactions:* With regard to the *nature of interactions*, the service-oriented paradigm is still more bound to the past than the agent-oriented one. Services interact with each other almost barely at a “syntactic level”, with one service invoking an operation exposed by another one and, after a given time, retrieving the produced result. We said “almost”, because, compared to the classical “method invocation” philosophy provided by OO systems, SOC gives increased importance to the dynamic selection and binding of operations. Using a special intelligent lookup service (e.g. the UDDI registry), a component can search for another service that satisfies a set of key requirements, such as quality of service, accuracy of results or response time. This kind of enhanced reflection technique becomes a fundamental asset from the standpoint of robustness and flexibility: it allows components to dynamically select or reconfigure their bindings, saving a proper amount of independence with respect to the traditional static binding approach. Service discoverability can be considered a promising semantic evolution of the OO polymorphism, since services are expected to match based more on their semantics (e.g. service behaviour under certain conditions, delays, reliability, etc.) rather than on their syntax (e.g. operation prototypes, parameter types, etc.). However, although currently the publisher can define certain service policies to express preferences and assertions about the service behaviour, research efforts are currently underway to continually extend the semantic information provided by service description documents.

The agent-oriented paradigm definitely chooses an interaction model based on semantics and human sociality. Software agents interactions occur at the knowledge level, through a declarative communication language, inspired by the speech act theory [8]. Interacting via this kind of agent-communication language, an agent has the capability to engage in social activities, such as cooperative problem solving or negotiation. The sequence of actions performed by an agent is therefore not statically defined, but depends mainly on its goals and on the environment where it lives. In AOP, the idea is that, as in declarative programming, the designer states her goals and lets the built-in control mechanism figure out what to do, at what time and by whom, in order to achieve them. Moreover, the resources available in the environment can modify the kind of action performed. The control mechanism implements some computational model, like the BDI model, which is undoubtedly more intuitive to the designer than the procedural model.

It must be pointed out that, increasing the abstraction level of interactions, as AOP does, introduces new challenging issues. For agents to interact productively, they must have a bit of knowledge about the expected behaviour of interacting partners, as well as the passive components of their environment. A consistent development effort must focus on modelling the environment, the world in which agents operate and of whom they have beliefs. Knowledge representation languages [17] are proving to be a promising way of describing the environment model, so that social agents can act and interact starting from common views of the world.

Unfortunately, the agents’ models will be often mutually incompatible in syntax and semantics, thus stressing the importance for semantic reconciliation (e.g. by means of some kind of ontology composition technique [26]).

*2) Flexibility of Interactions:* Although many complex systems are decomposable, complexity means also that it is impossible to know a priori about all potential links between the distributed components: interactions often occur at unpredictable times and trying to consider all the possibility at design time is a futile effort.

AOP provides a high degree of *flexibility* as regards the engineering of complex systems: it adopts the policy of deferring to runtime decisions about component interactions, endowing agents with the ability to initiate interactions and deal with unanticipated requests in a flexible manner.

Services, even if carefully designed, cannot provide such level of dynamic interactions, because they are passive entities with respect to agents. In the SOA world, interactions have to be planned and coordinated using choreography or orchestration techniques, recently standardized as Web Service extensions. The WS-BPEL (Web Services Business Process Execution Language) is an example of how a business process can be governed, specifying which services should be called, in which sequence and at what conditions.

*3) Interactions and Component Location:* When thinking about the architecture of a distributed application, interactions among the various components are usually considered independent of the components' location. Location is simply regarded as an implementation detail. Many technologies, such as CORBA, intentionally hide the location of components, making no distinction between interactions of components residing on the same host and components scattered among distant network nodes. However, in many distributed applications, location needs to be considered also during the design stage, since interactions can be remarkably different in terms of latency, partial failure and concurrency.

In the SOC model, services interact with each other, exchanging information through a communications framework that is capable of preserving a loosely-coupled relationship. This framework is based on *messaging*. Messages (e.g. expressed using SOAP protocol) are formatted following the service contract specifications in order to be correctly understood and processed by the target service. The size and number of the exchanged messages depend on the service contract and can be significant when big pieces of information must be exchanged or complex interactions are carried out. Moreover, the widespread use of wireless networks is making available communication channels with low bandwidth or reliability. The design of distributed applications becomes therefore more complex, in that it must aim at avoiding as much as possible the generation of traffic over the weaker links.

The SOC paradigm has only one way to achieve this goal, that is, to increase the granularity of the offered services. In this way, a single interaction between client and server must be sufficient to specify a large number of lower level operations, which are performed locally on the target service and do not need to pass across the physical link. Coarse granularity reduces dependencies between the interacting parts and produces fewer messages of greater significance [12]. Furthermore, the trend to create interfaces for the services that are coarser than those traditionally designed for RPC-based components has been encouraged by vendors as a means of overcoming some of the performance challenges associated with XML-based processing (e.g., SOAP messages are XML-based documents). However, the coarser the granularity of an interface, the less reuse it may be able to offer. If multiple functions are bundled in a single operation, it may be undesirable for clients that only require the use of one of those functions. Then, service interface granularity is a key strategic decision point that deserves a good deal of attention during the design phase.

Mobile Agents (a special kind of software agents presented in Section 2.1) could help because they allow, by their nature, to specify complex computations that can move across a network [10]. Hence, the services that have to be executed by a server that resides in a portion of the network, reachable only through an unreliable and slow link, could be described using a mobile agent; this agent, thanks to its mobility, can be injected into the destination network, thus passing once through this link. There, it could execute autonomously, needing no more connection with the node that sent it, except for the transmission of the final results of its computation (i.e. *disconnected operations*).

### C. Component Reuse and Customization

Nowadays, business process automation is proving that the centralization of control, persistency and authorization is often inefficient, impractical or simply inapplicable. The so called "buy vs. build" or "incremental development" is becoming more and more valid, albeit interpreted in the new scenarios: only a part of the components involved in a distributed computation are under the control of the designer, while the rest may be pre-existing off-the-shelf components that is mandatory or convenient to exploit. If the reuse of components is thus an important aspect, their customization is fundamental as well: an extensible service is likely to be reused more than a rigid one, since it is expected to meet the requirements of much more users/clients. In the following we shall analyse these two aspects.

*1) Service Reusability:* One of the great promises of SOC is that service reuse will lower development costs and speed up time to market. Service-orientation encourages reuse in all services, regardless whether immediate requirements for reuse exist. By applying design standards that make each service potentially reusable, the chances of being able to accommodate future requirements with less development effort are increased. If the service is designed following the SOC principles of autonomy and loose coupling, these weaker dependencies make the applicability of its functionality broader. Furthermore, if the service is designed to be *stateless*, this helps promoting reusability as well as great scalability: if a service is responsible for retaining activity state for long periods of time, its ability to remain available to other requestors will be impeded. Service statelessness supports reuse because it maximized the availability of a service and typically promotes a generic service design that defers activity-specific processing outside service logic boundaries. In turn, the reusability requirement facilitates all forms of reuse, including inter-application interoperability and composition (e.g. service orchestrations and choreographies).

The AOP view promotes instead reusability in different ways. Rather than stopping at reuse of subsystem components and rigidly preordained interactions, agents enable whole subsystems and flexible interactions to be reused within and between applications. Flexible interaction patterns, such as those enabled by the BDI model, and various forms of resource-allocation and auctions patterns have been reused in a significant number of applications.

*2) Service Customization:* As already said, any service operation in a SOA can be invoked and returns results using, for example, SOAP messaging. Message structure has been carefully thought to enable service reusability and customizability: the idea is to equip the message with embedded processing instructions and business rules, which allow them to dictate to recipient services how they should be processed. These allow messages to become increasingly self-reliant by grouping metadata details (in the SOAP header) with message content into a single package (the SOAP envelope). The processing-specific logic embedded in a message alleviates the need for a service to contain this logic. In other words, services in the SOC view should adapt their behavior to the requirements of their current clients, in order to provide the greatest chances of reuse. As a consequence, SOC imposes that service operations become more generic and less activity-specific. The more generic a service's operations are, the more reusable the service.

Likewise, agent mobility encourages the implementation of more generic, and thus highly reusable, service providers [6]. Servers providing an a priori fixed set of services accessible through a statically defined interface are inadequate in those distributed scenarios where new clients can request unforeseen operations at any time. Upgrading the server with new functionalities is only a temporary and inefficient solution, since it increases complexity and reduces flexibility. Mobile code technologies enable a scenario in which the server actually provides a unique service: the execution of mobile code. This feature allows the user to customize and extend the services according to its current needs, bringing the know-how (i.e., the method code) along its way roaming the network.

The possibility of customization granted by mobile code paradigms is therefore more powerful and expressive compared to embedding processing logic in SOAP messages; this, however, comes at the cost of an intrinsic fragility of the execution environment hosting external mobile agents (not only in the case of intentionally malicious agents, but also in the case of bad-designed or misbehaving code [25]).

### *D. Coping with Interoperability and Heterogeneity*

The problem of interoperability between heterogeneous technologies is gaining great interest in the academia but, first and foremost, among the major software vendors.

Web services standards have demonstrated the power of standardization and platform-vendor neutrality. The emerging SOC paradigm took the principle of openness of standards as one of its foundation stones: the cost and effort of cross-application integration are significantly lowered when applications being integrated are SOC-compliant.

The landscape of agent-oriented software seems to be more fragmented, although many efforts towards the definition of standards are growing in the research community. Several (Mobile) agent platforms have been developed, but one of the weaknesses of those platforms is the lack of true interoperability, being the strength of Service-Oriented systems. Many of the proposed agents platforms provide support for migration, naming, location and communication services, but they differ widely in architecture and implementation, thereby impeding interoperability and rapid deployment of mobile agent technology in the marketplace. To promote interoperability, some aspects of mobile agent technology have been standardized. Currently there are two standards for mobile agent technology: the OMG's Mobile Agent System Interoperability Facility (MASIF) and the specifications promulgated by the Foundation for Intelligent Physical Agents (FIPA). MASIF [15] is based on agent platforms and it enables agents to migrate from one platform to another, while FIPA [9] is based on remote communication services. The former is primarily based on mobile agents travelling among agent systems via CORBA interfaces and does not address inter-agent communications. The latter focuses on intelligent agent communications via content languages and deals with the mobility aspect of agents only since the FIPA 2000 release. In order to achieve the degree of outstanding platform neutrality and interoperability of SOC, some research programs are studying the possibility of an integration of MASIF/FIPA specifications into a commonly agreed standard for MAPs [1].

### *E. Security*

When application logic is spread across multiple physical boundaries, implementing fundamental security measures such as authentication and authorization becomes more difficult. In the traditional client-server model, the server is the owner of any security information, needed to recognize user's credentials and to assign privileges for the use of any protected resources. Well-established techniques, such as SSL (Secure Socket Layer), granted a so-called *transport-level* security, where the whole channel, by which requests and responses are transmitted, is protected.

SOC departs from this model by introducing substantial changes to how security is incorporated and applied. Relying heavily on the extensions and concepts established by the WS-Security framework, the security models used within SOC emphasize the placement of security logic onto the *messaging level*. SOAP messages provide header blocks in which security logic can be stored (e.g. by means of X509 certificates). So, wherever the message goes, so its security information does. This approach is required to preserve individual autonomy and loose coupling between services, as well as the extent to which a service can remain fully stateless.

The "mobility" concept in the agent-oriented paradigm poses new and more challenging security issues. Moving code, in addition to data, brings security problems that fit into two main categories: protecting host systems and networks from malicious agents and protecting agents form malicious hosts. Digital signatures and trust-management approaches may help to identify the agents and how much they should be trusted. The malicious host that attacks a visiting mobile agent is the most difficult and largely unsolved: such a host can steal private information from the agent or modify it to misbehave when it jumps to other sites.

Security is perhaps the most critical factor that has limited a widespread acceptance of the mobile agent paradigm for strategic applications, such as e-commerce, where sensitive transactions have to be performed with the highest level of security. Services interact with each other without moving any piece of application logic (e.g. a thread), but simply moving inert parameters data to invoke exposed service operations. Protecting passive data is usually more straightforward than protecting mobile code, albeit several research efforts [24] are being made to reduce the gap between the two approaches.

## IV. Integrating Services and Agents

We have analyzed, throughout this paper, some of the similarities and differences, strengths and weaknesses of two emerging paradigms in distributed software engineering: Service-Oriented Computing and Agent-Oriented Programming. It has been observed that they tackle complexity in software, often from very distant points of view, promising advantages to designers but also introducing architectural headaches. We are convinced that the silver bullet of distributed software paradigms cannot be identified in any of these individual paradigms: distributed systems in the future will likely benefit of ideas drawn from both of them, but this demands for some intelligent form of integration of the two approaches.

In the recent years, the emphasis of service-oriented architectures has been on the execution of services, as building blocks to decompose and automate complex and distributed business problems. The Web Service infrastructure is widely accepted, standardized, and is likely to be the dominant technology over the coming years. However, the next evolutionary step for services will be driven by the need to deal with target environments that become even more populous, distributed and dynamic. Therefore, many approaches are emerging for the future of these models and they all agree on one point: the integration between services and agents is more than feasible. For example, in the last issue of the AgentLink III Agent Technology Roadmap, Web Services are presented “as “a ready-made infrastructure that is almost ideal for use in supporting agent interactions in a multi-agent system” [2]. In this direction, different approaches to integration have been proposed and, in many cases, tested with some prototypal applications.

A first idea of integration consists in the mere enabling of interactions between the two worlds. In other words, some researchers [11] have experimented techniques to make agents and web services interoperate. In order to make web services invoke agent capability and vice versa, these systems try to formalize a proper mapping between the WSDL service contract and the Agent Communication Language (ACL). These approaches, however, have been criticized, since they try to blur the distinction between agency and service-oriented concepts: if agents are accessed through pre-defined, fixed interface operations (accepting parameters and returning results), they are implicitly treated as services, and as a consequence they loose the autonomy and intelligence belonging to agents. Vice versa, if a service behaves in a non-deterministic way and other services must interact with it using some high-level ACL, this service should be regarded conceptually as an agent instead. A more clear integration approach [7], [19] recognizes the conceptual difference between agents and services and proposes a functional layered view of their interactions. Services are the functional building blocks, which can be composed to form more complex services, but they remain passive entities used by agents in distributed applications: the agent are given some high-level goals; they are primarily responsible for adopting strategies or plans and translate them into concrete actions, such as invoking an atomic service or composing other services into new functional aggregates. In a few words, many researchers are expressing the relationship between services and agents, saying that services provide the computational resources, while agents provide the coordination framework [3].

A new research roadmap [13] is proposing a radical evolution of the concept of service, rather than an integration: the main idea is to give more “life” to services so that, instead of passively waiting for discovery, they could proactively participate in the distributed application, just like agents in multi-agent systems. Making services increasingly alive and enabling more dynamical interactions, services are expected to function as computational mechanism, enhancing our ability to model and manage complex software systems. As already said, a service knows only about itself, but not about its clients; agents are self-aware, but gain awareness of the capabilities of other agents as interactions among agents occur. Equipped with such an awareness, it has been advised that a service would be able to take advantage of new capabilities in its environment and could customize its service to a client, for example, improving itself accordingly.

## V. Conclusions

This paper presented a comparison between the Services-Oriented vision and the (Mobile) Agents one, as concerns the several issues in the development of complex distributed systems. We pointed out that each approach offers its own advantages, but some rules of thumbs emerge from the comparison: model entities of SOC are better fitting “closed” distributed systems, where the components are explicitly designed to organize themselves in a predefined (i.e. choreographic or orchestrated) fashion to achieve the fulfillment of a certain business process or workflow. “Open” systems are instead better manageable if a mobile agent approach is taken: in application scenarios, like pervasive computing or online auctions, it can be impossible to know a priori all potential interdependencies between components (what services are required at a given point of the execution and with what other components to interact), as a functional-oriented behavior perspective typically requires. In the latter case, agents can consider also the possibility of competitive behavior in the course of the interactions and the dynamic arrival of unknown agents.

Nevertheless, we think that an integration of the two paradigms is more than desirable. In our vision, services constitute an established, platform-neutral and robust computational infrastructure, made up of highly reusable building blocks, from which a new breed of distributed software paradigms, derived from the agent-oriented world, can emerge. This new phase seems to be already started, for example if we look at the research in the field of autonomic services [18], where researchers are exploring the possibility of embedding some form of self-management in the components that will provide the services of the future.

***Abstract*—In the building of agent systems developers can be supported by both appropriate methodologies and infrastructures, which guide them in the different phases of the development and provide useful abstractions.**

**Nevertheless, we assist to a situation in which methodologies and infrastructures are not connected each other: the products of the analysis and design phases could not always be exploited in the implementation phase in a direct way, even if sometimes CASE-tools are present to help in translating methodologies' diagrams in infrastructures' code. This leads to a "gap" between methodologies and infrastructures that is likely to produce fragmented solutions and to make the application maintenance difficult.**

**In this paper we face this issue, proposing three directions to solve the problem. We do not want to propose a "new brand" methodology and infrastructure tightly connected, rather, we aim at reusing as much as possible what already exists, not only in abstract terms, but also in concrete "fragments" of methodologies; an appropriate meta-language that describes how a methodologies works would be useful to more easily map them onto the infrastructures, or even to "compose" a new methodologies. A further approach is based on an "intermediate" layer between methodologies and infrastructures, which provides a mapping between the involved entities.**

## I. Introduction

THE demand of effective paradigms for developing complex systems is significantly increasing in the last years [16]. Developers are required to model and manage complex scenarios, often physically distributed; in addition, such a management should be more and more autonomous, in order to take the correct decisions with less human intervention as possible. The development of such intelligent complex systems must be addressed appropriately, with effective models and tools.

Unfortunately, the current situation presents two different approaches that are likely to be in contrast: a *top-down* approach, which follows the traditional software engineering directions by providing *methodologies* that however often discard the implementation phase; a *bottom-up* approach, which meets concrete requirements by providing *infrastructures* that are likely to lack model foundations. This situation leads to a "gap" between methodologies and infrastructures, with the consequence of fragmented solutions in the development of agent systems.

The *software agent* paradigm is one of the most exploited to build complex systems [16]. On the one hand, agents exhibit the features of *proactivity* and *reactivity*, which lead to a high degree of autonomy and a certain degree of intelligence. On the other hand, their *sociality* feature enables the building of systems where agents are distributed and interact to carry out common tasks, as happens in Multi-Agent Systems (MAS).

In our work, we have analyzed several agent methodologies and agent infrastructures, first to confirm the presence of such a gap, then to study some solutions to fill this gap. The aim of this paper is to point out the existing gap and to propose some approaches to fill it. Due to the page limitation and the fact that our work is at its beginning, in this paper we sketch three solutions without giving too many details, providing readers with the "flavor" of the possible directions.

In rest of the paper we start presenting the evaluated methodologies and infrastructures, and discussing about the gap between them (Section II). Then, the core of the paper is represented by the proposal of three possible approaches as solutions of such a gap (Section III). Finally, Section IV concludes the paper.

## II. The Gap between Methodologies and Infrastructures

In this section we briefly introduce the evaluated methodologies and infrastructures, and then point out the existing gap we are going to fill, sketching also some previous work. We remark that the aim of this paper is not to report comparisons: interested readers can refer to our previous work [7], [10], [24].

### A. Methodologies

Among several methodologies for developing agent systems, we have chosen the most spread ones:

- ADELFE (Toolkit for Designing Software with Emergent Functionalities) [4] defines a methodology to develop applications in which self-organization makes the solution emerge from the interaction of its parts, and it guarantees that the software is developed according to the AMAS (Adaptive Multi-Agent System) theory [11]. It is dedicated to the design of systems that are complex, open and not well-specified. It is based on well-known tools and notations coming from the object-oriented software engineering: UML and RUP (Rational Unified Process);

- Gaia [26] was the first methodology proposed to guide the process of developing a MAS from analysis to design, starting from Requirements Statements. It guides developers to a well-defined design for a MAS. A MAS is seen as an organisation of individuals, each of which playing specific roles in that organisation, and interacting according to its role. In its first version it suffers from several limitations: it is suitable only for designing closed MAS, and the notions it uses are not suitable for dealing with the complexity of real-word. Trying to overcome these problems its official extension is Gaia v.2;
- PASSI (Process for Agent Societies Specification and Implementation) is a step-by-step requirement-to-code methodology [12], for designing and developing Multi-agent societies, using the UML standard notation. It aims at using standards whenever it is possible and considers two different aspects of agents: (i) autonomous entities capable of pursuing an objective through autonomous decisions, action and social relationship and (ii) parts of a system. The modelling of requirements is based on use-case, and ontology has a central role in the social model. It aims at reusing existing portions of design code, using a pattern-based approach. Its design process is incremental and iterative;
- Prometheus [22] is a methodology for developing agent-oriented systems, and it aims at covering all the stages of software development [13]. It includes provision of "start-to-end" support; a hierarchical structuring mechanism that allows design to be performed at multiple levels of abstraction; and support for detailed design of the internals of intelligent agents. Prometheus also uses an iterative process over all its phases;
- SODA (Societies in Open and Distributed Agent spaces) [1], [20] is an agent-oriented methodology for the analysis and design of agent-based systems, focusing on inter-agent issues, like the engineering of agent societies and the environment for MAS. Its new version takes into account both the Agents and Artifacts (A&A) meta-model, and a mechanism to manage the complexity of system description;
- Tropos methodology is intended to support all phases of software development [5]; in Tropos, organizational architectural styles for cooperative, dynamic and distributed applications are defined to guide the design of the system architecture. It adopts Eric Yu's i* model which offers the notions of actor, goal, role and actor dependency as primitive concepts for modelling the applications. Tropos has two key features: the notions of agent, goal, plan and various other knowledge level concepts are fundamental primitives used uniformly throughout the software development process; a crucial role is assigned to requirements analysis and specification when the system-to-be is analysed with respect to its intended environment.

### B. Infrastructures

With regard to the agent infrastructures, we have considered the following ones:

- CArtAgO (Common Artifact for Agent Open environment) [25], exploits the concept of *workplace*, an organisational layer on top of *workspaces*. A *workspace* is a set of *artifacts* and *agents*, as a *workplace* is the set of *roles* and *organisational rules* being in force in a workspace. *Roles* can be played by *agents* inside the workplace, and they may or may not give permissions to *agents* to use some *artifacts* or to execute some specific operations on selected *artifacts*.
- JACK [2] is a multi-agent platform based on the BDI model; it is written in Java and is commercial-oriented. Following the BDI model, JACK enables the definition of agents' plans that start from the agents' knowledge and lead to the achievement of the agents' goals.
- JADE [3] (Java Agent DEvelopment framework) implements a FIPA-compliant general-purpose multi-agent platform fully implemented in Java language, that provides an agent-oriented infrastructure. The main concept of Jade is the *agent*, which is implemented by the *AgentJ* class and is associated to an Agent State, a Scheduler, and a Message Queue. Another important concept id the *behaviour*, which defines the main features of an agent. Jade offers a set of graphical tools that supports the debugging and deployment phases;
- MARS (Mobile Agent Reactive Spaces) [9] is a coordination medium based on programmable Linda-like tuple spaces for Java-based mobile agents. MARS allows agents to read and write information in the form of tuples adopting a pattern-matching mechanism. Moreover, its behaviour can be programmed to suit environment or application requirements. It it has been designed to complement the functionality of already available agent systems, and it is not bound to any specific implementation;
- RoleX (Role eXtension) [6] implements an infrastructure to manage roles for agents. It has been implemented in the context of BRAIN (Behavioural Roles for Agent INteractions) framework which proposes an approach where the interactions among agents are based on the concept of role. A *role* is defined as a set of *actions* that an *agent* playing that *role* can perform to achieve its task, and a set of *events* that an *agent* is expected to manage in order to act as requested by the *role* itself;
- TOTA (Tuples On The Air) [17] is a coordination middleware based on tuple spaces for multi-agent coordination, in distributed computing scenarios. TOTA assumes the presence of a network of possibly mobile *nodes*, each running a *tuple space*: each agent is supported by a local middleware and has only a local (one-hop) perception of its environment. Nodes are connected only by short-range network links, each holding references to a (limited) set of neighbour nodes: so, the topology of the network,

as determined by the neighbourhood relations, may be highly dynamic;

- TuCSoN (Tuple Centers Spread Over Networks) [21] is a coordination medium based on Linda-like tuple spaces; it is focused on the the communication and coordination of distributed/concurrent independent agents. In TuCSoN,the *Agent Coordination Context* (ACC) works as a model for the *agent* environment, by describing the environment where an *agent* can interact. It also enables and rules the *interactions* between *agents* and the environment, by defining the space of admissible agent *interactions*. ACC has first to be negotiated by each *agent* with the MAS infrastructure, and then the *agent* specifies which *roles* to activate: if the *agent* request is compatible with the current organisation rules, a new ACC is created, configured according to the characteristics of the specifies *roles*, and is released to the *agent* for active playing inside the organisation.

### C. The Gap

In our work we have studied the chance of integration between methodologies and infrastructures, evaluating whether and how the concepts considered by the methodologies can match with the concepts dealt with in the infrastructures. To this purpose, we exploited meta-models of both methodologies and infrastructures; in fact, the meta-model described the entities that represent the considered concepts of methodologies/infrastructures without looking at the different phases where they are involved, and allows to evaluate whether a matching exists and of which extent.

What emerges from our study is that there is not continuity between the methodologies and the infrastructures, presenting a gap between analysis and design on the one hand and development and implementation on the other hand. This gap concerns in particular the entities that represent the involved concepts. In fact, only few entities can be found in both methodologies and infrastructures with the same meaning, while others are present only in methodologies or infrastructures.

As an meaningful example better detailed in [8], consider the development of an application that simulates an auction. From a first analysis, the developer can design three roles, *bidder*, *auctioneer* and *seller* that can be implemented using an agent infrastructure. From a subsequent analysis, the design of a *broker* role emerges as needed in order to manage the real transactions from bidders and sellers. If there is a separation between the methodology and the infrastructure, i.e., there is not a connection between the "role" entity of the methodology and one or more entities of the infrastructure, the addition of a role could require the re-implementation of the application. Instead, if a connection is present, the modifications flow from the analysis/design to the implementation in a smooth way.

The lack of connections could be natural, since methodologies and infrastructures are likely to start from different needs; but it could lead to some problems; first, resulting in a fragmented development, but, more important, making maintenance very difficult: if a methodology entity has not a corresponding infrastructure entity, its change requires to find out how it was implemented.

As mentioned in the introduction, the reasons of such a gap are likely to derive from the different origins of methodologies and infrastructures: from the one hand, the traditional software engineering approaches follow a *top-down* direction; on the other hand, concrete requirements have called for implementation-oriented solutions providing platforms and frameworks to build applications. This gap could also reflect the twofold origin of the agent paradigm: artificial intelligence from the one hand, and distributed systems from the other hand.

Of course, there could be no need for exploiting infrastructure(s) not connected to a chosen methodology: there are different methodologies that have a natively compliant infrastructure. But we remark that the development of complex systems is likely to require the exploitation of different infrastructures, not always connected with the chosen methodology.

So, our aim is bridging agent methodologies and agent infrastructures in order to achieve a continuous support in the development of systems.

Previously, we have performed some work on specific issues.

As a first attempt, we try to map the methodologies' entities with the infrastructures' ones. To this purpose, first of all we have evaluated the entities common to the different infrastructures. This is useful to understand which the "core" entities are, which will deserve a support by the methodologies. This work is similar to build a common ontology that will semantically maps terms across methodologies and infrastructure, but the result will not cover all the necessary entities. So, we did not rely only on the *names* of the entities, but we spent an effort to map also entities with different names but the same meaning.

For instance, we have considered the PASSI methodology and the RoleX infrastructures, and we have produced a mapping based on their meta-models [8]. Molesini et al. have performed a similar attempt [18], considering one methodology (SODA) and three infrastructures (CArtAgO, TuCSoN and TOTA). As another example from our work, we have focused on the *role* entity, and we have evaluated how it is dealt with in methodologies and in infrastructures, in order to map the different approaches [23].

From these experiences, we have learned two main lessons. The former is that the exploitation of meta-models is very useful to understand the involved entities and their relationships; the latter is that a more global approach is needed.

## III. Proposed Approaches

Starting from the previous considerations, in this section we sketch three possible approaches that can fill the gap. Our work has just begun, so we will provide readers with its first results, which require further study in the future.

There are a lot of different methodologies and infrastructures, so we consider impossible to map each methodology and each infrastructure one in the other; instead we aim at more general solutions to help developer, especially those who have to integrate software agents in an existing application, but also those addressing new systems.

We also discarded the idea of creating a “new brand methodology” and a “new brand infrastructure” that can be used together, because they will be “yet another methodology” and “yet another infrastructure” to add in the context of the existing ones.

### A. *An Intermediate Layer*

The first solution is proposed taking into account existing or legacy components or applications that must be integrated.

This approach consists of defining an intermediate layer, which provides entities that are connected to the methodologies on the one hand and to the infrastructures on the other hand (see Fig. 1).

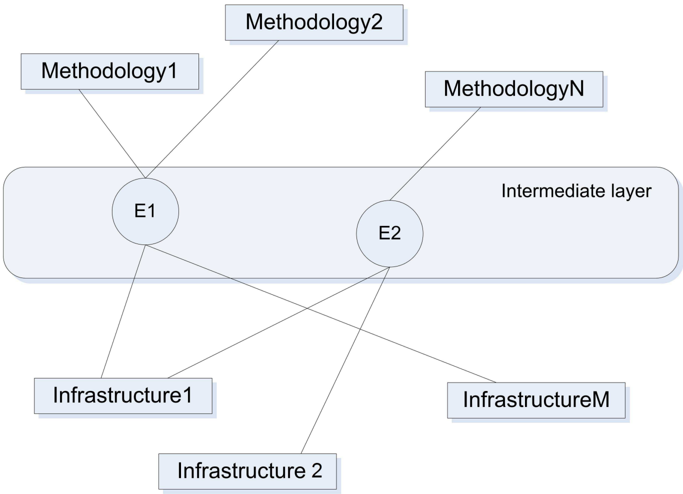

Fig. 1. An intermediate layer

From a particular point of view, this layer can be seen as an ontology, but we prefer to consider it more practically as a “common entities” layer, since it provides all the fundamental entities of the infrastructures chosen for the mapping; we have started from the most important ones, but then we are going to integrate all the others as well.

The entities that emerge from our study not only as common, but also as part of the foundation of the infrastructures, are:

- Agent
- Role
- Action
- Event

This layer can be exploited to map a methodology on every specific infrastructure. First of all, it can map entities starting from a direct mapping (one-to-one) and successively mapping the “composed” entities (one-to-n or n-to-one); during this work the studies of the mapping between methodologies’ entities and infrastructures’ ones previously presented can be very useful.

This new layer will permit to choose the preferred methodology and start to build the applications; then, when the infrastructure has to be chosen, the layer can be used to map the entities of the chosen methodology and the chosen infrastructures.

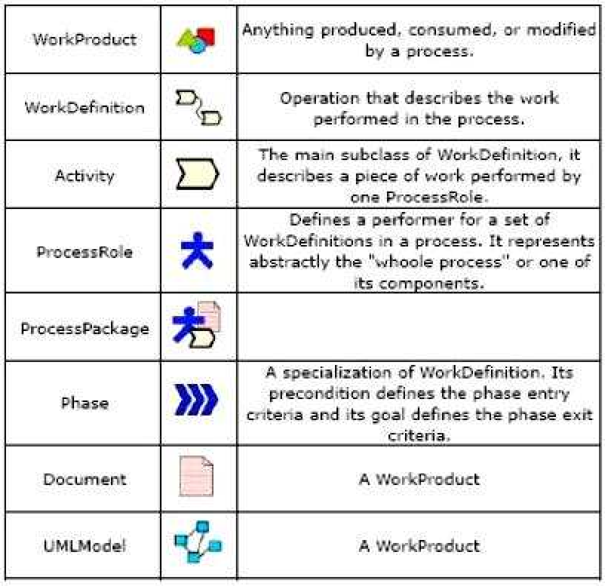
During this phase of translation, an interaction with the developer can be useful because not all the entities can be easily mapped, and sometimes, due to the chosen methodologies or infrastructures, the specifications of an entity by the developer can help the mapping. For example, MARS does not have the “event” concept, but has an “access event”, so the developer can be asked if the event is an access event or another one.

Of course this approach has some limitations, mainly because it is difficult to consider all the existing methodologies and infrastructures in a complete way; but it can be exploited for not forcing developers to choose a particular tool: it permits developers to be free in their choice, and to integrate existing applications.

### B. *SPEM*

An interesting idea to fill the gap is to use the most important features of methodologies and infrastructures to map them together; but it is very difficult because of their different languages and their different phases. If we have the same language for all the methodologies (and infrastructures) it can be possible to make a mapping and even to “select” useful parts of the considered methodologies.

This study can be possible using SPEM (Software Process Engineering Metamodel. In Fig. 2 we briefly present the 1.1 SPEM notation, which has been used for our studies; for further information see also [15] and [19].



| | | |
|---|---|---|
| WorkProduct | | Anything produced, consumed, or modified by a process. |
| WorkDefinition | | Operation that describes the work performed in the process. |
| Activity | | The main subclass of WorkDefinition, it describes a piece of work performed by one ProcessRole. |
| ProcessRole | | Defines a performer for a set of WorkDefinitions in a process. It represents abstractly the "whoole process" or one of its components. |
| ProcessPackage | | |
| Phase | | A specialization of WorkDefinition. Its precondition defines the phase entry criteria and its goal defines the phase exit criteria. |
| Document | | A WorkProduct |
| UMLModel | | A WorkProduct |

Fig. 2. The SPEM notation (v. 1.1)

With this “language” it is possible to describe processes and their components in term of pieces of process called “fragments”, using meta-models. This approach has been used by the OMG specifications, in the context of "FIPA Methodology Technical Committee" project [19], to translate some well known methodologies, like Adelfe, Gaia, Tropos, Passi, etc. in a common language; and the work is still going on with other methodologies. This approach can be used also for infrastructures if there is a clear meta-model to be used for the translation, even if today it is used only for methodologies.

SPEM specification is structured as a UML profile, and provides a complete MOF (Meta Object Facility)-based metamodel. Each fragment that is created is composed of (not necessary all of them) [15]:

1) A portion of process defined with a SPEM diagram;
2) One or more deliverables (artifacts like AUML/UML diagrams, text documents, and so on);
3) Some preconditions which said that it is not possible to start the process specified in the fragment without the required input data or without verifying the required guard condition;
4) A list of concepts (related to the MAS meta-model) to be defined (designed) or refined during the specified process fragment;
5) Guideline that illustrates how to apply the fragment and best practices related to that;
6) A glossary of terms used in the fragment;
7) Composition guidelines—A description of the context/problem that is behind the methodology from which the specific fragment is extracted;
8) Aspects of fragment: textual description of specific issues;
9) Dependency relationships useful to assemble fragments.

The main idea of SPEM is that a software development process is a collaboration between abstract active entities (*process roles*) that perform operations (*activities*) on concrete entities (*work products*).

SPEM can be used to translate all the different methodologies and infrastructures, to help developers to choose which to use for their applications.

Today, the most used version of SPEM is 1.1, but the 2.0 version is just be implemented, and there is also a tool that can validate the created fragments and their integration.

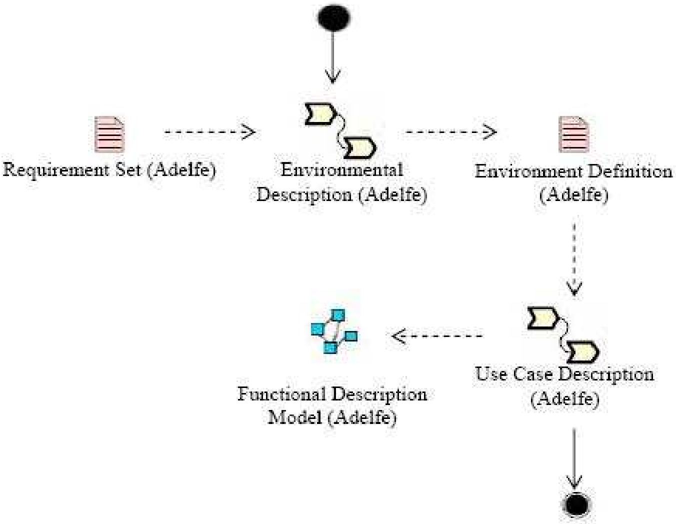
### C. A Composed Methodology

The last solution starts from the SPEM one and is the more radical, but it could be the most effective in the long term.

Given that the difficulties of the translation of all the methodologies and infrastructures is a very long work, a possible approach is to create a "composed methodology" that can be useful for developers, starting from SPEM fragments. This direction has been proposed also by the FIPA Methodology Technical Committee [14]. They have provided a repository of fragments to choose to compose an ad hoc methodology, adding the possibility to create new fragments.

To this purpose, we have selected some important fragments from the existing ones. In our study we have focused on (i) the common processes and entities of the methodologies and (ii) the entities that enable a connection with the main entities of the infrastructures. The composed methodology relies on different important fragments of ADELFE, PASSI, Gaia, Premetheus.

We have defined three phases: *Requirement* (Fig. 3), *Analysis* (Fig. 4) and *Design* (Fig. 5), while the *Implementation* phase is on going work.



Requirement Set (Adelfe)
Environmental Description (Adelfe)
Environment Definition (Adelfe)
Functional Description Model (Adelfe)
Use Case Description (Adelfe)

Fig. 3. Requirement phase

Some of these different fragments are well integrated, even if they come from different methodologies, while other fragments have been changed inside to match input and output of the different phases. This work has some difficulties because, as just said, entities with the same name but coming from different methodologies can not be used in the same way (e.g. the concept of ”agent” in ADELFE is adaptive, in PASSI is FIPA-like and in Prometheus is a BDI one). The implementation and validation of this composed methodology is still going on, trying to adjust the different fragments.

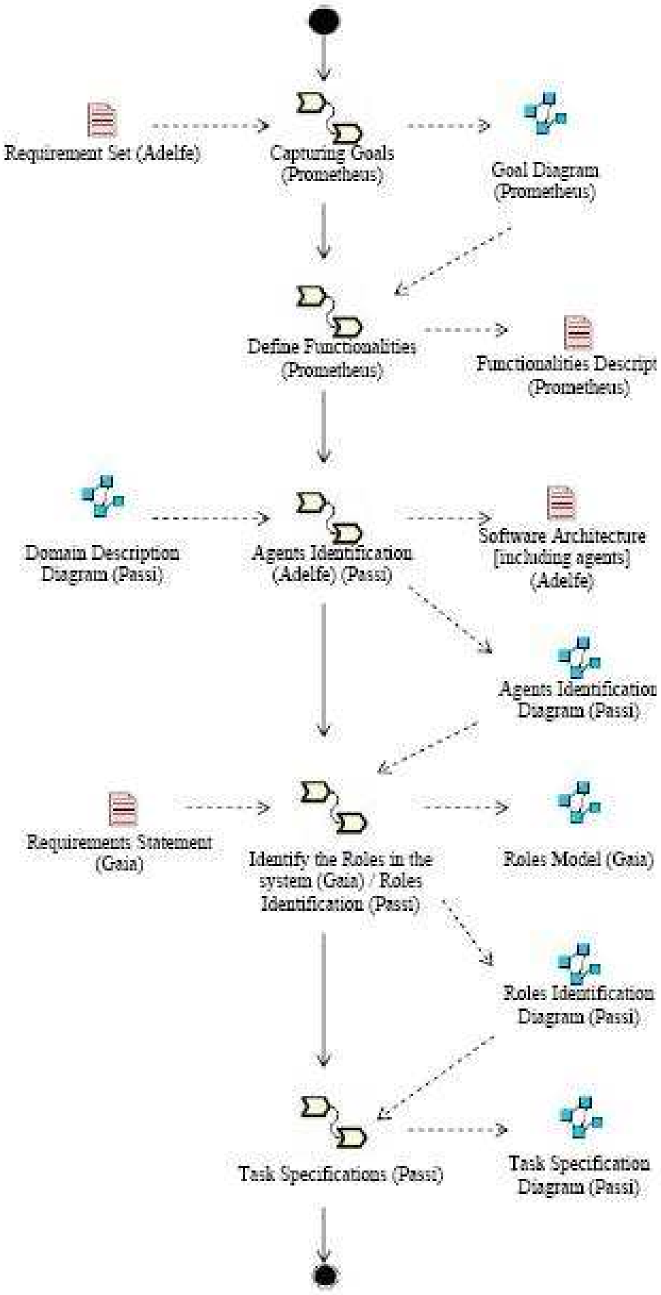
There are some advantages in exploiting fragments of existing methodologies. First, it is not "yet another methodology", because it takes concrete parts of the other methodologies, not only ideas and concepts; then, the exploited fragments have been tested by developer for different years and in different scenarios; further, there is already related documentation, case studies, tools and practice; finally, some developers can find some parts of the methodology they are used to.

Even if this third solution is more radical, it does not completely discard the existing background, on the contrary it tries to reuse (parts of) existing solutions and experiences.

## IV. Conclusions

In this paper we have addressed the gap existing between methodologies and infrastructures when developing agent systems.

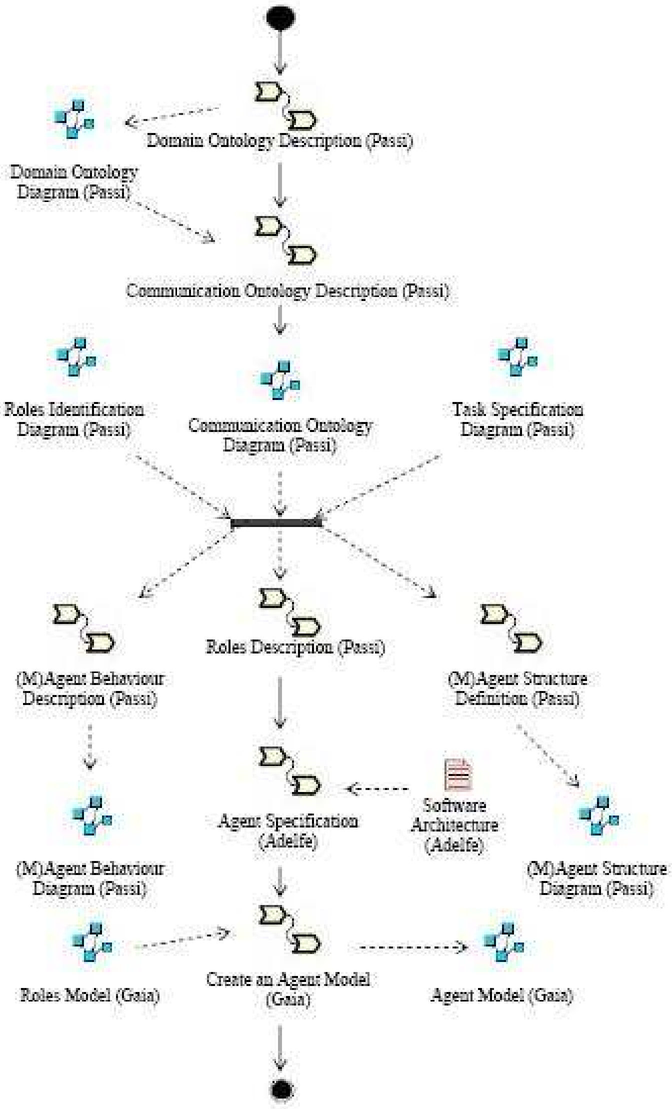
To fill this gap, we have proposed three possible directions. The first relies on an *intermediate layer*, which provides some common entities that are mapped to both methodologies' and infrastructures' ones. The second exploits SPEM, to



Requirement Set (Adelfe)
Capturing Goals (Prometheus)
Goal Diagram (Prometheus)
Define Functionalities (Prometheus)
Functionalities Descript (Prometheus)
Domain Description Diagram (Passi)
Agents Identification (Adelfe) (Passi)
Software Architecture [including agents] (Adelfe)
Agents Identificatior Diagram (Passi)
Requirements Statement (Gaia)
Identify the Roles in the system (Gaia) / Roles Identification (Passi)
Roles Model (Gaia)
Roles Identification Diagram (Passi)
Task Specifications (Passi)
Task Specification Diagram (Passi)

Fig. 4. Analysis phase

describe both methodologies and infrastructures by a common language, in order to make the mapping easier. Finally, the third approach proposes a new methodology, which is not “yet another methodology”, instead it is a “composed methodology” of fragments extracted from existing methodologies. The proposed solutions range from the most conservative one (useful when existing components are to be integrated with a reduced effort) to the most innovative one (more useful in the development of new systems), even if we have spent an effort to not discard the existing knowledge in the field.



Domain Ontology Description (Passi)
Domain Ontology Diagram (Passi)
Communication Ontology Description (Passi)
Roles Identification Diagram (Passi)
Communication Ontology Diagram (Passi)
Task Specification Diagram (Passi)
(M)Agent Behaviour Description (Passi)
Roles Description (Passi)
(M)Agent Structure Definition (Passi)
(M)Agent Behaviour Diagram (Passi)
Agent Specification (Adelfe)
Software Architecture (Adelfe)
(M)Agent Structure Diagram (Passi)
Roles Model (Gaia)
Create an Agent Model (Gaia)
Agent Model (Gaia)

Fig. 5. Design phase

The approaches sketched in this paper deserve still a lot of future work.

With regard to the *intermediate layer*, we must integrate also other entities beside the ones mentioned in Section III-A, and we must propose and test the possible mappings.

SPEM has recently been updated to version 2.0, promising different improvements that must be evaluated, considering also all the legacy work on this meta-language.

Also the definition of a *composed methodology* can benefit from the new version of SPEM, in particular form the capability of checking the correctness and the completeness of fragment composition.

Finally, whichever the chosen direction, it must be appropriately tested, possibly with formal tools, but certainly with concrete case studies.

***Abstract*—There are two main contributions of the work presented in this paper. First, extended PSA agent model is described. It is based on two new properties of so called *bootstrap agent*: multiplication and parallelism. Second contribution is application of extended PSA model to e-sourcing platform. This duo (e-sourcing and extended PSA model) shows enterprises can significantly increase resources acquisition and potential suppliers search.**

## I. Introduction

DURING last several years, the lowly, back-end sourcing process has been transformed into a strategic resource. Sourcing is now seen not only as a strategic player in the value chain, but as a major driver in the extended supply chain. To enhance their global operations, firms are seeking dynamic supply chain partnerships to increase the speed and intensity of their response to changes in customer demand and to lower costs and reduce risks.[4]

Traditionally, sourcing involves a number of communication mediums to facilitate all business processes between various parties. These include the use of mail, phone, fax, EDI and, more recently, email and the Internet. The current advances in information and communication technology have revolutionized procurement to turn it into a mechanism that enables diverse and geographically disperse companies to create alliances to meet a new form of Internet-oriented consumer demand.[2] Analysts believe that enormous cost savings and efficiencies can be achieved through the utilization of the electronic sourcing, a component of the B2B model. According to the Prime Consulting Group, global firms are optimistic on the level of savings that can be achieved through full implementation of e-sourcing strategies. The potential for savings is tremendous.[5] For instance, General Electric reports that it believes that the firm has saved over $US 10 billion annually through its e-sourcing activities.[4]

However, there are some limitations of e-sourcing. Firstly, there are thousands globally operating e-marketplaces, each with its own range of transaction mechanisms and additional facilities. The increasing number makes it impossible to browse them all by humans. Secondly, there are also differences between the requirements of a prospective participant for buying purposes and those organizations seeking participation as suppliers.[6] Thirdly, the environment of e-marketplaces is constantly changing—some e-marketplaces occasionally give much better offers than others, growing competitive and demand's changeability make the best offer finding difficult.

Those inconveniences can be satisfied by combining e-marketplace with agent technology.

Agent technology has been one of the most prominent and attractive technologies in computer science in the last decade. Software agents and their standards are being developed all the time by a lot of enterprises. Agents can be useful for e-supply chain configuration and management based on e-markets[1], which is strictly related to three particular properties of software agents. Firstly, agents are autonomous. A user can activate them, leave in the network and disconnect, provided agent mission is well defined. Secondly, such agent can be highly mobile. Agents enable dynamic supply chain configuration and reconfiguration in different environments. Thirdly, agents can be very intelligent, thus they are able to support efficient supply chain configuration. In case of e-procurement, agent technology is able to support efficient e-marketplaces, including partners who offer one another the best cooperation possibilities and conditions at a given time. There is a possibility to create temporal and dynamic supply chains aimed at executing a single transaction. This creates previously unknown opportunities for enterprises which can avoid stable supply chains, built on the basis of long-term contracts with rarely replaced business partners. [7][3]

The structure of the paper is as follows.

Section II presents the PSA agent model which is based on multi-dimensional versioning and segmentation of agent code, as well as on distribution of agent code and data over the network. The role of proxy agent and bootstrap agent is detailed. Finally, two extensions of the primary PSA model are discussed.

Section III shows application of the extended PSA model to e-sourcing platform. At the beginning environment of the approach is described. In the second part of this section features and functions of agents as well as exemplification of the approach are presented.

Section IV concludes the paper and shows the future work.

## II. Extended PSA Agent Model

According to the basic PSA (Polymorphic Self-Slimming Agent) model, an agent is composed of a sort of agent head, called *bootstrap agent*, and agent body.[7] Bootstrap agent is relatively small, thus it can be highly mobile. Its goal is to

978-83-60810-14-9/08/$25.00 © 2008 IEEE

move over the network and to decide whether a newly visited environment is potentially interested, taking into account agent mission defined by the user. If it is, then the bootstrap agent recognizes the specificity of the environment, afterwards it communicates with so called *proxy agent*, residing on the origin computer (i.e. a computer in which agent has been created by the user), asking for sending to the bootstrap agent an appropriate part of the code of agent body. Bootstrap agent communicates directly with the proxy agent using the messages in an agent-communication-language (ACL).[8][9]

It may happen that after some time, if the results of agent (i.e. bootstrap agent extended by agent body) activity are satisfactory, the bootstrap agent again communicates the proxy agent asking for the next part of agent body. This situation will be explained later.

If agent mission in the currently visited environment is completed then the agent body is removed from the environment and the bootstrap agent migrates to a new environment or it returns to the origin computer in order to merge with the proxy agent.

For the sake of platform independence and security, we assume that the bootstrap agent is interpreted by a visited environment. In other words the bootstrap agent is a source code, rather than partially compiled (pre-compiled) code.

There are four basic functions provided by the stationary proxy agent:

- It serves as a communication channel between the user and bootstrap agent: it knows current location of bootstrap agent and can influence the path of its movement, as well as tasks performed by the bootstrap agent.
- It encompasses all variants of the agent code that model the variability of agent behavior. Depending on what environment is currently visited by the bootstrap agent, and according to bootstrap agent demands, proxy agent sends a relevant variant of agent code directly to the bootstrap agent, thus enriching it with the skills required in this new environment and, as a consequence, enabling it to continue the global agent mission. Notice, that code transmission redundancy is avoided, since the unnecessary code (not relevant agent variants) remains together with the stationary component.
- It assembles data items that are sent to it directly from the bootstrap agent, extended by a proper agent variant, which are not useful for a mobile code, while could be interesting to the user. The data assembled is stored in so called *knowledge repository*.
- Whenever required, the proxy agent responds to the user who can ask about mission results and data already collected (e.g. a percentage of data initially required). If the user is satisfied with the amount of data already available, proxy agent presents the data to the user and finishes its execution (together with bootstrap agent).

To summarize the aforementioned discussion, one can easily determine the behavior and functions of a moving component (code). When it migrates to next network node, only bootstrap agent is transmitted, while the agent variant is just automatically removed from the previous node. There is no need to carry it together with the bootstrap agent, since it is highly probable that a new environment requires different agent variant. When migration ends, bootstrap agent checks its specificity, and sends a request for a corresponding agent variant transmission, directly to the proxy agent. When code is completed, the mobile agent component restarts its execution.

During the inspection of consecutive network nodes only the information that enriches the intelligence of a moving agent is integrated with agent bootstrap (thus it can slightly grow over the time). Pieces of information that does not increase the agent intelligence are sent by the mobile component of the agent directly to the stationary part, in order to be stored in the data repository managed by it. This agents feature, namely getting rid of unnecessary data, is called self-slimming.

Now we focus on possibilities of the PSA agent versioning, i.e. on the content of the proxy agent that is always ready to select a relevant piece of agent code according to a demand of the bootstrap agent. We distinguish three orthogonal dimensions of agent versioning:

- agent segmentation,
- environmental versioning,
- platform versioning.

*Agent segmentation.* Typically agent mission can be achieved by performing a sequence of relatively autonomous tasks (or stages). Thus the agent code is divided into so called segments corresponding to consecutive tasks that have to be realized. If one task is finished successfully, then the next one can be initiated. Thus, next segment of agent code is received from the proxy agent and agent execution switches to this new segment. Depending on whether agent behavior is sequential or iterative, the previous segment is automatically deleted (in the former case) or it remains in the execution environment (in the latter case).

To summarize, this versioning dimension, namely segmentation, models multi-stage nature of PSA agents.

*Environmental versioning.* Bootstrap agent can visit different environments providing different services, e.g. e-marketplaces, auction services. Moreover, every service can be implemented in a different way. For example, the e-marketplace can be implemented as a web-site or database application. Thus, depending on the specificity of environment being visited different version of agent segment is required.

In other words, the proxy agent keeps and manages sets of versions for each agent segment and takes care on their consistency, i.e. knows which versions can "go together".

To summarize, this versioning dimension, namely environmental, models polymorphic nature of PSA agents.

*Platform versioning.* Finally, every version of every agent segment is available in potentially many variants which are implemented for a particular target environment (i.e. for a particular hardware which runs agent environment: processor, operating system, network communication protocols etc.). There is one especial variant for each agent segment version, that is in a source form. It is sent to the environments which for the security reasons do not accept pre-compiled code. Besides this particular variant, the proxy agent keeps potentially unlimited number of partially compiled variants. If the environment accepts this sort of code, then the proxy agent delivers a variant matching hardware and system software parameters of this environment.

To summarize, this versioning dimension, namely platform, models platform independent nature of PSA agents.

Now we present two important extensions of the primary PSA model, which in our opinion, could be very useful in e-commerce applications (cf. section 3).

Firstly, it may happen that the chain of environments (nodes) visited and examined by a bootstrap agent is very long, before the relevant one is found. In order to increase the efficiency of examination, we allow for a single PSA software agent to have more than one copy of a bootstrap agent, behaving in the same way. In other words, it is possible for the proxy agent to send in parallel, say, *n* bootstrap agents addressed to different network locations. When allowed by visiting environments, they start to examine their specificity in asynchronous way. Their common goal is to find, as fast as possible, the most appropriate environment (e.g. e-marketplace) to fulfill the agent mission.

When all *n* bootstrap agents report the end of their activity and send back results, now it is up to the proxy agent to decide which one of the visited nodes will be examined by the PSA agent (i.e. consecutive variants of code segments). Then, only one of bootstrap agents (augmented by a code delivered to it on demand) continues its execution, while all the remaining *n-1* bootstrap agents automatically "dye" without further actions.

Secondly, we must allow the situation when more than one bootstrap agent reports to the proxy agent a success of examination, i.e. more than one potentially interesting network sites have been found. If they are just e-marketplaces, then perhaps instead of short visiting, they require continuous monitoring of announced offers, 24 hours per day in a long time period. To correctly deal with this situation, we assume that a single PSA agent may have many, so called *twin instances*, residing in different environments. They are fed with necessary code in-the-fly, by the same proxy agent, since they are just "twins" acting in a corresponding way, according to the same code repository kept by a single, shared proxy agent.

Twin instances are to some extent autonomous, thus in general they may work asynchronously. In this case the common proxy agent plays the role of a pure communication mean between them. It may happen, however, that there is a need for synchronicity between twin instances. For example, one instance can switch into next, say, third code segment only if the other one has already finished successfully the execution of first segment. In this case, bootstrap agent is responsible for coordination of instances execution, providing basic synchronization mechanisms.

## III. Application of Extended PSA Agent Model to E-Sourcing Platform

Information systems that support e- sourcing can be classified into four major segments: buy-side applications, sell-side applications, content applications and e-marketplace applications.[4]

In this section we focus on the last segment and we present the adaptation of Polymorphic Self-Slimming Agent Model into it. This new proposal expands the present opportunities offered by e-marketplaces.

Environment of the new approach

- The foundation of resources/suppliers searching is the *sourcing cluster*.
- *Sourcing cluster* (type of business cluster) is a group of enterprises which are looking for the same type of resources (e.g. steel, plastic, packaging, transportation, etc.) created within specific e-marketplace. All sourcing cluster data is stored within e-marketplace database.
- E-marketplaces are based on service-oriented architecture (SOA) which provides system interoperability.
- E-marketplaces coopetite[1] with each other in order to provide wider offers range for their customers.
- Each e-marketplace can have its own company priority managing mechanism. Each company has its own priority level participating on every e-marketplace ( *p-level* ) which can depend on: purchase/ sell volume, purchase/sell value, length of e-marketplace participation period, company size, annual income, country of origin, etc. Characteristics of the prioritization mechanism can be individually set on each e-marketplace.
- E-sourcing platform is a set of all potential interoperable e-marketplaces that can exchange information. Each e-marketplace receives interoperability level status. We distinguished three levels: full interoperability (F), quasi interoperability (Q), base interoperability (B).
- *F status* of e-marketplace must provide: offer browsing, *sourcing cluster* creation and management, agent negotiation, contract signing, partner evaluating (p-level changing), message exchange, and external systems (i.e. ERP, WMS) integration.
- *Q status* of e-marketplace must provide: offer browsing (obligatory), any combination of other *F status* features.
- *B status* of e-marketplace must provide: offer browsing.
- Each enterprise is represented by group of software agents (cf. section II).
- Only enterprises (their software agent representatives) can create or join sourcing clusters.
- Type of the resource in each sourcing cluster is the same.
- The more enterprises in sourcing cluster the bigger possibility to find needed resources.
- At the same time each e-marketplace is searched

[1] Coopetition is a neologism which matches cooperating and competition. Examples of coopetition include Apple and Microsoft building closer ties on software development and the cooperation between Peugeot and Toyota on a new city car for Europe in 2005.

only by one enterprise representative (software agent) from each sourcing cluster.

- E-marketplaces can be accessed by an arbitrary number of software agents (e.g. representing many suppliers) which work independently, or collaborate with other software agents.[3]
- The facilitates offered by the e-marketplace may extend to full execution, including financial and logistical services. [6]

Features and functions of agents

The main c haracteristics of the agents used in our approach are:

- robust ness (even when one or more individuals fail, the group of agents can still perform its tasks),
- self-organization (agents need relatively little supervision or top-down control because they are autonomous; agents have capabilities of task selection, prioritization, goal-directed behavior, decision-making without human intervention)
- flexib ility (agents can quickly adapt to a changing environment because they are very intelligent and reasoning).

Additionally, agents are mobile, so they can relocate their execution onto different places in the network.

We distinguished some groups of features and functions which are characteristic for a proxy and bootstrap agents active on e-sourcing platform.

- Features and functions of proxy agent:
    - It represents particular entities (e.g. purchaser, supplier, logistics service provider) which operate on e-marketplace.
    - It communicates not only with bootstrap agents, but with delegating users (human or IT system of enterprise (e.g. ERP system)).
    - It acts according to guidelines and entitlement granted by a delegating user.
    - It informs about the progress and the results of performed tasks.
    - It solves problems that appear during offers searching.
    - It co opetites with agents from competitive companies.
- Features and functions of bootstrap agent
    - It browses offers available at e-marketplaces.
    - It is responsible for checking and comparing offers of products and services.
    - It notifies proxy agent when a new offer appears and informs about the progress of the realization of the offer.
    - It is responsible for negotiation of terms of cooperation with the agent presenting the offer.
    - It is engaged in business contract monitoring and finally signing it.
    - It is obliged to inform proxy agent about problems and failures.

Exemplification of the approach

Let 's imagine that one company is not satisfied with its past relations with suppliers. Additionally company' transaction volume is still rising and customers want more customized products. Problems with suppliers mainly relate to shipment delays and rigid volumes of orders. This situation forces company to look for new partners to preserve its market position. Task of finding new, reliable suppliers is very difficult and time consuming, especially when company acts alone. Combination of e-sourcing and agent technology (extended PSA model) can inconceivably boost up this process. To start looking for new suppliers our company creates profile on one of available e-marketplaces. Each profile on our future e-marketplace is equipped with group of PSA agents (cf. section II). Then company finds a sourcing cluster on the e-marketplace. If there is no such cluster company creates one, but it still acts alone in searching potential suppliers. When company wants to be part of a bigger sourcing cluster it delegates proxy agent to find one on other e-marketplaces. Proxy agents send bootstrap agents to look through the e-sourcing platform (all e-marketplaces) to find proper sourcing cluster for the company. Company can determine conditions that sourcing cluster must meet (i.e. number of enterprises, size of enterprises, their locations, etc.). Of course for bigger scope of potential suppliers searching, company can participate in many clusters on many e-marketplaces.

But how these sourcing clusters help to find suppliers? Each company in sourcing cluster has its own proxy agent (company representative) and related group of bootstrap agents. Proxy agents of each company associated in the sourcing cluster delegate its bootstrap agents to search for precisely described resources (quantity, quality, price, shipping terms, etc.). Searching conditions ( *Cn* ) are determined individually by each company. *Cn* is a set of *i* conditions. $Cn = \{Cn_1,...,Cn_i\}$. Individual condition ( $Cn_i$ ) can have precise value (number or text) or can be described by text list or number range. When in *Cn* are conditions that can be negotiated or omitted proxy agents creates additional *Cnx* set of information where $Cnx_i$ represents possible state of condition *i*. Each $Cnx_i$ can have one of four states: *ob* for obligatory, *om* for omitted, *n* for negotiable and *n/om* for negotiable or omitted. The last state allows proxy agent to decide what to do with specific condition when resource is founded. Additionally *Cn* set is supplemented with the value of company's total demand for the resource ( *D* ).

Proxy agent delegates bootstrap agents to look for particular resource that meets *Cn* and satisfies *D*. We distinguished four possible scenarios of the resource searching process:

1. All *Cn* are met and *D* can be fully satisfied.
2. All *Cn* are met but *D* can be partially satisfied.
3. Not all *Cn* are met but *D* can be fully satisfied.
4. Not all *Cn* are met and *D* can be partially satisfied.

In cases (1) and (2) proxy agent just sends additional parts of the bootstrap agent source code that is responsible for next sourcing phase (i.e. contract signing). Scenarios (3) and (4) allow proxy agent to change not met $Cn_i$, to start negotiation phase or just to discard the supply offer. All above operations depend on e-marketplace status ( *F*, *Q* or *B* ). When proper features are supported by e-marketplace bootstrap agent source code can be extended with: contract signing procedures, negotiation procedures or message exchange procedures. If *D* is fully satisfied proxy agent informs other proxy agents within its sourcing cluster about founded resource. Information includes basic conditions for the purchase (i.e. supplier location, resource description, shipping information, currency, needed documents, etc.) and updated volume of the resource. All company-specific conditions are omitted in this information.

Above exemplification contains only mechanism for resource searching on external to sourcing cluster e-marketplaces. Implementation of the mechanism and its extension to purchasing, negotiation and contract signing are foundations for future work (cf. section IV).

## IV. Conclusions and Future Work

To summarize, research results reported in this paper mainly relate to well-known li mitations of e-sourcing, i.e. difficulties and restrictions in browsing e-marketplaces by humans, differences between requirements of a potential participant for buying purposes and those organizations seeking participation as suppliers, growing competitive and demands changeability at e-marketplaces that make the best offer finding difficult.

As proposed and explained in the paper, those inconveniences can be solved by software platforms implemented according to very promising and challenging for business – agent technology.

Future work will concern mainly further extensions of PSA model (cf. section II) towards its application in the area of widely understood e-sourcing activities, as well as prototyping experiences, based on the assumptions referred in the previous section (cf. section III). Authors find it also very interesting extending presented model with swarm intelligence algorithms (i.e. ant colony optimization (ACO), particle swarm optimization (PSO)).

# The Triple Model: Combining Cutting-Edge Web Technologies with a Cognitive Model in an ECA

Maurice Grinberg and Stefan Kostadinov
Central and Eastern European Center for Cognitive Science, New Bulgarian University,
Montevideo 21, 1618 Sofia Bulgaria
Email: mgrinberg@nbu.bg, stefan@yobul.com

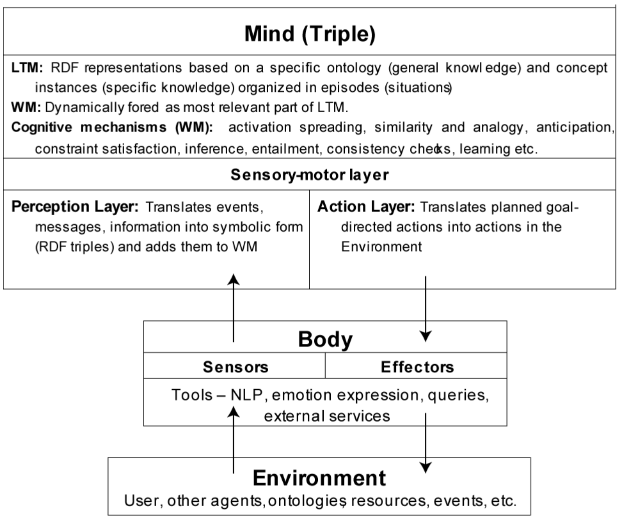
***Abstract*—This paper introduces a new model which is intended to combine the power of a connectionist engine based on fast matrix calculation, RDF based memory and inference mechanisms, and affective computing in a hybrid cognitive model. The model is called Triple and has the following three parts: a reasoning module making advantage of RDF based long-term memory by performing fast inferences, a fast connectionist mapping engine, which can establish relevance and similarities, including analogies, and an emotional module which modulates the functioning of the model. The reasoning engine synchronizes the connectionist and the emotional modules which run in parallel, and controls the communication with the user, retrieval from memory, transfer of knowledge, and action execution. The most important cognitive aspects of the model are context sensitivity, specific experiential episodic knowledge and learning. At the same time, the model provides mechanisms of selective attention and action based on anticipation by analogy. The inference and the connectionist modules can be optimized for high performance and thus ensure the real-time usage of the model in agent platforms supporting embodied conversational agents.**

## I Introduction

INTERNET has become an extremely rich environment, which starts to become comparable with a real life environment – the available information is too abundant and the existing options are too numerous to be considered and taken into account completely. Even in the case, in which we can make all possible inferences based on a large ontology in extremely short time (of the order of milliseconds), the increase of information seems to be too large to be useful. It seems that although there is some control in the way the information is presented, namely sometimes in a structured form, pure AI approaches are not sufficient to design and implement artificial cognitive systems in Internet that can achieve human level of performance. Analogously to robotics, accomplishing tasks in complex environments seems to require novel (with respect to GOFAI) approaches starting from the connectionist modeling and going to more and more biologically inspired architectures. Similarly, inference based on ontologies can be done extremely efficiently but this is a problem in itself because of the risks of information explosion.

In cognitive systems this problem is addressed first of all by introducing the concept of working memory (WM) which broadly speaking can represent the most relevant part of the long term memory (LTM) which contains all the knowledge an agent knows. The relevance of the information retrieved from LTM can be insured by activation spreading mechanisms, with the goal and the perceived input (e.g. task, scene etc.) as a source of activation (e.g. see [1]). Such activation spreading can use the connections in LTM or some other types of connection – associative, based on semantical similarity, etc. Other possible mechanisms of selectivity of the information used can be based on anticipatory mechanisms in perception and action (e. g. see [2]—[4]) or other selective attention mechanisms. The role of emotions in cognitive modeling and especially in embodied conversational agents (ECA) has been given a lot of attention recently (e.g. see [5]) and seems to be an important set of mechanisms which can add a lot in communication with users but also influence the reasoning processes. In the case of an ECA which is supposed to interact with users in real time, the problems of scalability and processing time become even more important and efficiency issues are of primary concern.

The model Triple, introduced here for the first time, is aimed at being a cognitive model for cognitive systems and particularly for ECA platforms. It includes, on one hand, several of the necessary mechanisms mentioned above and



Mind (Triple)
LTM: RDF representations based on a specific ontology (general knowl edge) and concept instances (specific knowledge) organized in episodes (situations)
WM: Dynamically fored as most relevant part of LTM.
Cognitive mechanisms (WM): activation spreading, similarity and analogy, anticipation, constraint satisfaction, inference, entailment, consistency checks, learning etc.
Sensory-motor layer
Perception Layer: Translates events, messages, information into symbolic form (RDF triples) and adds them to WM
Action Layer: Translates planned goal-directed actions into actions in the Environment
Body
Sensors
Effectors
Tools – NLP, emotion expression, queries, external services
Environment
User, other agents, ontologies, resources, events, etc.

Fig 1. A Mind-Body-Environment conceptualization of an ECA, using the Triple model as Mind.

978-83-60810-14-9/08/$25.00 © 2008 IEEE

on the other it tries to achieve maximal computational efficiency in order to allow real time functioning of the ECA. These two constraints lie at the basis of this model: adding all the useful cognitive modeling techniques which allow flexibility, context sensitivity and selectivity of the agent and in the same time – maximal computational optimization of the code and use of very efficient inference methods (e.g. see [6]).

Following this strategy, the model has been designed in three parts that function in parallel. The so called Reasoning Engine (RE) is coordinating and synchronizing the activities of the model and relates the agent with the environment (e. g. user, other agents, etc.) and with the tools the agent can use (e. g. tools to communicate with the user, make actions like access ontologies and data bases, search the Internet (see [3] and [4]), extract LSA information from documents, etc.). RE is also responsible for instance learning – storing of useful episodes in LTM after evaluation. The Inference Engine (IE) is used by RE and can operate on demand. Its main role is to augment parts of WM with inferred knowledge and do consistency checks.

The second part of Triple is the so-called Similarity Assessment Engine (SAE). It is designed to be a connectionist engine, based on fast matrix operations and is supposed to run all the time as an independent parallel process. The main mechanism is activation spreading in combination with additional mechanisms which allow to retrieve knowledge relevant to the task at hand. Communication of SAE with RE is elicited by events related to the level of activation. The SAE mechanisms are supposed to lead to the retrieval of information which is related to the task at hand at different level of abstraction.

The third part is the Emotion Engine (EE) which is based on the FAtiMA emotional agent architecture [7, 8]. FatiMA generates emotions from a subjective appraisal of events and is based on the OCC cognitive theory of emotions [9]. EE, similarly to SAE, is supposed to run in parallel and influence various parameters of the model like the volume of WM, the speed of processing, etc. (see [10] for a possible role of emotions in analogy making). In the same time it will allow achieving higher believability and usability based on the emotional expressions corresponding to the current emotional state of the agent.

The Triple model is connected to the DUAL/AMBR model [1] by inheriting some important mechanisms. Triple like DUAL/AMBR makes use of spreading of activation as a method for retrieval from memory of the most relevant episodic or general knowledge. The mapping of the knowledge retrieved to the task at hand and to the current input to the system is based on similarity and analogy in both models. However the underlying mechanisms are essentially different. In DUAL/AMBR knowledge representation is based on a large number of micro-agents which perform local, decentralized operations and are dualistic in the sense that they spread activation and perform symbolic operations at the same time. The messages exchanged between the micro-agents trigger the establishment of mappings, structural correspondence assessment (which stand for concepts and relations) and the speed of the symbolic processing of the messages depends on their so-called 'energy' (basically an integral over the recent activation). In Triple, an attempt has been made to achieve the same functionality on the basis of clearly separated symbolic mechanisms (reasoning, inference, consistency checks, anticipation, etc.) and connectionist mechanisms (spreading of activation over different types of connections, similarity assessment, distributed representations, etc.). A third component is the emotional module (EE) which is missing in DUAL/AMBR [10]. In DUAL/AMBR the 'duality' is achieved at the level of each micro-agent while in Triple it is achieved by two systems which run in parallel and communicate on event-driven basis. An important additional difference is that Triple is using a full fledged reasoning part in the standard AI sense, which is not available in DUAL/AMBR. The inference and entailment capabilities are integrated with the spreading of activation and evaluation of retrieval and action planning. Only the most active part of WM, corresponding to the focus of attention of the system is subject to augmentation based on inference and to other symbolic processing like evaluation, transfer, and action. The Amine platform [11] has similar augmentation mechanisms which are based on purely symbolic manipulation and are not conditioned by the attention of the system (see [11] and [12] for similar mechanisms like 'elicitation' and 'elaboration').

At this stage Triple inherits from DUAL/AMBR all the mechanisms of transfer of knowledge and anticipation from LTM based on analogy-like reasoning (e.g. see [3] and [4]) but additionally uses consistency checks and inference. The latter is expected to improve efficiency considerably because it will allow timely canceling of impossible plans and will not rely only on external feed back.

One of the main roles of an ECA is to be a sophisticated intelligent interface between a human and a virtual or real (artificial or natural) environments (e.g. see [13] and [14]). An example of such an environments is the Internet, as discussed above. In order to think of the agent as embodied and situated in any environment, the structure shown in Fig 1 has been adopted. The advantage of this representation is the possibility to consider physically and virtually embodied agents on equal footing. It supports also the conceptualization of Internet (or any virtual environment) made above which implies that sufficiently rich virtual environments should be considered as 'real' ones with respect to their richness and complexity. In Fig 1, the Mind is shown with its specific knowledge structures and tasks. The Sensory-Motor Layer makes a mediated connection between the Mind, and the Tools of the agent, which are the sensors and effectors that work with the Sensory-Motor Layer and perceive or act on the Environment. The Sensory-Motor Layer provides symbolically represented knowledge to the Mind and thus makes mediated connection between the Mind and the Environment.

The user occupies the central part in a ECA environment and has a complex set of goals, needs, interests, expectations and previous knowledge. On the other hand, as stressed for instance in [5], any interaction with the user has its affective and emotional background which is highly user and situation specific. In order for such an interface to be maximally efficient under these conditions it has to be highly personalized and context sensitive. It seems that this cannot be done only on the basis of statistical information gathering (e.g. like in a recommender system). The agent has to be a real personalized partner which remembers important (or all) past episodes of interaction with the user and thus is able to establish a deeper relationship with the her based on personalized common experience. For instance, in these memories, the satisfaction of the user should be encoded as, generally speaking, the agent is supposed to satisfy the user. This personalization is achieved in Triple by the rich episodic memory in which all kinds of episodes and information are stored: general knowledge, typical and specific situations, events and user evaluations of task completion outcomes. Examples of how such episodic knowledge can be used can be found in [3] and [4]. Episodes are a rich source of personalized experience and can be used for analogical reasoning or case-based reasoning. They represent a rich source for user-centred learning and generalization. They can encode, among other things, the preferences of the latter in various contexts, his/her definitions of key concepts, etc. and thus allow for information selection and form of presentation.

As our previous experience has shown [4], the success of such an approach is based on the richness of episodic knowledge and in the way the LTM part relevant to the task is accessed. The encoding of episodes is unavoidably specific and unique (a specific set of concept and relation instances is used). The specificity is guaranteed by the learning mechanism consisting in the storage (retention) of task completion episodes and knowledge provided by the user in LTM. It may turn out that the questions or goals are formulated differently than the episodes stored in LTM although using the same concepts, e.g. by using different relations between the same instances of concepts. In order to make use of previously encoded knowledge one needs mechanisms generating various equivalent representations to overcome the limitations of a specific encoding (e.g. the possibility to transform “John is the father of Mary” into “Mary is the daughter of John”). It is obvious that flexibility and reliability in this direction can be achieved only if the similarity and equivalence of knowledge could be assessed, as well as its consistency with previous knowledge. In order to be able to do so, the ECA should dispose of powerful inference and reasoning capabilities in order to achieve maximal flexibility. Thus in comparison to DUAL/AMBR, additionally to analogy making, the Triple model extensively uses rule-based inference and entailment based on previous knowledge based on its relevance.

In the following sections, the main principles of Triple will be presented in more detail and the implementation of the main modules discussed.

## II The Model Implementation

The model presented here is a continuation of an effort to design an ECA architecture with cognitively based mind for a real application [15]. The attempt to use the DUAL/AMBR architecture [1] made evident the existence of scalability problems and the need for faster and more flexible model mechanisms. This lead to the creation of the model Triple.

The embedding of Triple in a real agent platform is currently in progress but some simple evaluations have been already performed with partial functionality and showed promising results in terms of efficiency. The platform implementation (see [15] for details) uses the Nebula engine [16] for the multi-modal generation and NLP processing and speech synthesis [17, 18]. In order to provide the required speed of processing for a real-time application, fast OWLIM RDF inferencing and handling was provided [6] and adapted to the model needs. RDF triples representations and inference on them play a crucial role in the implementation of LTM and IE. All this, combined with the fast matrix-manipulation-based similarity assessment engine provides response time of a few seconds for simple tasks as estimated with the initial implementation of the model.

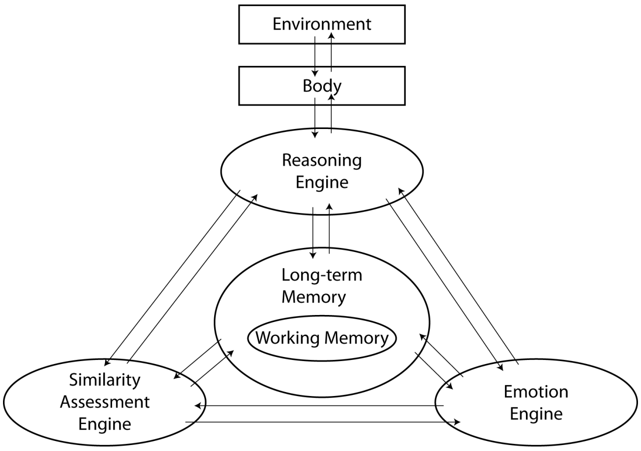


Fig 2. The Triple architecture and interactions among the IE, SAE and RE. (See the text for explanations.)

It should be stressed that the model is intended to be general enough and is not related in an essential way to the use of the specific tools quoted above.

A typical interaction episode with an user would be similar to the interaction episodes described in [4], where DUAL/AMBR has been used as a cognitive model. The user asks a question which is processed by NLP tool [17] and the information about the type of utterance (greeting, question, task, etc.), what is asked for (if the utterance is a question), and what is the knowledge contained in the utterance is expressed in RDF triples and attached to WM as instances of existing in LTM shared concepts. The set of nodes represents the goal or the task given by the user to the agent and is labeled as 'target'. The target could include any additional input accessible to the agent via its 'sensors'. The basic process of task completion is to augment this target set of nodes with knowledge from LTM or from external ontologies or sources and formulate an answer or reaction to the user utterance. The following subsections explain in detail how this is achieved and what is the interplay between the three processing modules of Triple presented schematically in Fig 2.

### A. Similarity Assessment Engine (SAE)

As discussed in previous sections, the agent's knowledge is represented as concepts (including relations) and their instances by nodes related through weighted links forming a semantic network which could include other types of connection (e.g. associative ones) especially in the episodic part (see [1]). The main problem to be solved by SAE is to assess the level of similarity or correspondence between two nodes typically belonging to the target (the task) of the agent and to LTM, respectively. The problem with similarity assessment is central for such approaches and has been extensively explored in the analogy and case-based reasoning literature (e.g. see [19, 20, 21] and the references there in). The Similarity Assessment Engine (SAE) is exploring some established and some new approaches in finding similarities aiming at the highest possible efficiency.

Typically, part of the nodes come from the target (e.g. a task by the user or an internal goal for the agent) and the others come from the active part of LTM and both form the WM content. The normalized similarity (lying between 0 and 1) between target and LTM nodes is taken to be the probability of correspondence between the two nodes. The basis for similarity evaluation can be quite various and generally speaking takes into account the taxonomic links and the proximity of the nodes in the semantic tree by using different types of distributed representations, some of which will be explained bellow. Additional mechanisms as the one proposed in [19] using Latent Semantic Analysis (LSA) [22, 23] and are based on semantic similarity.

The connectionist processing is based on the representation of the WM of the agent as a set of matrices, that reflect different dependencies among the concepts, relations and their instances. It should be stressed that there are no named connections in this representation and all relations including 'instance-of', 'sub-class', 'super-class' and others are represented as nodes, linked by weighted connections. Thus all the contents of the WM are represented as a vector of nodes (concepts, relations and their instances) and the connections are a matrix of weights. All the nodes related to the input and the goal for the agent are part of a 'target' set of nodes and the achievement of the goal (e. g. finding the answer of a question) is formed by augmenting this target set so that it contains the results of the processing and include completion of the goal or a failure. In order to do so the agent must retrieve knowledge similar (or analogical) to the input and transfer the required knowledge to the target or trigger a plan of actions in order to find it, e. g. search in an ontology or data source. So, to each node in WM a vector is attached, which contains distributed information about its definition, relations and actions in which it participates, its instances or super-classes, etc. which can be used to measure its similarity to other nodes. It should be noted that this distributed representation is spanned only over the nodes in WM, i. e. the nodes with sufficient activation. Moreover, each term in the distributed representation is multiplied by the corresponding node activation. This procedure will change the similarity between nodes depending on the activities of the nodes present in the WM. Thus similarity becomes dynamic and changes depending on the content of WM at a given time and thus is highly context dependent. For example if the neighboring nodes of a node have a higher activation than the higher concepts in the taxonomy more specific similarity will be found and if the higher concepts are with larger activation more abstract and high level similarity (analogy) will be established. The similarity depends on a similarity measure between any two such characteristic vectors (e.g. a normalized scalar product). This normalized similarity is interpreted in the model as the probability for useful correspondence between the two nodes which eventually will lead to the retrieval and mapping of the target task to a relevant part in LTM, which may contain the required knowledge for task completion.

This principle of similarity assessment seems to be quite general and we are planing to test and combine different implementations. All are based on the relations between the nodes in Triple LTM. Other methods we are considering are the ones based on Latency Semantic Analysis [15, 16] for the respective domains. Additional mechanisms, presently explored are related to spreading of different type of activation which require much more space and will be reported in a separate future publication as applied to a music domain. The SAE has been implemented using compiled Matlab code and making use of the sparse matrices manipulation routines.

### B. Emotional Engine(EE)

The Emotional Engine works continuously and in parallel with the SAE and provides continuous fine-tuning of the rest of the Mind modules and, from time to time – takes control over the reasoning process (see end of this section). The so-called fine-tuning is done as the EE is constantly decaying to a “neutral” state. The size of the Working Memory, the severity of the reasoning constraints, etc. all depend on the emotional state. As the emotional state changes over time, when major changes occur, events are sent to the Reasoning Engine. An example of such event is the case where an action of information retrieval from an Internet web-service is performed. If the service does not respond at all, the emotional state would decay over time and thus the action that triggered the emotional state would be suspended. This solution seems better than to have a fixed amount of “real” time (in seconds), as the EE depends on the time elapsed, the importance and desirability of the action performed, the initial emotional state and any other events that might occur in the meantime. When an action is interrupted if proven unsuccessful, or because the EE halted it, the next action in the line is going to be executed (see Reasoning Engine section for details). The details about this engine will be published in a forthcoming paper [8].

### C. Reasoning Engine (RE)

The reasoning engine integrates and controls the operation of the SAE, IE, and EE on one hand and the communication flow with the Body (and thus with the Environment) on the other (see Fig 2). It works with the sensory-motor part of the Mind by receiving the information from the sensors (user utterances, information about results from actions, etc.) and sending action commands to the Environment via the Body's tools (Multi-Modal Generation, Data Source Lookup, etc.). The main interactions with the Body and Environment are the same as the ones reported in [4] and are briefly explained in the next section.

### *I Information flow*

Information (in RDF triple form) received by the Mind is either a new information from the Environment (question, task, definition, etc.), or a response from an action (result from a tool). The human input is considered as information from the Environment and is processed by the NLP tool into a set of RDF triples. Each coalition, coming from the Body, is assigned a context, and if there is no current task, a new context is created.

When there is an action coalition of nodes transferred (see next section), the RE identifies the statements related to this coalition and sends them to the Body as an "action command". In order to be meaningful, this action command must adhere to the requirements of the specific tool it is addressed to.

### *II Main mechanisms*

When a new message is received from the Body, the RE adds it to WM (and thus – to LTM) and marks all the statements from the message as "target". All the parts of the message, that are not internal (e.g. which Tool generated the message) are marked as being "goal" for the system (see [4]). The target set (called "input" and "goal") is the source of activation for the SAE module. This module is started by RE and gives continuously information about similarities found between the target set and knowledge in WM and initially determines the focus of attention of the agent – the most active part in WM. SAE estimates the level of similarity and based on that RE establishes candidate correspondences between the target set and the LTM contents in WM in the so-called Similarity Assessment and Correspondence Processors.

It should be stressed that in all tasks the ultimate goal is to satisfy the user by providing the needed information or solution of the task.

More precisely, when the task is to answer a question this general goal would be to provide the user (or another agent) with the answer. Initially, the goal of the system is quite general but with the processing of the question it becomes more specific. For instance, for the currently implemented music domain [15], the goal could be to give the name of an album of a singer, his/hers religious status, birth date, etc. In the current, early development stage, the architecture does not have an explicit planning mechanisms, although the reinforcement learning (by always aiming at user's satisfaction), top-down learning (episode retention) and action decision are present and should allow the model to find better and better solutions over time and encode sequences of actions into episodes. During the future development, different approaches will be considered for inclusion like BDI features and emotionally guided planning.

As stated in the beginning of this section, messages from the Body are added to the WM and become source of activation for the SAE that starts to send similarity assessments to the RE. Those assessments are checked for obvious flaws and inconsistencies due to the fact that SAE is supposed to make analogies as well. If no flaws are found, they are transformed to established correspondences. When the correspondences between the target set and LTM are established the IE is used to verify and evaluate them and eventually the candidates are rejected or confirmed. Based on the existing correspondences, parts of past episodes are evaluated by the IE and transferred to the target set until eventually an action transfer is chosen and the appropriate action structure is added to the target set.

When an action structure is added to the target episode, it is automatically sent to the Body, along with its canonical representation. Each and every Tool that is going to receive and process the action command expects a specific format, and so a canonical message structure is needed. Those structures are kept in the Mind and are used when an action command is sent. Usually, they contain a sub-graph (always the same) that identifies the type of Tool to process the command, any additional information (as there might be Tools, carrying on various tasks) and the actual command.

Finally the user is provided with the result of the task and could give a feedback. If the task is considered completed (e. g. the question is answered and the user is satisfied with it) the whole episode with the task and its completion is stored in LTM as an experience episode. Any new knowledge acquired in the scope of the current task is isolated as general knowledge. In the current implementation, the user has two buttons in the interface – " praise" and "scold". If there is no button pressed after the answer is provided by the agent, the system assumes the user was satisfied and records the episode as successful. If the user presses the "praise" button, the episode is recorded as "more than successful" and if the user presses the "scold" button, the system records the episode as not-successful. In the latter case, this episode is recorded in the WM with very low chance of being retrieved in the future and as a negative example.

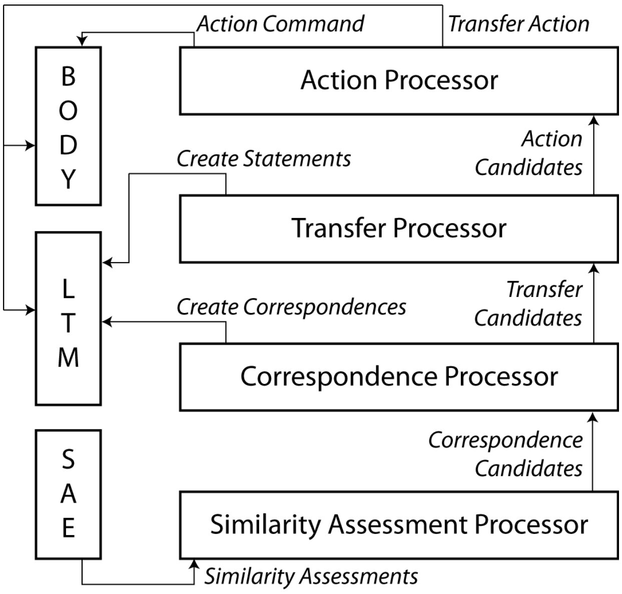

Fig 3: Reasoning Engine Modules.

### *III RE modules*

The RE is made of several procedures for handling incoming knowledge structures and with several modules that are called "processors." The latter are used asynchronously, serially and iteratively within the scope of a single task. They are briefly described here, as the implementation details are not so important for the model and as they are still subject of changes, assessment and fine-tuning.

The modules of RE are as follows:

- Similarity Assessment Processor: handles the initial similarity assessments from SAE, eliminates the inconsistency and establishes correspondence hypotheses (CH). The latter are sent to the Correspondence Processor. If there are no correspondences established, the module aborts execution of the current reasoning process and invokes again the SAE;
- Correspondence Processor: the correspondence hypotheses are processed by this module. Each correspondence hypothesis has a score assigned on the basis of the activation of the nodes it puts into correspondence and of its consistency with other correspondence hypotheses. The most active correspondence hypotheses are used as a base for the formation of a list of transfer requests that are sent to the Transfer Processor. Before this, the correspondence hypotheses are checked against the contents of the LTM (fast, low-cost and efficient process). It is still a point of research if the check against the LTM contents is more efficient if done only in SAP, only in the Correspondence Processor, or in both of them;
- Transfer Processor: removes inconsistent transfer requests, deals with contradictory ones and evaluates them on the basis of the activation of the corresponding nodes and relatedness to the current goal. This is the module that actually adds transferred knowledge to WM. This module also creates a list of action requests, which are sent to the Action Processor;
- Action Processor: receives a list of possible actions to execute from the Transfer Processor. Contradictory actions are evaluated, based on their activation and the one with the highest activation is executed. If the last action has proven unsuccessful (e.g. no answer from an information search tool after a fixed amount of time).

### IV Inference Engine (IE)

The RDF-based agent LTM provides the permanent storage of the agent knowledge. It is updated during operation of the model and can scale up to hundreds of thousands of statements. The current working prototype uses a LTM of less than ten thousand statements. The knowledge is expressed entirely with RDF triples and the model has mediated connection to the environment, as it receives and sends (to the 'Body') coalitions of RDF triples.

As mentioned above, the RDF representation provides the basis for extremely efficient reasoning-based (both by inference and analogy) augmentation of the  goal and the most active part of the WM (which has the focus of attention of the agent). This allows the system to "transfer" specific and relevant information at very high speeds. The inference capabilities and the RDF storage as a whole are also used for verification and consistency check by the memory retrieval and transfer of knowledge for task completion purposes (e.g. answering a user question). The episodes that are stored in the LTM are identified by the contexts of the statements. As one statement can be part of more than one context, there are nesting and overlapping contexts, allowing flexible behavior and less data multiplication.

The IE uses mechanisms which are used by many platforms. However the novelty here is the combination with connectionist activation spreading which selects the knowledge in LTM relevant to the task at hand. This mechanism is inherited from DUAL/AMBR [1] but, as explained bellow, is further developed to include an attentional focus and make specific use of inference based memory augmentation.

## V Conclusion

In this paper, the progress in the development of a new model for an embodied conversational agent is presented. Only the main ideas behind the model, its basic modules and the interplay among them are presented, although the largest part of the mechanisms have been implemented. The main focus was to outline the architecture of the model, the basic mechanisms allowing to increase its efficiency and the role of the reasoning engine in the interplay between the engines.

The main idea behind this model is to combine a rich cognitive model which would bring flexibility, context sensitivity, and selective attentional mechanisms with cutting edge fast machine learning algorithms like logical inference over ontologies and fast matrix calculations. At the core of the model is the combination of an connectionist similarity assessment and emotion modules which run continuously in parallel and a serial reasoning engine, which is based on inference over RDF triples. The main principle behind the connectionist engine is to combine activation spreading and semantic relevance and relational information in order to focus any further operations only on the most useful part of LTM. This fast selection of only a small part the agent's knowledge allow for its further augmentation by efficient inferences.

The three main 'engines' of the model – the reasoning, the emotional, and the similarity assessment engines – have been already implemented and parts of them tested. Although the results are very promising they are too preliminary to be reported here. The elaboration of the model, its full integration within a full fledged agent platform and tests with real users are currently in progress and will be the subject of a next papers. One of the latter will be focused on the detailed presentation and tests of the SAE and the other on the role of the EE as evidenced by simulations and usability tests.

## Acknowledgment

We would like to gratefully acknowledge the discussions with Dr. Hristo Laftchiev, Kiril Kiryazov, Atanas Kyriakov, and Damian Ognianoff about the presented model.
The work is supported by the project RASCALLI under FP6 of EC.

***Abstract*—We present an approach to plan representation in multi-actors scenarios that is suitable for flexible replanning and plan revision purposes. The key idea of the presented approach is in integration of (i) the results of an arbitrary HTN (hierarchical task network) -oriented planner with (ii) the concept of commitments, as a theoretically studied formalism representing mutual relations among intentions of collaborating agents. The paper presents formal model of recursive form of commitments and discusses how it can be deployed to a selected hierarchical planning scenario[1].**

## I. Introduction

COOPERATION between intelligent agents is usually established by means of negotiation resulting in a set of obligations for the participating agents that lead onwards to achievement of a common goal agreed to by the agents. Wooldridge and Jennings formalize the obligations by describing the cooperative problem solving by means of *social commitments* [1]—the agents commit themselves to carry out actions in the social plan leading onwards to achievement of their joint persistent goal [2].

The problem of distributed planning (DP) has been often discussed in the AI planning and multi-agent research communities recently (e.g. [3], [4], [5], [6]). Distributed planning has been viewed as either (*i*) planning for activities and resources allocated among distributed agents, (*ii*) distributed (parallel) computation aimed at plan construction or (*iii*) plan merging activity. The classical work of Durfee [3] divides the planning process into five separate phases: task decomposition, subtask delegation, conflict detection, individual planning and plan merging.

The distributed planning approach proposed in this paper does not provide constructive algorithms for dealing with either of the phases. Instead we propose a special mechanism for plan execution in distributed, multi-actor environment. As such it will affect all the phases of the Durfee's distributed planning architecture.

While classical planning algorithms produce a series of partially ordered actions to be performed by individual actors, we propose an extension of the product (but also an object) of the planning process so that it provides richer information about the context of execution of the specific action. The context shall be particularly targeted towards mutual relation between the actions to be performed by individual actors and shall be used mainly for replanning and plan repair purposes.

The planning problem we are trying to deal with can be informally understood as the task of solving a classical HTN (hierarchical task network) planning problem, defined by an initial partially ordered (causally connected) series of goals, by a set of admissible operators (defined by their preconditions and effects) and methods suggesting a decomposition of a goal into a lower-level planning problem. The plan can be sought for by an individual actor or in collaboration of multiple actors (sharing knowledge and resources). The product of planning is a set of partially ordered terminal actions, allocated to individual actors who agreed to implement the actions under certain circumstances. These circumstances are expressed by specific commitments including the following pieces of information:

- *commitment condition* that may be (*i*) a specific situation in the environment (such as completion of some precondition) or (*ii*) a time interval in which the action is to be implemented no matter what the status of the environment is or (*iii*) a combination of both.
- *decommitment conditions* specifying under which condition the actor is allowed to recommit from the commitment once the task is finished (e.g. notification) or once the task cannot be completed (e.g. a failure)

For long, multi-agent research community has been providing interesting results in the formal work in the field of agents' social commitment, as specific knowledge structures detailing agents individual and mutual commitments. The presented research builds on and extends this work.

The article is structured as follows. In the section II, the formal description of commitments by Wooldridge is extended, a recurrent notation formalizing the commitments is presented and its use for distributed planning purposes is shown using a scenario for verification. The section III gives a brief overview of the most relevant works to our approach. Finally, the last section concludes the paper.

## II. Commitments for Planning and Re-planning

As stated in the introduction, a social commitment is a knowledge structure describing an agent's obligation to achieve a specific goal, if a specific condition is made valid and how it can drop the commitment if it cannot be achieved. The commitment does not capture description how the committed goal can be achieved. Individual planning for a goal achievement, plan execution and monitoring is a subject of agents internal reasoning processes and is not represented in the commitment.

In the context of the planning problem defined in the Introduction, we understand the agent's specific goal (to which it commits) as an individual action, a component of the plan, which resulted from the given planning problem. While typical action in a plan contains only a precondition and an effect, in this paper we will describe how its representation can be extended so that the commitment-related information is included.

Michael Wooldridge in [7] defines the commitments formally as follows:

$$\begin{aligned}&(\mathsf{Commit}\ A\ \psi\ \varphi\ \lambda),\\ &\quad\lambda=\{(\rho_1,\gamma_1),(\rho_2,\gamma_2),\ldots,(\rho_k,\gamma_k)\},\end{aligned} \tag{1}$$

where $A$ denotes a committing actor, $\psi$ is an activation condition, $\varphi$ is a commitment goal, and $\lambda$ is a convention. The convention is a set of tuples $(\rho,\gamma)$ where $\rho$ is a decommitment condition and $\gamma$ is an inevitable outcome. The convention describes all possible ways how the commitment can be dropped. Generally speaking, the actor $A$ has to transform the world-state in such a way that the $\varphi$ goal becomes true if $\psi$ holds and any $\gamma$ has not been made true yet. The actor is allowed to drop the commitment if and only if $\exists i : \rho_i$ which is valid. A decommitment is allowed provided that $\gamma_i$ is made true. A formal definition in modal logic (working with the models of mental attitudes like Believes, Desires, Intentions, [8], and temporal logic where the operator AG denotes an the inevitability and operator $\curvearrowleft$ denotes the temporal until) follows as defined in [7]:

$$\begin{aligned}&(\mathsf{Commit}\ A\ \psi\ \varphi\ \lambda)\equiv\\ &\quad((\mathsf{Bel}\ A\ \psi)\Rightarrow \mathsf{AG}((\mathsf{Int}\ A\ \varphi)\\ &\qquad\wedge(((\mathsf{Bel}\ A\ \rho_1)\Rightarrow \mathsf{AG}((\mathsf{Int}\ A\ \gamma_1)))\curvearrowleft\gamma_1)\\ &\qquad\ldots\\ &\qquad\wedge(((\mathsf{Bel}\ A\ \rho_k)\Rightarrow \mathsf{AG}((\mathsf{Int}\ A\ \gamma_k)))\curvearrowleft\gamma_k)\\ &\quad)\curvearrowleft\bigvee_i\gamma_i).\end{aligned} \tag{2}$$

This definition is used in a declarative way. Provided that whatever the agent does during a specific behavior run complies with the above defined commitment, the expression 2 is valid throughout the whole duration of the run.

One of the goals of the research described in this paper was to provide a formalism for networked commitments to be used for replanning. As clearly stated in the introduction, the commitment conditions can represent variable bindings among preconditions and effects of the individual commitments achieved either by monitoring the environment status or by inter-agent communication (e.g. reception of a specific trigger message). Such representation would be very inflexible in practical applications as it would either need the agents to do nothing and wait for an inhibiting event to happen or risk that once an inhibiting event happens the agent will be busy performing other commitments. Therefore the agents may want to engage in booking and the commitment's precondition would contain fixed time when the commitment is supposed to be adopted. The most flexible approach would be a combination of both—inhibition event and preliminary booked time window, specifying when the inhibiting event is likely to happen. Let us assume that this is the case in the remainder of the paper.

In the distributed plan execution a failure may occur. The indirect impact of this failure may be e.g. a situation where the arranged inhibition event will not happen in the preliminary booked time window. Such occurrence may invoke replanning and allow some agents to e.g. drop unnecessary commitments. This is the reason why the commitments shall not be linked one with other not only via preconditions but also by means of variable bindings among individual agent's decommitment rules. Using these bindings, we can describe the causal sequentiality of the commitments and requests for particular decommitments—Fig. 1.

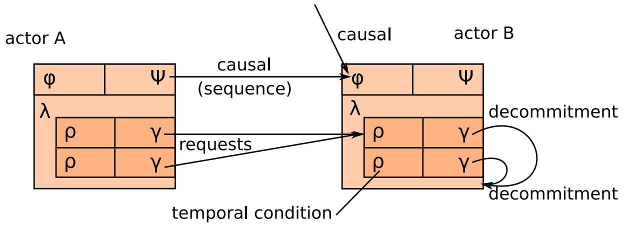

Fig. 1. Commitments and bindings—the actor A's commitment influences the actor B's commitment using the causal (sequential) link, the link is described using the $\psi$ and $\varphi$ clauses (e.g. $\psi = \texttt{building-is-ready(B)}$ and $\varphi = \texttt{ready(B)}$). The actor B's commitment is influenced by external causality too. The actor B's commitment can be decommitted in two cases: either the *temporal condition* $\rho$ becomes true or one of the actor A's rules *requests* the decommitting. The decommitment request is triggered by one of the actor A's $\rho$ conditions.

While we will be generalizing on the process of decommitment later in the paper, let us work for now with the specific particular decommitment case suggested in the previous paragraph. Let us assume one agent $A$ forcing decommitment of the other agent's $B$ commitment by means of setting a value of a variable contained in the other agent's commitment. The agent $A$ contains a commitment with a decommitment rule in the form $\langle\rho, v\rangle$ and the agent $B$ contains a commitment with a decommitment rule in the form $\langle v, \texttt{decommit}(B)\rangle \in \lambda_A$.The request is started by $\rho$ precondition of the actor $A$ (e.g. decommitting the $A$'s commitment). Thus the actor $A$ intends to make the variable $v$ valid. This causes the agent $B$ to intend to decommit by intending the variable decommit(B) to be valid (see Fig. 1).

This clear example uncovers two needed extensions of the classical social commitment model: (*i*) recurrence of the commitment form—enabling a possibility to disable (decommit) a decommitment request and (*ii*) explicit termination condition—describing termination without any intentional part.

### A. *Commitment Recurrence*

The original Wooldridge definition of a commitment makes a clear distinction between the commitment subject ($\varphi$) and the mini-goals set in the commitment convention ($\gamma$). While there is a mechanism for the agent to drop $\varphi$, a once adopted mini-goal $\gamma$ cannot be decommitted. Due to high dynamism and uncertainty of the target scenario, we assume the re-planning and plan repair mechanisms to be substantially more complex. We require that the mechanism would allow the agent to try out several different decommitment alternatives, based on the current properties of the environment. The set $\lambda$, allows listing various different decommitment rules, while no mechanism have been specified how different decommitment alternatives are tried out.

That is why we propose generalization of the commitment so that each goal in the commitment structure can be treated equally. Let us introduce the recursive form of a commitment, which enables the nesting of the commitments—Fig. 2:

$$\begin{aligned}&(\mathsf{Commit}\ A\ \psi\ \varphi\ \lambda^*), \lambda^* = \\ &\quad\{(\mathsf{Commit}\ x_1\ \rho_1\ \gamma_1\ \lambda_1^*), \\ &\quad(\mathsf{Commit}\ x_2\ \rho_2\ \gamma_2\ \lambda_2^*), \ldots, \\ &\quad(\mathsf{Commit}\ x_k\ \rho_k\ \gamma_k\ \lambda_k^*)\}.\end{aligned} \tag{3}$$

The formula 3 extends the definition in 2 not only by inclusion of a set of decommitment rules in each of the individual decommitment rules. It also allows the newly adopted commitments to be assigned to different actors. The delegation kind of decommitment between two agents $A$ and $B$ would have the following form:

$$(\mathsf{Commit}\ A\ \psi\ \varphi\ \{(\mathsf{Commit}\ B\ \rho\ \varphi\ \emptyset)\}), \tag{4}$$

representing that agent $A$ can drop the commitment towards $\varphi$ provided that $\rho$ is valid and provided that $B$ accepts a commitment towards $\varphi$ on $A$'s behalf.

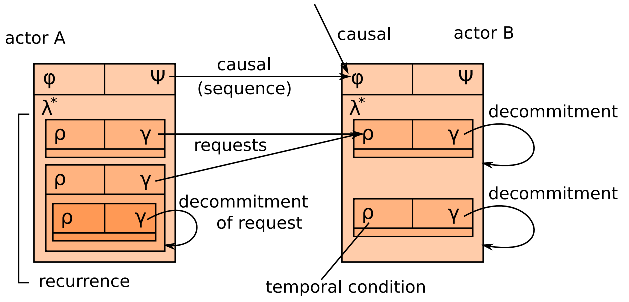

Fig. 2. Commitment and its $\lambda^*$ commitments—the Fig. 1. is extended by one *decommitment of request* which can be decommitted if the most inner $\rho$ condition becomes true. Decommitting of the request causes the actor B's commitment cannot be decommited by the actor A's convention goal any more. Here the recursive form enables the nesting of the inner commitment.

This form is very expressive in the sense of the description of exceptional states. It allows us to have a branched chain of individual nested commitments for each individual situation. The recursive nature allows us to describe an arbitrarily complex protocol using only one knowledge base structure—a recursive form of the commitment. The recursive form of the commitment is thus defined as:

$$\begin{aligned}&(\mathsf{Commit}\ A\ \psi\ \varphi\ \lambda^*) \equiv \\ &\quad((\mathsf{Bel}\ A\ \psi) \Rightarrow \mathrm{A}((\mathsf{Int}\ A\ \varphi) \wedge \bigwedge_j \lambda_j^*) \curvearrowleft \bigvee_i \gamma_i).\end{aligned} \tag{5}$$

### B. *Termination Condition*

We have explained in Section II that if the agent complies with the commitment, the formula 2 is always valid. However, this implication is not bidirectional. If we use this commitment definition for writing a computer program, running the behavior of an agent, we would need that all the runs that can be implemented by the formula 2 implement agent's correct commitment. In order to do this we need to show how a termination condition can be modeled by means of the social commitment. Let us assume we wanted to implement e.g. the blind commitment. According to [7] the blind commitment is defined as

$$(\mathsf{Commit}\ A\ \varphi) \equiv \mathsf{AG}(\mathsf{Int}\ A\ \varphi) \curvearrowleft (\mathsf{Bel}\ A\ \varphi) \tag{6}$$

Here the term $\mathsf{Bel}(A\ \varphi)$ is the simplest example of a termination condition. The termination condition here would be described using the $\lambda^*$ commitment as follows:

$$(\mathsf{Commit}\ A\ \mathtt{false}\ (\mathsf{Bel}\ A\ \varphi)\ \emptyset). \tag{7}$$

A general termination condition $t$ in the commitment model can be defined as follows:

$$(\mathsf{Commit}\ A\ \mathtt{false}\ t\ \emptyset). \tag{8}$$

The condition ($\mathtt{false}$) will never trigger the intention towards the termination condition—$t$. Termination condition of the rule plays an important role here as it will be added to the *until*-part of the commitment and allows the commitment to be valid even if the intention is dropped provided that the termination condition $t$ is valid. Therefore we can extend the set of decommitment rules with a set of termination conditions $\mathcal{T}$ as follows:

$$\begin{aligned}&(\mathsf{Commit}\ A\ \psi\ \varphi\ \{\lambda^* \cup \mathcal{T}\}), \mathcal{T} = \{t_1, \ldots, t_k\} \\ &(\mathsf{Commit}\ A\ \psi\ \varphi\ \{\lambda^* \cup \mathcal{T}\}) \equiv \\ &\quad((\mathsf{Bel}\ A\ \psi) \Rightarrow \mathrm{A}((\mathsf{Int}\ A\ \varphi) \wedge \bigwedge_j \lambda_j^*) \curvearrowleft \bigvee_i \gamma_i \bigvee_k t_k).\end{aligned} \tag{9}$$

### C. *Decommitment Rules*

We require the agents that perform intelligent planning and replanning by means of social commitments to be able to perform at least basic reasoning about the decommitment rules attached to the particular commitments. This is needed at the time of replanning, when an agent needs to decide which decommitment rule (i.e. a new commitment) to adopt, provided that conditions for more than one are satisfied. Similarly, agents, when they negotiate about who will accept which commitment, shall be able to analyze not only properties of the goal and costs associated with the goal completion process but also the various decommitment rules when considering likelihood of the particular failure to happen. Ideally, the agent shall be able to estimate costs of each decommitment rule. However, with the lack of information about the dynamics of the environment, we will be only able to partially order the decommitment rules by assigning them to different types. Let us introduce four different types of decommitment rules:

- *Termination conditions* (TC)—as described in the Section II-B. These are obviously the most preferred decommitment rules as no further action is required for dropping the particular commitment.
- *Individual commitments* (IC)—commitments that do not involve other agent than the agent itself. These commitments shall be used if the impact of a failure within the multi-agent community shall be minimized. Individual commitments shall represent several other ways how an agent can accomplish a given task.
- *Delegation* (D)—by using this type of commitments the agent shall be able to find some other agent who will be able to complete its commitment on the original agent's behalf. It is possible that such a commitment will contain unbound variables representing the need to search for an agent suitable for delegation.
- *Joint commitments* (JC)—these commitments provides mutually linked commitments (of several agents) via decommitment rules. In a replanning situation the joint commitments proactively assure that the cost of the failure is minimized. An example of the use of a joint commitment is decommitting another agent's linked commitment as explained in the Section II
- *Minimal social commitment* (MSC)—is the classical type of decommitment, where the agent is required to notify the members of the team about its inability to achieve the commitment.
- *Relaxation* (R)—is a special decommitment, where the original commitment is replaced with a new commitment with relaxed condition and/or goal. The new commitment must be consistent with all other bound commitments. Provided that the bound commitment is of other agent, the relaxation must be negotiated. The asked agent tries to fit the requested relaxed commitment into its knowledge base and eventually use some other decommitment rules of other commitments to change it and fulfill the request.

During the replanning process, the preference relation over the commitments is TC $\succ$ IC $\succ$ D $\succ$ JC $\succ$ MSC. The preference of R can be arbitrary managed by the agent in consideration of current circumstances.

### D. Commitment Graph

Using the extended form of the social commitment we can propose a graph notation of the commitments. The mutual bindings and commitments form a commitment graph—Fig. 3. The commitment graph describes the same properties of the mutual decommitting as the logical notation.

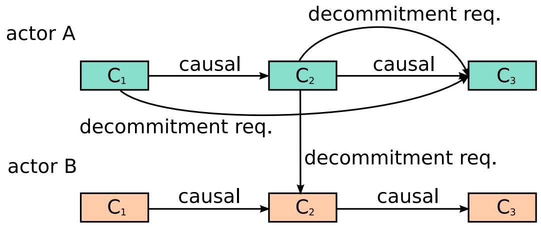

Fig. 3. Commitment graph—the *causal* links define the sequentiality of the commitments of each actor. The commitment $C_3$ of the actor A can be decommitted by both $C_1$ and $C_2$ commitments. The $C_2$ commitment of the actor B can be decommitted by actor A using the decommitment request.

The graph notation can be used to describe the process of the successive solving of the exceptional states. The process is based on the traversing through the commitment graph. The traversing starts with the first violated commitment. One of the decommitment rules is triggered (according to the violation type). As the decommitment rule is a commitment it starts an intetnion of the agent to terminate the commitment. In the case, that the intention is a decommitment request, the process crosses on the requested commitment (decommitment rule respectively) and starts one of the decommitment rules on the side of the requested commitment. Provided that the decommitment rule terminates the commitment wihout a need to request other decommitments, the process ends here and the violation is fixed.

### E. Deployment Scenario

The approach presented in this paper is being verified on a realistic simulation scenario—Fig. 4. The scenario is based on an island inspired by Pacifica Suite of Scenarios[2]. On the island, there are cities and a net of roads connecting them, but off-road movement is also enabled. There are also several seaports and airports. The scenario actors are several unit types (ground, armored, aerial or sea units), civilians and non-friendly units.

There are ground units, which are *Transporters* (can provide faster transportation of other unit(s), material or civilians), *Construction* (can repair damages or assemble/disassemble stationary units) and *Medical* (provides medical care for other units or some rescue operations). The *Armored* units for protection of other units or secure an area or convoy. The *Aerial*—the UAVs with an extended visibility range and *Sea* units for transportation over the water.

The scenario simulates limited information visibility and sharing. Due to this, the environment provides non-deterministic behavior from the single unit point of view. There are heterogenous independent self-interested units in the scenario that commit to the shared/joint goals. To fulfill the desired strategic goals in such environment, the units provide

[2] http://www.aiai.ed.ac.uk/oplan/pacifica

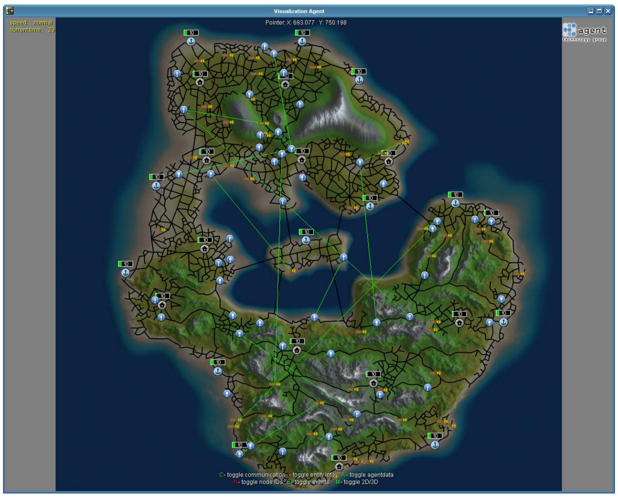

Fig. 4. Scenario island screenshot

complex cooperative actions on several levels of planning and control.

Planning and control of activities of individual units and actors in the scenario is loosely structured into three levels of detail. We recognize several layers of coordination and control:

- **Strategic layer:** The actors use aggregated meta-information from the tactical layer. This layer provides an overall strategic plan for middle and long term time horizon. High level planning and peer-to-peer coordination among the actors is possible (while non-transparent to the tactical level).
- **Tactical layer:** On this layer, the units use aggregated information from the individual layer, the information obtained through communication with each other and the information obtained from the strategic layer. The units and actors use classical planning and cooperation methods and can create new goals or adapt the goals received from the strategic level.
- **Individual layer:** On this layer, the units should perform reactive behavior based on obtained information and current goals.

The suggested coordination is hierarchical with respect of type of unit, area of operation and visibility. Three-layer architecture enables to separate middle- and long-term strategic planners from the real-time planning and control on the tactical and individual level. The strategic planner can utilize advanced planning methods with using aggregated meta-data from the whole system. On the other hand, the tactical planner has to provide real-time response and it uses limited information provided by individual layer of respective unit. On the tactical level local cooperation and information sharing of the field units is provided.

Each layer produces particular commitments and these commitments define the plan.

The strategic layer uses the HTN I-X planner [9] and a distributed resource allocation algorithm. The planner uses an abstract sub-domain derived from the scenario domain and produces an abstract plan. This plan is instantiated using negotiation about the resources—Fig. 5.

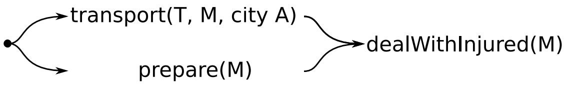

Fig. 5. Instantiated strategic plan—the medic unit $M$ was requested by the commander agent to fulfill a task: deal with the injured in city A, and it negotiated the transport with the transport unit $T$.

The instantiated plan is converted into commitments—Fig. 6. The conversion process creates a commitment according to the particular plan action ($\varphi = a$) and according to forward causality links of the plan.

The commitments of the tactical layer are based on strategic commitments. The layer uses negotiation to form the most suitable mutual commitments. The constraints for the negotiation respects the particular needs of the agents. The tactical commitments also define recommitments to the strategic layer and they can additionally refine some strategic commitment too. They are much more refined than the strategic commitment in the sense of spatio-temporal constraints, and particular world-states. The tactical commitments are most enriched by the $\lambda^*$ commitments. Thus, the most important part of the decommitting / replanning process is done by this layer.

An example of the tactical negotiation can be: A transport unit $T$ is planning the tactical commitment $moveto(l_1, l_2)$, it can find out it needs support from another unit. In this case, a negotiation process must find an appropriate support unit $S_p$ that proposes the most complying commitment (e.g. in terms of temporal constraints). If such a unit is found the JC is established, planned, and connected to other commitments in the knowledge base.

And finally, the individual layer plans commitments for later execution. These commitments copy the tactical commitments, but some of these can be omitted (e.g. $atPosition$ in the Fig. 6). Each individual commitment contains a decommitment request only to its parent commitment (from the tactical layer).

During the execution of the plan the commitments are processed. The commitment can evolve (Section II-C) according to the plan or due to unexpected environment interactions.

The monitoring of the commitments is triggered by a change of the world, e.g. a tick of the world timer, movement of a unit, a change of a world entity state, etc. The process evaluates all commitments in the actor's knowledge base. The value of the commitment defines the commitment state and can start the decommitting process.

One of the response to the unexpected situation can be relaxation. For instance, if a truck $T$ commits itself $C_1$ to move to position $l_1$ exactly at time $t_1$ and it faces an unknown risk combat zone the commitment has to be decommitted (because the time $t_1$ cannot be satisfied). So, $T$ tries to relax the commitment and thus changes the time constraint to $t_2$ (it plans a new route to $l_1$). And because the next bound commitment $C_2$ is constrained by time interval $\langle t_{min}, t_{max} \rangle$ where $t_2 > t_{min}$ and $t_2 < t_{max}$ the $C_2$ has not to be decommitted.

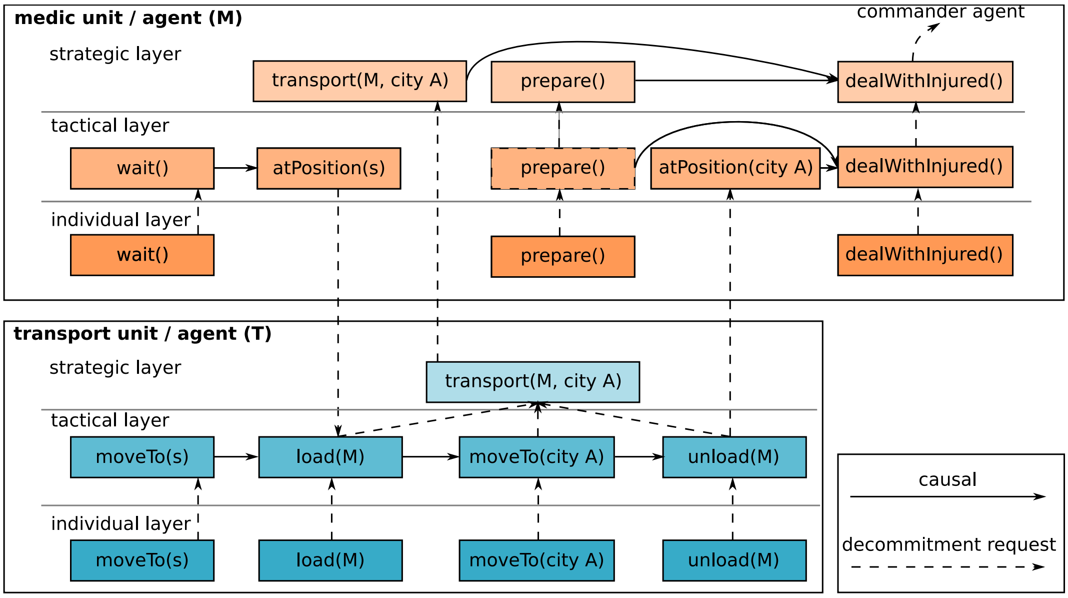

Fig. 6. Commitment bindings of multi-layer architecture for two units—the medic unit $M$ is committed to fulfill a task: deal with the injured in city A, and the transport unit $T$ is committed to transport the medic unit $M$ to city A. The figure shows the directions of the potential decommitment propagation among the layers of the actors.

Another example is the delegation of the commitment using negotiation. The current agent $A$ has to find a replacement agent $B$. If $B$ is found the agent's commitment passes on to the $B$. $B$ must integrate the commitment into its plan in the sense of the $\lambda^*$ commitments. The process of choosing $B$ is based on a measure of necessity to modify the current commitments of the proposing agent. For instance, let us have three trucks $T_1$, $T_2$ and $T_3$ and two builders $B_1$ and $B_2$. $T_1$ and $T_2$ commit $B_1$ and $B_2$ to move them to a location $l$. Let us assume that during the transport a problem occurs and as a result of it $T_1$ is no longer able to fulfill the commitment. In this situation, the commitment can be passed on either to $T_2$ or $T_3$. Since $T_3$ is idle, it is more appropriate to pass the commitment on to $T_3$ rather than $T_2$. $T_2$ would have to replan the current transportation commitment and all its successors.

The last example can be used to describe the usage of the nested commitments (commitment recurrence) too. In the case that $T_3$ cannot be accidently used, the $T_1$ cannot delegate the task to the $T_3$. This fact can be described using decommitting of the delegation decommitting rule in the $T_1$'s commitment base. Formally:

$$\begin{array}{l}(\text{Commit } T_1 \; \texttt{true} \; \texttt{is-transported}(B_1) \; \{ \\ \quad (\text{Commit } T_1 \; \texttt{immobile}(T_1) \; \texttt{delegated-to}(T_3) \; \{ \\ \quad\quad (\text{Commit } T_1 \; \texttt{immobile}(T_3) \; \texttt{true} \; \emptyset) \; \}, \\ \quad \ldots \textit{other decommitment rules} \\ \})). \end{array} \tag{10}$$

An agent can make a decision whether it is more suitable to re-run the strategic planning (which can be very costly and can lead to replanning of all plans of all other agents) or relax the commitment on its own (which would be probably a much less expensive operation).

## III. Related Work

Formalization of commitments has been extensively studied in the past using various formalisms, most of all building on and extending the BDI framework when describing obligations the agents adopt. Fasli [10] distinguishes two classes of obligations—general and relativized—and adoption of a social commitment by an agent is described as an adoption of a role. Thus, the agent promises its coherence with a (behavior) norm defined by the commitment. The framework extends BDI into a many-sorted first order modal logics to add concepts of obligations, roles and social commitments while it also uses branching temporal components from Computational Tree Logics (CTL) [11]. Besides strategies for adoption of social commitments by the agents the framework also defines strategies regarding conditions for a successful de-commitment from the agent's obligations.

Another formal representation of commitments considering temporal account has been introduced in [12]. CTL [11] has been extended to capture features not being usually considered in common approaches (but relevant for realistic environments), namely time intervals considered in commitments satisfaction, "maintenance" manner of commitments next to "achieve" manner of commitments and vague specification of time. Commitments have been formally defined using Backus-Naur Form as an $n$-tuple $(\text{Commit } id, x, y, p)$ where the commitment identified uniquely by its $id$ and the interpretation is that $x$ commits to $y$ to make the condition $p$ become true. The formal framework uses event calculus and defines operations $create(x, C)$, $cancel(x, C)$, $release(y, C)$, $assign(y, z, C)$, $delegate(x, z, C)$ and $discharge(x, C)$ above the commitments as well as new predicates $satisfied(C)$ and $breached(C)$ which evaluate the status of the commitments.

The past is considered linear while the future is branching. When created, the commitment is neither satisfied nor breached (the satisfaction of commitments is applied three-value logics). A commitment once satisfied or breached remains satisfied or breached once and for ever since the time.

Evolution of commitments in teamwork has been studied by Dunin-Keplicz [13]. Teamwork is explicitely represented using BDI framework by introducing a concept of a collective intention resulting in a plan-based collective commitment established within a group of agents adopting it. The teamwork consists of four consecutive stages—*(i) potential recognition*, *(ii) team formation*, *(iii) plan formation* and *(iv) team action*. The collective commitment based on a social plan (the collective intention) splits into sub-actions expressed as pairwise social commitments between agents. Establishment of the collective commitment consists in a consecutive execution of social actions defined at the particular stages: *(i)* `potential-recognition` → *(ii)* `team-formation` → *(iii)* `plan-generation` executed as `task-division` → `means-end-analysis` → `action-allocation` and *(iv)* `team-action` implemented as execution of respective actions allocated to each agent in the former stage. Naturally, the above-mentioned social actions are hierarchically bound from the first to the last stage. Dynamically evolving environment may cause unfeasibility of the allocated actions during the team action which results in a need for evolution of the collective commitment accordingly. In such a case, the maintenance of the collective commitment is achieved by invoking reconfiguration at the `action-allocation` level progressing upwards to higher levels of the hierarchy of social actions, possibly up to the `potential-recognition`. Finally, the collective commitment is adapted (another potential for the teamwork recognized) or dropped. The hierarchical manner of the reconfiguration allows for minimization of changes necessary to perform in order to adapt the collective commitment. The communication necessary for the reconfiguration is explicitly involved and formalized in the framework. Adaptation of the commitment is motivated by persistency of the joint intention which differs given a chosen intention strategy (*blind*, *single-minded* and *open-minded*). For the sake of not making the presented multi-modal logical framework even more complex and less tractable, temporal aspects of the cooperation are assumed to be expressed in a procedural way rather than by employing temporal and dynamic elements among the modalities used.

## IV. Conclusion and Future Work

This paper dealt with the problem of distributed planning used for replanning and plan repair processes. The classical work on commitments has been extended towards commitment recurrence for flexible and more expressive representation of replanning alternatives. Similarly, the termination condition has been defined as a specific type of commitment. The various types of commitments were classified according to the impact they may have on the other collaborating actors. This classification enables the agents to perform the right decision during the decommitment process.

This contribution represents only a starting point towards a more complex research effort that will be performed with social commitments within the context of distributed planning. We need to go beyond classification of the commitments to basic types and we need to design metrics and mechanisms that would allow agents to assign costs to each of the commitments. This will facilitate further research in design of scalable negotiation mechanisms allowing agents to negotiate the best commitments for their and social welfare perspectives.

Further integration of the HTN planning mechanism and the social commitments knowledge structure will be a critical research challenge we want to address. As described in the paper, we assume that the commitments resulted from the agent-oriented programming process and are uploaded from the agent's knowledge base. We plan to develop and design mechanisms for runtime creation of commitments from the hierarchical task networks, defining the planning problem and from the known hierarchy and knowledge of competency and abilities of the agents.

***Abstract*—Interactions and social relationships among agents are an important aspect of multi-agent systems. In this paper, we explore how such relationships and their relation to agent's objectives influence agent's decision-making. Building on the framework of stochastic games, we propose a classification scheme, based on a formally defined concept of *interaction stance*, for categorizing agent's behaviour as self-interested, altruistic, competitive, cooperative, or adversarial with respect to other agents in the system. We show how the scheme can be employed in defining behavioural norms, capturing social aspects of agent's behaviour and/or in representing social configurations of multi-agent systems.**

## I. Introduction

Recently, there has been a growing interest in studying complex systems, in which large numbers of agents pursue their goals while engaging in mutual interactions. Examples of such systems include real-world systems, such as diverse information and communication networks, as well as simulations of real-world systems, such as models of societies, economies and/or warfare. With the increasing diversity of these systems, there is a growing need to develop models which allow characterizing the behaviour of agents, and their interactions, in a compact form.

Fundamentally, the behaviour of an agent is driven by its objectives. In the absence of other constraints and influences, the agent is expected to perform actions which – incrementally but not necessarily monotonously – lead towards its objectives. In some situations, however, the way the agent acts can be affected by additional factors, be it the surrounding environment, agent's decision making capability or *its relations to other agents*. Knowing and understanding such factors may help in reasoning about the agent and in obtaining better prediction of its behaviour, compared to when only agent's overall objectives are considered.

Whereas the impact of the first two factors have been studied in several fields related to intelligent agents, including game theory and planning, comparatively less work seems to exist on relating agent's social relations, agents' objectives and the behaviour they ultimately execute. The aim of this paper is therefore to investigate and formalize *inter-agent relations* as an important behaviour-modifying factor in communities of social agents. Specifically, building on the framework of stochastic games and extending our earlier work [1], we propose a utility-based model which categorizes actions (and consequently also relationships among agents) as self-interested, altruistic, competitive, cooperative and adversarial. The concept of interaction stance allows to define, classify, and/or regulate agent behaviours not only with respect to agent's own objectives but also with respect to objectives of other agents in the system.

The rest of the paper is organized as follows. In Section II, we identify factors which affects how an autonomous agent pursues its objectives. Section III exposes the major part of the contribution – the classification model of agent's behaviour. Section IV shows several examples illustrating the application of the model. Section V overviews the related work and Section VI concludes with a summary.

## II. Agent's Decision Making

As already mentioned, the behaviour of an agent is primarily driven by its overall objectives (also referred to as *desires* in the BDI architecture [2]). Out of the factors which constraints/affect how the agent actually behaves, we can distinguish

- *social relations* to other agents – if an agent is cooperative with another agent, it may consider the other agent's objective in choosing the action it performs. If it has multiple alternatives how to fulfil its objectives, it can choose the one that would help the other agent or even follow a suboptimal course of action in order to help the other agent reaching its goals.
- *environment* can limit the available actions the agent is able to perform; additionally, the environment can make action outcomes non-deterministic due to its stochastic nature or interfering actions of other agents
- *decision-making capability* reflects the extent with which the agent is able to pursue its objectives. Some agents are purely reactive, others can use planning or predict changes of environment. The agent can be trying to reach a goal, but due to insufficient computational resources or some architectural limits end up choosing a suboptimal or even contra productive action. Decision making capability is closely related to the issue of *bounded rationality* [3].

Explicit consideration of different factors affecting agent's behaviour provides for a more detailed characterization of agent's decision making, in turn allowing to reason not only about agent's current behaviour but also about its behaviour in situations where some of these factors change.

For example, knowing than an agent A has a cooperative stance towards agent B allows to infer that, in the presence of agent B, the agent A will, if at all possible, perform actions that contribute towards achieving agent B's objectives if such actions are not necessarily optimum when agent A's objectives are considered alone (and which agent A would pursue if agent B was not present). Similarly, knowing that the environment prevents an agent from executing an action that contributes towards its objectives allows to infer that, should the environment state change favourably, the agent would execute the action (even if it has not performed it so far at all).

The rest of the paper is dedicated to formalizing the above given notions. Primarily, we focus on the effect of social relations, though the role of the environment is also considered to an extent.

## III. Interaction-based Classification Model

This section presents an interaction-based model developed for multi-agent systems with asymmetric agent's utility functions. The model allows classifying actions and their sequences with respect to their effects on utilities of agents in the system. It is based on the formalism of partially observable stochastic games [4] generalized to infinite state, action, and observation spaces and omitting the initial state and reward functions, which are substituted by agent utility functions.

The choice of utility functions as a linear combination of some predefined characteristics of the world as we define it later, over possibly more expressive reward functions is motivated primarily by the compactness of representation allowed by the former. The description of agents using utilities also seems closer to how people tend to think about agents – it is more straightforward to specify what an agent is trying to achieve in terms of the desired state of the world than trying to assign a reward for each possible state.

Although the underlying model of stochastic games is general enough to describe incompleteness of agent's knowledge about the world, we do not consider this factor in the current version of the model. Likewise, the explicit consideration of agent's possibly limited decision-making capability is currently not considered.

### A. Fundamental Definitions

**Definition 1.** The game model is a tuple $(\mathcal{I}, \mathcal{W}, \{\mathcal{A}_i\}, \{\mathcal{O}_i\}, \mathcal{P})$, where

- $\mathcal{I}$ is a finite set of agents (players) indexed by $1, \ldots, n$
- $\mathcal{W}$ is a possibly infinite set of all states of the world
- $\mathcal{A}_i$ is a set of actions available to agent $i \in \mathcal{I}$ and $\mathcal{A} = \mathsf{X}_{i \in I} \mathcal{A}_i$ is a set of joint actions where $a = \langle a_1, \ldots, a_n \rangle$ denotes a joint action
- $\mathcal{O}_i$ is a set of observations for agent $i$ and $\mathcal{O} = \mathsf{X}_{i \in I} \mathcal{O}_i$ is the set of joint observations where $o = \langle o_1, \ldots, o_n \rangle$ denotes a joint observation
- $\mathcal{P}$ is a set of Markovian state transition and observation probabilities, where $\mathcal{P}(w', o \,|\, w, a)$[1] denotes the probability that taking a joint action $a$ in a state $w$ results in a transition to state $w'$ and a joint observation $o$.

Another part of the formal model is the space of all possible world characteristics that could concern some agent. We refer to this space as the utility space and we assume that it is a subset of $\mathbb{R}^m$, where $m$ is the number of characteristics considered. A point in the utility space is a vector of world-specific values of these characteristics. Let us consider an example game in which an agent considers building a highway. Different characteristics the agent can consider in such a scenario include the impact on the traffic situation, financial cost or harm to the surrounding nature. Different agents have a different view on the importance of individual characteristics.

**Definition 2.** The *utility space* $\mathcal{U} \subseteq \mathbb{R}^m$ of a system is a vector space generated by all components of the utility functions in the system. We assume there exists a global utility function $\vec{u} : \mathcal{W} \to \mathcal{U}$ that assigns a utility vector to each state of the world.

Each agent in the world values the components of the utility space differently. A local scout organization cares more about trees and the local labour union values more employed workers. The government should consider both characteristics. The preferences of an agent over the utility space components (i.e. the characteristics) are expressed by a vector of real weights. The overall utility that an agent ascribes to a state of the world is then a preference-weighted sum of the utility components.

**Definition 3.** If $\vec{u}(w) \in \mathcal{U}$ is a point in the utility space corresponding to a state $w \in \mathcal{W}$ of a system and $\vec{u_A} \in \mathbb{R}^m, |\vec{u_A}| = 1$ is the preference vector of agent $A \in \mathcal{I}$, then the utility of the state $w$ for the agent $A$ is

$$u_A(\vec{u}(w)) = \sum_{i=1}^{m} u_A^i u^i = \vec{u_A} \cdot \vec{u}(w)$$

where the dot operation represents the dot product in $\mathbb{R}^m$. For a group of agents $\mathbf{G} \subseteq \mathcal{I}$ we define the preference vector as

$$\vec{u_{\mathbf{G}}} = \sum_{i \in \mathbf{G}} \vec{u_i}$$

Using this preference vector, the utility of the state of the world $w$ for the group is defined as

$$u_{\mathbf{G}}(\vec{u}(w)) = \vec{u_{\mathbf{G}}} \cdot \vec{u}(w)$$

[1] Since we do not focus on agents' observations, we will omit them in the following text, i.e. we will use this notation: $\mathcal{P}(w' \,|\, w, a)$.

### B. Normalization

Note that we require the preference vectors to be normalized for individual agents. The main reason for that is that we want to be able to compare and sum utilities of different agents. If we have two agents and both of them want to maximize only the amount of their money, we do not consider reasonable to say that one of them wants to maximize it more than the other. The difference comes only with introducing another utility component, e.g. harming innocent people. After that, the agents can differ in how much they want to maximize their money considering how their actions harm innocent people.

However, the preference vector for a group of agents is not normalized anymore. It expresses not only the preference relations between the different components, but also how big and consistent in the preferences the group is. A big group with agents that have random preference vectors has the group preference vector close to zero whereas a group of agents with identical preferences has a large preference vector in the direction of the preferences of individual agents.

The above definition of group preference vector also ensures the property of *associativity of subgroups*. If we have a set of agents grouped into several groups and we join the groups to create a bigger group including all the agents, the preference vector of the resulting group only depends on the individuals in the group and not on the subgroups they were previously part of. This property would not hold if we normalized group preference vector and combine the resulting normalized vectors.

### C. Action Utility

Although utility is usually defined for a state of the world, we also define it for an action in a state of world. The utility of an action is the difference between the utility of the state after the action is performed and the utility of the state before. However, such a definition does not take into account the potential non-determinism of action effects. Instead we define the expected utility of an action as the average utility of an action if it was performed an infinite number of times in the same state of the world.

**Definition 4.** If $w_0 \in \mathcal{W}$ and $a \in \mathcal{A}$ are a world state and a joint action, then we define the expected utility of the action $a$ in the world state $w_0$ as

$$\vec{eu}(a, w_0) = \left( \int_{\mathcal{W}} \mathcal{P}(w \mid w_0, a) \vec{u}(w) dw \right) - \vec{u}(w_0)$$

Note that $\vec{eu}(a, w_0) \in \mathcal{U}$.

### D. Taxonomy of Actions

There is nothing but joint actions in the real world. All agents are concurrently choosing from amongst a huge number of their individual actions and the world changes accordingly. Some actions can be easily attributed to a single agent, e.g. pressing a button, however many other actions may have multiple actors involved to a different degree, e.g. a car accident. The outcome of a joint action can also have multiple independent parts relevant to different agents.

Our main goal in this section is to classify joint actions as cooperative, self-interested, competitive and adversarial, with respect to different agents or groups thereof. Collectively, we refer to these classes as interaction stance. In order to do this, we need to separate the part of the action effect which is relevant for the group and to think about what could the group have done differently to change its influence to the part.

First of all, we need to get rid of the irrelevant components of the outcome. Consider two groups of agents with preference vectors $\vec{u_{\mathbf{G}}}$ and $\vec{u_{\mathbf{H}}}$. These two vectors generate a vector subspace of the utility space. If the directions of the preference vectors are the same or opposite, the subspace degenerates to a single dimension; otherwise it is a two-dimensional plane.

The model works also for one dimension, but let us assume a more general vector orientation. For any action, the important part for classification from the viewpoint of the groups $\mathbf{G}$ and $\mathbf{H}$ is *the projection of the action's expected utility vector to the subspace*. If we assume for a while, that a group of agents $\mathbf{G}$ is fully responsible for a joint action $a$ considering the groups $\mathbf{G}$ and $\mathbf{H}$, we can draw the action classification scheme as in Figure 1. Below we examine the different interaction stances in more detail. An action is considered self-interested from the group $\mathbf{G}$ if it increases the utility of the group.

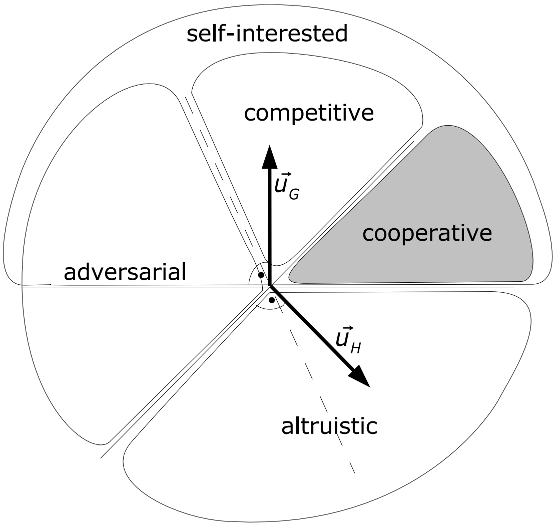

Fig. 1. Classification of a joint action.

**Definition 5.** We say that a joint action $a \in \mathcal{A}$ is *self-interested* for a group of agents $\mathbf{G} \subseteq \mathcal{I}$ in a state of the world $w \in \mathcal{W}$

$$\mathtt{si}_{\mathbf{G}}(a, w) \Leftrightarrow \vec{u_{\mathbf{G}}} \cdot \vec{eu}(a, w) > 0$$

We say that an action is cooperative with $\mathbf{H}$, if it changes the world in a way that increases the utility of both groups. Cooperative actions are symmetric. Actions that are cooperative from $\mathbf{G}$ towards $\mathbf{H}$ have exactly the same expected utility vectors as actions that are cooperative from $\mathbf{H}$ towards $\mathbf{G}$.

**Definition 6.** We say that a joint action $a \in \mathcal{A}$ is *cooperative* from a group of agents $\mathbf{G} \subseteq \mathcal{I}$ towards a group $\mathbf{H} \subseteq \mathcal{I}$ in a state of world $w \in \mathcal{W}$

$$\texttt{coop}_{\mathbf{G}\rightarrow\mathbf{H}}(a, w) \Leftrightarrow \vec{u_{\mathbf{G}}} \cdot \vec{eu}(a, w) > 0 \;\&\; \vec{u_{\mathbf{H}}} \cdot \vec{eu}(a, w) > 0$$

An action is competitive, if it does not decrease the utility of the group $\mathbf{H}$ more than it increases the utility of the group $\mathbf{G}$.

**Definition 7.** We say that a joint action $a \in \mathcal{A}$ is *competitive* from a group of agents $\mathbf{G} \subseteq \mathcal{I}$ towards a group $\mathbf{H} \subseteq \mathcal{I}$ in a state of the world $w \in \mathcal{W}$

$$\texttt{comp}_{\mathbf{G}\rightarrow\mathbf{H}}(a, w) \Leftrightarrow$$
$$\vec{u_{\mathbf{G}}} \cdot \vec{eu}(a, w) \geq |\vec{u_{\mathbf{H}}} \cdot \vec{eu}(a, w)| \;\&\; \vec{u_{\mathbf{H}}} \cdot \vec{eu}(a, w) < 0$$

An action is adversarial if it lowers the utility of the group $\mathbf{H}$ more then it increases the utility of the group $\mathbf{G}$ or even decreases the utilities of both the groups.

**Definition 8.** We say that a joint action $a \in \mathcal{A}$ is *adversarial* from a group of agents $\mathbf{G} \subseteq \mathcal{I}$ towards a group $\mathbf{H} \subseteq \mathcal{I}$ in a state of the world $w \in \mathcal{W}$

$$\texttt{adv}_{\mathbf{G}\rightarrow\mathbf{H}}(a, w) \Leftrightarrow$$
$$\vec{u_{\mathbf{G}}} \cdot \vec{eu}(a, w) < -\vec{u_{\mathbf{H}}} \cdot \vec{eu}(a, w) \;\&\; \vec{u_{\mathbf{H}}} \cdot \vec{eu}(a, w) < 0$$

The last interaction stance not yet defined is the altruistic action. We define it as an action which helps some other agent while lowering the utility of the performing agent.

**Definition 9.** We say that a joint action $a \in \mathcal{A}$ is *altruistic* from a group of agents $\mathbf{G} \subseteq \mathcal{I}$ towards a group $\mathbf{H} \subseteq \mathcal{I}$ in a state of the world $w \in \mathcal{W}$

$$\texttt{alt}_{\mathbf{G}\rightarrow\mathbf{H}}(a, w) \Leftrightarrow$$
$$\vec{u_{\mathbf{G}}} \cdot \vec{eu}(a, w) < 0 \;\&\; \vec{u_{\mathbf{H}}} \cdot \vec{eu}(a, w) > 0$$

At this point, we can define several classic game theoretic concepts in our framework. For example the utilities of a two player zero-sum game can be described by two vectors for which $\vec{u_A} = -\vec{u_B}$. Generally, we can define relationships between agents and group of agents based on the similarity of their weights of different utility components.

**Definition 10.** We say, that groups of agents $\mathbf{G}, \mathbf{H} \subseteq \mathcal{P}$ have *cooperative potential* if

$$\vec{u_{\mathbf{G}}}.\vec{u_{\mathbf{H}}} > 0$$

They have *adversarial potential*

$$\vec{u_{\mathbf{G}}}.\vec{u_{\mathbf{H}}} < 0$$

The definitions correspond to the correlation of agent payoffs used in game theory [5]. Two groups have cooperative potential if most of the self-interested actions of each group are cooperative with respect to the two groups. The adversarial potential occurs if most of self-interested actions are competitive or adversarial.

### E. Intentionality of Adversarial Action

The above defined concept of the adversarial action considers the effects of an action with respect to agents' individual and collective utilities. Classifying an agent as an adversary is based on the purely external analysis of agents behaviour, without taking into account agent decision-making capabilities and the influence of the environment on the executability and outcomes of its actions. The model presented so far can only represent whether the actions of a particular agent or a group of agents are helping or harming someone else.

In the real world, however, cooperative agents are often forced to choose the smallest evil, e.g. to choose an action that will harm the others least from all the available actions. In such situations, classifying the least harmful action as adversarial, as done by the model, might not be appropriate, as it may be the case that the agent has no other choice than to harm the other agents. A similar problem arises with the classification of the least beneficial action as cooperative if an agent can only perform beneficial actions.

This problem has been in part addressed in [6], where the concept of intentional adversarial action has been introduced. This definition assumes intentional adversariality based on agents' knowledge of adversarial nature of the particular action and agents knowledge of the existence of an alternative action that can be performed with less harmful effect. The definition could be loosely rewritten in the presented formalism as follows. If $\mathcal{A}^w_{\mathbf{G}}$ is the set of actions available to the group of players $\mathbf{G}$ in the state of world $w \in \mathcal{W}$ and $a_0 \in \mathcal{A}^w_{\mathcal{I}\setminus\mathbf{G}}$ is a combination of actions of the players that are not in $\mathbf{G}$, then an action $a = (a_0, a_{\mathbf{G}})$ is intentionally adversarial if

$$\texttt{adv}_{\mathbf{G}\rightarrow\mathbf{H}}(a, w) \wedge \exists a' = (a_0, a'_{\mathbf{G}}) \in \mathcal{A} \text{ such that}$$
$$\vec{u_{\mathbf{H}}} \cdot \vec{eu}(a, w) + \vec{u_{\mathbf{G}}} \cdot \vec{eu}(a, w) <$$
$$\vec{u_{\mathbf{H}}} \cdot \vec{eu}(a', w) + \vec{u_{\mathbf{G}}} \cdot \vec{eu}(a', w)$$

This definition is quite strict. If a player with almost all its actions adversarial towards someone does not perform the single least harmful action, it is considered adversarial.

An alternative approach to the definition of an intentionally adversarial action and to effective separation of agent's intention and the interfering effect of the environment is based on the concept of *neutral behaviour*. Which action should an agent choose so that nobody could legitimately accuse it of acting self-interestedly or adversarially? The best solution in our opinion is to consider neutral an agent which chooses its action randomly with uniform distribution. With respect to this, the neutral outcome of an action is not the zero vector, but the average outcome of all the actions performable in a certain state of world. This corresponds to the centre of mass of all performable actions.

**Definition 11.** If $\mathcal{A}^w_{\mathbf{G}}$ is the set of actions available to the group of players $\mathbf{G}$ in the state of world $w \in \mathcal{W}$ and $a_0 \in \mathcal{A}^w_{\mathcal{I}\setminus\mathbf{G}}$ is a combination of actions of the players that are not in $\mathbf{G}$ then the *neutral utility* is

$$\vec{c} = \frac{1}{|\mathcal{A}^w_{\mathbf{G}}|} \sum_{a_{\mathbf{G}} \in \mathcal{A}^w_{\mathbf{G}}} \vec{eu}((a_0, a_{\mathbf{G}}), w)$$

If we want to classify an action, we first have to subtract the neutral utility from its expected utility and classify the difference as described above. Based on the neutral utility, an intentionally adversarial action would be defined as follows:

**Definition 12.** We say that a joint action $a = (a_0, a_{\mathbf{G}}) \in \mathcal{A}$ is *intentionally adversarial* from a group of agents $\mathbf{G} \subseteq \mathcal{I}$ towards a group $\mathbf{H} \subseteq \mathcal{I}$ in a state of the world $w \in \mathcal{W}$

$$\begin{gathered} \texttt{adv\_int}_{\mathbf{G}\rightarrow\mathbf{H}}(a, w) \Leftrightarrow \\ \vec{u_{\mathbf{G}}} \cdot (\vec{eu}(a, w) - \vec{c}) < -\vec{u_{\mathbf{H}}} \cdot (\vec{eu}(a, w) - \vec{c}) \\ \wedge\, \vec{u_{\mathbf{H}}} \cdot (\vec{eu}(a, w) - \vec{c}) < 0 \end{gathered}$$

If the agent has no alternative to the action that is a subject of our investigation, its expected utility would be the same as the expected utility of the neutral action, and thus $(\vec{eu}(a, w) - \vec{c}) = 0$. This fact does not allow classifying the action as intentionally adversarial. The least harmful action from all possible actions also cannot be classified as intentionally adversarial. The last statement is generalized in the following proposition.

**Proposition 1.** *If there is an action $a = (a_0, a_{\mathbf{G}}); a_{\mathbf{G}} \in \mathcal{A}^w_{\mathbf{G}}$ intentionally adversarial from group $\mathbf{G}$ towards a group of agents $\mathbf{H}$ then there exists a sub-action $a'_{\mathbf{G}} \in \mathcal{A}^w_{\mathbf{G}}$ that forms an action that is less harmful to $\mathbf{H}$.*

$$\begin{gathered} \texttt{adv\_int}_{\mathbf{G}\rightarrow\mathbf{H}}(a, w) \Rightarrow\ \exists a'_{\mathbf{G}} \in \mathcal{A}^w_{\mathbf{G}} \\ \vec{u_{\mathbf{H}}} \cdot (\vec{eu}((a_0, {a'}_{\mathbf{G}}), w)) > \vec{u_{\mathbf{H}}} \cdot (\vec{eu}((a_0, a_{\mathbf{G}}), w)) \end{gathered}$$

*Proof:* Assume for contradiction that

$$\forall a'_{\mathbf{G}} \in \mathcal{A}^w_{\mathbf{G}}\ \vec{u_{\mathbf{H}}} \cdot (\vec{eu}((a_0, a'_{\mathbf{G}}), w)) \leq \vec{u_{\mathbf{H}}} \cdot (\vec{eu}((a_0, a_{\mathbf{G}}), w))$$

then using the definition of the neutral utility

$$\begin{aligned} \vec{u_{\mathbf{H}}} \cdot \vec{c} &= \frac{1}{|\mathcal{A}^w_{\mathbf{G}}|} \sum_{a'_{\mathbf{G}} \in \mathcal{A}^w_{\mathbf{G}}} \vec{u_{\mathbf{H}}} \cdot \vec{eu}((a_0, a'_{\mathbf{G}}), w) \\ &\leq \vec{u_{\mathbf{H}}} \cdot \vec{eu}((a_0, a_{\mathbf{G}}), w) \frac{1}{|\mathcal{A}^w_{\mathbf{G}}|} \sum_{a'_{\mathbf{G}} \in \mathcal{A}^w_{\mathbf{G}}} 1 \\ &= \vec{u_{\mathbf{H}}} \cdot \vec{eu}((a_0, a_{\mathbf{G}}), w) \end{aligned}$$

The inequality holds thanks to the assumption. Now look at the definition of intentional adversariality. The second condition in the definition is

$$\vec{u_{\mathbf{H}}} \cdot (\vec{eu}((a_0, a_{\mathbf{G}}), w) - \vec{c}) < 0$$

hence

$$\vec{u_{\mathbf{H}}} \cdot \vec{eu}((a_0, a_{\mathbf{G}}), w) < \vec{u_{\mathbf{H}}} \cdot \vec{c}$$

This contradicts the inequality above and thus concludes the proof. □ ■

The presented classification expects the agent to have full information about the world. This is usually not true, the information an agent has can be partial, incorrect, or the agent can even overestimate its capabilities. In this case the expected utility of an action changes to what agent believes is their expected utility and the perceived neutral utility becomes the average outcome of all the actions the agent believes it can perform.

### F. Traces of Actions

We can easily generalize the classification of actions to classification of runs in a multi-agent system in a straightforward way. The expected effect of the actions in a run on the utilities is the sum of the expected effects of the actions included in the run. Other definitions would be possible, but this one manifests the intentions of an agent with full information about the world, and is therefore most suitable for the classification of the interaction stance.

**Definition 13.** *Run* in a multi-agent system is a sequence of world states and actions

$$\rho = (w_1, a_1, w_2, a_2, ..., w_{k+1});\ w_i \in \mathcal{W}, a_i \in \mathcal{A}$$

where the state of the world is transformed from $w_i$ to $w_{i+1}$ via $a_i$.

**Definition 14.** Let $\rho = (w_1, a_1, w_2, a_2, ..., w_{k+1});\ w_i \in \mathcal{W}, a_i \in \mathcal{A}$ be a run of a multi-agent interaction, we define the *real utility* of the run

$$\vec{u}(\rho) = \vec{u}(w_k) - \vec{u}(w_1)$$

The *expected utility* of the run is

$$\vec{eu}(\rho) = \sum_{i=1}^{k} \vec{eu}(a_i, w_i)$$

The expected utility of a run can be classified in the same way as the expected utility of an action. By comparison of the of the utility vectors $\vec{u(\rho)}$ and $\vec{eu}(\rho)$, we can analyze how predictable or in a way intentional was the real outcome of a sequence of actions.

### G. Illustrative Example

To illustrate the use of the classification model introduced in the previous section, we apply it to a simulation of a flood relief operation. We consider three agents in the operation: the local government, humanitarian non-governmental organization (NGO) and separatists. The overall goal of the government, helped by the NGO is to stabilize the situation whereas the separatists want to take advantage of the situation is gain control over the affected regions.

Specifically, applying the proposed model, we identify the following utility components in the scenario: (1) the number of people with sufficient food and shelter, (2) the number of villages that are under the control of the government and (3) the state of the infrastructure damaged by the flood. One of the basic rules of the scenario is that the government cannot control a village, where people do not have enough food and shelter because of the riots that arise. The objectives of the three agents involved in the scenario are as follow. The government wants to maximize all three utility components. The NGO cares only about maximizing the number of people with food and shelter. Finally, the separatists also care about people's well-being, but prefer the government not to have control. Consequently, they do not want the infrastructure repaired, because it gives tactical advantage to the government.

If all three agents value all the utility components equally, then the normalized preference vectors, using the order in which the components were introduced above, are:

$$\vec{u}_{GOV} = (0.58, 0.58, 0.58)$$
$$\vec{u}_{NGO} = (1, 0, 0)$$
$$\vec{u}_{GNG} = (0.58, -0.58, -0.58)$$

Some of the relevant actions in the scenario are delivering food to a village, destroying food supplies in a village or rebuilding infrastructure in a village. Below, we classify these actions with respect to the government and separatist agent. If we project the expected utilities of the actions to the plane generated by their utility vectors, we get the situation depicted in Figure 2. A typical cooperative action of one of the players towards the other is delivering food to starving people. The expected utility of the action is $(1, 0, 0)$ and it improves the utility of both players to the same extent. A competitive action of the government towards the separatists is e.g. rebuilding infrastructure, with the expected utility of $(0, 0, 1)$. The utility the government gains from this action is the same as the loss of the separatists. An adversarial action of the separatists is destroying food supplies in a village with the expected utility of $(0, -1, 0)$. It lowers both players' utilities equally, because the food cannot be delivered to the starving people. Still, the separatists may choose to perform such an action with the intention to harm the government and with the anticipation of riots and subsequent government's loss of control over the village, which would eventually increase separatists utility.

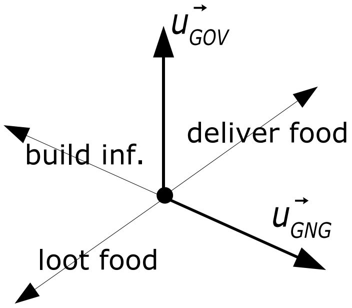

Fig. 2. Actions in the disaster relief scenario and their relation to the utilites of the Goverment and Separatists agent

## IV. Applications

In addition to providing formal grounding for a terminology used in categorising inter-agent relationships, the proposed scheme has several other applications.

### A. Interaction Norms

Exploring how expected and/or allowed behaviours of agents in open multi-agent systems can be described, monitored and possibly enforced is an active research topic. Most of the developed formalisms, however, focus on defining norms as restrictions on actions an agent must or must not take in particular situations, without explicit reference to utilities of other agents.

The concept of interaction stance, as formally introduced in this paper, allows to specify norms which involve such a reference. It can be e.g. stipulated that every agent must be cooperative with respect to the head agent of the community, or that it must not be adversarial to any other member of the community[2]. Instead of prescribing literally which behaviours are allowed, such *interaction-based norms* allows prescribing the behaviour *relative* to other agents. The advantage of interaction-based norms in their flexibility – should the utility of the administrator agent change (e.g. due resource congestion arising in the system), individual member agents must adjust their behaviour accordingly (e.g. stop bandwith-intensive transfers).

An important property of the proposed classification scheme is that it is operationalizable. Whenever an agent performs an action in the system, it is categorized and depending on the resulting category, respective norms can be applied.

### B. Agent Profiles

The interaction stance of an agent towards other agents (or classes thereof) can be made part of agent's profile. If combined with the knowledge of agent's base utility, a set of such profiles can provide for a compact representation of social relationships in agent community in way that allows reasoning about the behaviour of different (sub-)groups of agents in the system. Based on the profile of agents in a community and the profile of a potential new entrant, it can be determined whether the introduction of the new agent would benefit or harm the community.

### C. Case-based Reasoning

The compact description using agent profiles, each combining agent's base utility and its interaction stance towards other agents, can be further used in a case-based reasoning system. When an agent is to operate in a community with a particular configuration of agents, it can search the case base for a situation in which the same or similar agents with the same or similar interaction stances were involved. For example, a humanitarian relief operation can proceed differently if farmers are cooperating than if they are adversarial.

### D. Agent Design

Design of autonomous agents for open MAS is another application of the classification scheme. By taking into account the primary utilities of other agents in the system, the behaviour of the designed agent can be adjusted to implement

[2] Note that this is not possible for all combinations of agent's utlities.

the desired stance towards other agents in the system. Such an adjustment can be done off-line by a designer or on-line by the agent itself, provided agent's decision mechanism is flexible enough to realize such adjustment.

## V. Related Work

The different factors affecting how agents choose actions they perform have been widely studied in the literature. The impact of limited decision-making capabilities has been explored within the topic of bounded rationality (see e.g. [3]). The role of the environment in affecting agent's ability to achieve its objectives has been long-studied in planning; the concept of joint action capturing the effect of other agents' actions on the desired outcome of the action performed by the agent has been long-known in game theory and multi-agent reinforcement learning.

The concept of adversariality has been studied from game theoretical perspective with applicability in economical theories and wargaming [7]. The repeated games approach with incomplete information and knowledge was used to model attackers and defenders in information warfare [8]. In robotics domains (especially robocup soccer) the adversarial actors are preventing the other actors from effective achieving their goals [9], [10]. An incentive-based modelling and inference of attacker intent, objectives, and strategies has been reported in e.g. [11]. Recently behaviour of adversarial agents in multi-agent domains has been defined via motivation to cause a drop of agents' social welfare, even at the cost of the adversarial agents individual utility [1]. However, so far there seems to be no computer-science literature attempting to formally ground the otherwise frequently used informal notions of adversariality or altruism and relating them to agent objectives defined as utility functions.

## VI. Conclusion

In complex scenarios, agents do not always choose actions that lead optimally to the fulfilment of their objectives. The factors causing such a behaviour can be multiple, including agent's limited decision-making capability or the restrictive force of the environment. The paper focuses on the factor which has not yet been sufficiently addressed in this context – agent's social relationships to other agents. Agents may choose to perform actions not fully aligned with their objectives, if this helps or possibly prevents other agents from reaching *their* objectives.

In order to formalize such influence of social factors, we employ a formalism based on partially observable stochastic game to describe inter-agent interactions and define the concept of *interaction stance*, which categorizes agents' actions as self-interested, cooperative, competitive and adversarial. The classification is based on agents' preferences over different characteristics computed from the state of the system in consideration. We present two possible views of the classification. The first considers the effects of the actions of a group of agents towards other agents without taking into account actions available to the agents, whereas the other does take the real action options in account. The later approach allows differentiating between behaviours producing unintended negative effects and behaviours that are deliberatively adversarial. We show several applications of the model for the representation of norms, compact representation of social aspects of agent behaviour and representing social configurations of multi-agent systems.

In the future, we plan to include partial information about the world state, which can be represented via observations in the formalism, and extend the classification scheme to include agent beliefs about the world and the impact of their actions. Another important direction is the creation of methods for the reconstruction of agent utilities and their interaction stance from the observations of their actions in different social environments.

***Abstract*—Securely managing shared information in distributed environments across multiple organizations is a challenge. Distributed information management systems designed to this purpose, must be able to support individual organizations' information policies whilst ensuring global consistency and completeness of information. This paper describes a multi-agent based prototype implementation of a distributed information management system, for distributed digital criminal dossiers. The prototype implementation runs on the multi-agent platform AgentScape.**

## I. Introduction

MANAGING shared information securely and efficiently across multiple independent organizations is a challenge [2], [14]—the challenge this paper addresses. Individual organizations manage their own information locally on their own systems, according to their own information policies. If information is to be shared, however, additional system-wide policies and mechanisms are needed to manage global correctness and consistency.

One example of an environment in which information needs to be shared between multiple semi-independent organizations is the environment in which the Public Prosecution compiles and manages digital criminal dossiers. These criminal dossiers are currently being used in the Courts of Amsterdam and Rotterdam in a number of pilot studies. Earlier work in the Agent-based Criminal Court Electronic Support Systems (ACCESS) project [11], [12], [13] has focused on the high-level design and security of a distributed agent based architecture [4] that manages information based on the notion of *distributed digital criminal dossiers*. This paper describes a prototype implementation of a distributed information management system, that runs on the multi-agent platform AgentScape [7].

The main advantage of a distributed architecture is that it allows *physically* distributed information sources, such as Municipalities and the Prison Systems, to be, and thus remain, responsible for the integrity of their own information content in a digital dossier. By law, the Public Prosecution is responsible for the compilation and maintenance of criminal dossiers. Dutch law also dictates which information can and must be exchanged to facilitate compiling a criminal dossier[1].

In our approach the Public Prosecution has a central role and is responsible for providing the infrastructure that enables other organizations to securely add information and securely access information in criminal dossiers. Together, these organizations form a semi-open environment: an environment in which organizations are known and have control over their own information. This paper discusses some of the details involved in implementing a distributed agent-based information management system that allows *secure* information *exchange* across multiple organizations. In contrast, earlier work [1], [6] on distributed agent-based information management has mainly focused on *finding* information in *open* network, i.e., the Internet.

The remainder of this paper is organized as follows. The next section gives some background on the context in which the ACCESS prototype should function as well as on the AgentScape platform. Section III illustrates the design of the system in some detail and Section IV gives more information on the actual ACCESS prototype implementation. The paper ends with a discussion and conclusions.

## II. Background

This section briefly introduces the notion of *Distributed Digital Criminal Dossiers* compiled and managed by the Public Prosecution. See  [11], [12], [13] for more detail of compilation and management of distributed dossiers in complex and adaptive environments. This section also briefly introduces the AgentScape [7] agent platform on which the prototype runs.

### A. Context

In the semi-open environment in which the Public Prosecution compiles

and manages digital criminal dossiers, information is shared between multiple semi-independent organizations. On an experimental basis and in specific pilot studies such criminal dossiers have been used in the Courts of Amsterdam and

[1] Please note that all legal and procedural details discussed in this paper are interpreted in the context of Dutch law, but can be extended to legislation of other jurisdictions.

Rotterdam. This paper describes the architecture and implementation of a distributed multi-agent system architecture [4], designed to improve consistency, completeness, integrity and security of the information in digital criminal dossiers.

The physically distributed sources of information distributed over different organizations are depicted in Figure 1 below[2].

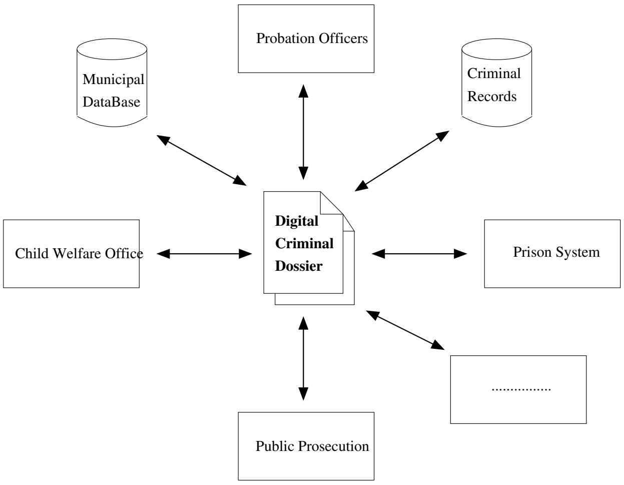

Fig. 1. Information Sources for a Digital Criminal Dossier

The Public Prosecution determines if (and when) an individual is to be prosecuted based on the law and the information available. Once decided, the Public Prosecution creates a criminal dossier for the case. Each newly created criminal dossier contains standard (meta-)data, and crime specific (meta-)data.

Different organizations are responsible for different information in the criminal dossier. Administrative information, for example, is managed and maintained by the defendant's local authorities[3] and information on a juvenile defendant's family situation and social environment is the responsibility of the Council for Child Welfare[4]. Distributing both the *data* (information) and the *responsibility* for the data ensures that information in digital dossiers is kept as up-to-date as possible. Changes in data are flagged by the relevant organizations and transmitted to the Public Prosecution for synchronization of the complete (distributed) criminal dossier.

The criminal dossier as a whole is the responsibility of the Public Prosecution whilst relevant data are maintained and stored by the organizations responsible for the data. The Public Prosecution is responsible for synchronization of the data within the digital criminal dossier as a whole and for the final version of the dossier that is sent to the judge for judgement in trial.

Note that the term 'dossier' is overloaded. In this paper the focus is mostly on *criminal* dossiers. Other dossiers include administrative dossiers, dossiers managed by the Council for Child Welfare, and, in general, all documents types that can contain references to other documents. In the remainder of this paper the term 'dossier' refers to dossiers in general, while 'criminal dossiers', 'administrative dossiers' etc, refer to specific dossier types.

### B. AgentScape

AgentScape [7] is a multi-language mobile agent middleware platform designed to support scalable, secure, distributed multi-agent applications. Agents can migrate between virtual domains called *locations* and can negotiate resource requirements before migrating [5]. An AgentScape location consists of one or more hosts running the AgentScape middleware, typically within a single administrative domain. Each AgentScape location runs a *location manager* process on one of its hosts. Each host has its own *host manager*. An example of two AgentScape hosts is depicted below in Figure 2. Multiple locations together with a lookup service form an AgentScape *world*: a distributed multi-agent system. The prototype implementation, discussed in this paper, is an example of an AgentScape world.

The AgentScape *kernel* provides low-level secure communication between the higher level middleware processes and between agents, and provides secure agent mobility. *Agent servers* provide language dependent run-time environments for agents, *Web service gateways* [8] support Web service access and monitoring using the SOAP/XML protocol. Two versions of the kernel have been implemented, in Java and in C.

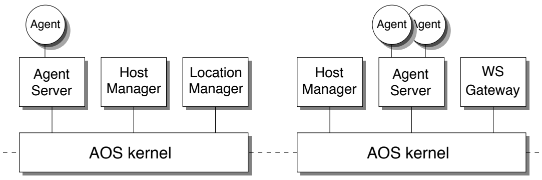

Fig. 2. The AgentScape middleware architecture.

## III. Application Design

The ACCESS prototype application is designed to be managed decentrally. Data is stored in digital criminal dossiers, fields of which are distributed among different locations (organizations). The contents of each field in a criminal dossier is automatically updated by the location responsible. This section describes how the information and locations are structured.

### A. Distributed Digital Criminal Dossiers

Dossiers are implemented with a light weight 'skeleton' framework based on XML. Fields in this XML document

[2] In this context, the Police have a special role. The Police provide information needed for compiling criminal dossiers by others (Public Prosecution, Probation officers etc), but cannot, for example, change information in criminal dossiers once a criminal dossier has been created by the Public Prosecution. Thus, information exchange between the Police and other organizations does not occur via distributed digital criminal dossiers.

[3] In the Dutch context all citizens are obliged to be registered in one and only one Municipality. Municipalities are responsible for keeping administrative records of their residents. Please note that not all countries have such administrative records at the governmental level, e.g. the USA do not maintain any administrative records at this level.

[4] In the Dutch context, it is the task of the Council for Child Welfare to investigate all aspects of a crime that involves minors, including the family situation and other relevant social factors, and to provide a motivated advice for suitable punishment (if applicable) of the suspect to the Courts.

contain keywords and references to other (possibly, but not necessarily, XML-based) documents. The distributed nature of the dossier is acquired through references to documents on both local and remote systems.

The root of each criminal dossier, created by the Public Prosecution, always includes the dossier number, creation date, access control lists, type of offense, (a reference to) the defendant's administrative data (in an administrative dossier), and the original police report concerning an incident. It also includes mandatory and optional information for each specific offence. Such information is used by the Public Prosecution to check completeness of a criminal dossier—a criminal dossier is only complete if all mandatory information is present. It provides the structure needed for automated completeness checks [12].

This paper assumes that standard XML templates exist for each type of offence, and that these templates are used by the Public Prosecution to structure the meta-data in a criminal dossier[5].

A distributed digital criminal dossier thus consists of a number of documents in a networked structure distributed over physically distributed locations with the Public Prosecution as the central coordinator. Note that a digital criminal dossier may only be referenced by other digital criminal dossiers. All digital criminal dossiers themselves are controlled by the Public Prosecution, an important security requirement. The root of each criminal dossier, maintained by the Public Prosecution, also contains information such as logging information on who altered or accessed information when, and when the last backup of the dossier was made.

### B. Principals

Many users interact with the information management system (using agents) concurrently, from different locations (organizations). These users can be divided into three types with different administrative rights:

1) *Users of the information management system*
Users of the information management system interact (read, write) with dossiers to perform their jobs as judges, (legal) clerks, public prosecutors, etc. As users of the information management system they cannot add or remove dossiers and templates, and they don't have permission to change the configurations of the system.
2) *System administrators with administrative rights of the infrastructure*
Administrators can be further divided into world and location administrators. The world administrator, a person assigned this role by the Public Prosecution, maintains the AgentScape world. Note that the world includes the lookup service and the central user and template repositories (also see Section IV-C). Location administrators, are assigned their roles by the locations they represent, have the task to maintain local configurations and infrastructure, i.e., the host machines, within their location. Both types of administrators can add users to the system and specify their roles (judge, prosecutor etc).
3) *The owner of the criminal dossiers—the Public Prosecutor*
The Public Prosecutor is the owner of all criminal dossiers. The Public Prosecutor is the only person who can create (or destroy) new criminal dossiers. The Public Prosecutor assigns access rights to roles (see below), and roles to users.

Note that in our approach, access to (and subsequent manipulation of) a dossier by users of the first type, users of the information management system, is only possible via agents. The owner of the criminal dossiers, the Public Prosecutor, also uses agents to create and delete dossiers. These agents are their only means of accessing the system—the 'single point of entry' for each user into the information management system.

### C. Access Control

The semi-open nature of the application domain makes access control a particularly interesting challenge.

The solution proposed in this paper is based on a two-tier access model. The first level in the model is based on role based access control (RBAC) [10]. Each 'role', such as judge, lawyer, public prosecutor, or clerk, has certain rights with regard to the criminal dossier. This typically depends on specific security policies, for example, a clerk may only add information to a criminal dossier, not delete or modify anything, while a public prosecutor may change existing information in the criminal dossier and even create new criminal dossiers. Roles are also distinguished for all of the organizations associated with a dossier. The role based access control list is generated from the high level security policies. Each template includes the RBAC list associated with the offence for which the template has been designed, specifying which access rights are associated with which role.

Additionally, the second access level uses access control lists (ACL) [3] to determine the access rights of an individual user, within each of these organizations, *after* the RBAC list has granted access based on the user's role. Each individual dossier, i.e., an instantiation of a template, specifies, in its meta data, the names of specific users and their access rights: it specifies per user who may read or change, information in a dossier. For example, suppose that a specific RBAC assigns judges (those with the role of judge) read access to a specific type of dossier. The ACL, however, specifies which individual judges have permission to read a specific instance of a dossier. It may specify that only Judge A has read access. In this case, Judge B, although a judge, may not read the contents of this particular dossier instance. Thus in order to read fields in a digital dossier (via an agent) a user not only has to be assigned a specific role, he/she also has to be on the access control list of a specific dossier.

This distinction between roles and individual users is crucial in all dynamic environments. Security policies are based on this distinction. Security policies based on *roles* are relatively

[5] See [12] for a proposal to use automatic clustering techniques to construct (part of) this information automatically.

static (or at least ‘long lived’) and are typically globally valid (at all possible locations), while *individual*-based access control lists are typically dynamic (or ‘short lived’) and often apply to specific dossiers. Individual-based control lists change, for example, when a dossier is handed over to another clerk within the same organization, or to another judge. The combination of static and dynamic access control rules are designed to limit ‘label creep’ [9], (i.e., that access control regulations make *all* data more difficult to access, including the less sensitive information.) Section III-D describes how this two-tier access control mechanism is represented in dossier templates and instances. Note that the ACL is not mandatory—if not specified the globally defined RBAC lists are used to regulate access to dossiers.

Once roles have been distinguished and access rights assigned to users, users need to be able to be identified by the different systems within the different organizations. Authentication is needed. In practice, authentication is done by assigning each user a name and a password. Each username is assigned one or more roles. This information is stored in a central user data repository[6] which is unique for the specific environment, i.e., an ACCESS world and managed by the world administrator. This repository can only be accessed by users within this world who have been assigned the role and the right to maintain this information.

Users, however, do not interact directly with any one of the systems or repositories. A user interacts with an agent that represents that user, see Section IV-A below. Once authenticated, a user’s agent is provided with a unique set of credentials with which his/her agent can be identified/authenticated.

Note that access control is not the only security issue in this environment. Other security features, such as secure communication between location, backup mechanisms, integrity checks and others, are discussed in detail in [13].

### D. Data Types

As stated earlier, dossiers are structured according to templates. Which template is used depends on the offence (for criminal dossiers) and may also depend on other information (e.g. administrative dossiers, probation dossiers, etc). A template specifies the constraints and the (type of) information that a dossier must or may contain. The listing in Figure 3 shows a (simplified) example of a template in XML format. The template describes administrative dossiers that store information of a subject.

This template shows a role based access control list (RBAC). The RBAC list in a template states the permissions each of the roles have on dossiers that are based on this template. The RBAC list in the template in Figure 3 states that (all) mayors have the right to both read and write entries in dossier instances (but not in dossier templates) and that all mayors furthermore have the right to change the (optional) ACL of a dossier instance. Administrative clerks may both read and write administrative dossiers based on this template and judges are only granted read access.

```
<Template>
<Meta>
<Name>AdminInfo</Name>
<ID type="Value" mandatory="true"
    content="Integer" />
<RBAC>
    Mayor:R-W-ACL,
    AdminClerk:R-W,
    Judge:R
</RBAC>
<ACL type="Value" mandatory="false"
     content="String List"/>
</Meta>
<Fields>
<Field name="Name" mandatory="true"
     type="Value" content="String"/>
<Field name="Title" mandatory="false"
     type="Value" content="String"/>
<Field name="SocialNum" mandatory=true"
     type="link" content="SocNum"/>
</Fields>
</Template>
```

Fig. 3. An example of a dossier template containing administrative information

The template also names the fields in a dossier instance, including their format, and specifies whether a field is mandatory or optional. In this listing, “Name” and “SocialNum” (social security number) are mandatory, “Title” is optional. Name and Title are String values, SocialNum is a link to a dossier. The link must in this case, always point to a dossier of type “SocNum”.

Depending on their assigned roles and permissions, users may be able to modify a dossier instance, however they are never allowed to modify the template. The RBAC list inside a dossier can only be modified by the world administrator, if permission is given by a public prosecutor. Note that the RBAC list is mostly static and will typically not change often.

The following listing shows an example of an instance of part of the administrative dossier, based on the template “AdminInfo” depicted in Figure 3. Consistency of required fields and types are checked automatically. More sophisticated consistency checks (spanning multiple dossiers) are performed by specialized agents, see Section IV-A. As required by the template, string values for the mandatory fields “Name” and “SocialNum” are specified.

The mandatory social security number field “SocialNum” contains a link (format `[refId]@[location]`) pointing to dossier ID 12432, located at location “SocNumRepos”. The link points to a dossier possibly at another location. The precise content of this dossier is beyond the scope of this paper. In the AgentScape implementation of the ACCESS prototype, different locations store different kinds of information. Links point to different types of documents, e.g. pdf files (such as the original arrest warrant), movie files, dna profiles and other document types, stored locally or remotely.

The administrative dossier has the RBAC list inherited from the administrative dossier template. Note that the RBAC

[6] A data repository is typically a database running on a location.

```
<Dossier>
<Meta>
<Template>AdminInfo</Template>
<ID value="123876"/>
<RBAC> <!--Inherited from template-->
     Mayor:R-W-ACL,
     AdminClerk:R-W,
     Judge:R
</RBAC>
<ACL> Judge:Judy:R <!-- only Judge Judy
   is allowed to read this dossier.
   Access rights for mayors and
   administrative clerks are still
   determined by the RBAC list. -->
</ACL>
</Meta>
<Fields>
<Field name="Name" value="George"/>
<Field name="Title" value="Dr"/>
<Field name="SocialNum"
      value="12432@SocNumRepos"/>
</Fields>
</Dossier>
```

Fig. 4. An example of an (administrative) dossier instance –based on the template in Figure 3– containing administrative information

inside a dossier instance is a local cache of the template RBAC and is only used in case of malfunctions (e.g. when the network is down). But whereas the RBAC specifies the permissions for all dossiers based on this template, the dossier ACL specifies the permissions for this specific dossier, thereby refining the RBAC list. For the dossier instance in Figure 4 the ACL refines the access of judges: According to the RBAC list, of the template in Figure 3, all judges are allowed to read administrative dossiers of this type. The ACL of the administrative dossier instance refines the RBAC and restricts the read access to only one judge,the judge named “Judy”. The ACL does not specify any information on users with role “Mayor” or “AdminClerk”. Thus users that have these roles are not further restrained in their access rights. In summary:

- The dossier ACL is optional. If the ACL is not specified in the dossier, then the RBAC list in a document’s template determines the access rights assigned to users on the basis of the roles they have been assigned.
- The dossier ACL is more restrictive than the template RBAC. If a user’s role is not assigned specific rights in a document template’s RBAC list, the user cannot be assigned these rights in the dossier’s ACL. If this error occurs, it is noted, and access denied.
- If the dossier ACL contains a rule for role R, then users with role R will only be granted access if he/she is mentioned in this rule. (If the dossier ACL does not contain a rule for role R, then users with role R automatically gain all rights from the template’s RBAC list.)

Note once more that a dossier ACL is a refinement of a template’s RBAC list. A dossier ACL can be made whenever appropriate.

### E. Data Repositories

Within the ACCESS prototype application, information is stored at different locations. There is a central repository for user information and templates (managed by the world administrator), and one or more central repository for the root files of individual distributed digital criminal dossiers. These criminal dossiers contain references to information stored decentrally in repositories managed by repository owners responsible for the contents.

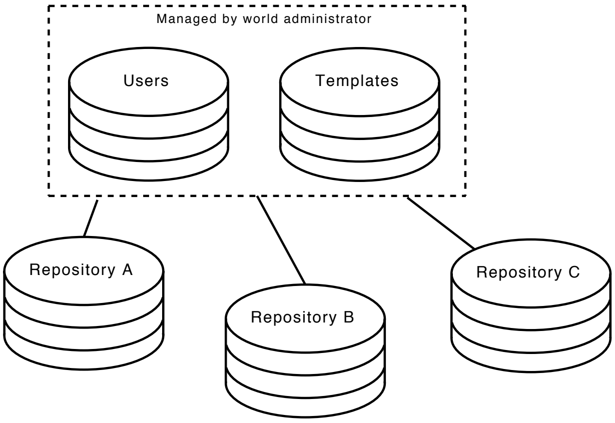

Fig. 5. ACCESS world organization

Users of the information management system at one location can include references to dossiers at other locations in their own dossiers, allowing information at the different locations to be managed by independent owners. Consequently, all updates to a dossier X at location A will automatically be part of all dossiers referring to dossier X from all other locations.

The ACCESS prototype is implemented as an AgentScape world. The world has its own lookup service, with the names of locations and their addresses. Access to services or repositories, outside the AgentScape world is only possible via a WS-Gateway [8]. This issue is not further addressed in this paper. The complete ACCESS world is illustrated in Figure 5.

## IV. Prototype Implementation

The ACCESS prototype is agent-based and runs on AgentScape. The implementation is not AgentScape specific and can, with some minor changes, be implemented in other agent platforms. The prototype supports communication between the agents and various repositories, and implements the security policies described above. The architecture of the ACCESS prototype is described below.

### A. Agents

The ACCESS architecture distinguishes a number of different types of agents, of which the first two form an intrinsic part of the system.

1) *Repository agents*
Repository agents regulate access to documents in repositories. Each repository agent is responsible for the documents in one repository. Repository agents regulate access to documents on the basis of agent credentials,

the policies specified in the RBAC lists of document templates, and the ACL of specific dossiers. Note that each repository agent has access to the templates and user information to check if a particular user agent (actually, the user behind the agent) is allowed to perform certain operations.

2) *User agents*
User agents represent the users of the information management systems. These agents interact with the repository agents to acquire access to a repository, i.e., each individual user agent sends the credentials of the user they represent, their dossier ID and the actions the agent wants to perform to the relevant repository agent. Once authorized, a user agent can then perform the action requested e.g. read, write (part of) the dossier managed by the repository agent.

3) *Functional agents*
Functional agents add new functionality to the ACCESS prototype. They can be inserted at runtime. Typical examples include: (i) *Consistency agents* are responsible for consistency checks across different repositories, between different dossiers. The consistency agent at the Public Prosecution is responsible for consistency of the information across repositories, as specified in the crime related template. (ii) *Completeness agents* are responsible for the completeness of the information in criminal dossiers. (iii) *Timeliness guarding agents* monitor time constraints (e.g. statute of limitations) with and across dossiers and take action when necessary.
Other dedicated agents can be deployed for specific tasks, guarding other specific types of constraints and regulations.

Depending on the specific requirements of a domain and the underlying infrastructure, different choices can be made with respect to the agents deployed. For example, repository agents may be responsible for flagging constraint violations (e.g. age $< 18$) or dedicated agents may be deployed for this purpose. The ACCESS prototype currently supports the first two types of agents and examples of agents of the other types.

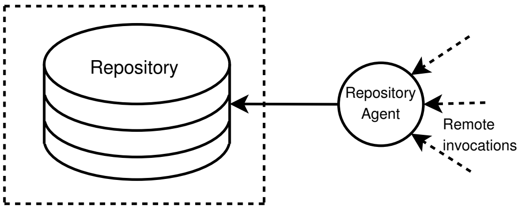

Fig. 6. Repository access by agent

AgentScape is responsible for running the agents and for the communication between agents. An agent's request (for access to a dossier at a different location, in fact, a remote method invocation) is always forwarded to the relevant repository agent, possibly at a different location, on a different host. Figure 6 shows how a repository agent provides other agents access to a repository.

One of the main features of the ACCESS prototype is that it supports incremental design. Agents can be added to the system as needed, adding new functionality, in fact, at runtime.

## B. Distribution

One of the main concepts in the ACCESS prototype is that each individual organization manages its own dossiers in its own repositories locally, within an AgentScape location. These locations are (often physically) distributed. A lookup service provides the names and addresses of the repositories within a world. This lookup service contains all the information for a single ACCESS application, i.e., for one Public Prosecution office[7].

## C. System Architecture

To access dossiers in the ACCESS world, a user of the information management system interacts with his/her user agent (an AgentScape agent). All communication with other agents is performed through this agent. The user's agent uses the user's credentials (derived from username and password), to acquire access to the different repositories.

In the current implementation, the user is presented with a graphical user interface (GUI) that communicates with the data repositories through the user agent. While the actual GUI window is running outside of AgentScape, all communication and authentication checks run inside the AgentScape platform in the ACCESS world. For an overview see Figure 7.

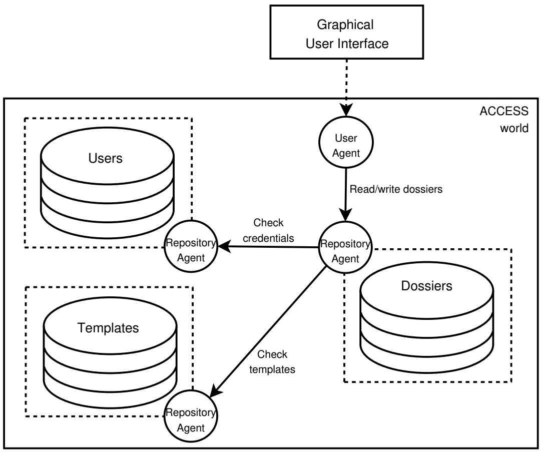

Fig. 7. Architecture of the ACCESS prototype

In theory, all users of the information management system could use their user agent to gain access to all dossiers in all repositories. In practice, however, whether they are actually allowed to view or edit the dossiers, depends on the agent's credentials, the dossier template's RBAC list and the dossier's ACL.

[7] When creating a world, the lookup service is the first thing to be started. Then at the central location, i.e., the Public Prosecution, the user and template repositories are created. These repositories are managed by the world administrator: the user that created the AgentScape world.

## V. Discussion & Conclusions

Information management in a distributed environment, such as the Public Prosecution and the organizations with which it cooperates, is an inherently difficult task. The use of multi-agent technology has clear advantages, as this paper demonstrates.

The basic system provides distributed and secure access to criminal dossiers for all users inside the ACCESS prototype. All information in the distributed digital criminal dossiers is maintained by local organizations, such as Municipalities, the Public Prosecution and others, providing local control and global access to information. In addition, information is always kept as up-to-date as possible, e.g. if a defendant moves, this is immediately reflected in the criminal dossier, once a Municipal updates this information in the (linked) administrative dossier.

Additional functionality can be added gradually in a modular fashion by means of new dedicated agents. Local organizations can add their own specialized agents and more globally useful agents can be distributed to all organizations. Again allowing maximum local control and global cooperation.

From a security point of view, as long as the computer system of the Public Prosecution has not been compromised, the digital criminal dossiers are not at risk. The computer systems of the Public Prosecution, however, need to be trusted completely. The lookup service, dossier templates and global authentication mechanism are all hosted by the Public Prosecution. If other systems are compromised the digital criminal dossiers are not necessarily effected. Automatic consistency checking, performed each time part of a dossier is altered, detects modifications. If these modifications are unwarranted and detected by both the dedicated agent and the user, once informed, the original data can be restored from a secure backup service.

The current prototype implementation in AgentScape supports several hundred dossier instances distributed over half a dozen locations. Future research will examine how well the implementation scales in a large scale distributed environment (10,000+ dossier instances on 50+ hosts).

The complete ACCESS prototype including a complete distribution of AgentScape can be found at http://www.agentscape.org.

## Acknowledgments

This research is supported by the NLnet Foundation, http://www.nlnet.nl, and is conducted as part of the Agent-based Criminal Court Electronic Support Systems (ACCESS) project, http://www.iids.org/access, initiated by the VU University Amsterdam together with the Courts of Amsterdam and Rotterdam, and financed by the Dutch Court for Jurisdiction (Dutch: Raad voor de Rechtspraak) and by the NWO TOKEN program.

# 3^rd^ International Symposium Advances in Artificial Intelligence and Applications

DEDICATED TO THE MEMORY OF PROFESSOR RYSZARD S. MICHALSKI

INTERNATIONAL Symposium on Advances in Artificial Intelligence and Application (AAIA) will be held within the framework of the International Multiconference on Computer Science and Information Technology, and will be co-located with the XXIV Fall Meeting of Polish Information Processing Society. Each year during the AAIA we plan to celebrate one outstanding Polish scientist who contributed to the field of Artificial Intelligence.

AAIA'08 will bring researchers, developers, practitioners, and users to present their latest research, results, and ideas in all areas of artificial intelligence. We hope that theory and successful applications presented at the AAIA'08 will be of interest to researchers and practitioners who want to know about both theoretical advances and latest applied developments in Artificial Intelligence. As such AAIA'08 will provide a forum for the exchange of ideas between theoreticians and practitioners to address the important issues.

Papers related to theories, methodologies, and applications in science and technology in this theme are especially solicited.Topics covering industrial issues/applications and academic research are included, but not limited to:

- Knowledge management
- Decision Support System
- Approximate Reasoning
- Fuzzy modeling and control
- Data Mining
- Web Mining
- Machine learning
- Neural Networks
- Evolutionary Computation
- Artificial Immune Systems
- Ant Systems in Applications
- Natural Language processing
- Image processing and understanding (interpretation)
- Applications in Bioinformatics
- Hybrid Intelligent Systems
- Granular Computing
- Architectures of intelligent systems
- Robotics
- Real-world applications of Intelligent Systems

*Abstract*—**The Location Management problem corresponds to the management of the network configuration with the objective of minimizing the costs involved. It can be defined using several different schemes that principally consider the location update and the paging costs. The Location Area and Reporting Cells are two common strategies used to solve the location management problem. In this paper we present a new approach that uses the Differential Evolution algorithm applied to the reporting cells planning problem, with the objective of minimizing the involved location management costs. With this work we want to define the best values to the differential evolution parameters and respective scheme, using 12 distinct test networks, as well as compare our results with the ones obtained by other authors. The final results obtained with this approach are very encouraging.**

## I. Introduction

THE use of mobile networks is growing every day and being applied to the most of newly and renovated applications for data transfer, voice and fax services among many others mobile services. Because of this, communication networks [1] must support a big number of users and their respective applications maintaining a good response without loose quality and availability. With the goal that mobile networks keep this quality it is necessary to consider the mobility management when making design of the network infrastructure.

Mobility management is a very important point because it includes the process of hand off management that enables the mobile network to locate roaming mobile terminals, and also the process of location management that enables the mobile network to find the current location of a mobile terminal in order to make or receive calls. We are mainly concerned with location management because it involves the user movements and tracing, with the objective of minimizing the involved costs.

The location management is partitioned in two main operations: location update that corresponds to the notification of current location, performed by mobile terminals when they change their location in the mobile network, and location paging (inquiry) that represents the operation of determining the location of the mobile user terminal, performed by the network when it tries to direct an incoming call to the user.

There exist several strategies of location management, which are divided in two main groups: static and dynamic schemes [2]. The static schemes consider the same behavior of the network for all users, while the dynamic schemes consider different network topologies for different users based on the individual user's call and mobility patterns. A survey of different dynamic techniques based on users' behavior such as timer-based, distance-based, movement-based (among others) may be seen in [2]. As static techniques, the most common ones are always-update, never-update, and location area schemes [2], [3], among others. The reporting cells (RC) represents another static location management strategy that also is very used.

In this paper we present a new approach to solve the reporting cells problem and minimize the involved costs, using the Differential Evolution (DE) based algorithm. Section II presents an overview of the reporting cells planning and the respective involved costs. In section III, the DE based algorithm is described including its parameters and respective possible schemes. In section IV are explained the details of algorithm implementation and network preparation. Section V includes the experimental results and presents the results produced by the four distinct experiments. In section VI analysis and comparisons with other authors' results and other artificial life techniques are shown. Finally section VII includes conclusions and future work.

## II. Reporting Cells Planning Problem

In this section we will explain the reporting cells scheme and how it is applied in the calculus of the location management cost.

### A. Reporting Cells Scheme

The reporting cells planning scheme was proposed by Bar and Kessler in [4] with the objective of minimizing the cost of tracking mobile users.

This strategy is characterized by defining a subset of cells as reporting cells and the others as non-reporting cells (nRC), as it is possible to see in Fig. 1a (RC represented with value 1 and in blue color and nRC represented with value 0 and in white color). The mobility terminals only perform a

a) b)

Fig 1. a) Reporting Cells planning b) Vicinity values

new location update when they change their location and move to one reporting cell. If an incoming call must to be routed to the mobile user, the search can be restricted to his last reporting cell known and their respective neighbors non-reporting cells.

It is necessary to calculate for each cell the vicinity factor, which represents the maximum number of cells that the user must page when an incoming call occurs.

The vicinity value of a reporting cell corresponds to the number of non-reporting cells that are reachable from this reporting cell, without crossing other reporting cells, and adding the reporting cell itself. For example, considering the calculus of vicinity factor for the cell number 5 (RC) in Fig. 1a, we must count the number of neighbors that are nRCs (cells 0, 1, 4, 9, 12 and 13) and also include the RC itself, which makes a total of 7 neighbors. This total number of neighbors will correspond to the vicinity factor of this RC.

If we are calculating the vicinity value of a non-reporting cell it is necessary to consider the maximum vicinity value among the reporting cells from where this one can be reached. This means that if a non-reporting cell belongs to the neighborhood of more than one reporting cell, the calculus has to be done for all the reporting cells and then, the maximum number is set as the vicinity factor of the respective non-reporting cell. If we consider the cell number 9 (nRC), in Fig. 1a, we can observe that it belongs to the neighborhood of at least two RCs (more precisely four cells: number 5, 8, 10 and 14). Because of that, the calculus of vicinity factor must be done for all those RCs and after this, the maximum number will be considered as the vicinity factor for this nRC. The vicinity factor for cells 5, 8, 10 and 14 is respectively 7, 7, 6 and 6, so the maximum value that represents the vicinity factor of cell number 9 is 7.

Considering the reporting cells planning of the Fig. 1a and calculating all the vicinity factors, the result will be the one presented on Fig. 1b.

### *B. Location Management Cost*

The location management (LM) cost is principally divided in two fundamental operations of location update and location paging. The location update (LU) cost corresponds to the cost involved with the location updates performed by mobile terminals in the network, when they change their location and must register the new one. The location paging (P) cost is caused by the network when it tries to locate a user's mobile terminal, during the location inquiry, and normally the number of paging transactions is directly related to the number of incoming calls. LM involves several other parameters and components that are considered to be equal for all strategies and does not make influence when comparing the results obtained by different strategies. Because of that these cost are not considered for the total cost.

From earlier studies and experiments [3], [5] we have seen that the generic formula to obtain the LM cost is:

$$Cost=\beta * N_{LU}+N_{P} \qquad (1)$$

The total cost of location updates is given by $N_{LU}$, the total cost of paging operations corresponds to $N_P$ and $\beta$ is a ratio constant used in a location update relatively to a paging transaction in the network. To each location update is imputed a much higher cost than to each paging operation, because of the complex process that must be executed for each location update performed, and also because most of the time a mobile user moves without making any call [6]. Due to all of that, the cost of a location update is normally considered to be 10 times greater than the cost of paging, that is, $\beta$=10 [5].

In the reporting cells scheme the location updates only are performed when a mobile user enters in a reporting cell and the vicinity factor of each cell must be considered. Because of that the generic formula given by (1) must be readjusted and it is formulated as [7]:

$$Cost=\beta * \sum_{i\in s} N_{LU}(i)+\sum_{i=0}^{N} N_{P}(i) * V(i) \qquad (2)$$

Here we can see that $N_{LU}(i)$ corresponds to the number of location updates associated to the reporting cell *i*, *S* indicates the subset of cells defined as reporting cells, $N_P(i)$ is the number of incoming calls attributed for cell *i*, *N* is the total number of cells that compound the mobile network configuration and *V(i)* is the vicinity factor attributed for cell *i*.

We will use this formula with the objective of minimize the LM cost, using the reporting cells strategy.

## III. Differential Evolution

The Differential Evolution (DE) is a population-based algorithm, created by Ken Price and Rainer Storn [8], whose main objective is functions optimization. This algorithm is one strategy based on evolutionary algorithms that has some specific characteristics. It has a key strategy to generate new individuals by calculating vector differences between other randomly-selected individuals of the population.

### *A. DE Parameters*

DE algorithm uses four important parameters: population size *NI*, mutation *F*, crossover *Cr* and selection operators as well as different schemes presented in the following sub-section. For further information about the four parameters, refer to [8].

### *B. DE Schemes*

DE can be implemented using 10 different schemes suggested by Price and Storn [8]. These schemes, exposed in Table I, are classified based on notation *DE/x/y/z*, where *x* specifies the vector to be mutated, *y* correspond to the number of difference vectors used in mutation of *x* (normally 1 or 2) and *z* represents the crossover scheme. The vector *x* may be chosen randomly ('rand') or as the best of current popula-

TABLE I. DE SCHEMES

| Scheme | Mutant vector generation |
|---|---|
| DE/best/1/exp | $x_i = x_{best} + F\,(x_{r1} - x_{r2})$ |
| DE/rand/1/exp | $x_i = x_{r3} + F(x_{r1} - x_{r2})$ |
| DE/randtobest/1/exp | $x_i = x_{r3} + F(x_{best} - x_{r3}) + F(x_{r1} - x_{r2})$ |
| DE/best/2/exp | $x_i = x_{best} + F\,(x_{r1} + x_{r2} - x_{r3} - x_{r4})$ |
| DE/rand/2/exp | $x_i = x_{r5} + F\,(x_{r1} + x_{r2} - x_{r3} - x_{r4})$ |
| DE/best/1/bin | $x_i = x_{best} + F\,(x_{r1} - x_{r2})$ |
| DE/rand/1/bin | $x_i = x_{r3} + F(x_{r1} - x_{r2})$ |
| DE/randtobest/1/bin | $x_i = x_{r3} + F(x_{best} - x_{r3}) + F(x_{r1} - x_{r2})$ |
| DE/best/2/bin | $x_i = x_{best} + F\,(x_{r1} + x_{r2} - x_{r3} - x_{r4})$ |
| DE/rand/2/bin | $x_i = x_{r5} + F\,(x_{r1} + x_{r2} - x_{r3} - x_{r4})$ |

tion ('best') and *z* may be binomial ('bin') or exponential ('exp') depending on the type of crossover used.

### C. DE Algorithm

The pseudo-code of the DE algorithm, using the *DE/best/1/exp* is presented in Fig. 2. It starts by defining and evaluating the initial population through calculating the fitness value for each individual. After that, until the termination condition is not reached, the necessary individuals are picked and a new one is produced according to the selected DE scheme and respective rules. This new individual is evaluated and compared with the old one. Just the one with the best fitness value will be chosen and pass for population of the next generation.

## IV. IMPLEMENTATION DETAILS

In this section we explain the fitness function implemented to evaluate the solutions obtained, present the test networks used and expose the original definition of parameters.

```
Initialize the population
Evaluate the initial population
While (termination condition not satisfied) {
        Randomly select ind. $xr1 \neq xbest$
        Randomly select ind. $xr2 \neq xr1$ and $\neq xbest$
        Generate trial ind.: $xtrial = xbest + F(xr1 - xr2)$
        Use Cr to define the amount of genes changed
            in trial individual
        Evaluate the trial individual
        Deterministic selection
}
```

Fig 2. DE Algorithm Pseudo Code with Scheme *DE/best/1/exp*

### A. Fitness Function

In this study the fitness function is used for measuring the total location management cost of each potential solution, which is defined according to the equation (2). This means that for each potential solution generated, it is calculated the fitness value, which corresponds to the network configuration by means of reporting cells and non-reporting cells.

### B. Test Networks

Other authors have studied the reporting cells strategy, but most of them do not present the test networks used, so it is not possible to compare our approach with them. However, in [7] it is presented a set of twelve test networks, representing four groups defined by size, that have been generated and are available in [9] as benchmark. In this work we used these twelve test networks with the objective of compare final results. In Table II it is shown, as an example, the test network 1 that represents a 4x4 cells configuration. The first column indicates the cell identification, the second column corresponds to the number of location updates *NLU* and the third represents the number of incoming calls *NP*.

### C. Parameters Definition

The initial definition of parameters is an important step because it represents the basis for the algorithm evolution. First it is defined the initial population of candidate solutions that corresponds to the individuals.

Each individual is compound by *N* genes, where the *N* value is the number of cells in the network and each gene represents the information about the cell type, which can be a reporting cell or a non-reporting cell.

To define the initial population we have set, with a probability of fifty percent, the type of each cell as RC or nRC.

Initially it is also necessary to set the DE algorithm parameters and that has been done with a number of individuals *NI* equal to 10, the mutation factor *F* set to 0.5 and the crossover value *Cr* defined as 0.1. For the DE scheme it has been selected the *DE/rand/1/bin*. The number of generations represents the terminal condition when the algorithm is executed and it is set to 1000.

Throughout the different experiments, the parameters values have been adjusted with the specific objective of obtaining the best results for each test network.

## V. EXPERIMENTAL RESULTS

In this section we explain the four distinct experiments applied to each test network with the objective of study in more detail the best configuration of DE. For each experiment, and for all combination of parameters, 30 independent runs have been performed in order to assure its statistical relevance. In each experiment the final results, of the best fitness values obtained (lower cost value), are presented and explained the decisions taken.

### *A. Experiment 1 – Determining NI*

The number of individuals that will compound the initial population must be the first experiment because it is the basis of the algorithm implementation. In order to accomplish that, we have fixed, as referred in *IV.C. Parameters Definition,* the values of crossover *Cr*=0.1, the mutation *F*=0.5, DE scheme as *DE/rand/1/bin* and the stop criterion as 1000 generations, considering our experience from earlier experiments that we have performed [3].

With this experiment we have concluded that, increasing of *NI* value, it is possible to observe a positive evolution of the results (see fitness results in Table III ), but just until the value of *NI* =175, because after that we start observing worse results and stop increase in *NI* =225. Considering this and the average evolution we concluded that *NI* =175 would be the elected value for the second experiment.

### *B. Experiment 2 – Determining Cr*

The second experiment has the objective of selecting the *Cr* value that obtains the best results. To proceed with this experiment we fixed the value of *NI* to 175 (from experiment 1), and maintained the other parameters as defined in the beginning of experiment 1.

This experiment has been executed using different values for *Cr*: 0.1, 0.25, 0.50, 0.75 and 0.90. Analyzing the results obtained, we could conclude that best values were obtained with *Cr*=0.1 and *Cr*=0.25. Because of that, with the objective of taking more complete conclusions, we decided to execute the algorithm with values 0.15 and 0.20. Finally, as it is possible to see in , we could conclude that *Cr*=0.15 is the one that performs better.

TABLE IV. EXPERIMENT 2: DETERMINING THE BEST CR

| Test Network | Cr – Fitness Evaluation | | | | | | |
|---|---|---|---|---|---|---|---|
| N. (Dim) | 0.1 | 0.15 | 0.20 | 0,25 | 0.50 | 0.75 | 0.90 |

### C. *Experiment 3 – Determining F*

The determination of the best value for mutation, *F*, is the purpose of the third experiment. So, in order to perform this experiment it was fixed the value of *NI* to 175 (from experiment 1), the value of *Cr* to 0.15 (from experiment 2) and the others maintained as in the two earlier experiments.

After finishing these executions and examining the results (see Table V) we conclude that *F*=0.5 is the one that permits to obtain the best results.

### D. *Experiment 4 – Determining DE Scheme*

Finally, with this fourth experiment we pretend to select the most adequate DE scheme, the one that permits to obtain the best results (lower fitness value). For that, we fixed the best values for each parameter (defined in the three earlier experiments) as: *NI*=175, *Cr*=0.15 and *F*=0.5, and executed the algorithm applying the ten DE schemes presented in section *III.B*.

Once finished all the executions, and observing the respective results shown in Table VI, it was possible to conclude that the scheme *DE/rand/1/bin* is the one with a better performance, because it is the one that obtains better fitness values for all the test networks. With these results we may say that the binomial schemes perform better than the exponential ones and that it is also better to choose randomly the individuals used to create the trial individual.

Finishing these four experiments we had determined the best DE configuration, applied to the reporting cells plan ning problem, setting the parameters as *NI* =175, *Cr* =0.15, *F* =0.5 and *DE/rand/1/bin* as the most adequate DE scheme.

## VI. ANALYSIS AND COMPARISONS

In this section we pretend to analyze the results obtained, compare them with those shown in [7] and present the configuration for best solutions.

Finally we apply the best DE configuration to the test networks presented in [10] and compare results produced with this DE configuration, with the ones of other artificial life techniques.

### A. *Analysis and Comparison of Results*

Analyzing the experimental results we could conclude that with this approach it is possible to obtain the same minimum fitness values (considered optimal in [7]), as the ones obtained in [7] with a Hopfield Neural Network with Ball Dropping (HNN+BD) and a Geometric Particle Swarm Optimization (GPSO) for ten of the twelve test networks used.

For the other two test networks the results are very similar because: for the test-network-10 our fitness value is 386,951 and in [7] the one obtained by the HNN+BD is 386,351; and for the test-network-12 our fitness value is 371,829 and in [7] the value obtained by HNN+BD and GPSO is 370,868. Relatively to the average values it is possible to say that they are very similar.

In fig. 3 the configuration for each test-network solution is shown and it is possible to observe that most of them split each one in subnetworks.

### B. *Comparison with other Artificial Life Techniques*

After obtaining the best DE configuration applied to the reporting cells planning problem we decide to apply it in

TABLE VI. EXPERIMENT 4: DETERMINING THE DE SCHEME

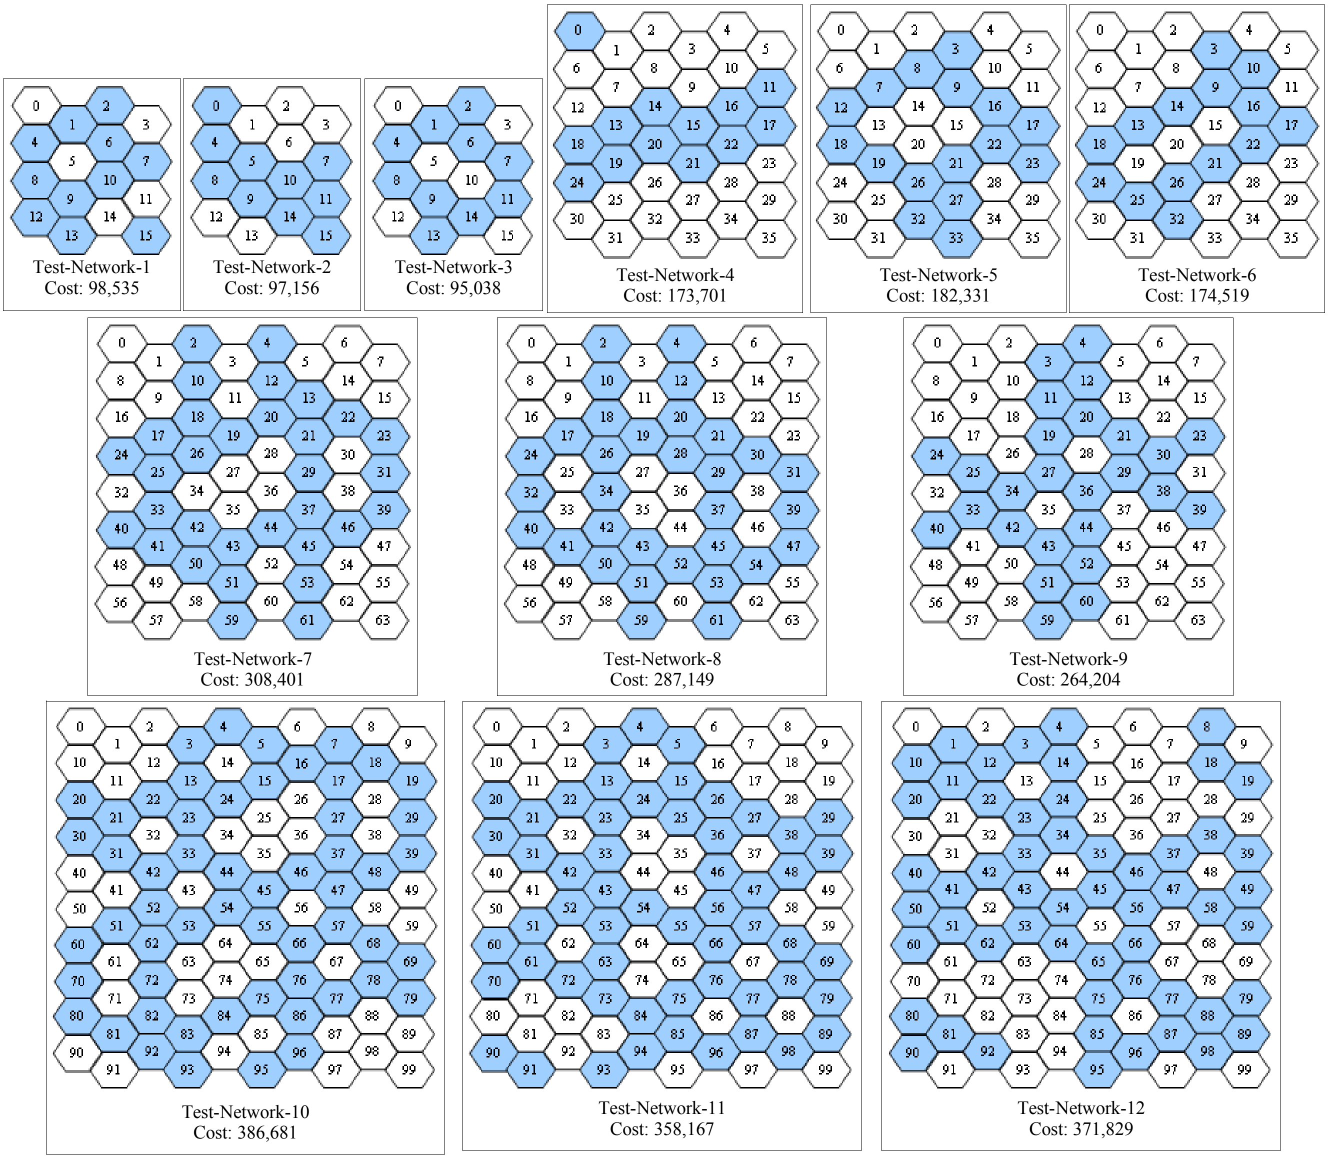

*Fig 3. Test-Network Solution with Reporting Cells Configuration*

other test networks, and analyze the performance with the objective of comparing with other artificial life techniques. We decided to use 3 test networks presented in [10] (also referred in [7]) in order to compare our results with those produced by the application of Genetic Algorithms (GA), Tabu Search (TS) and Ant Colony algorithm (AC).

Making the additional experiments we conclude that our approach performs well. Using the Test-Network-1 (4×4 instance provided in [10]) we obtain the same fitness value as the GA, TS and AC, that is, 92,883 with a total of 10 reporting cells.

Our approach generates a better solution when solving the Test-Network-2 (6×6 instance provided in [10]), comparing with GA and AC. The fitness value obtained by the GA is 229,556 with a total of 26 reporting cells in the network [7], [10], while, the cost obtained by DE in this work is 211,278 with 24 reporting cells. TS presents the same cost 211,278 and the fitness value obtained by AC is 211,291.

Finally, for the Test-Network-3 (8×8 instance in [10]) DE again surpasses the results obtained in [10] by the GA, TS and AC. Concretely, the fitness value obtained by the GA and TS is 436,283, the one obtained by AC is 436,886 while, the cost obtained by DE in this work is 436,269 with a total of 39 reporting cells.

## VII. Conclusion

In this paper we have discussed the use of differential evolution algorithm (DE) applied to the reporting cells planning problem. To the best of our knowledge, this is the first time that DE is employed for this task (this is another contribution of this paper).

We have studied in detail the best configuration of DE including parameters and scheme. After more than 10,000 runs, they are *NI*=175, *Cr*=0.15, *F*=0.5 and *DE/ran/1/bin* as the best DE scheme.

We have shown that our approach produces interesting results because when compared with ones of other authors, that use HNN+BD and GSPO, they are equal or very similar.

Comparing the performance of DE algorithm with other artificial life techniques as genetic algorithm (GA), tabu search (TS), and ant colony algorithm (AC), we may say that it performs well because improves the results obtained by those ones.

As future work we pretend applying other evolutionary algorithms to the RC problem comparing their results with the ones accomplished by the DE algorithm. We also have the intention of testing our approach with test networks generated by using real data.

## Acknowledgment

This work was developed in part thanks to the project OPLINK (TIN2005-08818-C04-03). Thanks also to the Polytechnic Institute of Leiria, for the economic support offered to Sónia Almeida-Luz to make this research.

# Towards Word Sense Disambiguation of Polish

Dominik Baś, Bartosz Broda, Maciej Piasecki
Institute of Applied Informatics, Wrocław University of Technology, Poland
Email: {bartosz.broda, maciej.piasecki}@pwr.wroc.pl

***Abstract*—We compare three different methods of Word Sense Disambiguation applied to the disambiguation of a selected set of 13 Polish words. The selected words express different problems for sense disambiguation. As it is hard to find works for Polish in this area, our goal was to analyse applicability and limitations of known methods in relation to Polish and Polish language resources and tools. The obtained results are very positive, as using limited resources, we achieved the accuracy of sense disambiguation greatly exceeding the baseline of the most frequent sense. For the needs of experiments a small corpus of representative examples was manually collected and annotated with senses drawn from plWordNet. Different representations of context of word occurrences were also experimentally tested. Examples of limitations and advantages of the applied methods are discussed.**

## I. Introduction

POLYSEMY of word forms seems to be an intrinsic feature of the natural language and can be observed in any natural language including Polish. It is a stumbling block for semantic text processing and complicates access to meanings in a semantic lexicon. One needs an algorithm choosing the most appropriate meaning of the given word form in relation to the given context. This need was noticed as early as in 50s, and continuous works on *Word Sense Disambiguation* (henceforth abbreviated to WSD) have been performed since 70s, e.g. the *Word Expert* system of Wilks [1].

Research on WSD has been conducted for English but also for many other languages. Despite its importance, it is very hard to find published works, working systems or practical results for Polish. Development of the corpus annotated by word senses and next development of a WSD algorithm is planned as a part of the project on the construction of the National Corpus of Polish [2].

Our main objective is to developed a robust WSD method for Polish which will be based on the Polish wordnet called *plWordNet* [3], as the source of lexical meanings. However, as such a far going enterprise requires a lot of time and workload, we decided to start with a much more limited experiment. The goal of the work presented here was to develop a WSD algorithm for selected Polish words going in the line of *lexical sample* task of Senseval Evaluation Exercises [4]. Also, lexical sample task is one approach to minimise the utilised resources, especially manual work.

As we wanted to achieve a relatively high accuracy, from the very beginning we assumed a supervised learning model and a construction of a small training corpus, in which selected words were manually annotated with plWordNet synsets. In the case of the supervised learning algorithms one can control which senses are learned and identified in text. Nevertheless, research on unsupervised sense discovery have been also performed in parallel, e.g. [5], [6].

## II. Construction of the Training Corpus

As none of the existing Polish corpora has been semantically annotated, we decided to select subcorpus of the IPI PAN Corpus (IPIC) [7] and extend it with annotation by word senses for occurrences of chosen words. We selected 13 different base word forms corresponding to several polysemous lexemes and homonyms. Choosing the subset, we tried to represent the variety of different problems for WSD. We selected polysemous lexemes possessing from 2 to 7 senses, where some of the senses have homonymous character, i.e. those senses represent separate homonyms of the same morphological base form. We included homonyms, as they express very different meanings and it should be easy to differentiate between their senses. The important factor in selection was also the coverage of plWordNet, which still does not describe some rare senses. Finally, we also tried to compose the set of words as consisting of words that are intuitively less or more difficult for possible WSD algorithms. The selected set includes:

1) ***agent*** (4 senses, English translation: *agent*),
2) ***automat*** (3: *automaton*, *automatic machine* and *machine-gun*),
3) **dziób** (4: *beak*, *bow*, *mouth* (semantically marked) and *face* (semantically marked)),
4) ***język*** (2: *language* or *tongue*),
5) ***klasa*** (6: *class*, *classroom*, *form*, *grade*),
6) ***linia*** (6: *line*, *route*, *figure*, *contour*),
7) ***pole*** (3: *field*),
8) ***policja*** (2: *police*, *police station*),
9) ***powód*** (2: *reason* and *protection* (person)),
10) ***sztuka*** (6: *art*, *play*, *craft*, *item*),
11) ***zamek*** (4: *castle*, *door lock*, *zipper* and *breechblock*),
12) ***zbiór*** (7: *set*, *collection*, *harvest* and *file*),
13) ***zespół*** (5: *team*, *gruop*, *band*, *company*, *complex* and *unit*).

Henceforth the selected base word forms will be called *training words*.

For sense inventory we used plWordNet - a resource under development, but it has already reached the size of 14 677 lexical units and is publicly available for research [3]. plWordNet follows the general scheme of the Princeton WordNet but it was constructed from scratch in bottom-up way. The starting point was the list of about 10 000 most frequent word base forms from IPIC. As a result plWordNet includes the

978-83-60810-14-9/08/$25.00 © 2008 IEEE

most frequent and most general Polish words and multiword lexical units (some of them were added by lexicographers during construction). In a way typical for wordnets, plWordNet introduces a fine grained distinction of senses.

IPIC is the only available large, morphosyntactically annotated corpus of Polish and consists of about 254 millions of tokens. We started construction of the semantically annotated subcorpus with finding all IPIC documents including at least one of the training words. Next, the documents had to be manually inspected in order to balance the number of examples for different training words, and their occurrences representing different senses. As the frequencies of senses vary in large extent, it was necessary to analyse hundreds of training word occurrences in order to find an example of some rare sense. For some sense it was difficult to find enough examples, e.g. the training word *dziób* occurs 536 times in IPIC, but after the manual inspection of all cases we found that the emotionally marked sense of *dziób* meaning *mouth* can be spotted only 9 times. Our experiments confirm phenomenon observed for English [8]—even for general and frequent words some senses are underrepresented even in a large corpora.

While selecting documents for the training subcorpus we took into account their genres and origins. The subcorpus consists of literature works, press articles and news, scientific works and legal texts. We paid special attention to avoiding situations in which all examples for some sense would be taken from the same source text. It could negatively bias the disambiguation process, as some characteristic or even idiosyncratic properties of the given text (e.g. originating from the style of the given author) could be learned by the disambiguator.

Annotation of the subcorpus was done with the help of the modified version of the annotation editor called *Manufakturzysta* [9] constructed especially for the IPIC XML format [7] based on the XCES general format. Occurrences of training words were annotated with synset identifiers from plWordNet. Annotation was performed mainly by one of the co-authors. However, in many difficult cases in which the appropriate assignment of a sense to word occurrence was unclear, the other two co-authors were consulted. The final decision often was difficult as plWordNet is still under construction and there was always possibility that some sense of the given training word is not described in plWordNet yet.

Collocations, like *pole chwały* (*field of glory*) or *ugryźć się w język* (*to bite one's tongue*), appeared to be a problem. They should be treated as the multiword lexemes, but mostly there are not present in plWordNet and, moreover, the elimination of such occurrences of training words would decrease the limited number of examples for some sense. That is why we decided to annotate training words in collocation occurrences with their literal meaning in some cases. In the example above, *język* was annotated with the sense *tongue* (i.e. body part).

We had started with annotating all training word occurrences in the documents of the subcorpus, but shortly we realised that our time limitations are too tight and we would get a very imbalanced numbers of training examples for subsequent senses, as the sense frequencies vary a lot. So, in the second phase of manual annotation we tried to identify only examples including less frequent senses[1]. The whole subcorpus includes about 1 500 semantically annotated training word occurrences, however, the sense frequencies are not still balanced yet. For some senses we could find only few examples in the whole IPIC. The detailed numbers concerning annotated occurrences of training words and their senses are presented in Table I.

TABLE I
ANNOTATED TRAINING WORDS AND SENSES.

| Word | No. of senses | Annotated senses | No. of examples |
|---|---|---|---|
| *agent* | 4 | 69/22/2/123 | 216 |
| *automat* | 3 | 28/31/46 | 105 |
| *dziób* | 4 | 31/17/24/9 | 81 |
| *język* | 2 | 22/54 | 76 |
| *klasa* | 6 | 9/51/6/13/29/7 | 115 |
| *linia* | 6 | 15/4/35/12/4/12 | 82 |
| *pole* | 3 | 69/25/2 | 96 |
| *policja* | 2 | 23/41 | 64 |
| *powód* | 2 | 137/122 | 259 |
| *sztuka* | 6 | 5/12/37/19/12/11 | 96 |
| *zamek* | 4 | 19/36/19/18 | 92 |
| *zbiór* | 7 | 16/16/1/15/3/32/3 | 86 |
| *zespół* | 5 | 60/1/3/28/29 | 121 |

## III. APPLIED WSD ALGORITHMS

We based our current work on the previous experience from the creation of WSD systems, which were constructed mainly for English and were described in literature, e.g. [8]. We wanted to investigate behaviour of several known approaches adapted to the Polish language and Polish language tools and resources. We assumed the following scheme of processing:

1) Morphosyntactic processing of the training corpus (there is no shallow parser available for Polish).
2) Extraction of feature vectors describing occurrences of training words and storing them in the ARFF format (*Attribute-Relation File Format*).
3) Training and testing classifiers in the *Weka* system [11].

The key issue is the choice of types of features that will be used in training vectors. We surveyed types of features most frequently used in WSD systems, e.g. [8]. Lacking more advanced language tools, we assumed as the basic paradigm the *bag of words* model—Yarowsky and Florian [12] showed that omission of bag of words resulted in the decreased accuracy. Finally we have chosen five types of features:

1) *Parts of Speech* in the ±2 text window around the training word occurrence (PoS)—information concerning parts of speech, or more precisely more fine grained division into 32 *grammatical classes*, comes from the TaKIPI morphosyntactic tagger [13] applied during preprocessing of the corpus. A training vector includes numerical identifiers of grammatical classes.

[1] A similar strategy was applied during the construction of the Basque semantically annotated corpus built for the Senseval-3 competition [10]. In this corpus, the minimal number of training examples per word $w$ was set to $N_w = 75 + 15 \times |senses(w)|$, where $senses(w)$ is the set of senses of $w$.

2) *Collocation words* in the $\pm 2$ text window (Coll)—word base forms of all grammatical classes (except punctuation signs) which occurred in the close context of the $\pm 2$ text window. The lematisation was done by TaKIPI. No statistical filter was applied to the found occurrences. Found word base forms are represented by identifiers in the training vector.
3) The first noun to the left and to the right of the training word occurrence (Nouns)—nouns are important meaning bearers in the text. Information concerning nouns with which the training words is associated in text can be an important factor in determining the sense of the training word. Nouns are analysed on the level of their base forms. The appropriate elements of the training vector store the numerical identifiers.
4) *Wider context* of the training word (henceforth WCont)—described by base forms of words occurring in a larger text window. In a way typical for the bag of words model, the context is represented by the boolean vector, where 1 means that the corresponding base forms occurred in the given context. For the selection of base forms for the representation of contexts, we tested three methods:
   - selection by frequency—only most frequent base forms,
   - method of Ng and Lee [14],
   - selection by the Quantity of Information [15].

Concerning the description of the larger context, the selection of the most frequent base forms (4) is the simplest one. All base forms occurring in the context of training words more than the established threshold $k$ are included in the set describing the context—the bag of words. The value of $k$ is set experimentally.

According to the Ng and Lee method (4) we try to estimate the probability $p(s|b)$ of describing the given sense $s$ of the training word $w$ by the given base form $b$ occurring in the context of $w$ [14]:

$$p(s|b) = \frac{f(s,w,b)}{f(w,b)} \times \frac{1}{f(b)} \tag{1}$$

where:

- $f(s,w,b)$ is the frequency of $b$ in those contexts in which $w$ occurs in the sense $s$,
- $f(w,b)$—the frequency of $b$ in the contexts of $w$ in any sense,
- $f(b)$—the total frequency of $b$ in the whole corpus.

In the measure of the Quantity of Information we attempt calculating how characteristic is the given base form $b$ for the sense $s$ of the training word $w$, i.e. how much information it delivers [15]:

$$Q(b,w) = -log\frac{1+N(b,w)}{1+|senses(w)|} \tag{2}$$

where $N(b,w)$ is the number of senses of $w$, such that they co-occur with $b$ in the context.

We can also filter base forms used in the context description by a stop list or by the morphosyntactic properties of their occurrences, e.g. filtering out base forms of some grammatical classes.

## IV. Experiments

For the experiments we concentrated our attention on Machine Learning algorithms which are implemented in Weka 3.4.14 [11] and which can be applied to small sets of training examples. Finally, we selected three algorithms representing different types of classifier used for WSD:

- *Naïve Bayes* (henceforth NB)— representing probabilistic methods in WSD,
- *k Nearest Neighbours* (kNN)—methods based on similarity to examples,
- *Decision Tables* (DT)—methods based on discriminating rules,

All experiments were done in *Weka* environment on the basis of previously prepared vectors describing training examples. Evaluation was performed in *Weka Experiment Environment*. Because of the small size of dataset, we used the scheme of *leave-one-out cross-validation* for all tests.

### A. Thresholds selection

In the first set of experiments we tried to discover sub-optimal values for the subsequent thresholds used in the methods of base form selection for the wider context. In the case of the Ng and Lee method and Quantity of Information we were looking for the values of both factors that result in higher WSD accuracy. For selection by frequency we were looking for the minimal frequency threshold above which the base forms have a positive influence on the accuracy.

In the case of all selection methods the higher the threshold is the smaller is the number of base forms used for the description of contexts. We remove less useful descriptors—base forms—and decrease the level of noise in data by increasing the thresholds values. As different Machine Learning algorithm (and constructed classifiers) express different possibilities in coping with noise in training data, we had to define separate sets of threshold value for the subsequent classifiers.

The used selection methods can be divided into two groups. The Ng and Lee method takes into account frequencies of base forms collected for the whole corpus. On this basis it eliminates base forms that do not have influence on the WSD process, like conjunctions and prepositions. This method has problems only with elimination of numerals, as lexemes not contributing to WSD.

The two other methods, i.e. Quantity of Information and selection by frequency do not include a similar mechanism. Thus, we had to extend them with a manually created filtering rules and a stop-list to eliminate such informationally vague base forms[2].

[2] Conjunctions, prepositions and numerals comprise about 18% of tokens in IPIC [16].

TABLE II
THRESHOLD VALUES ESTABLISHED EXPERIMENTALLY FOR THE CONTEXT DESCRIPTION SELECTION.

| | Method of selection | | |
|---|---|---|---|
| Classifier | Frequency | Ng and Lee | QI |
| NB | >2 | >0.001 | >0.5 |
| kNN | >6 | >0.001 | >0.7 |
| DT | >4 | >0.001 | >0.2 |

TABLE III
COMPARISON OF AVERAGE ACCURACY ACHIEVED USING DIFFERENT CLASSIFIERS AND SELECTION METHODS ON THE REDUCED SET OF TRAINING WORDS.

| | Classifier | | |
|---|---|---|---|
| Method | NB[%] | kNN [%] | DT[%] |
| Frequency | 75.92 | 57.74 | 67.92 |
| Ng and Lee | 79.02 | 74.33 | 66.54 |
| QI | 78.54 | 69.10 | 69.50 |

The first experiments were performed on the data collected for four selected training words: *agent*, *sztuka*, *dziób* and *zamek*. The reason for this limitation was the high computation cost of the experiments. As the result we took the average from all experiments. During the experiments the training vectors included only the wider context features (WCont), as only these features are influenced by the selection methods.

The final sub-optimal values for thresholds were identified on the basis of analysis of values obtained for all base forms occurring in the contexts of the four training words. The obtained threshold values are presented in Table II—they were consequently applied in all following experiments.

In the case of the selection by frequency, results are dependent on the size of the text window and the number of training examples. The size of the window was set to ±20 tokens. After changing the size we would have to define the threshold value again.

The highest threshold values were obtained for the KNN algorithm for all three methods. Table II shows that it is more sensitive to noise in data in comparison to the other two methods, which was expected. However, limiting the context description to the most informative base forms can increase its accuracy to a large extent.

The results obtained for the Ng and Lee method are similar to the results achieved for English [14].

Having the sub-optimal threshold values extracted, we compared all three methods of selection on the data set of the four training words. The results of the comparison presented in relation to all three classifier types are given in Table III.

In the case of both: Naïve Bayes and kNN the best results were achieved while using the Ng and Lee method. Contrary, Decision Table produced the best result in combination with the selection based on Quantity of Information.

### B. Feature selection

In the next set of experiments, we wanted to identify a sub-optimal set of features for the description of training data. We performed these test on the full set of 13 training words. As all training words are nouns we could omit feature expressing grammatical class of the word being disambiguated (in the centre of the context) without loss of information.

TABLE IV
AVERAGE ACCURACY FOR ALL TRAINING WORDS IN RELATION DIFFERENT SETS OF TRAINING FEATURES.

| | Classifier | | |
|---|---|---|---|
| Features used | NB[%] | kNN [%] | DT [%] |
| WCont | 89.80 | 72.94 | 75.61 |
| WCont + PoS (±2) | 88.79 | 70.08 | 77.88 |
| WCont + Coll(±2) | 88.88 | 71.24 | 73.52 |
| WCont + Nouns | 77.83 | 62.51 | 66.25 |

As the starting point we assumed the wider context set of features (one feature for each base form included to the context description). Next we extended WCont with combination of the other types of features. The results being average from all 13 training words are presented in Table IV.

On the basis of the average results for all words (Table IV) we can observe that only Decision Table classifiers produce higher result after adding PoS (±2) features to the training vectors. The detailed analysis of the results obtained for subsequent words showed that the influence of PoS (±2) features varies significantly in relation to particular words. For example, in the case of the training word *policja* and the kNN classifier after adding the PoS (±2) features its accuracy increased by 7.8%, while in contrast, for the same word and Decision Tables, the combination of the WCont features with the Coll(±2) features increased the accuracy by 34.4%. Such differences can be explained on the basis of the inspection of training examples. There are two senses distinguished for the word *policja* in the corpus:

- (English *police*) an institution protecting order and safety,
- (English *police station*) a place—a police station.

In the case of the second sense, the word *policja* is very often a part of the adverbial place describing some placement or destination, e.g. *pojechał na policję* (*went to the police station*). This kind of association is barely visible according to WCont features (bag of words), but after adding collocation words or grammatical classes from the nearest context as features becomes much more prominent.

We noticed that Naïve Bayes and kNN classifiers react in a similar way to the extension of training vectors by additional features. In contrast, the Decision Table classifier returns identical results for many words regardless of changes in the training features set. It can be caused by the low values achieved by this features and the lack of their influence on the final decisions.

### C. Analysis of the results

The best results achieved for subsequent words using different classifiers are presented in Table V. The accuracy was calculated in all cases according to the one-leave cross-validation, and only the parameters of classifiers varied.

Base line has been calculated as the ratio of the number of examples for the dominating sense of the given word to the total number of examples for the given word, i.e. the base

TABLE V
BEST RESULTS IN ONE-LEAVE CROSS-VALIDATION FOR SUBSEQUENT TRAINING WORDS IN RELATION TO THE USED CLASSIFIERS.

| | Classifier | | | |
|---|---|---|---|---|
| Word | NB [%] | kNN [%] | DT [%] | base line |
| *agent* | 93.98 | 88.43 | 94.44 | 56.94 |
| *automat* | 90.95 | 64.76 | 57.14 | 43.81 |
| *dziób* | 76.54 | 64.2 | 59.26 | 38.27 |
| *język* | 78.95 | 71.05 | 71.05 | 71.05 |
| *klasa* | 82.5 | 56.67 | 63.04 | 44.35 |
| *linia* | 54.88 | 47.56 | 47.56 | 42.68 |
| *pole* | 95.83 | 87.5 | 91.67 | 71.88 |
| *policja* | 87.5 | 79.69 | 98.44 | 64.06 |
| *powód* | 84.17 | 74.9 | 91.12 | 52.90 |
| *sztuka* | 57.29 | 53.13 | 59.38 | 38.54 |
| *zamek* | 86.96 | 79.35 | 66.3 | 39.13 |
| *zbiór* | 79.07 | 50 | 60.47 | 37.21 |
| *zespół* | 74.38 | 67.77 | 67.77 | 49.59 |
| **average** | 80.23 | 68.08 | 71.36 | 50.03 |

line equals the accuracy of a simple majority classifier. For all words, base line calculated in this way is much higher than the base line of a random choice (compare Table I for the number of senses).

Almost all results are higher than the base line. Only for the word *język* the kNN and Decision Table classifiers produced results comparable to the base line.

One can notice the worst results, i.e. being only slightly above the base line, were achieved for words: *język*, *linia* and *sztuka*. In the case of *linia* and *sztuka* one could expect such resuts, as both words posses several polysemous senses, which are difficult to be differentiated. The low results for the word *język* is a little surprising, and it is probably an artefact of the training corpus.

The best results were achieved for the words: *zamek* and *agent*. All sense of the first one are exactly homonyms, so the meaning differences should be clear for classifiers. On contrary, the good result of *agent* is biased by the training corpus to some extent. The examples for two from the four senses of *agent* come from the same set of documents of the very similar type: the set of legal documents produced in the Parliament of Poland (*Dziennik Ustaw*). Thus the characteristic vocabulary occurring in these documents could simplify the differentiation of these two senses and could increase the average score.

Moreover, one should remember, that all the words being disambiguated are nouns, and for nouns the results achieved in WSD are mostly higher than for other Parts of Speech.

Large part of the results supports our initial assumptions that words with many homonymous senses are easier for WSD. However, we could also observe some exceptions to this scheme, which can be explained on the basis of detailed analysis of the results and the training corpus.

## V. CONCLUSIONS

During the performed experiments, WSD algorithm based on the Naïve Bayes achieved the accuracy 30% above the baseline on average, the Decision Table classifier 21% above the base line on average, and the kNN classifier 18% above the base line. It is worth to emphasise that the worst results was produced by the classifiers based on kNN algorithm, which is claimed in literature, e.g. [8], to be one of the best for WSD. But according to Escuedro [13], we need to introduce weighting of examples and features and sophisticated similarity metrics in order to achieve better accuracy with kNN than with Naïve Bayes. As we wanted only to compare different approaches in relation to Polish, we did not apply such extensions. For the kNN algorithm, the introduction of the different values for the $k$ parameters could be helpful, as well.

We got also quite low results while extending training vectors with additional features, that is often performed in WSD systems. But a closer look into the detailed results for subsequent words shows that in the case of at least some words (*policja*, *język*, *powód*, *automat*) the accuracy increased with additional features. It seems that the optimal solution is selection of different sets of training features for subsequent words and applying them in relation to a word being disambiguated. It shows that the general schemes worked out for English should not be directly transferred to Polish.

The most informative type of features appeared to be the wider context, i.e. the bag of words approach. Its positive influence can be even increased by the application of a thesaurus and grouping synonyms or clustering based on automatically extracted Measures of Semantic Relatedness [17], [18], [19].

The main disadvantage of the wider context based representation is its strong dependence on the type of text for which it is applied. It is especially visible in the case of specific texts like: legal texts or scientific works, in which a specialised vocabulary is over-represented[3]. Words from this specific vocabulary rarely occurs in the rest of a large corpus, so are highly ranked by the automatic methods of selection. Classifiers trained on the basis of the wider context representation are difficult to transfer from one domain to the other.

Moreover, we noticed that the wider context representation is especially sensitive to some errors in the corpus annotation. For example, in the first phase of corpus annotation all occurrences of training words were annotated. In the case of some occurrences, training words were located very close to each other even in the range of the text window of the wider context. So the same base form occurrences were taken to the representation of more than one training word, e.g. we present below a snippet from the training corpus which includes two occurrences of the word *automat*:

"*Nikt natomiast nie ubezpieczył się od zabicia przez automat z zimnymi napojami. A takie automaty zatłukły już 15 osób, które usiłowały siłą wyciągnąć puszkę po wrzuceniu pieniędzy i bezskutecznym naciskaniu guzika [...]*"

(*Nobody has insured himself from being killed by a drinks machine. In the meantime such machines have already beaten to death 15 persons who were trying to pull out a can using*

[3] However, training classifier based on the wider context representation on a representative subcorpus is its advantage.

*force after they had thrown money into it and had been pressing a button without result.*)

In the example above, the distance between the occurrences of *automat* is 6 tokens, i.e. much less than the text window of the wider context. The descriptions of both occurrences are collect from the same tokens in large extent. Thus two very similar training examples are constructed. During training they can introduce some bias, when the number of training examples is small, during testing they can increase the result while separated into the training and testing part of the corpus. In order to avoid such cases, we need to carefully select locations of training examples or to filter an existing corpus.

The results of our investigations are very positive for processing the Polish language. The performed experiments showed the construction of WSD system for Polish on the basis of limited language resources and tools is possible. Obviously with the larger number of disambiguated words one can expect decrease in the average result, but still methods developed for English seem to work for a typologically different language like Polish.

***Abstract*—It is autumn 2012…The VMware Infrastructure …3, 4 editions virtualised crucial components of IT environment, i.e. computing (CPU, RAM), networking and storage. However, an important element was overlooked. Which one? A user. There was no mechanism built in into VI3/VI4 that would support administrator in gaining effectively the skills of implementing solutions advised by manufacturer, the so-called recommendations (“best practice”, etc.). Either, the high level of user’s skills (primarily, administrator’s ones) were not treated as a valuable resource of LAN infrastructure that could be (should be) used, while a “surplus” could be virtualised for a common good of the society (local and/or global), concentrated around the enterprise-class infrastructure virtualisation technology. The latest edition, VI5 beta, brings also an important change in this respect in the form of a new module, VMware Usering, which is directed in the current version (i.e. beta version) first of all towards security hardening, i.e. the linguistic inference has been accomplished by a method of fuzzy control basing on the knowledge-base built on the recommendation of VI5 beta manufacturer. The VMware Usering is a set of tools, stimulating users to take up actions being consistent with manufacturer’s recommendations (VMware User Hardening) and virtualising (optionally for administrators with HIGH $_{\text{FUZZY}}$ rating) the competence resource of advanced users (VMware User Competence Sharing). The rise of a resistance level of IT infrastructure to increasing threats of internet security is also a manufacturer’s own interest, therefore one can expect in the near future a popularisation of VMware Usering-class solutions as an important tool supporting an average internet surfer in his/her solitary struggle against crackers at the level of 8th OSI model layer .**

## I. Introduction

IT IS autumn 2015… Computer software is not only a code with specific functionality. It is also – and perhaps first of all – a knowledge, experience and competences of computer programmers enclosed (also outside the code) in a set of the so-called recommendations. Owing to them, a user can avoid obstacles and traps of the interference of tens (hundreds) of options (chances) “at choice”. Obviously, a user can but does not have to… The tandem of software functionality and user competence (including the use of recommendations) determines at last the quality of IT solution.

Apart from controlling and managing a specific functionality of IT system, an important issue (in present-day internet times) is to pay due attention (at least 10% of daily work time with IT system?) to IT security questions. Besides implementing hardware and software solutions, a key element is the quality of the weakest link, i.e. the quality of knowledge and user competence.

Probably the IT infrastructure that works on-line with the Internet is helpless (except for entries in system logs) when administrator has turned off (perhaps unintentionally) its protecting systems, i.e. firewall/IDS/IPS (exposing the same its resources to the prey of crackers). With some exaggeration, we can probably describe the past IT systems as “deaf-mute” ones, i.e. helpless on the one hand “to admin insanity/ignorance”, while not using completely the experience and professionalism of brilliant user (administrator) on the other hand. There was no feedback in them: “reprimand for making and sticking to an error” and first of all rewarding “good behaviour consistent with manufacture’s recommendations” [1]-[3].

Two extremely popular previous versions, VI3 and VI4, virtualised crucial hardware and software components of IT infrastructure, forgetting however about a key link (for its proper functioning), i.e. about a user.

Together with VI5 beta Enterprise, we are receiving a tool, VMware Usering, stimulating (supporting intensively) a user for taking up actions that are consistent with manufacturer’s recommendations, i.e. VMware User Hardening (VMware UH) as well as a tool virtualising the competence resource (of advanced users with f(UR):= HIGH rating), i.e. VMware User Competence Sharing (VMware UCS).

## II. Usering Security, or Educational Self —Tuning in the 8th Layer of OSI Model.

### *A. Admin in the “open loop” of acquiring competence/ knowledge/ experience.*

The detailed discussion of VMware Usering mechanism surpasses the frames of the present paper. It is sure enough that descriptions referring to most new mechanisms available in VI5 edition will show in the near future. Below, only the essence of VMware UH and VMware UCS operation will be

978-83-60810-14-9/08/$25.00 © 2008 IEEE

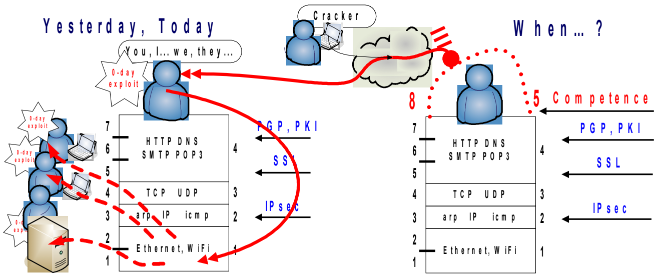

Fig 1 . User Hardening, a tool supporting the user in counteracting internet attacks from the 8th layer of OSI model: Competence layer.

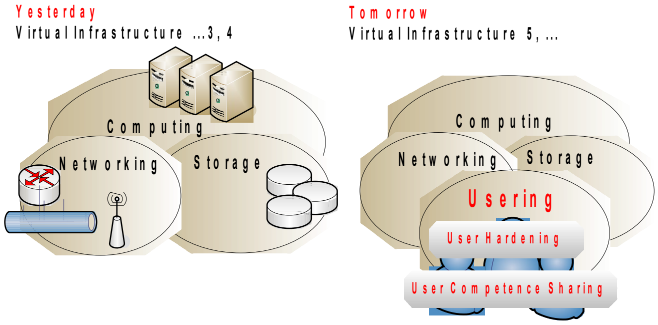

Fig 2. Usering, next virtualized component of the enterprise-class IT environment.

illustrated on selected examples. Not many users have knowledge of availability of VMware UH also for older editions of Virtual Infrastructure 3 and 4 (after installing additionally manufacture's patches to Virtual Center server ver. 2 or 3). In the present version (i.e. VI5 beta), VMware UH is using manufacturer's recommendations that are connected with IT security hardening, i.e. Vmware UH.

Until recently, almost all of us have accepted quietly a common practice that responsibility of admin is to "become" (of a sudden the best) or "becoming" an expert (at last after many months /sometimes many years) (No 1 problem), who will be able, apart from managing classic IT resources, to "keep a tight rein on" (meaning: extend knowledge of) a common user of virtual infrastructure.

The no 1 problem is a process (frequently long-lasting one) of coming in admin competence to the knowledge level of software engineers (authors) (VMware team): from studying "case study"/"best practice" "helps" /pdf files/ through specialist courses to own experience/experimenting with test/ production network. Direct contact/exchange of experience (meaning: sharing with each other) between computer programmer/software engineer (author) and a user/administrator has been out of question (apart from a small group using Help Line). Out of hundreds / thousands of documentation pages, few users "shell out" most important procedures, primarily those advised by manufacturer, i.e. recommendations. And what is the effect of this?

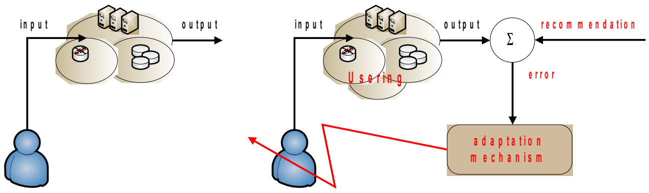

Fig 3. User in the "opened (left)/ closed (right) loop", or educational self-tuning.

The IT system has quietly permitted sometimes to "demolish" itself, or sometimes to "tune up perfectly", depending on admin competence. A common practice, used also by a manufacturer, was to record important events (unfortunately) in many scattered logs/data-bases. Every admin will admit that effective daily tracking (and first of all correlating any number) of tens/hundreds/thousands of scattered events is almost impossible with the quality comparable at least to solutions of Intrusion Detection/Prevention System type. The process described above can be summarised unfortunately as "admin all alone in the open loop of acquiring knowledge":

- lack of built-in mechanism that evaluates *on-line* and *on-time* the conformity of user actions (including admin) with the advised manufacturer's recommendations, e.g. admin can of course do "everything, but it will be good if he/she does not take up actions that decrease the system security, does it?
- lack of mechanism (rewarding/promoting one) that uses user competence and acquired knowledge for the good of local/global user society concentrated around a specific technology (except for enterprise discussion lists),
- similarly to counteracting the waste of resources of the non-virtualised server computing type, we all agree with the thesis that one can counteract with equal determination the waste of acquired knowledge and competence of professional users.

### B. Admin in the "closed loop", or educational self-tuning.

When closing feedback loops, we receive immediately profits:

- administrator sees "without delay" the effect of his/ her actions (choices of options, configurations, activation/deactivation…, etc.) on "educational self-tuning error" (minimum one the best) with respect to advised manufacturer's recommendations,
- evaluation of "educational self-tuning error" (difference between user choice/decision and manufacturer's recommendation) is made (in the present version, i.e. VI5 beta) with fuzzy logic method: except for interference of the "black-white" type, i.e. zero/"no conformity"/"maximum error" vs. one/"100% conformity"/"zero-value error", we are using affiliation degrees (set of real numbers within a range of ≤0; 1 ≥) for a fuzzy set that represents one of the values of linguistic variable *competence* { *Low, Medium, High* }:

error of educational self-tuning $_{FUZZY}$ := recommendations of manufacturer $_{FUZZY}$ – decisions of administrator $_{FUZZY}$

- apart from the c onformity with important manufacturer’s recommendations, one can evaluate “educational self-tuning error” for a common user who, when acting within authorisations (permissions), i.e. making use of trappings (privilege) attributed to his/her part (role), can be “rewarded with a neutral mark or higher *f* ( *UH* )” for “moving” inside the cage determined by the role” and “punished with a neutral mark or lower *f* ( *UH* )” even for taking up “only attempts” to make use of privileges not attributed to his/her role”.

### C. *VMware User Hardening $_{security}$ (VMware UH $_{security}$ ).*

Abstract he mechanism that allows for closing the educational loop of feedback is just VMware UH module (apart from VMotion, VMware HA, VMware DRS and two other novelties in VI5 beta version, it is the next option for Standard and Enterprise versions requiring the licence). In VMware UH, the interference has been accomplished by a method of fuzzy control (computational intelligence), basing on the knowledge-base constructed on manufacturer’s recommendations [6],[7].

UH $_{security}$ : User Hardening $_{security}$

$e_{FUZZY} \cong r_{FUZZY} - d_{FUZZY}$

- ○ e {$e_1$ , $e_2$ … $e_n$ }- error of educational self-tuning
- ○ r {$r_1$ , $r_2$ … $r_n$ } - recommendations of manufacturer
- ○ d {$d_1$ , $d_2$ … $d_n$ } - decisions of administrator
- *f* ( *UH* ):= { *LOW* $_{FUZZY}$ , *MEDIUM* $_{FUZZY}$ , *HIGH* $_{FUZZY}$ }
- Objective: local evaluation (automatically and without delay) of administrator’s (user’s) implementation of recommendations (of manufacturer)

The key element of fuzzy control is expert knowledge-base constructed on manufacturer’s recommendations:

(+) It is recommended…

(-) VMware does not recommend using…

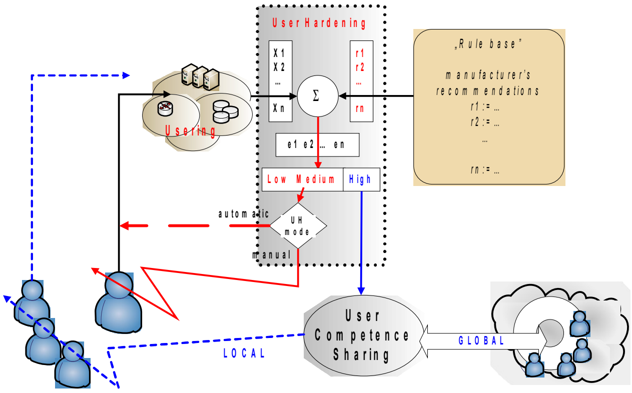

Fig 4. Concept of using computational intelligence in the “closed loop” of educational self-tuning of User Hardening module-tuning.

written in the form of (IF… Then…) rules

IF *premiss1* AND *premiss2* AND…

Then *conclusion1* AND *conclusion2* …

that use the values of linguistic variable fuzzy logic described by means of appropriate fuzzy sets. The VMware UH does not analyse “every step” of user; it take into account only these actions, for which a manufacturer’s recommendation exists in the knowledge-base. In the supplement Appendix, the examples of manufacturer’s recommendations are given (scattered in rich documentation) that increase the IT security of infrastructure with respect to its crucial components: ESX Server Host, Service Console, Virtual Machine and VirtualCenter.

In order to illustrate the essence of VMware UH $_{security}$ operation, we will use the first recommendation from the Appendix that refers to ESX installation and evaluate a possible “educational self-tuning error”, taking into account:

- default setting of manufacturer,
- decisions of administrator,
- recommendations of manufacturer,

hat is:

- error of educational self-tuning $_{FUZZY}$ := recommendations of manufacturer $_{FUZZY}$ -
  – decisions of administrator $_{FUZZY}$

*f* ( *UH* ):= *HIGH* $_{FUZZY}$

What does it mean in reality? As early as a few minutes of ESX 3 installation, administrator should “brake down” default settings (but not recommended by VMware!) in case of production environment (and not a test one) in order to ensure HIGHER security and aim at *f* ( *UH* ):= *HIGH* $_{FUZZY}$ mark [4], [5] :

- default setting “Create a default network for virtual machines” is not recommended for production environment by VMware manufacturer.

„ *[…] If the “Create a default network for virtual machines” is selected, virtual machine network traffic will share this adapter with the service console. This is not a recommended configuration for security purposes”*

Conclusion:

- as early as a few minutes of administrator contact with infrastructure software, we can evaluate a probable

- error of educational self-tuning $_{FUZZY}$ :=

recommendations of manufacturer $_{FUZZY}$ – decisions of administrator $_{FUZZY}$

and interfere according to fuzzy control nomenclature about evaluating admin competence of the type:

- increase
- neutral
- decrease

receiving, e.g.:

$\mu$ ( LOW FUZZY ):= 0.0; $\mu$ ( MEDIUM FUZZY ):= 0.2;

$\mu$ (HIGH FUZZ ):= 0.8 $\Rightarrow$ :→ (UH):= 82% HIGH FUZZY

### D. *VMware UH $_{security}$ : manual – automatic (autopilot) mode.*

The VMware UH $_{security}$ (in VI5 beta version) default operation mode is *manual* , i.e. presenting the error of educational self-tuning (with indication to recommended options) without enforcing choices/decisions/methods of user action consistent with manufacturer’s recommendations. An interesting mode is *automatic* , which for the profile of VMware UH $_{security}$ edition, as a *security hardening* , will approve (similarly to the *transaction* mechanism in the data-base nomenclature) only these decisions of user, which will not decrease (but rather increase) the global level of infrastructure security for production network.

## III. VMware User Comptetence Sharing (UCS)

Natural consequence of minimising the error of educational self-tuning $_{FUZZY}$ of the competence resource for a specific user of VMware UH module at a respectively high level (e.g. over 75%) HIGH $_{FUZZY}$ is to move to next stage on the way to full Usering, i.e. to virtualise the competence resource of advanced users with VMware UCS module by "sharing"/"participation" for the good of local and/or global user society. The idea of VMware UCS functioning is springing from the mechanism of self-education of professional internet discussion list users. A particularly good example is the mechanism that supports evaluation of the importance/quality of post contents of the moderated discussion list VMWare VMTN Discussion Forums...Novice, Expert, Champion, and Guru. The VMware UH $_{\text{security}}$ fulfills a similar role to a moderator and opinions of internet surfers, but at a local level in evaluating the practical competence of a user who manages the advanced infrastructure.

VMware UCS uses of course a VMware UH $_{\text{security}}$ filter :

VMware UH $_{\text{security}}$ : *filter_HIGH* {user1_ *LOW* , user2_ *HIGH* , … userN_ *MEDIUM* }= user2 and can work in the following modes (different possibilities are tested in the present beta version; final VMware UCS operation modes should be determined within the nearest months after all test are concluded):

- Local_info: users indicated by user2 (all, selected,…) will be familiarised with the current ranking of VMware UH $_{\text{security}}$ evaluation,
- Local_sharing: during taking up actions that are inconsistent with manufacturer's recommendations, a user has to receive a counter-signature from the user with HIGH mark,
- Global _sharing: a user2 user with HIGH mark receives a possibility/invitation from VMware manufacturer for co-operation for the good of the society concentrated around the product (its scope and form is determined by manufacturer).

## IV. Conclusion

Internet surfers should be equipped with knowledge and competence that allow on the one hand for effective acquiring of advanced skills for daily management of (work with) modern IT systems, while enable counteracting against misuses from the part of less or more organised groups of internet crackers on the other hand. Because quick achievement of the aforesaid objectives is important for the well-comprehended business-like own interest of manufacturer, thus we can expect in the near future a popularisation of solutions of the VMware Usering class as an important tool that supports, among others, an average internet surfer in his/her alone struggle with crackers at a level of the 8th layer of OSI model. Undoubtedly, the strength of this solution lies in the skilful connection of a tool set that stimulates users for taking up actions, which are consistent with recommendations of VMware UH manufacturer and (optionally for administrators with $f(UH)$:= $HIGH_{FUZZY}$ mark) virtualising the competence resource of VMware UCS users.

## Appendix

Examples of manufacturer's recommendations that increase IT security of infrastructure with respect to its crucial components [8]-[11].

### ESX Server Host:

Do Not Create a Default Port Group

Use a Dedicated, Isolated Network for VMotion and iSCSI

VMware best practices recommend that the service console and VMotion have their own networks for security reasons

Do Not Use Promiscuous Mode on Network Interfaces

Protect against MAC Address Spoofing (MAC address changes, Forged transmissions)

Secure the ESX Server Console

Mask and Zone SAN Resources Appropriately

Protect against the Root File System Filling Up

### VirtualCenter:

Manually changing Most Recently Used to Fixed is not recommended. The system sets this policy for those arrays that require it. For active/passive storage devices, Most Recently Used is highly recommended

Comparing Raw Device Mapping to Other Means of SCSI Device

Virtual Machine

Disable Unnecessary or Superfluous Functions

Limit Data Flow from the Virtual Machine to the ESX Server Host

Isolate Virtual Machine Networks

Minimize use of the VI Console

### Service Console:

Isolate the Management Network

Configure the Firewall for Maximum Security

Use VI Client and VirtualCenter to Administer the Hosts Instead of Service Console

Use a Directory Service for Authentication

Strictly Control Root Privileges

Limiting Access to su. Using sudo

Establish a Password Policy for Local User Accounts

Limit the Software and Services Running in the Service Console

Do Not Manage the Service Console as a Linux Host

Establish and Maintain File System Integrity

Maintain Proper Logging

***Abstract*—The construction of a wordnet from scratch requires intelligent software support. An accurate measure of semantic relatedness can be used to extract groups of semantically close words from a corpus. Such groups help a lexicographer make decisions about synset membership and synset placement in the network. We have adapted to Polish the well-known algorithm of Clustering by Committee, and tested it on the largest Polish corpus available. The evaluation by way of a *plWordNet*-based synonymy test used Polish WordNet, a resource still under development. The results are consistent with a few benchmarks, but not encouraging enough yet to make a wordnet writer's support tool immediately useful.**

## I. Introduction

THE construction of a wordnet for yet another language, especially from scratch, requires a significant effort. There is a high pay-off: wordnets are essential in a fast growing number of applications. One way of reducing the cost is to facilitate wordnet development by automatic tools that suggest missing synsets and relations among them. Two paradigms of extracting semantic relation are cited [1]: based on patterns and based on clustering. The existing methods, however, extract relations between *lexical units* (LUs), while the problem of synset construction has been left open.

*Measures of Semantic Relatedness* (MRSs) based on *distributional semantics* generate a continuum of relatedness values for pairs of LUs. Even a casual look at a list of LUs most related to a given unit $u$ reveals numerous semantic relations: synonymy and antonymy (with similar distributional patterns), hypernymy, meronymy, metonymy, LUs semantically linked to $u$ by some situation type, and so on. Precise annotation of a list of pairs of related LUs with different types of semantic relations is a difficult manual task, and low inter-annotator agreement is likely if the task is performed without context. Any definition of hypernymy, meronymy and in particular synonymy is stated as a textual description that relies on the annotator's language competence and, at best, is supported by a diagnostic substitution test. Semantic and pragmatic constraints make many LUs semantically related to many other LUs. This view of wordnet relations, especially including near-synonymy – the basis for determining synsets – suggests that these relations are just weakly identifiable characteristic subspaces in the continuum of semantic relatedness.

Carefully selected lexico-syntactic patterns can identify pairs of LUs by a hypernymy-type relation, but their coverage (recall) is limited, precision imperfect, and a sharp distinction among remote, indirect hypernyms and more direct close hypernyms, or even near-synonyms, is not possible on a large scale.

MSRs and lexico-syntactic patterns deliver only some clues. The notion of a synset is not exactly constructively defined. To approximate synset structure automatically, several clues may have to be combined. A densely interlinked group of LUs strongly related via a MSR seems to be a natural first approximation.

The main objective of our research is the identification of tightly interlinked groups of words as representing near-synonymy and close hypernymy. Next, on the basis of the extracted groups, we identify LUs represented by lemmas belonging to groups and their sense as described by groups. Finally, we propose to extend a wordnet semi-automatically with the collected synsets and LUs.

Several clustering algorithms have been discussed in literature for the task of grouping LUs. Among them, Clustering by Committee (CBC) [2], [3] has been reported to achieve good accuracy in comparison to *plWordNet*. It is often referred to in the literature as one of the most interesting clustering algorithms, e.g. [4].

CBC relies only on a modestly advanced dependency parser and a MSR based on pointwise mutual information (PMI) extended with a discounting factor [3]. This MSR is a modification of Lin's measure [5] analysed in [6] in application to Polish. Both measures are close to the RWF measure [7] that achieves good accuracy in comparison to Polish WordNet [8].

Our goal was to analyse CBC's applicability to an inflected language for which there is a limited set of language processing tools, and to extract LU groups for the purpose of extending Polish WordNet. We expected to identify several groups of high internal similarity for a polysemous word. Moreover, we wanted to improve CBC's accuracy and to analyse its dependence on several thresholds which are explicitly, but also implicitly, introduced in CBC. We were looking for a more objective and straightforward evaluation of the algorithm results than originaly proposed in [3].

Applications of CBC to languages other than English are rarely reported in the literature. Tomuro et al. [9] mentioned briefly some experiments with Japanese, but gave no results. However, differences between languages, and especially differences in resource availability for different languages, can affect the construction of the similarity function at the heart of CBC. Moreover, CBC crucially depends on several thresholds whose values were established experimentally. It is quite unclear to what extent they can be reused or re-discovered for different languages and language resources.

## II. The CBC Algorithm

The CBC algorithm has been well described by its authors [2], [3]. We will therefore only outline its general organisation, following [3] and emphasising selected key points. We have reformulated some steps in order to name consistently all thresholds present in the algorithm. Otherwise, we keep the original names.

```
I    Find most similar elements
        1) for each word $e$ in the input set $E$, select $k$ most
           similar words considering only $e$'s features
           above the threshold $\theta_{MI}$ of mutual information
II   Find committees
        1) extract a set of unique word clusters by average
           link clustering, one highest-scoring cluster per
           list
        2) sort clusters in descending order and for each
           cluster calculate a vector representation on the
           basis of its elements
        3) going down the list clusters in sorted order,
           extend an initially empty set $C$ of committees
           with clusters similar to any previously added
           committee below the threshold $\theta_1$
        4) for each $e \in E$, if the similarity of $e$ to any
           committee in $C$ is below the threshold $\theta_2$, add
           $e$ to the set of residues $R$
        5) if $R \neq \emptyset$, repeat Phase II with $C$ (possibly $\neq \emptyset$)
           and $E = R$
III  Assign elements to clusters
        • for each $e$ in the initial input set $E$
          1) $S$ = identify $\theta_{T200} = 200$ committees most
             similar to $e$
          2) while $S \neq \emptyset$
             a) find a cluster $c \in S$ most similar to $e$
             b) exit the loop if the similarity of $e$ and $c$
                is below the threshold $\sigma$
             c) if $c$ "is not similar" to any committee in
                $C^1$, assign $e$ to $c$ and remove from $e$ its
                features that overlap with $c$'s features
             d) remove $c$ from $S$
```

CBC has three main phases, marked by Roman numerals above. In the initial Phase I, data expressing semantic similarity of LUs are prepared. Here, CBC shows strong dependency on the quality of the applied MSR – the most important CBC parameter – and the MSR is transformed by taking into consideration only some features (the threshold $\theta_{MI}$) and the $k$ most similar LUs.

In the next two phases, the set of possible senses is first extracted by means of committees; next, LUs are assigned to committees. A *committee* is an LU cluster intended to express some sense by means of a cluster vector representation derived from features describing the LUs included in it. Committees are selected from the initial LU clusters generated by processing the lists of the $k$ most similar LUs, see II.1 and II.2. However, only the groups dissimilar to other selected groups are added to the set of committees, because the committees should ideally describe all senses of the input LUs, see II.3. The set of committees is also iteratively extended in order to cover senses of all input LUs, see the condition in III.4.

Committees only define senses. They are not the final LU groups we are going to extract. The final LU groups – ideally sets of near synonyms – are extracted on the basis of committees in Phase III. Each LU can be assigned to one of several groups on the basis of the similarity to the corresponding committees. It is assumed that each sense of a polysemous LU corresponds to some subset of features which describe the given LU. In step III.2.c, each time a LU $e$ is assigned to some committee $c$ (i.e. the next sense of $e$ has been identified) CBC attempts to identify the features describing the sense $c$ of $e$ and remove them before the extraction of the other senses of $e$ . The idea behind this operation is to remove the sense $c$ from the representation of $e$, in order to make other senses more prominent. However, the implementation of the *overlap* and *remove* operations is straightforward: values of all features in the intersection are simply set to 0 [2]. It would be correct if the association of features and senses were strict, but it is very rarely the case. Mostly, one feature derived from lexico-syntactic dependency corresponds in different amount to several senses. A less radical solution for sense representation removal is proposed in Section V.

## III. CBC Applied to Polish

Our initial intention was to re-implement CBC as published in [2], [3], in order to analyse and compare its performance for Polish. However, we face two problems – there are significant typological differences between the two languages and the availability of language tools differs. For example, unlike English (for which CBC was originally designed), Polish is generally a free word-order language; much syntactic information is encoded by rich inflection. This makes the construction of even a shallow parser for Polish more difficult than for English, e.g. noun modification by another noun is marked by the genitive case, but genitive is also required by negated verbs, and the noun modifier can occur either in a pre-modifying or post-modifying position. On the other hand, there are possibilities of exploring morpho-syntactic relations between word forms (but not in the case of the noun-noun modification). As no verb subcategorisation dictionary is

[1] We interpret this as $c$'s similarity being below an unmentioned threshold $\theta_{ElCom}$.

available for Polish, the identification of verb arguments in text is almost impossible, and semantic description of nouns can be based on relations to verbs only to a small extent.

CBC begins by running a dependency parser on the corpus. No similar tool exists for Polish. In [7], [6] a similar problem was successfully solved by applying several types of lexico-morphosyntactic constraints to identify a subset of structural dependencies mainly on the basis of morphological agreement among words in a sentence and a few positional features like noun-noun sequence of modification. A direct comparison of MSRs based on parsing and on constraints is not yet possible, but the constructed constraint-based MSRs have good accuracy when compared with *plWordNet* [8] by a modified version of *WordNet-Based Synonymy Test* (WBST) [10]. By applying the constructed MSR we got results comparable with the results achieved by humans in the same task [11]. We therefore assumed that the constructed MSR is at least comparable in quality to the one used in [2], [3], and we adopted the constraint-based approach here, applying the same constraints as in [7].

As in [6], [7], the applied constraints are written in the JOSKIPI language and run by the engine of the TaKIPI morphosyntactic tagger [12]. Each noun $n$ is described by the frequency with which occurrences of $n$ in the corpus meet two lexico-morphosyntactic constraints: modification by *a specific adjective* or *an adjectival participle*, and co-ordination with a *a specific noun*.

MRSs and clustering algorithms constructed for Polish can be evaluated on the basis of *plWordNet*, but *plWordNet* is still quite small in comparison to Princeton *plWordNet* (henceforth PWN). It includes mostly general words and lacks many senses for the words described. This complicates the analysis of the evaluation.

All experiments were run on the IPI PAN Corpus [13] (IPIC), the largest annotated corpus of Polish, extended with a corpus of the on-line edition of a Polish daily, 1993-2001) [14] (Rz). The joint corpus (IPIC+Rz) includes about 368 million tokens, around 2.56 times more than the corpus used in [3]. IPIC+Rz, however, is not well balanced: legal and scientific texts are over-represented, so intuitively rare words may have inflated frequencies, but many “popular” words have low frequencies. TaKIPI does not distinguish proper names. Lemmatization makes more errors than it is the case for English.

Several thresholds used in the CBC algorithm (plus a few more in the evaluation) are the major difficulty in its exact re-implementation. Moreover, any method of the CBC optimisation in relation to thresholds was not proposed in [2], [3] and the values of all thresholds were established experimentally in [2]. There also was no discussion of their dependence on the applied tools, corpus and characteristics of the given language. We will discuss the values of most of these thresholds:

- $k$ – the tested value range: $[10, 20]$ [2, p. 53], but the final choice is not given,
- $\theta_{MI}$ – the exact value is not presented, but it is claimed that $\theta_{MI}$ “had no visible impact on cluster quality” [2, p. 53],
- $\theta_1 = 0.35$ [2, p. 55],
- $\theta_2 = 0.25$ [2, p. 55],
- $\theta_{T200} = 200$ [2, p. 58],
- $\sigma$ – different values tested [2, pp. 95-96], while the best score was reported with $\sigma = 0.18$, however, in the chart on pp. 96 of [2] the best result is presented for $\sigma = 0.1$, which we assumed as the default value.

A crucial threshold $\theta_{ElCom}$ – it influences the process of assigning elements to word groups in Phase III – is not overtly named in the algorithm [3], [2]; the values applied to $\theta_{ElCom}$ are unknown. The possibility that $\theta_{ElCom}$ is identical with $\sigma$ is excluded by the order of steps: 2b comes before 2c. For $\theta_{T200}$ no other values were tested but it is reasonably high: it is unlikely ever to have more than 200 senses of a word. Besides the unknown value of $\theta_{ElCom}$, other thresholds seem to depend on the corpus and, especially, on the properties of the MSR.

To extract clusters in Phase II, we applied the CLUTO package [15], which allowed us to analyse the influence of several clustering strategies, namely: *UPGMA*, *i1*, *i2*, *h1*, *slink* and *wclink*, besides the average-link clustering originally applied in CBC. During the first experiment, we used a MSR based on PMI, constructed according to the equations presented in [3]. The results of this experiment appear in Table I.

In the experiments presented in [11], [6], MSR based on Rank Weight Function used for the transformation of feature frequencies generally surpassed several other types of MRS known from the literature, some of them similar to the PMI measure applied in CBC, e.g. see [11], [6]. In the second experiment we replace PMI MSR with RWF MSR.

## IV. Evaluating CBC on Polish

As we wrote in section III, all experiments were run on the IPIC+Rz corpus. We wanted to evaluate the algorithm’s ability to reconstruct *plWordNet* synsets. That would confirm the applicability of the algorithm in the semi-automatic construction of wordnets. We put nouns from *plWordNet* on the input list of nouns ($E$ in the algorithm). Because *plWordNet* is constructed bottom-up, the list consisted of 13298 most frequent nouns in IPIC plus some most general nouns, see [8]. The constraints were parameterised by 41599 adjectives and participles, and 54543 nouns – 96142 features in total.

### A. Evaluating Extracted Word Senses

Evaluation of the extracted word senses proposed in [3], [2] is based on comparing the extracted senses with those defined for the same words in PWN. It is assumed that for a word $w$ a correct sense is described by a word group $c$ such that $w \in c$ if a synset $s$ in PWN such that $w \in s$ is sufficiently similar to $c$. The latter condition is represented by another threshold $\theta$.

The notion central to the evaluation proposed in [3], [2] is similarity between wordnet synsets. The definition of similarity was based on probabilities assigned to synsets and derived from a corpus annotated with synsets. This kind of synset similarity is very difficult to estimate for languages for which there is no such corpus, as is the case of Polish. In order to avoid any kind of unsupervised estimation of synset probabilities, we used a slightly modified version of Leacock's similarity measure[16]:

$$sim(s_1, s_2) = -log(\frac{Path(s_1, s_2)}{\max_{s_a, s_b} Path(s_a, s_b)}), \qquad (1)$$

$Path(a, b)$ is the length of a path between two synsets in *plWordNet*.

Except for synset similarity, we follow [3], [2] strictly in other aspects of word sense evaluation. Synset similarity is used to define the similarity between a word $w$ and a synset $s$. Let $S(w)$ be a set of wordnet synsets including $w$ (its senses). The similarity between $s$ and $w$ is defined as follows:

$$simW(s, w) = max_{t \in S(w)} sim(s, t) \qquad (2)$$

Similarity of a synset $s$ (a sense recorded in a wordnet) and a group of LUs $c$ (extracted sense) is defined as the average similarity of LUs belonging to $c$. However, LU groups extracted by CBC have no strict limits – their members are of different similarity to the corresponding committee (sense pattern). The core of the LU group is defined in [3], [2] via a threshold $\kappa$[2] on the number of LUs belonging to the core. Let also $c_\kappa$ be the core of $c$ – a subset of $\kappa$ most similar members of $c$'s committee. The similarity of $c$ and $s$ is defined as follows:

$$simC(s, c) = \frac{\sum w \in c_\kappa simW(s, u)}{\kappa} \qquad (3)$$

We assume that a group $c$ corresponds to a correct sense of $w$ if

$$max_{s \in S(w)} simC(s, c) \geq \theta \qquad (4)$$

The wordnet sense of LU $w$, corresponding to the sense of $w$ expressed by a LU group $c$, is defined as a synset which maximizes the value in formula 4:

$$arg\, max_{s \in S(w)} simC(s, c) \qquad (5)$$

The question arises why this evaluation procedure is so indirect. Why do we not compare the cores of the LU groups with wordnet synsets? The answer is seemingly simple. Both in Polish and in English, certain matches are hard to obtain. LU groups are indirectly based on the MSR used. They do not have clear limits, and still express some closeness to a sense, but not to a strictly defined sense. On the other hand, wordnet synsets also express a substantial level of subjectivity in their definitions, especially when they are intended to describe *concepts*, which are not directly observable in language data. The proposed indirect evaluation will measure the level of resemblance between the division into senses made by wordnet writers and that extracted via clustering.

As stated previously, the selection of committees is critical, because it affects the remainder of the algorithm. Obviously, the criterion function for agglomerative clustering used in step of Phase II is important in this process. We therefore measure the precision of assigning words to correct sense using different criterion functions. The results appear in Table I. We used default values for thresholds: $\theta_1 = 0.35$, $\theta_2 = 0.25$, $\sigma = 0.1$, $\theta_{MI} = 250$ and $k = 20$. We assumed that default value for $\theta_{ElCom}$ is 0.2. Previous investigation of the properties of RWF [6] revealed that it behaves differently than MSRs based on mutual information. We chose different default values for RWF: $\theta_1 = 0.2$, $\theta_2 = 0.12$. Also, $\theta_{MI}$ does not apply to RWF, so for fair comparison we used another threshold – on the minimal frequency with which a word appears in any relation $min_{tf} = 200$ and on the minimal number of different relation in which the word appeared with $min_{nz} = 10$.

The selection of threshold values was done on the basis of experiments. Automatising this process is a very difficult problem, as the whole process is computationally very expensive – one full iteration takes 5-7 hours on a PC 2.13 GHz and 6 GB RAM, that makes e.g. application of Genetic Algorithms barely possible.

The differences between slink, UPGMA and i2 (see Tab. I) are very small. We have chosen the i2 criterion for further experiments because of its efficiency.

TABLE I
PRECISION FOR DIFFERENT CRITERION FUNCTION OF THE AGGLOMERATIVE CLUSTERING ALGORITHM.

| | PMI | | RWF | |
|---|---|---|---|---|
| | Precision | No. of words | Precision | No. of words |
| UPGMA | 22.59 | 2993 | 38.42 | 682 |
| i1 | 23.45 | 2980 | 35.72 | 744 |
| i2 | 22.37 | 2995 | 38.81 | 742 |
| h1 | — | — | 31.88 | 345 |
| slink | 22.70 | 2982 | 37.59 | 665 |
| wclink | 22.98 | 2981 | 34.14 | 703 |

The comparison – presented in Table I – of the influence on CBC of both MSRs used, PMI and RWF, is a little misleading; in these cases the number of clustered words is very different. This was caused by keeping the same value of the threshold $\sigma = 0.1$ for both versions. It seems that the value of $\sigma$ must be carefully selected for each type of MSR separately.

In Table I we can see that the differences in the algorithm of agglomerative clustering used in generating committees influence the final precision. The best, i2, leads to visibly better committees and word groups.

Because the value of $\sigma$ is so important for the result, we tested its several values with the other parameters fixed (RWF MSR, i2 clustering, $\theta_{ElCom} = 0.2$):

- $\langle \sigma = 0.1$, precision = 38.81, number of words assigned = 742$\rangle$,
- $\langle \sigma = 0.12, P = 40.33, N = 719 \rangle$,
- $\langle \sigma = 0.15, P = 40.99, N = 688 \rangle$,
- $\langle \sigma = 0.18, P = 42.14, N = 655 \rangle$.

With the increasing value od $\sigma$ the precision increases, but the number of words clustered drops significantly. The tendency persists for higher values of both thresholds, e.g. $\langle \theta_{ElCom} = 0.3, \sigma = 0.25, P = 45.4, N = 522 \rangle$. When we set $\sigma$ small and $\theta_{ElCom}$ we get relatively good precision but more words

[2] We changed the original symbol $k$ to $\kappa$ so as not to confuse it with $k$ in the algorithm.

clustered, e.g. $\langle\theta_{ElCom} = 0.3, \sigma = 0.1, P = 38.81, N = 742\rangle$. It means that, contrary to the statement and chart in [2], tuning of both thresholds was important in our case.

In order to illustrate the work of the algorithm, we selected two examples of correct word senses extracted for two polysemous LUs. The word senses are represented by committees described by numeric identifiers. In this way it is emphasised that committee members define only some word sense and are not necessarily near synonyms of the given LU.

LU: **bessa** *economic slump*

id=95 committee:{ niezdolność *inability*, paraliż *paralysis*, rozkład *decomposition*, rozpad *decay*, zablokowanie *blockage*, zapaść *collapse*, zastój *stagnation* }

id=153committee:{ tendencja *tendency*, trend *trend* }

LU: **chirurgia** *surgery*

109 committee:{ biologia *biology*, fizjologia *physiology*, genetyka *genetics*, medycyna *medicine* }

196 committee:{ ambulatorium *outpatient unit*, gabinet *cabinet*, klinika *clinic*, lecznictwo *medical care*, poradnia *clinic*, przychodnia *dispensary* }

Now, the same but with the proposed *heuristic of minimal value activated*, see Section V.

LU: **bessa**

64 committee: {pobyt *stay*, podróż *travel*} – a spurious sense

95 committee: **as above**

153 committee: **as above**

LU: **chirurgia**

109 committee: **as above**

171 committee: {karanie *punishing*, leczenie *treatment*, prewencja *prevention*, profilaktyka *prophylaxis*, rozpoznawanie *diagnosing*, ujawnianie *revealing*, wykrywanie *discovering*, zapobieganie *preventing*, zwalczanie *fight*, ściganie *pursuing, prosecuting*} – a correct additional sense found

196 committee: **as above**

Next, two examples of committees and the generated word groups.

- **committee 57**: {ciemność *darkness*, cisza *silence*, milczenie *silence = not speaking*}
- **LU group**: {cisza, milczenie, ciemność, spokój *quiet*, bezruch *immobility*, samotność *solitude*, pustka *emptiness*, mrok *dimness*, cichość *silence (literary)*, zaduma *reverie*, zapomnienie *forgetting*, nuda *ennui*, tajemnica *secret*, otchłań *abyss*, furkot *whirr*, skupienie *concentration*, cyngiel *trigger*, głusza *wilderness*, jasność *brilliance*}
- **committee 69**: {grota *grotto*, góra *mountain*, jaskinia *cave*, lodowiec *glacier*, masyw *massif*, rafa *reef*, skała *rock*, wzgórze *hill*}
- **LU group**: {góra, skała, wzgórze, jaskinia, masyw, pagórek *hillock*, grota, wzniesienie *elevation*, skałka *small rock*, wydma *dune*, górka *small mountain*, płaskowyż *plateau*, podnóże *foothill*, lodowiec, wyspa *island*, wulkan *volcano*, pieczara *cave*, zbocze *slope*, ławica *shoal*}

Finally, an example of a polysemous committee and the LU group generated on this basis. The group clearly consists of two separate parts: animals and zodiac signs.

- **committee 11**: bestia *beast*, byk *bull*, lew *lion*, tygrys *tiger*
- **LU group**: {lew, byk, tygrys, bestia, wodnik *aquarius*, koziorożec *capricorn*, niedźwiedź *bear*, smok *dragon*, skorpion *scorpio*, nosorożec *rhinoceros*, bliźnię *twin*, lampart *leopard*, bawół *buffalo*}

The last examples clearly show the role of the committee in defining the main semantic axis of the LU group. Two general LUs but semantically different occurring in the same committee makes it ambiguous between at least two senses. Such a committee results in inconsistent LU groups created on its basis. Thus the initial selection of committees is crucial for the quality of the whole algorithm, and the CBC quality depends directly on the MSR applied.

### B. Evaluating by a Synonymy Test

The estimation of synset similarity is not reliable without synset probabilities, at least as the basis of a reimplementation of the evaluation proposed in [3], [2]. We have therefore constructed an additional measure of the accuracy of clustering. We assumed that proper clustering should be able to clear the MSR from accidental or remote associations. That is to say, if two words belong to the same word group, it is a strong evidence of their being near-synonyms or at least being closely related in the hypernymy structure.

In WordNet-Based Synonymy Test (WBST) [10], [11], for each LU $q$ we create a set of four possible answers $A$ in such a way that only one $p \in A$ belongs to the same synset as $q$. The three detractors are selected randomly but do not belong to any synset either of $q$ or $p$. Next, we evaluate the accuracy of choosing $p$ among $A$ on the basis of MSR: we automatically select $max_{a \in A} MSR(q, a)$. In the evaluation of clustering on the basis of WBST we use sequentially two criteria in answering a single WBST question. The results of clustering is the primary criterion, and the MSR is secondary. Here is the algorithm of selecting the answer for a pair $\langle q, A\rangle$:

1) if there is only one $a$ such that $a$ belongs to a LU group of $q$, return $a$
2) if there is a subset $W_A \subseteq A$ whose every element is in one word group with $q$ (not necessarily the same one), for each $a \in W_A$:
   a) calculate the rank position of $rank(a, q)$ in a LU group of $q$ on the basis of similarity to the committee
   b) select subset $W_H R \subseteq W_A$ of elements with the highest rank
   c) if $|W_H R| > 1$, return $max_{a \in W_H R} MSR(a, q)$
3) return $max_{a \in A} MSR(a, q)$

If more possible answers belong to one of the LU groups of $a$, we need to compare them. Each element of a LU group has some similarity to this group's committee, but the similarity values depend on the size of the committee. Committees are represented by centroids calculated from feature vectors of the members. With more members the number of non-zero features increases, and the average values for most features are smaller, so the resulting values of the similarity to the elements of the word group are lower. Instead of the exact similarity values, we arrange all LU group elements in the linear order of their similarity. The resulting ranks are next used in step 2a to compare different possible answers.

If the results of clustering do not give enough evidence to select the answer, we select the answer on the basis of the MSR alone.

We generated 2726 WBST questions from *plWordNet*. The RWF MSR applied alone to solving the test gave 90.97% accuracy (2480 correct and 246 incorrect answers).

TABLE II
ACCURACY IN WBST TEST. SIZE$_{CBC}$ EXPRESSES % OF RESPONSES GIVEN BY CBC.

| | Acc. [%] | Acc., CBC only[%] | CBC q. | Size$_{CBC}$[%] |
|---|---|---|---|---|
| UPGMA | 90.61 | 93.94 | 495 | 18 |
| i1 | 90.68 | 94.30 | 491 | 18 |
| i2 | 90.54 | 94.32 | 493 | 18 |
| h1 | 89.62 | 85.89 | 319 | 12 |
| slink | 90.35 | 93.13 | 466 | 17 |
| wclink | 90.28 | 93.50 | 523 | 19 |

The application of the combined algorithm based on CBC and RWF MSR achieved the accuracy of 90.68% (see Table II). The result of CBC-based algorithm is only slightly worse, but the conclusion is that CBC clustering did not bring any improvement to RWF MSR in its ability to distinguish between a near-synonym and non-related LUs.

In the next experiment we applied RWF MSR and the CBC-based algorithm to solving a (much more difficult) Enhanced WBST (EWBST) proposed in [11]. In EWBST wrong answers are randomly selected from LUs which are *similar* to the proper answer. The similarity is defined on the basis of a wordnet, *plWordNet* in our case. RWF MSR scores 55.52% in EWBST. The result of CBC-based algorithm is significantly lower in EWBST than the result of RWF MSR alone. LU groups generated by CBC include too many loosely related LUs. Assigning a LU to a LU group depends on the similarity to the committee vector and the implicit threshold $\theta_{ElCom}$. Both MSRs generated on our corpus using morphosyntactic constraints can have different levels of values for different lists of the most semantically related LUs. This complicates setting the value of $\theta_{ElCom}$ and generating more consistent word groups.

The results of the evaluation by synonymy test are consistent with the results in IV-A and reveal the source of low precision: loosely related LUs are too often grouped in the same groups. The achieved results of CBC evaluation are in contrast with the better score of RWF MSR alone.

## V. IDENTIFYING SUBSEQUENT SENSES

CBC can assign a LU $w$ to several LU groups, because $w$ can be similar to several committee centroids. It is assumed that the representation of different senses can depend on different features. In order to emphasise the representation of subsequent senses in the vector of $w$, some the features overlapping with the committee centroid $v_c$ are removed from the vector of $w$ in step 2c. We found this technique too radical. We performed a manual inspection of data collected in a co-occurrence matrix. We concluded that it is hard to expect any group of features to encode some sense unambiguously. Moreover, some features have low, accidental values, while some are very high. Finally, vector similarity is influenced by the whole vector, especially when we analyse the absolute values of similarity by comparing it to a threshold, e.g. $\sigma$ in step 2b of CBC.

TABLE III
ACCURACY IN EWBST TEST. SIZE$_{CBC}$ EXPRESSES % OF RESPONSES GIVEN BY CBC.

| | Acc. [%] | Acc., CBC only[%] | CBC q. | Size$_{CBC}$[%] |
|---|---|---|---|---|
| UPGMA | 54.47 | 59.81 | 642 | 24 |
| i1 | 54.55 | 60.82 | 684 | 25 |
| i2 | 54.80 | 62.42 | 660 | 24 |
| h1 | 54.43 | 49.08 | 379 | 14 |
| slink | 54.47 | 60.60 | 637 | 23 |
| wclink | 54.40 | 56.07 | 601 | 22 |

Assuming that a group of features and some part of their ‘strength’ are associated with a sense just recorded, we wanted to look for an estimation of the extent to which feature values should be reduced. The best option seems to be the extraction of some association of features with senses, but for that we need an independent source of knowledge for grouping features, as it was done in [9]. Unfortunately, it is not possible in the case of a language with limited resources like Polish. Instead, we tested two simple heuristics ($w(f_i)$ is the value of the $f_i$ feature, $v_c(f_i)$ – the value of $f_i$ in the committee centroid):

- minimal value – $w(f_i) = w(f_i) - min(w(f_i), v_c(f_i))$,
- the ratio of committee importance – $w(f_i) = w(f_i) - w(f_i)\frac{v_c(f_i)}{\sum v_c(\bullet)}$.

In the minimal value heuristics we make quite a strong assumption that a feature is associated only with one sense on one of the sides: LU and committee. The lower value identifies the right side. The ratio heuristics is based on a weaker assumption: the feature corresponds to the committee description only to some extent.

The application of both heuristics was tested experimentally. We used the settings that resulted in the best precision in Table I, namely RWF MSR, i2 used for initial clustering and the original technique of removing features. The minimal-value heuristics increased the precision from 38.8% to 41% on 695 words clustered. The usage of the ratio heuristic improves the result even further – the precision rises to 42.5% on 701 words clustered. A manual inspection of the results showed that the algorithm tends to produce too many overlapping senses while using the ratio heuristic.

## VI. Conclusions and Further Research

Several explicit and implicit thresholds defined in the algorithm make the re-implementation of CBC difficult. Moreover, most of the thresholds seem to depend on the MSR used and, unfortunately, on the corpus. Any optimisation method would be difficult to apply because of the complexity of the whole CBC process. One full iteration takes 5-7 hours on a PC 2.13 GHz and 6 GB RAM (excluding the initial collection of feature frequencies from the corpus). A method that associates the thresholds with some properties of the corpus or MSR would be necessary. We plan to investigate the ways in which at least a subset of thresholds could be derived from the properties of the used MSR and statistical properties of corpora used for the construction of the MSR.

Our experiments on the application of various clustering algorithms to committee extraction shows the dependency of the whole CBC on this initial step. Moreover, committees often express more than one sense. That results in inconsistent LU groups. Once created, a committee is not verified or amended during the subsequent steps of the algorithm. It would be hard, but some method of committee splitting or verifying could improve the consistency of groups.

The achieved precision is much lower than reported in [2], [3] but quite comparable to that reported for a re-implementation of CBC for English done in [9]. Thus, instead of limited resources for Polish, e.g. lack of a dependency parser and typological differences of Polish in relation to English, we were successful in transferring the method. The achieved accuracy shows the limitations of CBC.

The selection of committees in Phase II is restricted to one committee per a list of related LUs. However, such a list can represent more than one sense in the case of a polysemous LU for which the list was generated.

Infrequent words in the corpus are a serious problem, because they generate high values of MSR with other infrequent words. Committees generated for such words negatively bias the whole CBC algorithm. We achieved better results when we constructed committees only from words that are frequent in the corpus, e.g. $\geq 1000$ occurrences.

The original solution of feature removal when assigning LUs to LU groups seemed to be too simplistic. We considered two simple heuristics of decreasing feature value in extent related to the potential feature correspondence to the sense represented by the committee. Both heuristics resulted in the improvement of the precision of word sense extraction. We will investigate this issue further.

Most senses and LU groups generated by CBC are helpful but of too low accuracy to be a tool willingly used by a fastidious linguist who works on extending a wordnet.

We have identified several key elements in CBC that decide about its accuracy: applied MRS, clustering algorithm used for the identification of committees, identification of feature-sense association together with the algorithm of extraction of subsequent senses from LU description and finally the problem of optimisation of the numerous threshold values. Except the last point, we proposed some solutions to all elements but, while we achieved improvement in all of them, all of them seem to be still open research questions.

***Abstract*—This paper presents an immune-based approach to problem of binary classification and novelty detection in high-dimensional datasets. It is inspired by the negative selection mechanism, which discriminates between self and nonself elements using only partial information. Our approach incorporates two types of detectors: binary and real-valued. Relatively short binary receptors are used for primary detection, while the real valued detectors are used to resolve eventual doubts. Such a hybrid solution is much more economical in comparison with "pure" approaches. The binary detectors are more faster than real-valued ones, what allows minimize computationally and timely complex operations on real values. Additionally, regardless of type of encoding, the process of sample's censoring is conducted with relatively small part of its attributes.**

## I. Introduction

NATURAL Immune System (NIS) prevents organism against intruders called *pathogens*. It consists of a number of cells, tissues, and organs that work together to protect the body. The main agents responsible for the adaptive and learning capabilities of the NIS are white blood cells called lymphocytes and produced by the thymus, spleen and bone marrow.

There are two kinds of lymphocytes: B- and T-lymphocytes called also B- and T-cells for brevity. Lymphocytes start out in the bone marrow and either stay there and mature into B-cells (this process is called *affinity maturation*), or they leave for the thymus gland, where they mature into T-cells. Both the types of lymphocytes have separate jobs to do: T-lymphocytes are like the body's military intelligence system, seeking out their targets and sending defences to lock onto them. B-cells are like the soldiers, destroying the invaders that the intelligence system has identified. It is obvious, that lymphocytes have to tolerate own cells of the organism; otherwise the organism could be self-destroyed.

To better imagine, how difficult and complex is the task of proper classification of different cells and microorganisms, we can mention that the total number of various types of pathogens is far greater then $10^{16}$, whereas there are "only" about $10^6$ own cells types. Despite of such huge diversity of infectious organisms, we require, that efficiency of immune systems has to be at the very high level as every intrusion can case disease or even can lead to die. Moreover, what is a characteristic feature of NIS, T-lymphocytes are "learned" only on the own cells, without any examples of pathogens. It means, that even never seen intruders can be properly recognized as they are different from own cells. This process called *negative selection* is only a small part of complex learning process performed by NIS. A reader interested in detailed description of immune system is referred to e.g. [12], [18].

Mentioned features of NIS are very desirable in many domains such as: intrusion detection systems (IDS), computer viruses detection, novelty detection and other binary classification purposes. Especially, a defending of computer networks against various types of attackers seems to be a natural application domain for immune based algorithms as there is a relatively easy to find out similarities between them. Both systems should effectively, with very high efficiency, recognize undesirable objects (binary classification) which constantly harass them. The huge diversity of intruders, additionally described by significant (from the computational complexity point of view) number of various types of attributes (labels, real and integer values, etc.), makes this problems relatively difficult to solve.

The approach presented in this paper was designed mainly for high-dimensional datasets. It is an effect of many experiments performed with the use of various types of detectors [9], [10], [4] and various affinity measures [3]. At the cost of lengthen learning stage (what is not crucial from e.g. IDS point of view), there is possible to increase the efficiency and significantly speed up the classification process.

This paper is organized as follows. Section II presents current state in this domain. Section III presents the proposed approach to classifying the high-dimensional datasets. Conducted experiments and its results are described in Section IV. Section V concludes the results and discusses a possibility of application of presented approach for other domains.

## II. Background

### A. Negative Selection

The *negative selection* algorithm, proposed by Forrest et. al, [6], is inspired by the process of thymocytes, i.e. young T-lymphocytes, maturation. It is designed to discriminate between own cells (called *self*) and others (called *nonself*).

978-83-60810-14-9/08/$25.00 © 2008 IEEE

To be more formal, denote $U$ the problem space, or Universe of discourse and let $S \subset U$ be a subset of elements (e.g. measurements represented as binary strings or real-values) representing typical behavior of a system under considerations (*self*). Then the set of elements characterizing anomalous behaviour, $N$ can be viewed as the set-theoretical complement of $S$ (*nonself*):

$$N = U \backslash S \tag{1}$$

The negative selection algorithm relies upon generation of so-called *detectors*, or *receptors*, being a counterpart of T-lymphocytes, in such a way, that a freshly generated detector $d$ is added to the set $D$ of valid detectors only if it does not recognize any self element. In the simplest case the detectors are generated randomly, but smart techniques are requested in general [6].

To mimic the process of self/nonself recognition we must designate an affinity measure, $match(d, u)$, specifying the degree with which a detector $d$ bonds a given element $u$, see e.g. [18] for details. Usually, $match(d, u)$ is modeled by a distance metric or a similarity measure [7]. Majority of detection rules induce so-called *holes* ($H$), i.e. regions of $N$ which are not covered by any detector and therefore samples from this region will be classified as self.

In real-life applications, it is not possible to gather all elements of $S$, because typically only its subset is observed. Therefore, it is assumed, that $S$ is composed of $S_{seen}$ and $S_{unseen}$

$$S = S_{seen} \cup S_{unseen}, \tag{2}$$

and only $S_{seen}$ is taken into the training phase (i.e. the phase of detector's generation). As a result, the detectors from the set $D$ can recognize not only nonselfs from $N' \subset N$, but also some elements from $S_{unseen}$ and it can result in wrong classification of not seen self samples.

In Fig. 1, there are presented possible combination of $S$, $N$ and $H$ regions. In Fig. 1(a) there is no holes as the self samples fully covers a space $S$ and a detectors fully covers $N$ region. This is only theoretical situation, not met in real applications. The desirable situation is in Fig. 1(b); detectors not covers $S_{unseen}$ region. In this case, holes plays an important role as they are *"necessary to generalize beyond the training set"* (Stibor [15]). Problems of overfitting and underfitting are showed in Fig. 1(c) and Fig. 1(d), respectively. In both cases, a detectors covers either too much or too low of space, what leads to decreasing the accuracy of negative selection algorithms.

### B. Optimal repertoire of detectors

In negative selection, the time complexity of classification as well as space complexity is relevant to the number of generated detectors. Every censored sample, in pessimistic case, have to be matched with all detectors from $D$. Thus, to decrease the complexity of classification process, it is desired, to generate minimal number of detectors covering a maximal part of $N$. A perfect set of detectors should cover themselves in minimal way and then each of them can be able to recognize different subsets of $N$ (optimal repertoire of detectors).

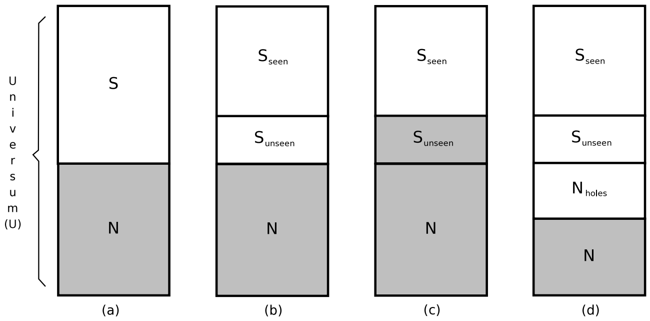

Fig. 1. Examples of possible combination of Self($S$), Nonself($N$) subsets, holes and regions covered by detectors (greyed regions).

This problem is especially important in on-line systems where huge dataset have to be classified without significant delays (i.e. IDS, virus detection, etc.).

### C. Representing samples

To model the interactions (matching) between self and nonself samples we need three elements:

- proper samples encoding,
- appropriate affinity function (matching rule), and
- appropriate algorithm enabling generation of the receptors.

The choice of appropriate representation for samples gathered in the datasets seems to be a key issue. Typically, most of the samples are encoded as vectors of real-valued numbers. Unfortunately, this type of representation can involve the use of many time consuming operations (like multiplication and division), e.g. when classification process have to compute a distance between two samples to measure the degree of similarity between them. Therefore, in the case of huge dataset containing tens of attributes, the choice of this type of representation seems to be far from optimal, especially when the time of classification is crucial.

Since there, two types of samples representation were regarded in negative selection algorithms: binary and real-valued.

*1) Binary representation:* Primary, this type of representation was applied by Forrest et al. [5] to capture anomaly sequences of system calls in UNIX systems and next to model the system for monitoring TCP SYN packets to detect network traffic anomalies (called LISYS) [8].

In case of binary encoding, we identify the Universe with $l$-dimensional Hamming space, $\mathbb{H}^l$ consisting of the binary strings of fixed length $l$:

$$\mathbb{H}^l = \{\underbrace{000...000}_{l}, \underbrace{000...001}_{l}, \ldots, \underbrace{111...111}_{l}\}$$

Hence the size of this space is $2^l$. The most popular matching rules used in this case are:

(a) $r$-contiguous bit rule [11], or
(b) $r$-chunks [2].

Both the rules say that a detector bonds a sample only when both the strings contain the same substring of length $r$. To detect a sample in case (a), a window (part of detector) of length $r$ ($0 \leq r \leq l$) is slided through censored samples of length $l$. In case (b) the detector specifies substring and its position within a string. In both the cases nonself samples are recognized based only on partial information.

Below an example of matching ($r$-contiguous rule) a sample by a detector for affinity threshold $r = 3$ is given:

$$\begin{array}{ll} \overbrace{1\;0\;\mathbf{0}\;\mathbf{0}\;\mathbf{1}\;1\;1\;0}^{l} & \text{sample} \\ 0\;1\;\underbrace{\underline{\mathbf{0}\;\mathbf{0}\;\mathbf{1}}}_{r}\;0\;0\;1 & \text{detector} \end{array}$$

It is obvious, from optimal repertoire point of view (see Section II-B), that shortest detectors are more desirable as they are able to detect more samples. However, Stibor [16] showed the coherence between $r$ and $l$ values for various $|S|$, in the context of the probability of generating detectors. He distinguished three phases:

- Phase 1 (for lowest $r$) – the probability is very near to 0,
- Phase 2 (for middle $r$) – the probability rapidly increase from 0 to 1 (so called *Phase Transition Region*),
- Phase 3 (for highest $r$) – the probability is very near to 1.

Hence, we should be interested in generating receptors with medium length $r$ (belonging to second region) and eventually with larger values of $r$ if coverage of $N$ is not sufficient. It is worth to emphasize, that detectors can not be too long, due to exponential increase in the duration of learning process, which should be finished in reasonable time.

Hofmeyr in [8] developed immune-based IDS, called LISYS, using binary representation and $r$-contiguous rule as a matching function. Detectors, were randomly generated and each network TCP SYN packet was encoded as a binary string of length 49 (32-bits external IP address, 8-bits local address, 8-bits type of service and 1 bit for indicating the server machine). However, he used only 4 attributes which, in the most cases, are not sufficient to detect intruders. For example, Snort [13], one of the most popular open source IDSs, involve the use several (or even tens) parameters at least, significantly lengthen the dimension of space $l$.

*2) Real-valued representation:* To overcome scaling problems inherent in Hamming space, Ji and Dasgupta [10] proposed real-valued negative selection algorithm, termed as *V-Detector*.

It operates on (normalized) vectors of real-valued attributes; each vector can be viewed as a point in the $d$-dimensional unit hypercube, $U = [0, 1]^d$. Each self sample, $s_i \in S$, is represented as a hypersphere centered at $c_i \in U$ and constant radius $r_s$, i.e. $s_i = (c_i, r_s)$, $i = 1, \ldots, l$, where $l$ is the number of self samples. Every point $u \in U$ which lies within any self hypersphere $s_i$ is considered as a self element. Also, detectors $d_j$ are represented as hyperspheres: $d_j = (c_j, r_j)$, $j = 1, \ldots, p$ where $p$ is the number of detectors. In contrast to self elements, the radius $r_j$ is not fixed but is computed as the Euclidean distance from a randomly chosen center $c_j$ to the nearest self element (this distance must be greater than $r_s$, otherwise detector is not created). Formally, we define $r_j$ as

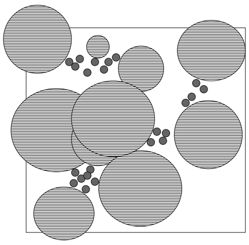

Fig. 2. Example of performance V-Detector algorithm for 2-dimensional problem. Grey circles denotes self samples, dashed circles denotes V-detectors, dashed area denotes detector which recognize all samples laying outside the space spanned over all self samples and white areas denotes holes.

$$r_j = \min_{1 \leq i \leq l} dist(c_j, c_i) - r_s \tag{3}$$

The algorithm terminates if predefined number $p_{max}$ of detectors is generated or the space $U \backslash S$ is sufficiently well covered by these detectors; the degree of coverage is measured by the parameter $co$ – see [10] for the algorithm and its parameters description.

In its original version, the V-Detector algorithm employs Euclidean distance to measure proximity between each two samples. Therefore, self samples and the detectors are hyperspheres (see Figure 2). Formally, Euclidean distance is a special case of Minkowski norm ($L_m$, where $m \geq 1$), which is defined as:

$$L_m(\mathrm{x}, \mathrm{y}) = \left( \sum_{i=1}^{d} |x_i - y_i|^m \right)^{\frac{1}{m}}, \tag{4}$$

where $\mathrm{x} = (x_1, x_2, \ldots, x_d)$ and $\mathrm{y} = (y_1, y_2, \ldots, y_d)$ are points in $\Re^d$. Particularly, $L_2$-norm is Euclidean distance, $L_1$-norm is Manhattan distance, and $L_\infty$ is Tchebyshev distance.

However, Aggarwal et. al [1] observed that $L_m$-norm loose its meaningfulness of proximity distance when the dimension $d$ and the values of $m$ increase. Thus, for example, Euclidean distance is the best (among $L_m$-norms) similarity metric when $d$ is about 5. For higher $d$, metrics with lowers $m$ (i.e. Manhattan distance) should be used.

Based on this observation, Aggarwal introduced *fractional distance metric* with $0 < m < 1$, arguing that such a choice is more appropriate for high-dimensional spaces. Experiments, reported in [3], partially confirmed efficiency of this proposition. For $1 < m < 0.5$, more samples were detected, in comparing to $L_2$ and $L_1$ norms. However, for $m < 0.5$ efficiency rapidly decreased and for $m = 0.2$, none samples were detected. Moreover, the same experiments showed also a trade-off between efficiency, time complexity and $m$. For fractional norms, the algorithm runs slower for lowers $m$;

duration of learning processes for $L_{0.5}$ were even 2-3 times longer than for $L_2$.

One of the additional consequence of applying fractional metrics for V-Detector algorithm is the change of the shape of detectors. Figure 3 presents the unit spheres for selected fractional $L_m$-norms in 2D.

## III. Proposed approach

In [4] we proposed to use the dual representation of samples. The main motivation was to reduce duration of classification process as well as to improve the detection rate, especially in the case of high-dimensional datasets. When we attain this goal, then immune algorithms will be even more attractive alternative to traditional, i.e. *not immune* approaches in many domains i.e. computer security, spam detection, etc.

For example, IDSs which can represent on-line classification systems, should be able to analyze all network connections, regardless of intensity network traffic. The large number of various parameters which should be taken into consideration and still increasing the number of signatures of potential attackers, requires the use of computers with higher and higher computational power. Thus, signatures of normal (legal) behavior, offered by *negative selection*, seems to be reasonable solution, especially, when more effective models and algorithms will be developed.

The scheme of dual receptors is presented in Figure 4. It involves generating both types of detectors. Binary detectors, plays only the role of preliminary detection and those samples which are not recognized by them are censored by V-Detector algorithm. Thus, we do not expect that binary receptors covers the space $N$ in very high degree, as it can takes too much time. More important aspect is its length. They should be relatively short (with high generalization degree) to detect in the possible shortest time as much as possible nonself samples and then the profits of this approach will increasing. The optimal length of binary detectors $r$ can be easily tuned. Usually, it is placed at the end of *phase transition region* (see Section II-C1). Then, both probability of detecting detectors as well as the corresponding to it coverage of $N$ space are sufficiently high.

To construct binary receptors, after normalization to unitary hypercube, self samples should be turned into binary representation. For every attribute $x$ ($x \in [0, 1]$) the quantization function $Q$ can be expressed as:

$$Q(x) = \lfloor M * x \rfloor, \tag{5}$$

where $\lfloor\cdot\rfloor$ is floor function and $M$ is the number of ranges (clusters). In our case, the optimal number of clusters is $M = 2^{bpa}$, for $bpa = \{1, 2, \ldots\}$ ($bpa$ - bits per attribute).

In [4] and [3] we conducted experiments on datasets containing about 30-40 attributes. For such dimensionality, Euclidean and Manhattan distance metrics provide too low detection rates, what was confirmed by performed experiments. As could be expected, fractional distances produced quite good results (about 70-80%), but we should keep in mind that, in comparison to $L_2$ and $L_1$ norms, they are much more computationally complex.

Unfortunately, there are many datasets which consist of 50 and more attributes (even up to 250), i.e. spam detection, handwritten recognition and even time series. In this case, probably none of known metrics is able to measure the similarity properly when the whole set of attributes is used. Thus, in this paper, we propose to incorporate the sliding window for both binary as well as real-valued detectors.

Let $w$ ($w \leq d$) be the window's length for real-valued detectors. Then, to censor a sample by only one detector, there is a need to calculate $d - w + 1$ distances (instead of 1 in original case), in the pessimistic case. Hence, for example, if $d = 100$, $w = 20$ and $|D| = 1000$, even about $81000$ such operation can be needed to determine, if a sample belong to set $S$ or $N$. Similarly, process of detector's maturation, which depends on $d$, $w$ and $S$, will be also much more durable. Thus, especially for very high-dimensional datasets, binary receptors plays very important role in proposed model.

## IV. Experiments and Results

This section presents only a small part of conducted experiments with most valuable results. Several datasets (presented in I) from Machine Learning Repository and Keogh's were used. For all dataset relatively shorts binary receptors were generated with lengths $l = \{5, 7, 10, 12, 15, 17\}$

For all datasets, relatively shorts binary receptors were generated with lengths $r = \{5, 7, 10, 12, 15, 17\}$ and $bpa = \{1, 2, 3\}$ to examine its usefulness in our model. Selected results are presented in Table II.

One can see, that binary detectors allow to at least 30-40% detection of nonself samples. Moreover, for properly tuned values $r$ and $bpa$, its efficiency increases even up to 80-100%

TABLE I
BRIEF DESCRIPTION OF USED DATASETS.

| Madelon | 1 | 10 | 50 | 2.50 |
| | | 12 | 834 | 16.10 |
| | | 15 | 18530 | 68.60 |
| | | 17 | 100012 | 95.50 |
| Leaf | 1 | 5 | 10 | 21.27 |
| | | 7 | 94 | 55.85 |
| | | 10 | 974 | 75.00 |
| | | 15 | 32620 | 79.25 |
| | 2 | 7 | 75 | 90.95 |
| | | 10 | 875 | 96.80 |
| | | 15 | 32355 | 98.93 |
| | 3 | 12 | 3540 | 100.00 |
| CBF_B | 1 | 12 | 259 | 34.26 |
| | | 15 | 18804 | 54.28 |
| | | 17 | 109255 | 58.22 |
| | 2 | 12 | 2754 | 72.26 |
| | | 15 | 29078 | 81.84 |
| | | 17 | 124673 | 88.98 |
| KDD_ICMP | 1 | 12 | 259 | 34.26 |
| | | 15 | 32536 | 42.02 |

for almost all tested datasets. Thus, one can expected, that such results, should significantly lighten the real-valued detectors.

Next, there was investigated the possibility of applying real-valued receptors for testing datasets. V-Detector algorithm was executed with the following parameters (like in all the experiments described in this section):

- window's length $w = \{5, 10, 15, 20, 25, 30\}$,
- distance norms: $L_2$, $L_1$, $L_{0.7}$, $L_{0.5}$,
- detector's radius $d_r = 0.001$,
- estimated coverage $co = 99.99\%$,
- all self samples were used in learning stage to generate receptors. In consqequence, false positives (number of incorrectly classified self samples) is equal 0 in all cases.

Figures 5 and 6 shows the detection rates for Spambase and Madelon datasets, respectively. It is worth to emphasize, that in our case, detection rates denotes only the number of correctly recognized nonself samples, without correctly classified all selfs. Thus, is difficult to compare obtained results with other approaches, which incorporate all types of samples in at the learning stage.

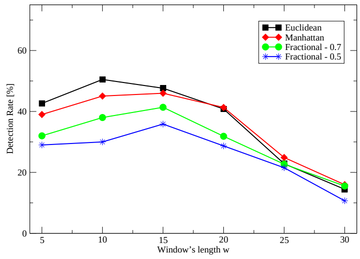

Fig. 5. Spambase. Detection rates for V-Detector algorithm.

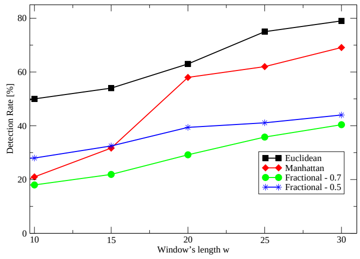

Fig. 6. Madelon. Detection rates for V-Detector algorithm.

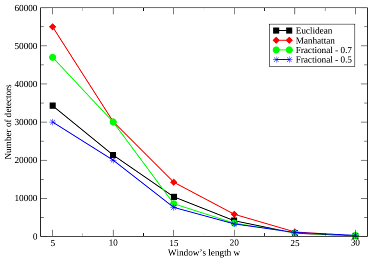

Fig. 7. Spambase. Number of detectors generated by V-Detector algorithm.

Moreover, one can see, for Spambase dataset Euclidean distance gives an optimal results when $w = 10$; for other, considered in this paper similarity metrics, higher efficiency is observed for $w = 15$. It is consistent with presented theoretical reflections [1] and experimental results [3]. On the other hand, for Madelon dataset, detection increase with $w$ (up to 80%).

The duration of classification process, in the case of V-Detector algorithm is proportional to the cardinality of receptor's set. Also, in this case, obtained results are different for presented datasets. For Spambase, number of detectors decreases when $w$ increase. However, for Madelon dataset, we can observe, that for $w = 15$ number of receptors is lowest. In contrast to Spambase, it does not decreases for high $w$ values, what results in very high detection rates.

Finally, the best combinations of parameters for both types of detectors were chosen to achieve the most optimal solutions for our model, considered in this paper. Table III presents the most valuable results. For most testing datasets results are satisfactory. Only for Spambase, detection of *nonself* samples is only slightly higher than 60%.

## V. CONCLUSION

The model presented in this paper base on the negative selection mechanism, developed within domain of Artificial

Immune Systems. It is designed for high-dimensional datasets, which are very difficult to classify, due to the lack of appropriate similarity metrics. Sliding window method applied for both types of detectors can be viewed as the one of the possibility to overcome the scaling problem. However, although the detection rates where quite satisfactory, duration of learning as well as classifying processes leave a lot to be desired. Fortunately, significant (and in some cases almost all) part of nonself samples can be relatively quickly detected by binary receptors, which are the power of this model.

Generally, applying only one type of receptors is not able to guarantee the sufficient coverage of nonself space $N$ in reasonable time, especially, when dataset contains a thousands and more samples. Moreover, even slight increase in one of the following set of parameters: $d$, $w$ and $|S|$, significantly influence on the performance of applied algorithms.

Obtained results are very preliminary and should be confirmed with other datasets in the future, regardless of its applications. Moreover, in our opinion, presented model can be, almost directly, applied to detect the various types of anomalies in time series. And it should be a direction of our future investigations.

## ACKNOWLEDGMENT

This work was partly supported by Technical University of Bialystok grant W/WI/1/08.

Experiments were performed on a compute cluster at Faculty of Computer Science, Technical University of Bialystok.

*Abstract*—**Data cleaning is a process of maintaining data quality in information systems. Current data cleaning solutions require reference data to identify incorrect or duplicate entries. This article proposes usage of data mining in the area of data cleaning as effective in discovering reference data and validation rules from the data itself. Two algorithms designed by the author for data attribute correction have been presented. Both algorithms utilize data mining methods. Experimental results show that both algorithms can effectively clean text attributes without external reference data.**

## I. Introduction

NOWADAYS , information is the most important asset of the majority of companies. Well-maintained information systems allow the company to make successful business decisions. On the other hand, if the information is incomplete or contains errors, it may lead the company to financial loss due to incorrect strategic or tactical decisions.

The purpose of this article is to present current situation in the area of data cleaning and discuss possibilities of application data mining methods in it. The structure of this article is following: first chapter focuses on the area of data quality and data cleaning and presents a categorization of data quality issues. In its last section related work and research in this area is briefly presented. The second chapter of this article contains a discussion of possible applications of data mining methods in the area of data cleaning. The core of this chapter is the presentation of two heuristic data cleaning algorithms designed by the author that utilize a data mining approach. This chapter also contains the results of the experiments performed using the algorithms and a discussion of possible improvements.

### *A.* Data Quality and Data Cleaning

As information is defined as data and method for its interpretation, it is only as good as the underlying data. Therefore, it is essential to maintain data quality. High quality data means that it is “fit for use”[11] and good enough to satisfy a particular business application. The following data quality measures allow one to quantify the degree to which the data is of high quality, namely:

- completeness: all the required attributes for the data record are provided,
- validity: all the record attributes have values from the predefined domain,
- consistency: the record attributes do not contradict one another; e.g. the ZIP code attribute should be within the range of ZIP codes for a given city,
- timeliness: the record should describe the most up-to-date state of the real-world object it refers to. Moreover, the information about an object should be updated as soon as the state of the real world object changes,
- accuracy: the record accurately describes the real world object it refers to; all the important features of the object should be precisely and correctly described with the attributes of the data record,
- relevancy: the database should contain only the information about the object that are necessary for the purpose they were gathered for,
- accessibility and interpretability: the metadata describing the sources of the data in the database and transformations definitions it has undergone should be available immediately when it is needed.

In most cases it is almost impossible to have only “clean” and high-quality data entered into the information system. According to the research report of The Data Warehousing Institute (TDWI), “25% of critical data within Fortune 1000 companies will continue to be inaccurate through 2007. Poor quality customer data costs U.S. business an estimated $611 billion dollars a year in postage, printing, and staff overhead” [2].

Data cleaning, also known as data cleansing and data scrubbing, is the process of maintaining the quality of data. The data cleaning solution should involve discovering erroneous data records, correcting data and duplicate matching.

Data cleaning has two main applications: Master Data Management[10][12] solutions and data warehouses [10] [11], but is also often used in transactional systems.

### *B.* Data Quality Problems

According to [14], data quality issues may be divided into two main categories: issues regarding data coming from one source and issues regarding data from multiple sources. Both main categories may be further divided into subcategories: data quality issues on the instance and on the record level.

#### *1)* One data source – schema level issues

This type of data issues is caused in most cases by source database design flaws. If the source table does not have a primary key constraint that uses a unique record identifier,

978-83-60810-14-9/08/$25.00 © 2008 IEEE

we may have two records referring to separate real world objects bearing the same identifier. If a domain check constraint is missing, a column may contain values outside a specified range, e.g. more than two values describing sex. If a not-null constraint does not exist, a record may lack a value for a mandatory attribute.

If a source schema does not have reference constraint, we may have records in one table referencing non-existent records in another table.

#### *2)* One data source – record level issues

This type of issues is related to the errors that occur at the point of data entry into the source system. Typical errors involve:

- misspellings – caused either by OCR imperfections, e.g. ‘1’ (digit one) may be replaced with ‘l’ (lower case L), typos, or phonetic errors,
- default values for mandatory attributes,
- inconsistencies (e.g. incorrect ZIP code for a city),
- misfielded values, i.e. correct values but placed in wrong attributes, e.g. country=”Warsaw”,
- duplicate records: more than one record referring the same real world object.

#### *3)* Multiple data sources – schema level issues

Multiple source schema level errors are caused by different data models in each of the source systems. For example, there may be homonyms or synonyms at the attribute level (attributes with the same name, but different meaning or attributes with different names but the same meaning), different levels of normalization, different constraints, or different data types.

#### *4)* Multiple data sources – record level issues

This kind of data quality issues is the cross-product of all the aforementioned issues. In addition, there may be other problems:

- different units of measure for the same attribute (meters vs. inches, $ vs. €, etc.),
- Different constraints/domains; e.g. `Sex= {M, F}` ; `Sex= {0, 1}` , etc.,
- Different levels of aggregation: daily vs. weekly, monthly vs. annually,
- Duplicate records - the same object from the real world may have different representations in different source systems.

### *C.* Data cleaning areas and related work

The following primary areas of data cleaning may be distinguished, namely:

- Duplicate matching: in case of integrating multiple sources it may happen that one or more sources contain records denoting the same real world object. The records may have various degrees of data quality. Therefore, one of the tasks of the data cleaning solution is to identify duplicates and join them into a single record whose data quality would be high. This problem is known as “merge/purge” or record linkage problem. Duplicate matching is also used to discover duplicates on the higher level, e.g. records of people that share the same address. This problem is known as household detection [14]. The research in this area (e.g., [3][14] [15][18] ) is focused on devising methods that are both effective, i.e. result in high number of correct matches and low number of incorrect matches, and efficient, i.e. performing within the time constraints defined in the system requirements.
- Data standardization and correction: in case of different domains used in different source systems the data cleaning solution should transform all the values used in those system into one correct set of values used in the target system. Moreover, if any incorrect values appear, the role of the data cleaning is to identify those values and alter them. Works that concern this issue use various methods ranging from statistical data cleaning[8] to machine learning[4][12].
- Schema translation: as source systems may utilize different data models, the task of data cleaning solution is to provide a mapping from those data models to the target data model. This may require splitting free-form fields (e.g. “address line 1”) into an atomic attribute set (“street”,” home no”, “zip code”). The research in this field focuses on devising methods that are capable of performing this process automatically [6]

## II. Application of Data Mining Methods in Data Cleaning

All current data cleaning solutions are highly dependent on human input. The deliverable of the profiling phase - the first phase of a data quality assessment [13], is a set of metadata describing the source data which is then used as an input for the creation of data validation and transformation rules. However, the validation rules have to be confirmed or designed by a business user who is an expert in the business area being assessed. It is not always easy or straightforward to create such a set of business rules. The situation is very similar where duplicate matching is concerned. Even if business rules for record matching are provided, e.g. “Equal SS-N’s and dates of birth”, it may be impossible to match duplicate records, as any of the data quality issues may occur thus preventing from exact matching. Therefore, if incorrect SS-N’s or dates of birth stored in different positional systems occur, exact-matching business rules may not mark the records as duplicates. As far as attribute standardization and correction is concerned, data cleaning solutions are only as good as the reference data they use. Reference data is a set of values which are considered to be valid for a given attribute, e.g. list of states, countries,car models, etc.

The aim of research led by the author of this article was to examine if data mining methods may be used to solve tasks mentioned in the above paragraph. As data mining is the process of discovering previously unknown knowledge from data, it can be used to discover data validation rules and reference data directly from the data set. Table I contains possible application of data mining methods within the area of data cleaning..

The main focus of this article is attribute correction. Other data cleaning tasks are subject to further research. This article presents two applications of data mining techniques in the area of attribute correction: context-independent attribute correction implemented using clustering techniques and context-dependent attribute correction using associations. The next sections of this chapter present two algorithms created by the author that are supposed to examine the possibility of application of data mining techniques in data cleaning. Both algorithms are intended for use in the application of text-based address and personnel data cleaning.

### A. Context independent attribute correction

As mentioned in the previous section, attribute correction solutions require reference data in order to provide satisfying results. The algorithm described in this section is used to examine if a data set may be a source of reference data that could be used to identify incorrect entries and enable to correct them. The algorithm aims at correcting text attributes in address and personal data.

Context-independent attribute correction means that all the record attributes are examined and cleaned in isolation without regard to values of other attributes of a given record.

The key idea of the algorithm is based on an observation that in most data sets there is a certain number of values having a large number of occurrences within the data set and a very large number of attributes with a very low number of occurrences. Therefore, the most-representative values may be the source of reference data. The values with low number of occurrences are noise or misspelled instances of the reference data. Table II shows an excerpt from the distribution with values sorted alphabetically and then descending according to the number of occurrences. The attribute being examined comes from the sample data set used in this experiment and is derived from an Internet survey. As it may be noticed, there are many (6160) records that have the value “Warszawa” and very few that have a value that closely resembles “Warszawa”. Therefore, the value “Warszawa” is most likely the correct value of the attribute and should enter the reference data set while the remaining values are misspelled and should be corrected to “Warszawa”.

The aim of the algorithm is to create a reference data set and a set of substitution rules that could be used to correct misspelled values.

Table II .
Location attribute distribution

| Location | Number of occurrences |
|---|---|
| Warszawa | 6160 |
| Warszwa | 8 |
| Warszaw | 4 |
| Warsawa | 1 |
| Warszawaa | 1 |
| Warzawa | 1 |
| Warzsawa | 1 |

#### 1) Algorithm definition

The algorithm utilizes two data mining techniques: clustering and classification using the “k-nearest neighbours” method.

The algorithm has two parameters: distance threshold - *distThresh* being the minimum distance between two values allowing them to be marked as similar, and occurrence relation – *occRel*, used to determine whether both compared values belong to the reference data set. This parameter was introduced because it is possible that there are two values that may seem similar terms of the distance but that may represent two different objects of the real world that should create separate entries in the reference data set.

To measure the distance between two values a modified Levenshtein distance [5] was used. Levenshtein distance for

Table I.
Location attribute distribution

| | Clustering | Association rules | Classification |
|---|---|---|---|
| **Data standardization/attribute correction** | X | X | |
| **Duplicate matching** | X | | |
| **Validation rules generation** | | | X |
| **Outlier detection** | X | | |
| **Missing attribute prediction** | | X | X |

two strings is the number of text edit operations (insertion, deletion, exchange) needed to transform one string into another.

The algorithm for attribute correction described here utilizes a modified Levenshtein distance defined as

$$\hat{Lev}(s_{1,}s_2)=\frac{1}{2}\cdot(\frac{Lev(s_{1,}s_2)}{\|s_1\|}+\frac{Lev(s_{1,}s_2)}{\|s_2\|}) \quad (1)$$

where $Lev(s_1,s_2)$ denotes a Levenshtein distance between strings $s_1$ and $s_2$. The modified Levenshtein distance for two strings may be interpreted as an average fraction of one string that has to be modified to be transformed into the other. For instance, the Levenshtein distance between “Warszawa” and “Warzsawa” is 2, while the modified Levenshtein distance for “Warszawa” and “Warzsawa” is 0.25. The modification was introduced to be independent of the string length during the comparison.

The algorithm consists of following steps:

1. Preliminary cleaning – all attributes are transformed into upper case and all the non-alphanumeric characters are removed
2. The number of occurrences for all the values of the cleaned data set is calculated.
3. Each values is assigned to a separate cluster. The cluster element having the highest number of occurrences is denoted as the cluster representative.
4. The cluster list is sorted descending according to the number of occurrences for each cluster representative.
5. Starting with first cluster, each cluster is compared with the other clusters from the list in the order defined by the number of cluster representative occurrences. The distance between two clusters is defined as the modified Levenshtein distance between cluster representatives
6. If the distance is lower than the *distThresh* parameter and the ratio of occurrences of cluster representative is greater or equal the *occRel* parameter, the clusters are merged.
7. If all the clustered pairs are compared, the clusters are examined whether they contain values having distance between them and the cluster representative above the threshold value. If so, they are removed from the cluster and added to the cluster list as separate clusters.
8. Steps 4-7 are repeated until there are no changes in the cluster list i.e. no clusters are merged and no clusters are created.
9. The cluster representatives form the reference data set, and the clusters define transformation rules – for a given cluster cluster elements values should be replaced with the value of the cluster representative.

As far as the reference dictionary is concerned, it may happen that it will contain values where the number of occurrences is very small. These values may be marked as noise and trimmed in order to preserve the compactness of the dictionary.

*2) Results*

The algorithm was tested using a sample data set derived from an Internet survey. The data record is define as a tuple {*First Name*, *Last Name*, *Occupation*, *Location*}. There were about 30057 records divided into 6 batches of 5 thousand records. The attribute that was the source of the data for cleaning was “Location”. During review 1166 elements – 3.88% of the whole set, were identified as incorrect and hence subject to alteration.

Table III contains example transformation rules discovered during the execution of the algorithm

Table III.
Example transformation rules

| Original value | Correct value |
|---|---|
| Warszwa | Warszawa |
| Warszaw | Warszawa |
| Warsawa | Warszawa |
| Warzsawa | Warszawa |

In order to test the correctness of the algorithm, following measures are used:

- $p_c$ – percentage of correctly altered values
- $p_i$ – percentage of incorrectly altered values
- $p_0$ – percentage of values marked during the review as incorrect, but not altered during the cleaning process.

The measures are defined as

$$p_c=\frac{n_c}{n_a}\cdot 100$$
$$p_i=\frac{n_i}{n_a}\cdot 100 \quad (2)$$
$$p_0=\frac{n_{00}}{n_0}\cdot 100$$

where $n_c$ is the number of correctly altered values, $n_i$ the number of incorrectly altered values, $n_a$ the total number of altered values, $n_{00}$ the number of elements initially marked as incorrect that were not altered during the cleaning process and $n_0$ the number of values identified as incorrect.

Fig 1 and Table IV show the dependency between the *distThresh* threshold parameter and defined measures.

It can be observed that the percentage of values altered is growing with the increase of the *distThresh* parameter. It is caused by decreasing the restrictiveness of the algorithm in assigning values as similar. The percentage of correctly altered values reaches its highest values of 92.63% at 0.1, however, for that value of the parameter only about 7% of previously identified incorrect entries are corrected. The percentage of incorrectly altered values is also growing due to the greater tolerance for duplicate matching criteria. However, it is possible to define a value of the parameter to achieve the optimal ratio of the correctly altered values avoiding a large number of incorrect values. In the case of the data examined the optimal value of the attribute was 0.2 where 20% of incorrect entries were altered, 79.52% of which were altered correctly. What is still a subject to further experiments is the optimal value of the *occRel* parameter. Also the clustering method used here could be replaced by other clustering methods which could improve the number of correctly altered values, but might have negative influence on the cleaning execution time, as method used here does not require comparison between all the values from the cleaned data set.

The algorithms displays better performance for long strings as short strings would require higher value of the parameter to discover a correct reference value. However, as it was noted in the previous paragraphs, high values of the *distThresh* parameter results in larger number of incorrectly altered elements.

This method produces as 92% of correctly altered elements which is an acceptable value. The range of the applications of this method is limited to elements that can be standardized for which reference data may exist. Conversely, using this method for cleaning last names could end with a failure.

The major drawback of this method is that may classify as incorrect a value that is correct in context of other attributes of this record, but does not have enough occurrences within the cleaned data set.

Table IV.
Dependency between the measures and the *distThresh* parameter for context-independent algorithm

| **distThresh** | $p_c$ | $p_i$ | $p_0$ |
|---|---|---|---|
| 0 | 0.0 | 0.0 | 100.0 |
| 0.1 | 92.63 | 7.37 | 92.45 |
| 0.2 | 79.52 | 20.48 | 36.96 |
| 0.3 | 67.56 | 32.44 | 29.25 |
| 0.4 | 47.23 | 52.77 | 26.93 |
| 0.5 | 29.34 | 70.66 | 23.41 |
| 0.6 | 17.36 | 82.64 | 19.04 |
| 0.7 | 7.96 | 92.04 | 8.92 |
| 0.8 | 4.17 | 95.83 | 1.11 |
| 0.9 | 1.17 | 98.83 | 0.94 |
| 1.0 | 0.78 | 99.22 | 0 |

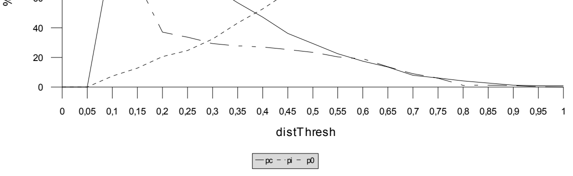

Fig 1: Dependency between the measures and the *distThresh* parameter for context-independent algorithm.

### B. *Context-dependent attribute correction*

The context-dependent attribute correction algorithm is the second of the algorithms designed by the author that utilizes data mining methods. Context-dependent means that attribute values are corrected with regard not only to the reference data value it is most similar to, but also takes into consideration values of other attributes within a given record. The idea of the algorithm is based on assumption that within the data itself there are relationships and correlations that can be used as validation checks. The algorithm generates association rules from the dataset and uses them as a source of validity constraints and reference data.

#### *1) Algorithm definition*

The algorithm uses association rules methodology to discover validation rules for the data set. To generate frequent itemsets the Apriori[17] algorithm is utilized.

The algorithm described in this chapter has two parameters *minSup* and *distThresh*. The first of the parameters - *minSup*, is defined analogically to the parameter of the same name for the Apriori algorithm used here. The other parameter – *distThresh*, is the minimum distance between the value of the "suspicious" attribute and the proposed value being a successor of a rule it violates in order to make a correction.

Although association rules algorithms normally have two parameters: *minSup* and *minConf*, i.e. minimal confidence for generated rules, the algorithm used here does not use the latter of the two. However, the algorithm can be modified to complete the missing attribute values. In such cases the *minConf* can be used to determine the minimal confidence the rule must have in order to fill in the missing value.

For calculating distances between textual attributes the modified Levenshtein distance described in previous section is used.

The algorithm has following steps:

1. Generate all the frequent sets, 2-sets, 3-sets and 4-sets.
2. Generate all the association rules from the sets generated in the previous step. The rules generated may have 1, 2, or 3 predecessors and only one successor. The association rules generated form the set of validation rules.
3. The algorithm discovers records whose attribute values are the predecessors of the rules generated with an attribute whose value is different from the successor of a given rule. These records are marked "suspicious".
4. The value of the attribute for a "suspicious" row is compared to all the successors of all the rules it violates. If the relative Levenshtein distance is lower than the distance threshold, the value may be corrected. If there are more values within the acceptable range of the parameter, a value most similar to the value of the record is chosen.

### 2) *Results*

The algorithm was run on a set of 287198 address records. The data records are tuples defined as `{street, location, zip code, county, state}`.

The rule-generation part of the algorithm was performed on the whole data set. The attribute correction part was performed on a random sample of the dataset consisting of 2851 records. During a review 399 attribute values were identified as incorrect for this set of records .

To verify the performance of the algorithm, measures $p_c$ – the percentage of correctly altered values, $p_i$ – the percentage of incorrectly altered values, and $p_0$ – the percentage of values not altered, as defined in previous section are used.

Table V and Fig 2 show the relationship between the measures and the *distThresh* parameter. The *minSup* parameter was arbitrarily set to 10.

Table V.
Dependency between *distThresh* parameters and measures for context dependent algorithm

| **distThresh** | $p_c$ | $p_i$ | $p_0$ |
|---|---|---|---|
| 0 | 0.00 | 0.00 | 100.00 |
| 0.1 | 90 | 10 | 73.68 |
| 0.2 | 68.24 | 31.76 | 46.62 |
| 0.3 | 31.7 | 68.3 | 36.09 |
| 0.4 | 17.26 | 82.74 | 33.83 |
| 0.5 | 11.84 | 88.16 | 31.33 |
| 0.6 | 10.2 | 89.8 | 31.08 |
| 0.7 | 9.38 | 90.62 | 30.33 |
| 0.8 | 8.6 | 91.4 | 28.82 |
| 0.9 | 8.18 | 91.82 | 27.32 |
| 1.0 | 7.77 | 92.23 | 17.79 |

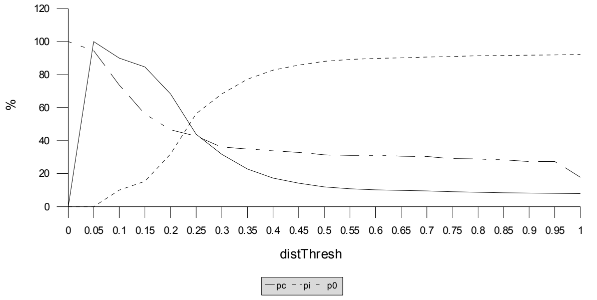

Fig 2: The dependency between the distThresh parameter and measures for context-dependent algorithm.

The results show that the number of values marked as incorrect and altered is growing with the increase of the *distThresh* parameter. Contrary to the same observation in case of context-independent cleaning, this number never reaches 100%. This proves that some attributes that may at first glance seem incorrect, are correct in the context of other attributes within the same record. The percentage of correctly marked entries reaches its peak for the *distThresh* parameter equal to 0.05. The result is better than in the case of context-independent cleaning as the number of correctly altered values for this value of the parameter is equal to the total number of altered values. This also proves that context-dependent cleaning algorithm performs better at identifying incorrect entries. The number of incorrectly altered values is growing with increase of the parameter. However, a value of the *distThresh* parameter can be identified that gives optimal results, i.e. the number of correctly altered values is high and the number of incorrectly altered values is low. In case of this experiment the value of the parameter is 0.15.

Some areas of improvement for this method may be identified. A possible change in the algorithm could involve adding one more parameter – the *minConf* for generated rules. This parameter has the same meaning as the *minConf* parameter of the Apriori algorithm. This would enable pruning the "improbable" rules and limit the number of incorrectly altered values. Also generating the rules using cleaned data would result in better algorithm performance.

## III. Conclusion

The results of the experiments verifying correctness of both algorithms for attribute correction prove that using data mining methods for data cleaning is an area that needs more attention and should be a subject of further research.

Data mining methodologies applied in the area of data cleaning may be useful in situations where no reference data is provided. In such cases this data can be inferred directly from the dataset.

Experimental results of both algorithms created by the author show that attribute correction is possible without an external reference data and can give good results. However, all of the methods described here definitely necessitate more research in order to raise the ratio of correctly identified and cleaned values. As it was discovered in the experiments, the effectiveness of a method depends strongly on its parameters. The optimal parameters discovered here may give optimal results only for the data examined and it is very likely that different data sets would need different values of the parameters to achieve a high ratio of correctly cleaned data.

The above experiments utilized only one string matching distance (Levenshtein distance) was used. It is possible that other functions could result in better output and this should be explored in future experiments.

Moreover, further research on application of other data mining techniques in the area of data cleaning is planned.

***Abstract*—Real-time execution of planned routes often requires re-planning, especially in dynamic, highly unpredictable environments. Ad-hoc re-planning in case of failure of an optimal (suboptimal) plan leads to deterioration of solution quality. Moreover, it becomes costly and often unmanageable under real time constraints. This paper describes an approach of a partitioning scheme for urban route planning problem domain into a hierarchy of subproblems and an algorithm for rule-based top-down route derivation. A hierarchical, rule-based approach is aimed at granular planning for generating robust, multi-variant plans.**

## I. Introduction

ROUTE planning became a classic problem of Artificial Intelligence [1]. Simultaneously, numerous practical planning algorithms were developed and the worked-out techniques found practical applications in complex, realistic domains. There is a very large group of problems which can be solved by an Artificial Intelligence planning techniques and the AI methods are explored in practice. Such problems include mobile robot route planning, production line scheduling, development of automated game playing strategies and, last but not least, vehicle route planning.

There have been developed a number of well-founded plan generation techniques, mostly based on graph-search procedures [2]. A recent handbook on planning provides a comprehensive review of the domain [3]. Practical applications became a part of everyday life [4], [5], [6], [7].

The route planning problem becomes especially nice and interesting results are obtained when the search takes place in regular, sparse graphs, and such a situation takes place during route planning for long distances with use of highways and motor-roads for most of the planned route. On the other hand, efficient planning in a large, congested city, under real time constraints and under highly unpredictable traffic conditions remains quite a challenge even for most sophisticated systems. In fact, even the problem statement should be different here with respect to the classics of planning a route incorporating mostly motorways and inter-city roads. The unpredictability of urban traffic conditions and the relatively dense road network are both factors intrinsic in the urban route planning and making it a difficult task. Modern planning systems often provide unreliable results for such class of hard planning problems, sometimes failing to provide them in time or do not provide them at all.

This paper describes an approach to planning based on combination of plan from components calculated a priori. A set of rules assigned to each such component provides a ready-to-use solution to be selected depending on external conditions and the aimed destination. Instead of a single, optimal plan, a bunch of similar, alternative plans is in use; when execution of one of them fails, another one is activated immediately. A partitioning scheme for urban route planning problem domain into a hierarchy of subproblems and an algorithm for rule-based top-down route derivation are outlined. A hierarchical, rule-based approach is aimed at granular planning for generating robust, multi-variant plans.

In our previous research, we focused on various aspects of urban route planning which can be improved by using methods of artificial intelligence. These include prediction of traffic conditions [8], induction of granularity over plan solutions [9] and adaptation of well-known computer network routing protocols to broadcast partial solutions between plan nodes [10], [11].

The decision to take up the rule-based hierarchical approach to solving urban route planning problems can be best justified by presenting the currently used methods for route planning, their shortcomings and research done to date regarding improvement of those methods.

### A. State of the art

Commercially available computer-based route planning systems date back to the 1980s. At the time, products such as AutoRoute had to cope with harsh limitations of computer resources. The vast development of processing power even in portable personal computers remedied that problem, but the search algorithms and optimality criteria remained mostly unchanged since that time.

Classical planning algorithms are based on informed graph-search methods, such as various modifications of the famous $A^*$ algorithm and its descendants (e.g. $IDA^*$) [1], [3]. The criteria for optimality used by such "classical" route planning methods are, in most cases, limited to:

- finding the shortest route (the so-called *shortest-path algorithms*,

- time-optimal solutions requiring finding the least time-consuming route (where the travel time is calculated using naive criteria based on the type of route, not taking the prevailing traffic conditions into account),
- finding the least expensive route (by adding estimated fuel consumption and road fees/taxes).

The above generic possibilities can be extended by requirement to go through some indicated middle-points, avoid some forbidden points, avoid left-turn, as well as other user preferences.

In general, the worked out planning methods, combined with the processing power of modern computers, are enough for most applications in long-distance route planning, especially when planning is performed *a priori* – before the travel begins. The search graph is usually relatively sparse, and binary congestion warning/road segment exclusion methods provide sufficient means of route customization.

### B. Shortcomings of classical planning methods

The planning process becomes more problematic complex task when the following conditions occur:

- the search domain becomes more dense, and hence the effective branching factor is too high for systematic planning; too many alternative plans are to be considered,
- more complex criteria have to be taken into account in the search process, especially ones influenced by unknown, unpredictable conditions,
- it is necessary to perform re-planning, due to a change of traffic conditions or driver disobedience,
- robustness of the plan becomes of primary importance, i.e. the user wants to have a *reliable* plan working under almost any conditions instead of an optimal one, but fallible under expected traffic conditions.

The aforementioned shortcomings become especially apparent in situations where planning has to be performed in real time, namely when the planning methods are used in real-time mobile navigation devices. Such devices often offer limited processing power, making algorithm efficiency even more crucial.

### C. Previous research

Efficient plan generation under heavy traffic conditions in complex urban environments has not deserved intensive study in the literature [3]. An approach based on pure graph-search methods seems to be of limited usability. A study of use of methods based on *case-based* approach was presented in [12].

Knowing that pre-computed solutions have to be calculated *a priori*, we focused on several methods providing a compromise between combinatorial explosion and calculation time.

Article [9] introduced a new approach to solving planning problems, based on the concept of maintaining a set of alternative solutions to allow quick plan switching without the need of re-planning. A new concept, called solution robustness, was introduced to allow non-standard optimality criteria. A robust solution is one that is unlikely to fail.

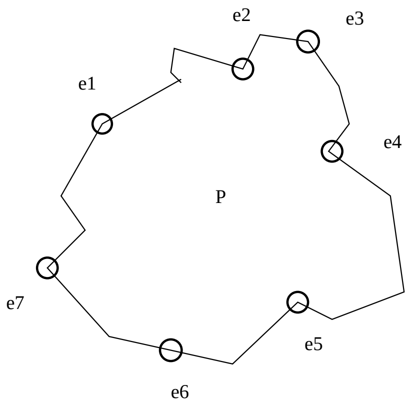

Fig. 1. A schematic presentation of a granule of the planning area with entries.

A different approach was presented in [10]. The concept, based on dynamic computer network routing protocols, is based on partial solution broadcasting between search domain nodes (usually representing junctions). Each node would maintain a “routing table”, providing the next node to be visited in order to reach a given destination node.

## II. Granular hierarchical planning: an intuitive outline of the approach

Since the proposed approach is quite different from the classical ones based on graphs search procedures, below we present an outline of basic ideas of knowledge representation and planning techniques in use.

First, let us point out to the principal assumptions forming foundations of the approach:

- excessive part of planning is performed off-line, a priori, prepared and stored in forms of rules ready-to-use on desire,
- such rules for components of knowledge specific for the area of planning; they can be re-used whenever necessary,
- a plan has hierarchical structure; recursive going up and down is possible,
- instead of a single-thread plan multi-thread (granular ones) are enforced,
- re-planning consist in finding and adapting almost ready plan using prepared a priori knowledge components.

The very basic idea is that a graph modelling the network of routes is divided into separate granules covering it. A granule is and area restricted by some border line where there are some distinguished entry points through which one can enter and leave this area. A good example – for intuition – is a city having several entry roads or a specific district with some entry point. Some illustrative picture of such a granule $P$ with seven entry points is given in Fig. 1. The entry points of granule $P$ are denoted as $P.e1, P.e2, \ldots, P.e7$.

The complete area of planning is divided into such granular components covering it; the principle is to use natural borders and having as small number of entry points as possible. Granules are interconnected by links. In Fig. 2 we have

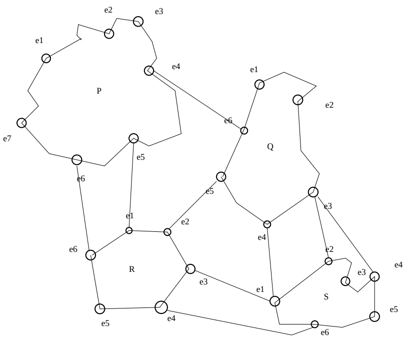

Fig. 2. A schematic presentation of a four interconnected granules within the planning area with entries.

some four interconnected granules, namely $P$, $Q$, $R$ and $S$. For example, granules $P$ and $Q$ are connected by a single link $P.e4--Q.e6$, while granules $Q$ and $S$ are connected through three links, namely: $Q.e4--S.e1$, $Q.e3--S.e2$ and $Q.e3--S.e3$. For simplicity we assume that all such interconnections are symmetric.

Now, a simple plan to go from an initial location $I$ (located within some granule, say $P$) to some destination goal location $G$ (located within some other granule, say S) is a sequence of the form:

$$\begin{aligned}\pi\colon l_I(I--P.e4), P.e4--Q.e6, e6Qe4,&\\ Qe4--S.e1, l_G(S.e1--G),&\end{aligned} \tag{1}$$

where

- $l_I(I--P.e4)$ is a partial plan to move from $I$ to $P.e4$ within $P$; it may be necessary to employ classical search techniques to generate this part,
- $l_G(S.e1--G)$ is a partial plan to move from $S.e1$ to $G$ within $S$; it may be necessary to employ classical search techniques to generate this part,
- $P.e4--Q.e6$, and $Qe4--S.e1$ are just trivial transition links,
- $e6Qe4$ is a set of computed a priori plans to move from $Q.e6$ to $Q.e4$ with $Q$; a plan from the set can be selected according to optimality criteria (a shortest one or a cheapest one) or depending to current time, weather, traffic conditions, etc.

Two further important issues are as follows.

First, any granule can be lowest-level one, where entries are just interconnected through an indivisible network of roads, or a higher level granule covering a set of interconnected granules inside.

Second, for any granule $P$ there is a set of rules, for convenience represented in the tabular XTT form, where each rule is of the form:

$$entry = P.e_i \wedge out = P.e_j \wedge \psi \longrightarrow plan = \pi(P,i,j,\psi).$$

For the granules of the lowest level, a plan $\pi(P,i,j,\psi)$ is just a path through the graph modelling the network of roads. For any higher level granules a plan $\pi(P,i,j,\psi)$ can incorporate higher level notation such as (1); recall that granules of higher levels are recursively divide into lover level ones.

TABLE I
A SCHEME OF A SIMPLE RULE-BASE TABLE FOR STORING PLANS

| entry | out | cond | plan |
|---|---|---|---|
| P.e1 | P.e2 | $\psi_1$ | $\pi(P,1,2,\psi_1)$ |
| P.e1 | P.e3 | $\psi_2$ | $\pi(P,1,3,\psi_2)$ |
| $\vdots$ | $\vdots$ | $\vdots$ | $\vdots$ |
| P.e6 | P.e7 | $\psi_{46656}$ | $\pi(P,6,7,\psi_{46656})$ |

## III. Important definitions

The original form of a route planning problem domain is a graph. Nodes represent individual states (usually junctions), and vertices (edges) represent the connections (roads, streets). Edge weights represent the value of the quality indicator, according to the chosen optimality criteria. As it is possible that there is more than one connection between two nodes, a modified definition for a graph must be used.

*Definition 1 (Graph):* Let $N$ be a finite set of nodes and let $E$ be a finite set of edges. A graph $G$ is a four-tuple

$$G = (N, E, \alpha, \omega) \tag{2}$$

where $\alpha$ and $\omega$ are functions assigning, to every edge $e \in E$, its start node $n_I \in N$ and end node $n_G \in N$, respectively:

$$\alpha : E \rightarrow N, \quad \omega : E \rightarrow N \tag{3}$$

Please note that every node $n \in N$ will have precise $(x, y)$ coordinates, denoting the geographical location of a given junction.

As the graph represents a fragment of a map – i.e. a city or a part of it, it will most likely be connected with the outside world using roads. We shall therefore create virtual nodes at every exit road, representing entry or exit from the current fragment of the map. That set of nodes shall be called terminators and be defined as $N_T \subset N$. Geographic coordinates for such virtual nodes shall be outside the boundaries of the map region.

*Definition 2 (Terminator):* A terminator is a virtually-created node $n \in N_T \subset N$, representing entry into or exit out of the domain of the planning process. As junctions outside the domain are not of interest to the planning process, each node $n \in N_T$ may only have at most *one* edge leading to another (non-virtual) node $n' \notin N_T$, $n` \in N$ and, optionally, at most *one* edge in the reverse direction.

Basing upon the graph definition above, we shall now provide the definitions for hierarchical graph partitioning.

*Definition 3 (Partition):* We shall say that a series of sets $P_1, P_2, \ldots, P_n \subset N$ are partitions and define a partitioning scheme of a graph $G$ if:

- $P_1 \cup P_2 \cup \ldots \cup P_n = E$, i.e. the subgraphs cover all nodes of the graph $G$ being partitioned,
- $P_i \cap P_j = \emptyset$, $i, j = 1, 2, \ldots, n$, $i \neq j$, i.e. any given node can belong to only one of the resulting subgraphs,

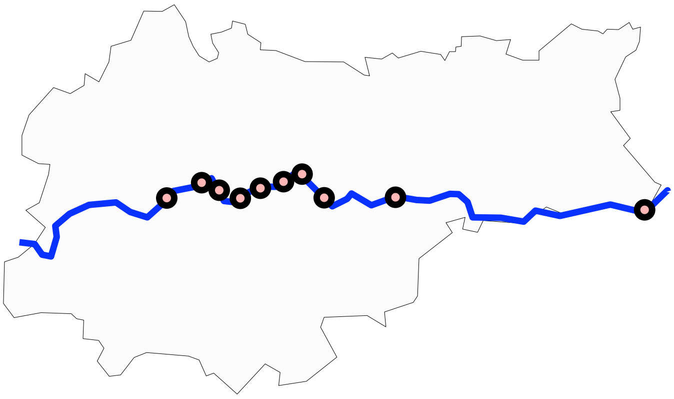

Fig. 3. An outline map of the city of Kraków, showing the boundary between two particles, marked out by the Vistula river, as well as internal links between those partitions.

- every subgraph defined by partitions $P_i$, $i = 1, 2, \ldots, n$ is connected.[1]

In practice, partition boundaries will often be natural or human-made landmarks which provide a limited number of options of crossing them. Bridges or railways are examples of such landmarks. To clarify the concept of the partition, Fig. 3 shows an outline map of the city of Kraków divided naturally into two partitions by the river Vistula. Circles denote the limited number of ways to get from one partition to another. Definitions of neighboring partitions, partition links and partition boundaries are intuitive. Formal definitions follow.

*Definition 4 (Neighboring partitions):* We say that partitions $P_i$ and $P_j$ are neighboring if there is at least one pair of nodes connected directly by an edge such that one node belongs to $P_i$ and the other belongs to $P_j$:

$$\exists n_i, n_j : n_i \in P_i, n_j \in P_j, (n_i, n_j) \in E \tag{4}$$

*Definition 5 (Partition link):* An internal partition link (partition link) between two partitions $P_i$ and $P_j$ is an edge $l \in E$, $l = (n_i, n_j)$, such that $n_i \in P_i$ and $n_j \in P_j$. We say that link $l$ is associated with partitions $P_i$ and $P_j$: $l \sim P_i$, $l \sim P_j$.

Intuitively, a partition link provides the means of getting from one partition to another. Coordinates of a link can in fact be defined as an arbitrarily chosen point belonging to the road leading from junction $n_i$ to junction $n_j$. In practice, this will often be the crossing point between the road and the landmark object used to define the partition in the first place.

On Figure 3, internal links (in this case: bridges) are represented as small circles.

*Definition 6 (External partition link):* Let $G$ be a graph being the input for the partitioning process at level $m$, as described by section III-A. An external partition link is an edge $l_x \in E$, $l_x = (n_i, n_j)$ such that:

- $n_i \in N_T$ or $n_j \in N_T$, or:
- for $m = 1, 2, 3, \ldots$ $(m \neq 0)$, $n_i$ and $n_j$ belong to two neighboring partitions at level $m - 1$.

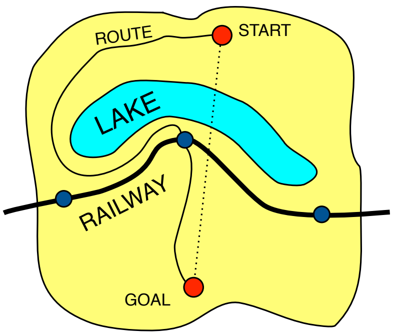

Fig. 4. An example map with a missing partition boundary and the resulting non-optimal solution.

*Definition 7 (Partition boundary):* The boundary $L_i$ of partition $P_i$ is defined by the set of all its links associated with it:

$$L_i = \{l \in E : l \sim P_i\} \tag{5}$$

Geometric representation of the boundary can be perceived as a series of line segments, joining successive pairs of links, in a way that each linking road is crossed only once.

On Figure 3, the Vistula river is the boundary.

Every partition shall have an array of traversal rules.

*Definition 8 (Traversal rule):* Let $P$ be a partition as defined by Definition 3, and $L$ be its boundary, as defined by (5). A traversal rule is a five-tuple:

$$R = (P, l_I, l_G, g, \Phi, \Psi) \tag{6}$$

where $P$ is the partition, $l_I \in E$ is the entering link, $l_G \in E$ is the exit link, $g$ is the traversal cost (depending on chosen optimality criteria), $\Phi$ is an optional set of optional validity values (e.g. time of day) and $\Psi$ is the traversal plan to be followed.

*Definition 9 (Traversal plan):* A traversal plan $\Psi$ of length $n - 1$ from link $l_I$ to link $l_G$ through partition $P$ at level $m$ is defined as follows:

$$\Psi = (l_I, P_1, l_1, P_2, l_2, \ldots, l_{n-1}, P_n, l_G) \tag{7}$$

where $P_i$ $(i = 1, 2, \ldots, m)$ are partitions at level $m + 1$ (sub-partitions of $P$), and $l_i$ $(i = 1, 2, \ldots, m)$ are links between partitions $P_i$ and $P_{i+1}$.

### *A. Partition hierarchy*

As mentioned before, the partitioning scheme is hierarchical, e.g. every partition $P_i$ on level $n$ may become the source graph for partitioning on level $n + 1$. On level 0, the source graph is identical to the search domain.

*Definition 10 (Elementary partition):* A partition $P_i$ at level $n$ which is not divided into other sub-partitions (i.e., no sub-partitions of it exist at level $n + 1$) shall be called an *elementary partition*.

Partitioning should be performed to the point when route planning within a partition can be performed in negligible time using classical shortest path algorithms.

[1] A graph is connected if there is a path connecting any two nodes.

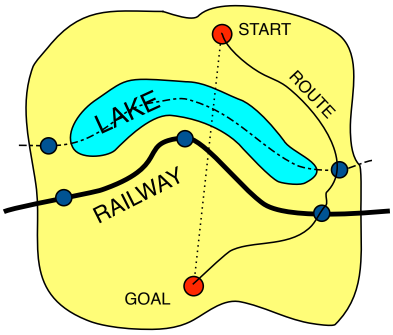

Fig. 5. An example map after adding the missing partition.

In order to maintain consistency throughout the entire hierarchy, partitioning has to be balanced.

*Definition 11 (Partition balancing):* If $L_i$ is the boundary of partition $P_i$ at level $n$, and that partition becomes the source for partitioning at level $n+1$, the set of external links $L_x$ for partitions created by dividing partition $P_i$ equals the boundary of that partition ($L_i$) at level $n$.

## IV. Map partitioning procedures

The process of map partitioning is where intelligent processing actually takes place, thus it requires expert knowledge to be performed properly – to ensure that the entire system yields feasible and optimal results.

The complexity level of the problem makes development of automatic partitioning methods difficult. Therefore, we shall now focus on providing general guidelines for map partitioning, and to discuss the implementation feasibility of an automatic partitioning solution.

### A. Guidelines for partitioning strategies

The primary guideline for partitioning the map is appropriate selection of abstraction levels and partition boundaries. For instance, if a significant landmark is likely to be an obstacle, a partition boundary should be placed accordingly to its size.

For example, please compare the partitioning schemes presented on figures 4 and 5. On figure 4, the partition has been split into two sub-partitions (at the next level), using the railway as the boundary. The algorithm presented below uses geometric criteria to order (or choose) the links used (dotted line between the start and the goal). Therefore, it will assume that the middle railway crossing is the one most likely to be used. If the planning strategy is unfavorable (i.e., full review is not done)

### B. Traversal plan calculation

For each non-elementary partition, a traversal plan needs to be established. Similarly to the partitioning itself, this article assumes that the traversal plans are prepared by experts. However, rough plans may be pre-computed using simple criteria, such as location of exits and known road network irregularities. Such aid should provide satisfactory results, especially on high abstraction levels. However, it should in all cases be reviewed by an expert.

Automated map partitioning and traversal plan calculation methods are indeed possible, but they are not covered in this article, as they involve preparation of the search domain, and not solving the planning problem itself.

## V. Algorithm proposal

Please note that the algorithm is in an early stage of development and therefore some of the assumptions made by it can seem rather naive. Its purpose is to illustrate which stages benefit from using the foundations described in the preceding section.

The algorithm is divided into two main procedures:

- calculate point-to-point route,
- traverse entire partition.

The first procedure (described in section V-A) does not take great benefits from the approach described here, but is needed as an "access road" to true partition traversal. Please note that at any level, the point-to-procedure does not utilize the rule tables associated with partitions.

The *Traverse entire partition* procedure (described in section V-B) is where rule-based processing takes place. No search procedures are utilized, until the elementary partitions are reached and the subproblems become trivial.[2]

### A. Calculate point-to-point route

This is the main procedure used for route planning.

1) Input arguments: $n_I$ (start node), $n_G$ (goal node).
2) Recursively locate $n_I$ and $n_G$ to partitions on all applicable levels. (Determine start and goal node addresses).
3) Assume that $P_I$ is the level $0$ partition of node $n_I$, and $P_G$ is the level $0$ partition of node $n_G$.
4) Define point $p$. Assign the $n_I$ to $p$.
5) Allocate a node of the search graph used to store search options. Assign $n_I$ to the node.
6) Repeat: (build the search tree)
    a) Draw a line segment from $p$ to $n_G$ and select the internal link $l \sim P_I$.
    b) Add the links between $P_I$ and its neighboring partitions as nodes of the search graph, ordered by the distance from the line drawn in the previous point[3], and add appropriate edges.
7) For all nodes linked with the start node $n_I$, recursively calculate the point-to-point route from $n_I$ to the geographic location of the link defined by the given node.
8) For all nodes linked with the goal node $n_G$, recursively calculate the point-to-point route from the geographic location of the link defined by the given node to $n_G$.

[2] Nevertheless, routes for elementary partitions can also be pre-calculated in order to achieve full independence from search algorithms in the *Traverse entire partition* part of the algorithm.

[3] To reduce complexity, the number of nodes added at each level can be limited, either by setting a limit or by defining the maximum distance from the line drawn in step 6a.

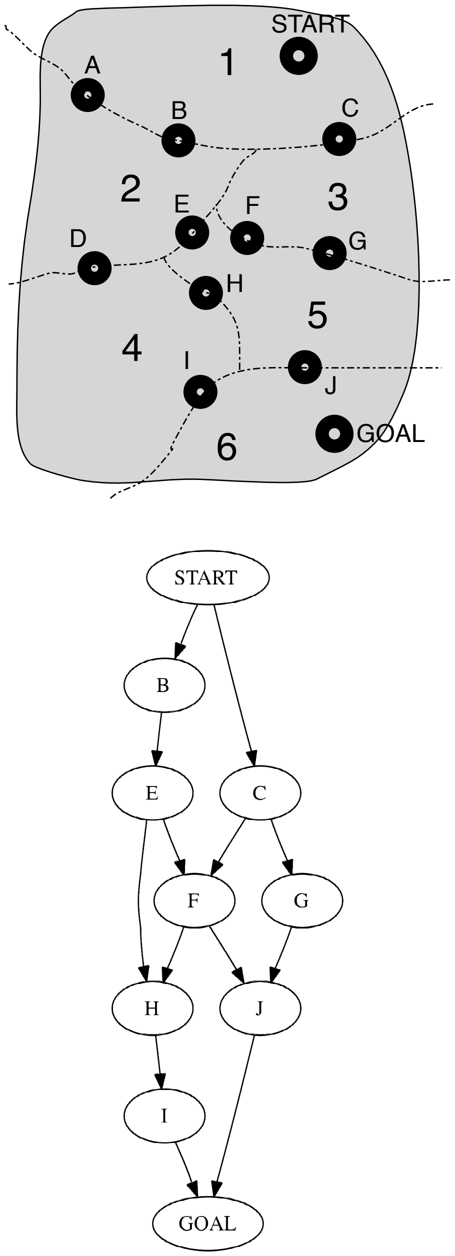

Fig. 6. An example division of a planning problem in to subproblems.

9) For all other nodes, solve the Traverse entire partition problem from their parents in the search tree.
10) For all leaves of the search tree, calculate the point-to-point route from the geographic location of the link defined by the given node to $n_G$.

### B. Traverse entire partition

This procedure is executed if there is an entire partition (at a given level) to be traversed. It only applies to non-elementary partitions (see definition 10).

1) Input arguments: $P$ (partition), $l_I$ (start link), $l_G$ (goal link), $\Phi$ (additional criteria; optional).
2) Match rule $R = (P, l_I, l_G, g, \Phi, \Psi)$ with the most favorable value of $g$.
3) Retrieve traversal plan $\Psi$ ($\Psi = (l_0, P_1, l_1, P_2, l_2, \ldots, l_{n-1}, P_n, l_n)$).
4) Let $n$ be the length of $\Psi$.
5) For $i$ from 1 to $n$, recursively traverse entire partition $P_i$ from node $l_{i-1}$ to node $l_i$.

### C. Execution example

As the *Calculate point-to-point route* algorithm may not seem trivial, we provide an example of its operation. Figure 6 shows a rather simple partition, divided into 6 sub-partitions, labelled 1-6. Internal links between those partitions have been labelled as A-J. The start node is located in partition 1, the goal node – in partition 6. Below the drawing is the search graph generated by the procedure described in section V-A.

The *Calculate point-to-point route* algorithm will be used to solve the following subproblems:

- $START \rightarrow B$
- $START \rightarrow C$
- $I \rightarrow GOAL$
- $J \rightarrow GOAL$

The *Traverse entire partition* algorithm will be used to solve the following subproblems:

- $B \rightarrow E$
- $C \rightarrow F$, $C \rightarrow G$
- $E \rightarrow F$
- $F \rightarrow H$, $F \rightarrow J$
- $G \rightarrow J$
- $H \rightarrow I$

## VI. Conclusion

The article provides some outline for a new rule-based approach to solving planning problems, with special emphasis on vehicle route planning in dense, urban areas under unpredictable traffic conditions. In such cases re-planning may be of excessive use, and granular planning may proof to constitute a robust approach.

The algorithm provided is at an early stage of development, but is a good illustration of the formal foundations described above.

Future work includes:

- development of automatic map partitioning schemes,
- practical implementation of described methods,
- improvement of the search algorithms.

***Abstract*—In this paper, a nonlinear system identification based on support vector machines (SVM) has been addressed. A family of SVM-ARMA models is presented in order to integrate the input and the output in the reproducing kernel Hilbert space (RKHS). The performances of the different SVM-ARMA formulations for system identification are illustrated with two systems and compared with the Least Square method.**

## I. Introduction

SYSTEM identification treats the problem of constructing mathematical models from observed input and output data. Three basic entities must be taken into consideration to construct a model from data [1]:

1) Data: represent the input and the output data of the system;
2) Candidate models: are obtained by specifying within which collection of models the suitable one exists;
3) Identification method: determining the best model guided by the data.

In the literature of system identification, a large variety of nonlinear methods were used, such as neural networks, high order statistic and fuzzy system [2], [3], [4]. However these models have weaknesses. For example in neural network case, some problems appear, like slow convergence speed and local minima. Support Vector Machines (SVMs) overcomes these problems and seems to be a powerful technique for nonlinear systems where the required model complexity is difficult to estimate.

The Support Vector Machines (SVM) was originally proposed as an efficient method for pattern recognition and classification [3]. Then the technique became a general learning theory. The Support Vector regressor (SVR) was subsequently proposed as the SVM implementation for regression and function approximation [5]. SVM has been widely used to solve problems in text recognition, bioinformatics [6] and bioengineering or image processing [7] and these represent only a few of the practical applications of support vector machines. The key characteristic of SVM is that it maps the input space into a high dimensional feature space or a reproducing kernel Hilbert space through some nonlinear mapping, chosen a priori, in which the data can be separated by a linear function.

The autoregressive and moving average (ARMA) modelling is used when the candidate model is linear and time invariant. The explicit consideration of ARMA models in some reproducing kernel Hilbert space (RKHS) based on support vector machines (SVM-ARMA$_{2k}$) presents a new approach for identifications applications [9]. An analytical relationship between residuals and SVM-ARMA coefficients allows the linking of the fundamentals of SVM with several classical system identification methods. Additionally the effect of outliers can be cancelled [9]. By using the Mercer's Kernels trick, a general class of SVM-based nonlinear system identification can improve model flexibility by emphasizing the input-output cross information (SVM-ARMA$_{4k}$), which leads to straightforward and natural combinations of implicit and explicit ARMA models (SVR-ARMA$_{2k}$) and SVR-ARMA$_{4k}$) [10].

In this paper, we present the different SVM-ARMA models for the system used in [9] and for Bessel difference equation. We present the sensitivity of the SVM-ARMA models to the training data and to the noise power. Additionally, we compare our models with the least square method (LS) and we show each one's performance and the moment they exhibit the same results.

This work is structured as follows: we present the SVR algorithm for nonlinear system identification in section I. In section II, we summarize the explicit ARMA models in RKHS. Simulations and examples are included in section IV. Finally, in section V, we conclude the work.

## II. SVR System Identification

Consider a nonlinear system whose input and output are DTP $\{x_n\}$ and $\{y_n\}$. Let $u_n = [u_n, u_{n-1}, \dots, u_{n-Q+1}]$ and $y_{n-1} = [y_{n-1}, y_{n-2}, \dots, y_{n-P}]$ represent the states of input and output DTP at instant n. The vector $z_n = [y_{n-1}^T, u_n^T]^T$ correspond to the concatenation of the two DTP at that instant *n*.

Giving a training set $\{z_i, y_i\}_{i=1}^N \in \Re^d$ with $d = P + Q - 1$. The linear regression model is:

$$y_n = \langle w, \phi_n(z_n)\rangle + e_n \; . \tag{1}$$

where $\phi(z_n) : \Re^P \times \Re^Q \to H_z$ represents the high dimensional feature space, or RKHS, which is nonlinearly mapped from the

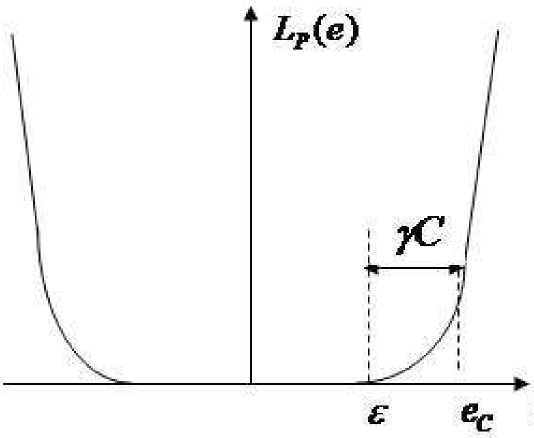

Fig. 1. $\varepsilon$-Huber cost Function.

input space,$\langle\cdot,\cdot\rangle$ represents the dot product and $e_n$ denotes error terms, or residuals, comprehends both measurement and model approximation errors.

In SVR, several cost functions for residuals (CFR) have been used, such as Vapnik's loss function [3], Huber's robust cost [8] or the ridge regression approach [6]. However, in [9] they used $\varepsilon$-Huber CFR, which is a more general cost function that has the above-mentioned ones as particular cases. This cost function is depicted in 1 and it is expressed as:

$$l_p(e_n) = \begin{cases} 0, & |e_n| < \varepsilon \\ \frac{1}{2\gamma}(|e_n| - \varepsilon)^2, & \varepsilon < |e_n| < e_C \\ C(|e_n| - \varepsilon) - \frac{1}{2}\gamma C^2, & |e_n| > e_C \ . \end{cases} \tag{2}$$

where $e_C = \varepsilon + \gamma C$. The $\varepsilon$-Huber CFR can deal with different kinds of noise thanks to the three different intervals.

Using the $\varepsilon$-Huber CFR cost function, the algorithm of SVR system identification corresponds to the minimization of:

$$L_P = \frac{1}{2}\sum_{j=1}^{H_z} w_j^2 + \frac{1}{2\gamma}\sum_{n\in I_1}(\xi_n^2 + \xi_n^{*2}) + C\sum_{n\in I_2}(\xi_n + \xi_n^*) - C\sum_{n\in I_2}\frac{\gamma C^2}{2} \ . \tag{3}$$

with the constraints:

$$y_n - w^T\phi_n(z_n) \le \varepsilon + \xi_n \qquad \forall n = n_0, \cdots, N \ . \tag{4}$$

$$-y_n + w^T\phi_n(z_n) \le \varepsilon + \xi_n^* \qquad \forall n = n_0, \cdots, N \ . \tag{5}$$

where $\xi_n$,$\xi_n^*$ are the slack variables or losses, $\xi_n^{(*)} \ge 0$ ($\xi_n^{(*)}$ represents both $\xi_n$and $\xi_n^*$), $I_1$ is set of samples for which $\varepsilon < \xi_n^{(*)} < e_C$, $I_2$ is the set of samples for which $\xi_n^{(*)} > e_C$, $n_0$ is given by the initial conditions and $N$ is the number of available samples.

By introducing a nonnegative coefficient, Lagrange multiplier, for each constraint ($\alpha_n$ to (4) and $\alpha_n^*$ to (5)), we obtain the Lagrangian for this problem [6] this way:

$$\begin{aligned} L_{PD} = {} & \frac{1}{2}\sum_{j=1}^{H_z} w_j^2 + \frac{1}{2\gamma}\sum_{n\in I_1}(\xi_n^2 + \xi_n^{*2}) + C\sum_{n\in I_2}(\xi_n + \xi_n^*) \\ & - C\sum_{n\in I_2}\frac{\gamma C^2}{2} + \sum_{n=n_0}^{N}\alpha_n(y_n - w^T\phi_z(z_n) - \varepsilon - \xi_n) \\ & + \sum_{n=n_0}^{N}\alpha_n^*(-y_n + w^T\phi_z(z_n) - \varepsilon - \xi_n) \ . \end{aligned} \tag{6}$$

By minimizing the Lagrangian with respect to the primal variables $w_j$ and $\xi_n^{(*)}$ we obtain:

$$w = \sum_{n=1}^{N}(\alpha_n - \alpha_n^*)\phi_z(z_n) = \sum_{n=1}^{N}\beta_n\phi_z(z_n) \ . \tag{7}$$

and $0 < \alpha_n^{(*)} < C$, where $\beta = \alpha_n - \alpha_n^*$

The dual problem is obtained by introducing (7) in (6) and it is expressed as:

$$\begin{aligned} L_D = {} & -\frac{1}{2}(\alpha - \alpha^*)^T[G + \gamma I](\alpha - \alpha^*) + (\alpha - \alpha^*)^T y \\ & + \varepsilon 1^T(\alpha - \alpha^*) \ . \end{aligned} \tag{8}$$

where $G$ is gram matrix of dot product or kernel matrix with $G_{ij} = \langle\phi_z(z_i), \phi_z(z_j)\rangle = K_z(z_i, z_j)$, $\alpha_n^{(*)} = [\alpha_1^{(*)}, \ldots, \alpha_N^{(*)}]^T$ and $y = [y_1, \ldots, y_N]^T$. Finally the predicted output for a new observed sample $y_r$ given $z_r$is:

$$\hat{y}_r = \sum_{n=1}^{N}\beta_n K_z(z_n, z_r) \ . \tag{9}$$

With the kernel function $K_z(z_n, z_r)$, we can deal with feature space of arbitrary dimension without having to compute the map $\phi_z$explicitly. Any function that satisfies Mercer's condition can be used as the kernel function [6]. The widely used Gaussian Mercer's kernel is given by $K_z(z_i, z_j) = exp(\frac{-\|z_i - z_j\|^2}{2\sigma^2})$, where $\sigma^2$ is the kernel parameter.

## III. SVR System Identification and Composite Kernels

A family of composite kernels appears in SVM formulation by exploiting the direct sum of Hilbert spaces [10], which allow us to analyse the explicit form of ARMA process in feature space.

### A. Explicit ARMA In Feature Space

By using two possibly different nonlinear mappings $\phi_n(u_n) : \Re^Q \to H_u$ and $\phi_y(y_n) : \Re^P \to H_y$, the input and output state vectors $u_n$ and $y_n$ can be separately mapped to RKHS $H_x$ and $H_y$. So, an ARMA difference equation can be built using two linear models; MA (moving average) in $H_x$ and AR (auto regressive) in $H_y$:

$$y_n = a^T\phi_n(y_{n-1}) + b^T\phi_n(u_n) + e_n \ . \tag{10}$$

where $a = [a_1, \dots, a_{H_u}]^T$ and $b = [b_1, \dots, b_{H_y}]^T$ are vectors representing the coefficients MA and AR of the system, respectively, in RKHS. After formulating the primal problem, stating the Lagrangian and making its gradient to zero, removed the primal variables and formulating the dual problem, the SVM-ARMA$_{2k}$ is obtained by including the kernel matrix $K(z_n, z_r) = K_y(y_{n-1}, y_{r-1}) + K_u(u_n, u_r)$ in (9) [10]:

$$\hat{y}_r = \sum_{n=1}^{N} \beta_n (K_y(y_{n-1}, y_{r-1}) + K_u(u_n, u_r)) \ . \qquad (11)$$

where $K_y(y_{i-1}, y_{j-1}) = \langle \phi_y(y_{i-1}), \phi_y(y_{j-1}) \rangle$ and $K_u(u_i, u_j) = \langle \phi_u(u_i), \phi_u(u_j) \rangle$ are two different Gram matrices, one for the input and the other for the output.

### B. Composite Kernels

The SVM-ARMA$_{2k}$ model could be limited in some cases, because (11) provides an apparent uncoupling between the input and the output. This limitation will be come out explicitly when strong cross information between the two DTP is present. An SVM-ARMA model considering the input and output could simultaneously solve this problem. By using the sum of Hilbert spaces property, the kernel components are:

$$\begin{aligned} K(z_i, z_j) = K_y(y_{i-1}, y_{j-1}) + K_x(u_i, u_j) \\ + K_{xy}(u'_i, y'_{j-1}) + K_{yx}(y'_{i-1}, u'_j) \ . \end{aligned} \qquad (12)$$

When including this kernel in (9), we obtain the SVM-ARMA$_{4k}$ [10].

A new algorithm SVR-ARMA$_{2k}$ can be built by considering the combination between SVR and SVM-ARMA$_{2k}$

$$K(z_i, z_j) = K_y(y_{i-1}, y_{j-1}) + K_x(u_i, u_j) + K_z(z_i, z_j). \quad (13)$$

or an other one, SVR-ARMA$_{4k}$ by combining SVR and :

$$\begin{aligned} K(z_i, z_j) = K_y(y_{i-1}, y_{j-1}) + K_x(u_i, u_j) \\ + K_{xy}(u'_i, y'_{j-1}) + K_{yx}(y'_{i-1}, u'_j) + K_z(z_i, z_j). \end{aligned} \quad (14)$$

## IV. Experimental Results

To examine the performance of SVM-ARMA formulations and to compare it with standard SVR and Least Square method, we use two examples. We focus on radial basis function (RBF) $K_z(z_i, z_j) = exp(\frac{-\|z_i - z_j\|^2}{2\sigma^2})$, where $\sigma^2 \in \Re$ represent the width of the kernel.

For the first example, the prediction performance is evaluated using the mean square error in test set:

$$MSE = \sqrt{\frac{1}{N} \sum_{i=1}^{N} (y_i - \hat{y}_i)^2}$$

where $N$ denotes the total number of data points in the test, $y_i$, $\hat{y}_i$ are the actual value and prediction value respectively

For the second example, we use the normalized mean square error in test set:

$$nMSE = \log_{10} \sqrt{\frac{MSE}{var(y)}}$$

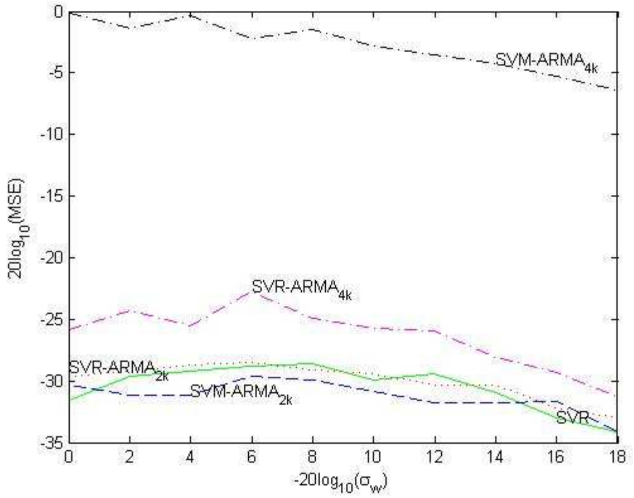

Fig. 2. The MSE as a function of additive noise of power $\sigma_w$.

To train our models, we use the cross validation method; 100 data are used as training data and 100 as testing data. For the first example, the results are averaged over 100 realizations and for example 2, over 200 realizations.

**Example1:** The first example of a system to be identified is [9]:

$$y_n = 0.03y_{n-1} - 0.01y_{n-2} + 3x_n - 0.5x_{n-1} + 0.2x_{n-2} \ . \quad (15)$$

The Input DTP is a white Gaussian noise sequence of unit variance $\{x_n\} \sim N(0, 1)$. An additive small variance random process, $\{e_n\} \sim N(0, 0.1)$, corrupts the corresponding output DTP and modelling the measurement errors. The observed process is $\{o_n\} = \{y_n\} + \{e_n\}$.

Impulsive noise $\{j_n\}$ is generated as a sparse sequence, for which 30% of the samples, randomly placed, are of high-amplitude, having the form $\pm 10 + U(0, 1)$, where $U()$ represents the uniform distribution in the given interval. The remaining are zero samples. The observations consist of DTP input $\{x_n\}$ and the observed output plus impulsive noise; $\{o_n\} + \sigma_w\{j_n\}$. Values of $\sigma_w$ go from 18 to 0 dB [9].

We tried various values for $\varepsilon$, $\gamma$, $C$. For all the SVM-ARMA formulations, $\varepsilon = 0$ is used. In SVM-ARMA$_{4k}$, the values of SVM parameters that give the minimum MSE in testing set are like $C = 1$ and $\gamma = 0.01$, but for other SVM-ARMA models they are fixed in $C = 100$ and $\gamma = 0.001$. The results of our first system are shown in Figure 2, 3, 4, 5, 6. In Figure2, the SVM-ARMA$_{2k}$ model exhibit better performance, whereas SVM-ARMA$_{4k}$ and SVR-ARMA$_{4k}$ provide a poor model in terms of prediction error, that can be explained by the poor cross information between the input and output.

On the other hand, we compare the performance of SVM-ARMA models with the least square method, in which we use the same expression of the kernel components in each case (for example, in the case of SVR-ARMA$_{2k}$, the kernel components are like $_K = K_x + K_y + K_z$ for SVM and LS methods). The results are shown in Fig.3-a, 4-a, 5-a, 6-a, 7-a, and they show

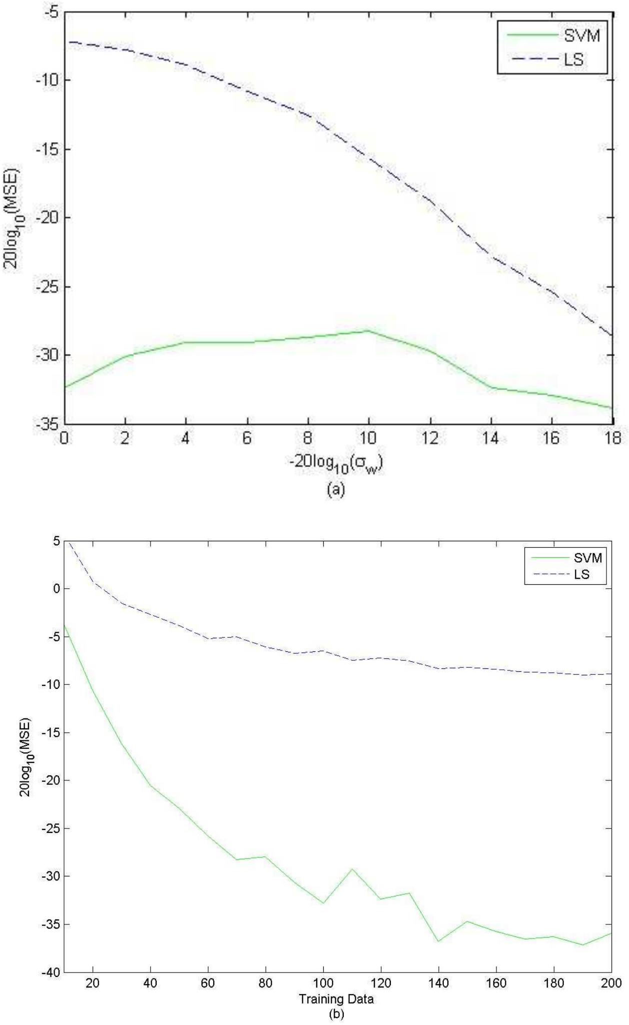

Fig. 3. (a) The MSE as a function of additive noise of power $\sigma_w$ for SVR model. (b) The MSE as a function of training data for SVR model, where $\sigma_w = 1$.

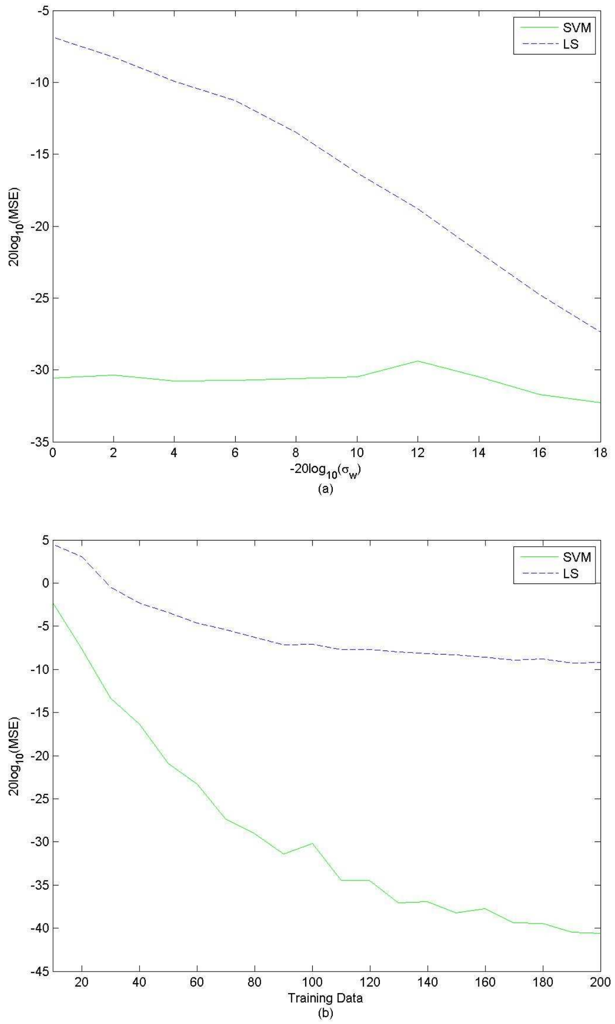

Fig. 4. (a) The MSE as a function of additive noise of power $\sigma_w$ for SVM-ARMA$_{2k}$ model. (b) The MSE as a function of training data for SVM-ARMA$_{2k}$ model, where $\sigma_w = 1$.

that the SVM method exhibits a good performance in high impulsive noise power with a difference of almost 24 dB in comparison with LS method. Besides, SVM-ARMA methods show that there is no significant difference between the different values of MSE as a function of noise parameter, $\sigma_w$, which mean that the SVM-ARMA models, in this example, are not sensitive to the noise parameter $\sigma_w$.

Fig.3-b, 4-b, 5-b, 6-b, 7-b show that in the case of high impulsive noise power, $\sigma_w = 1$, the minimum MSE of SVM and LS methods are stabilized in affixed values even if the number of training data is augmented. We can say that the MSE is saturated. The SVM method needs 160 training data to saturate and LS requirements 100 data, but SVM gives a very small MSE in comparison with LS.

**Example2**: The second system to be identified is described by the difference equation of Bessel:

$$\left\{ \begin{array}{c} u(t) = 0.6\sin^{\alpha}(\pi t) + 0.3\sin(3\pi t) + 0.1\sin(\alpha t) \\ \tilde{y}(t+1) = \frac{\tilde{y}(t)\tilde{y}(t-1)[\tilde{y}(t)-2.5]}{1+\tilde{y}^2(t)+\tilde{y}^2(t-1)} \\ y(t+1) = \Re[\tilde{y}(t+1)] \end{array} \right. . \quad (16)$$

where $\Re[.]$ denotes the real part and $\alpha$ is a random variable uniformly distributed in the interval $[3,4]$ with the mean $E\{\alpha\} = 3.5$.

For all the SVM-ARMA formulations, the SVM parameters, $\varepsilon = 0$, $C = 100$ and $\gamma = 0.01$ are used.

From Table 1, we notice that Bessel equation exhibits the best performance in SVM-ARMA$_{2k}$ and that the SVM-ARMA algorithms show the same results as the LS method.

Table 2 reports the nMSE of Bessel difference equation corrupted with additive Gaussian noise. The SVM formulations give the same value of nMSE, 0.003 dB, and the SVM method exhibits the same results as LS method.

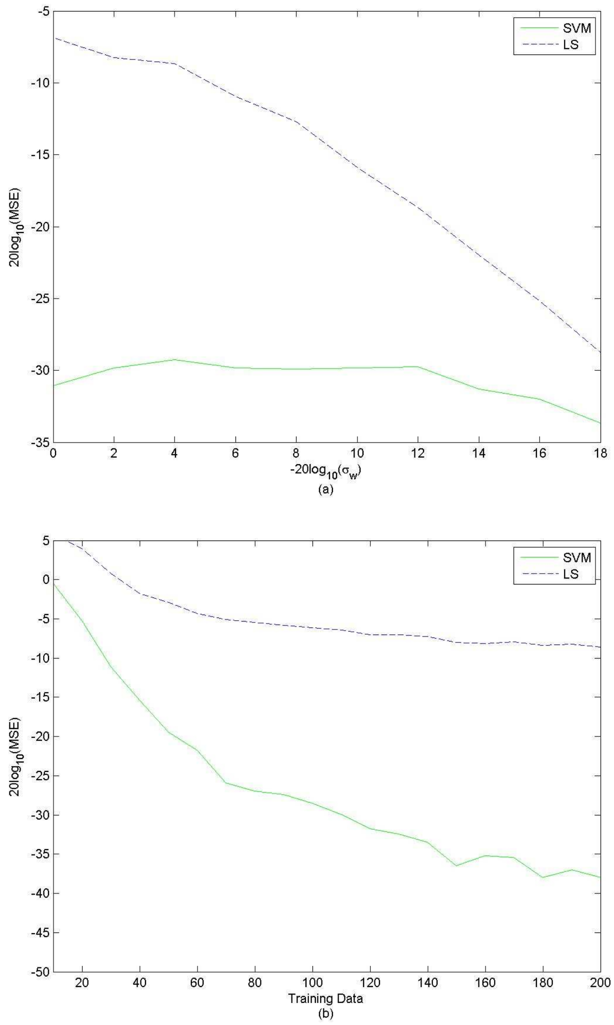

Fig. 5. (a) The MSE as a function of additive noise of power $\sigma_w$ for SVR-ARMA$_{2k}$ model. (b) The MSE as a function of training data for SVR-ARMA$_{2k}$ model, where $\sigma_w = 1$.

TABLE I
THE nMSE OF BESSEL EQUATION.

| | | LS method |
|---|---|---|
| SVR | -0.927 | -0.927 |
| SVM-ARMA$_{2k}$ | -0.935 | -0.935 |
| SVR-ARMA $_{2k}$ | -1.045 | -1.045 |
| SVM-ARMA $_{4k}$ | -1.246 | -1.045 |
| SVR-ARMA $_{4k}$ | -1.262 | -1.045 |

TABLE II
THE nMSE OF BESSEL EQUATION WITH GAUSSIAN NOISE.

| | | LS method |
|---|---|---|
| SVR | 0.003 | 0.003 |
| SVM-ARMA$_{2k}$ | 0.003 | 0.003 |
| SVR-ARMA $_{2k}$ | 0.003 | 0.003 |
| SVM-ARMA $_{4k}$ | 0.003 | 0.003 |
| SVR-ARMA $_{4k}$ | 0.003 | 0.003 |

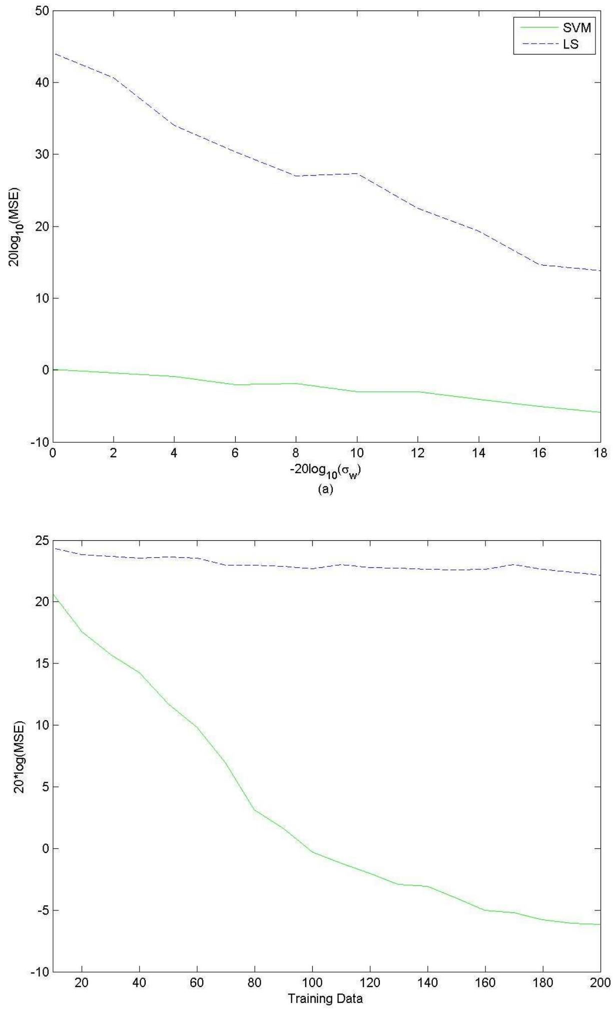

Fig. 6. (a) The MSE as a function of additive noise of power $\sigma_w$ for SVM-ARMA$_{4k}$ model. (b) The MSE as a function of training data for SVM-ARMA$_{4k}$ model, where $\sigma_w = 1$.

Therefore, we may conclude that SVM-ARMA methods provide as good results for Bessel difference equation as the best method LS, with and without additive Gaussian noise.

## V. CONCLUSION

This paper has presented a full family of SVM-ARMA methods for nonlinear system identification in RKHS. These methods are proposed by taking the advantage of composite kernel, in which dedicated mappings are used for input, output and cross terms. Simulation results show the performance of the different SVM-ARMA models and compare it with the least square method.

# The Expert System Approach in Development of Loosely Coupled Software with Use of Domain Specific Language

Piotr Grobelny
University of Zielona Gora,
Faculty of Electrical Engineering, Computer Science and Telecommunication,
Podgorna 50, 65-246 Zielona Gora, Poland
Email: P.Grobelny@weit.uz.zgora.pl

*Abstract*—**This paper addresses the problem of supporting the software development process through the artificial intelligence. The expert systems could advise the domain engineer in programming without the detailed experience in programming languages. He will use and integrate, with the help of deductive database and domain knowledge, the previously developed software components to new complex functionalities. The Service Oriented Architecture (SOA) and loosely coupled software allow to fulfill these requirements. The objective of this document is to provide the knowledge representation of atomic Web Services which will be registered as the facts in the deductive database as well as the inferring techniques. Also, the use of Domain Specific Language (DSL) for modeling domain engineer's requests to the expert system will be considered within this document.**

## I. Introduction

THE aim of this document is to propose a new approach of software development supported by the artificial intelligence. The loosely coupled software, especially the Web Services go towards the need of developing software families through domain engineer which has no detailed experience in computer programming, but has strong expert knowledge. This process could be supported by expert systems.

The background of the consideration is the domain engineering approach [7] which relies on developing software families from reusable components which are parts of common domain system. In the future, the software can be named service-ware, where all resources are services in a Service Oriented Architecture (SOA). The main idea of this approach is that business processes engineer operates on atomic services, not on the software or hardware that implements the service [8].

The method proposed within this paper could be used in large companies enabled on SOA for realizing business processes management (BPM) applications. Web Services are considered a promising technology for Business-to-Business (B2B) integration. A set of services from different providers can be composed together to provide new complex functionalities.

### A. Concept

The expert system plays the role of decision supporting system. Its task is to provide the proposition of complex service (workflow of atomic Web Services) basing on the domain engineer's request explained by means of Domain Specific Language (DSL). The facts in the deductive database are delivered by software developer who implements new functionalities fashioned as the Web Services compliant with enterprise SOA infrastructure. Software developer registers the atomic service model into facts database and also the service instance in SOA registrars (see concept overview in [1]).

The author of this paper proposed in previous work [2] the proof of concept prototype based on the Java framework for intelligent discovery and matchmaking atomic Web Services within integrated workflow called complex service. Thus, the problem of knowledge representation in Services Oriented Architecture as well as usage of DSL will be considered in next sections.

### B. Problem Statement and Challenges

The issue of writing computer program through other computer program is very idealistic challenge, so it seems to be realistic when some assumptions have been fulfilled. The loosely coupled software based on a collection of Web Services that communicate with one another within the distributed systems, which are self-contained and do not depend on the context or state of the other services, allows for discovery of new program functionalities by expert system. The next assumption is that all actors described in concept should use common domain name space (domain objects) expressed through domain ontologies (for instance Web Service Modeling Ontology [9]).

The aim of research work described within this document is to provide the sufficient knowledge representation system which consists of rules, facts and Domain Specific Language. The properly defined service models, which involve interface description, semantic specification as well as information about service quality (QoS) and non-functional properties, registered as the facts in expert system will enable inferring knowledge about enterprise software resources by domain engineer and matchmaking them as new applications.

## II. Related work

The author of [10] describes the semantic service specification, which is the basis for the composition of services to application service processes. Semantic-specified services are the condition for the development of complex functionality within application service processes. The first requirement of the semantic service specification is an existing domain ontology, which describes the domain specific concepts as well as associations and attributes of these concepts. A further requirement for the description of the semantic service specification is a unified description language. The F-Logic language [11] and its extension called Flora-2 [12] have been used. F-Logic is a deductive, object oriented database language which combines the declarative semantics and expressiveness of deductive database languages with the rich data modeling capabilities supported by the object oriented data model [10].

The author of this paper proposes other approach to explain the service models using Java language expressions. The main objective for this solution is to combine in one programming language: knowledge about services, expert system (rule engine) compliant with JSR-94 specification (implementation of the Java Rule Engine API, which allows for support of multiple rule engines [13]) as well as J2EE middleware which is the powerful development platform for Services Oriented Architecture [15]. In the previous paper author proposed the architecture for complex services prototyping and proven the feasibility of this approach on the Java platform using the developed prototype [2].

Domain Specific Language is the way of extending the rule to problem domain. In addition, DSL can be used to create front-ends to existing systems or to express complicated data structures. A DSL is a programming language tailored especially to an application domain: rather than being for a general purpose, it captures precisely the domain's semantics [22]. DSL can act as "patterns" of conditions or actions that are used in rules, only with parameters changing each time [19]. Rules expressed in Domain Specific Language have human-readable form and match the expression used by domain experts [22]. The domain engineer models the request to the deductive database as one rule instead of a lot of source code lines and nested loops in structural programming languages or SQL statements.

## III. Implementation

Web Services are software applications with public interfaces described in XML. A proper service description answers three questions about a service: what the service does (including its non-functional description), where it is located, and how it should be executed [16]. The Fig. 1 presents the simplified atomic service model proposed by author of this paper which answers these questions.

All model elements has been described in details in previous author's paper [1] therefore only some Quality of Service (QoS) generic parameters such as execution price and execution duration  will be considered to illustrate the problem of making decisions in fuzzy surroundings as well as usage of Domain Specific Language.

This paper presents the object-oriented approach to usage rule- and model based expert system [23][6] in development of loosely coupled software on Java platform. The author delivers the solution for creating the object-oriented knowledge databases (deductive databases) which consist of atomic service models stored as the facts as well as for inferring the knowledge through rules.

### A. Atomic Service Models as Facts in Knowledge Database

All pieces of information stored in deductive database establish the knowledge representation system. In previous work [1][2] the author proposed the decision tables formalisms to explain the facts as the production rules. Decision tables specify what decisions should be made when some conditions are fulfilled [4].

The knowledge representation system K which distinguishes the condition and decision attributes can be called a decision table:

$$K=(U,A,C,D) \qquad (1)$$

Where U is a nonempty, finite set called universe, A is a nonempty set of primitive attributes and C, D ⊂ A are two subsets of attributes called condition and decision attributes. Any implication

$$\phi \rightarrow \psi \qquad (2)$$

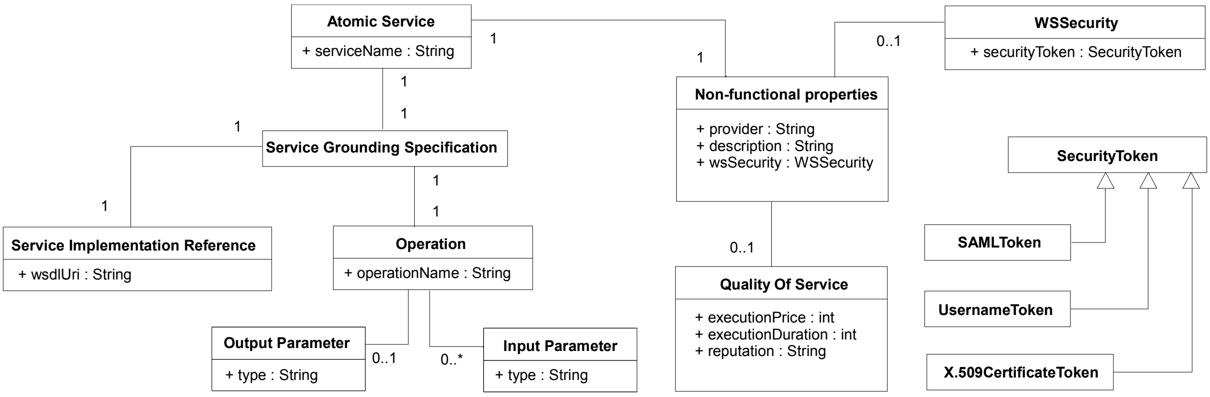

Fig 1. The simplified model of atomic service

is considered as the decision rule and Φ, Ψ are called predecessor and successor respectively.

If $\Phi \rightarrow \Psi$ is decision rule and P contains all attributes occurring in Φ (condition attributes) and Q contains all attributes occurring in Ψ (decision attributes) then this decision rule can be called PQ-rule.

Let's consider the real decision table (see Table I) which represents the knowledge system from geographic information systems (GIS) domain in Services Oriented Architecture and the facts are explained as the PQ-rules. The use case scenario and the services landscape were described within author's previous paper [2].

The columns P1-P6 represent the condition attributes and column Q1 represents the decision attribute of the PQ-rule. These PQ-rules are stored as facts in expert system database. The formula (3) formalizes a possible representation of PQ-rule from Table I in accordance to the formula (2).

$$P1=getMap \ \wedge \ P2=\{Coordinates\} \ \wedge \ P3=Map \ \rightarrow \ Q1=GisMap \quad (3)$$

The author of this paper prepared the facts database in terms of PQ-rules regarding formula (3) and Table I as the Java class which is loaded into the working memory of expert system. The previous document [1] presents the implementation of the selected fact which expresses the atomic service model with compliance to Jboss Drools [19] object-oriented expert system.

### B. Making Decisions in Fuzzy Surroundings

Respectively to formula (3) the facts regarding the membership functions could be explained as the PQ-rules as shown in Table II. Let's consider the example membership functions of fuzzy sets "low execution duration" and "average execution price". These functions should be provided by experts and can be explained in object-oriented manner as suggested in [3].

In the paper [1] has been presented the Java object with implemented membership function for QoS parameter "execution duration" and DSL pattern "low".

The fuzzy sets theory [5][14] allows for making decisions in fuzzy surroundings. The fuzzy set A in certain nonempty space X is defined as collection of couples as shown in (4).

$$A=\{(x,\mu_A(x));x\in X\} \quad (4)$$

where

$$\mu_A : X \rightarrow [0,1] \quad (5)$$

is the membership function of fuzzy set A.

Formula (6) represents the **symbolic** presentation of fuzzy set A for the finite number of elements X = {$x_1$, ... , $x_n$}, A⊆ X

$$A=\frac{(\mu_A(x_1))}{x_1}+\frac{(\mu_A(x_2))}{x_2}+\ldots+\frac{(\mu_A(x_n))}{x_n}=\prod_{i=1}^{n}(\frac{(\mu_A(x_i))}{x_i})$$ ( 6

)

where

$$\frac{(\mu_A(x_i))}{x_i}, i=1,\ldots,n \quad ( 7 )$$

denotes the pair ( 8 ) and symbol "+" has the symbolic character, as well.

$$(x_i,\mu_A(x_i)), i=1,\ldots,n \quad ( 8 )$$

The fuzzy surroundings consists of fuzzy constraints C and fuzzy decision D. Let's consider the set of options $X_{op}$={x}. The fuzzy constraint is defined as fuzzy set C specified on $X_{op}$ and described through membership function $\mu_c$: $X_{op} \rightarrow$ [0,1].

Let's consider the *n* fuzzy constraints $C_1$ , … $C_n$ where *n* >1. The fuzzy decision D is determined though formula (9).

$$D=C_1\wedge C_2\wedge\ldots\wedge C_n \quad ( 9 )$$

taking into account ( 10 )

$$\mu_D(x)=T\{\mu_{C_1}(x),\ldots,\mu_{C_n}(x)\}, x\in X_{op} \quad ( 10 )$$

where T denotes the t-norm MIN operator as shown in (11)

$$\mu_D(x)=MIN(\mu_{C_1}(x),\ldots,\mu_{C_n}(x)) \quad ( 11 )$$

The maximal decision is the option $\dot{x}$ ∈ X $_{op}$ selected in the manner described in formula ( 12 )

$$\mu_D(\dot{x})=max(\mu_D(x)), x\in X_{op} \quad ( 12 )$$

The author took under consideration a situation, when the inference engine proposed three services from Table I regarding to defined constraints $C_1$ - "low execution duration" and $C_2$ - "average execution price". These services establish the options collection $X_{op}$={"MapProvider", "PrintMap", "GisMap"} which are denoted respectively $x_1$, $x_2$, $x_3$. The task of the reasoning process is to take the maximal decision

TABLE I.
THE EXAMPLE OF DECISION TABLE WITH SELECTED ATOMIC SERVICE MODEL ATTRIBUTES

| **Operation** | **Input Parameters** | **Output Parameter** | **Provider** | **Execution Price** | **Execution Duration** | **Service Name** |
|---|---|---|---|---|---|---|
| *P1* | *P2* | *P3* | *P4* | *P5* | *P6* | *Q1* |

| provideMap | {Location} | Map | GIS Maps | 110$ | 49ms | MapProvider |
| drawSegment | {Coordinates, Coordinates, Map} | Segment | GIS Company | 0$ | 5ms | DrawSegment |
| computeDistance | {Coordinates, Coordinates} | Distance | ITS | 0$ | 1ms | ComputeSegmentDistance |

TABLE II .
THE EXAMPLE OF DECISION TABLE WITH MEMBERSHIP FUNCTIONS

| QoS | DSL Pattern | Membership Function Object |
|---|---|---|
| *P1* | *P2* | *Q1* |
| execution duration | low | LowExcutionDurationMembership Func |
| execution price | average | AverageExcutionPriceMembership Func |

$\dot{x}$ as the best proposition regarding the constraints $C_1$ and $C_2$.

The formulas ( 13 )( 14 ) specify the fuzzy constraints $C_1$ and $C_2$ using symbolic notation from ( 6 ) which points out the computed certainty factor (CF) for each option.

$$C_1 = \frac{0{,}024}{x_1} + \frac{0{,}95}{x_2} + \frac{0{,}649}{x_3} \qquad (13)$$

$$C_2 = \frac{0{,}799}{x_1} + \frac{1{,}0}{x_2} + \frac{0{,}4}{x_3} \qquad (14)$$

Regarding the formulas ( 9 ) and ( 10 ) the fuzzy decision D could be denoted as shown in formula ( 15 ).

$$D = \frac{0{,}024}{x_1} \wedge \frac{0{,}95}{x_2} \wedge \frac{0{,}4}{x_3} \qquad (15)$$

The maximal decision $\dot{x}$ assigned basing on formula (12) points the option $x_2$—“PrintMap” as the best proposition of atomic Web Service in context of defined constraints.

### C. The Use of Domain Specific Language

The domain engineer models the request to the deductive database as the production rules presented in formula (2) manner. These rules allow the experts to express the logic in their own terms [19] of Domain Specific Language (DSL):

```
rule "Service options"
when
    There is a service where
        - output parameter equals "Map"
    There is a service with "low" execution dura-
    tion
then
    Create service options set
end

rule "Make decision in fuzzy surroundings"
when
    There is maximal decision for service options
    set
then
    Propose the best service
end
```

The DSL expressions should be transformed to the notation accepted by shell of expert system:

```
[condition]
There is a service where=
$as: AtomicService ($qos : qos, $serviceName :
serviceName)

[condition]
- output parameter equals "{value}"=
outputParameter == "{value}"

[condition]
There is a service with "{value}" execution dura-
tion=
FuzzyRules ($patternED : pattern == "{value}",
$featureED : feature == "execution duration",
$membershipFuncED : membershipFunc,
eval($membershipFuncED.value($qos.executionDura-
tion) > 0));

[consequence]
Create service options set=
ArrayList al = new ArrayList();
al.add(new Double($membershipFuncED.value($qos.ex-
ecutionDuration)));
al.add(new Double($membershipFuncEP.value($qos.ex-
ecutionPrice)));
insert (new Option ($as, al));
```

The result of `Service options` reasoning rule is the option collection X $_{op}$ with values of the certainty factor (CF):

```
– Option: MapProvider
  low execution duration CF: 0.024,
  average execution price CF: 0.799

– Option: PrintMap
  low execution duration CF: 0.95,
  average execution price CF: 1.0

– Option: GisMap
  low execution duration CF: 0.649,
  average execution price CF: 0.4
```

The outcome of the `Make decision in fuzzy surroundings` rule is the best service proposition (`Proposed service: PrintMap, max membership level: 0.95`) in context of defined constraints established basing on the maximal decision formula as shown in (15).

As the expert system the JBoss Drools [9] rule engine based on the Rete algorithm [20] has been used. Drools implements and extends the Rete algorithm which is called ReteOO, what signifies that Drools has an enhanced and optimized implementation of the Rete algorithm for object-oriented systems [21].

## IV. CONCLUSION

The presented approach allows to support the domain engineer in developing applications from business processes management area. The domain engineer has no detailed experience in computer programming, but has strong expert knowledge. He can model the requests to the deductive database as the production rules in human-readable format with usage of Domain Specific Languages instead of several lines and nested loops of programming language code. The author discussed within this paper the knowledge representation in SOA and making decisions in fuzzy surroundings with the help of DSL patterns.

The further research will be focused on refinement of reasoning process with usage of other techniques of the artificial intelligence, development of domain specific languages for

GIS domain as well as discovery and matchmaking workflow of complex services.

The use of expert system seems to be a promising way of programing loosely coupled software systems by the domain experts. Also the Java platform strongly focused on Web Services as well as available object-oriented deductive databases allow for application of proposed solutions in business processes management.

***Abstract*—The paper introduces solution of Coalition Formation Problem (CFP) in Multi-Agents Systems (MAS) based on evolutionary algorithm. The main aim of our study is to develop an evolutionary based algorithm for creation of coalitions of agent for solving assumed tasks. We describe the coding schema and genetic operators such as mutation, crossover and selection that occurred to be efficient in solution of CFP. Last part of the document provides a brief comment on our research results.**

***Index Terms*—Coalition formation, evolutionary algorithm, multi–agent systems**

## I. Introduction

CONCEPT of agents (term agent will be used without distinction between software and hardware agents) is strongly connected with artificial intelligence (AI). Because the term “agent” is defined in literature in many different ways we will use definition first proposed in [7]:

**Agent** is software or hardware computer system that is/has:

1) Autonomous: agent takes actions without interference of a human and has control over taken actions,
2) Social ability: agents communicate (between themselves and/or with people),
3) Reactivity: agents have some perception of environment that they are part of and may react to changes in the environment,
4) Activity: agents may take actions to change their environment in order to achieve their goals.

When the environment contains at least two agents we talk about multi-agent system (MAS). Very often MAS are distributed. Many aspects of such systems have been widely discussed in literature. In this paper we present a new solution of the problem of coalition formation (CFP).

### A. Coalition Formation

Many tasks cannot be completed by a single agent because of limited resources or capabilities of agents. Very often, even if a task may be completed by a single agent, his performance may occur too low to be acceptable. In such a situation agents may form groups to solve the problem by cooperation. Many organizational paradigms have been distinguished in the context of MAS (see [9]). This work is focused on coalitions—groups of cooperative agents, working together on a given task, short-lived and goal-directed, being a flat structure. Initially agents are independent and do not cooperate. When they cannot complete their tasks individually agents may exchange information and try to form coalitions which gives them best efficiency (of course the efficiency must be defined in terms of solved problem).

Evaluation of all possible shapes of coalitions depends exponentially on the number of agents. For example having $m$ agents and $n$ tasks to solve all $n^m$ coalitions (with each coalition delegated to a particular task) must be evaluated to guarantee that the best coalition shape was found. Finding the optimal partition of agents set by checking the whole space may occur too expensive (in terms of time). Short lifetime of coalition may lead to a situation when time of computation is far longer than the time of existence of a particular coalition. Therefore it may create a bottleneck of a MAS. Many methods have been proposed to solve CFP. Further part of the introductory chapter will give a short summary of them.

### B. CFP—a short overview

*1) Any-time solution with worst case guarantee:* Original work given by [8] presents any-time solution with worst case guarantee. The idea is based on a remark, that searching subset of possible coalition shapes that contains all possible subsets of the set of agents may guarantee quality of the solution. That is why the best solution must consist of already searched and evaluated subsets (best solution is not worse than the best solution found so far). To make the idea clear [8] suggested representing all partitions as a graph of coalition structures (Fig. 1):

Level $LV_i$ denotes that the structures belonging to this level consist of i coalitions. Searching $LV_1$ and $LV_2$ assures that all subsets have been checked and may provide guarantee on the result. Then [8] suggests searching bottom up (in the picture levels $LV_4$, $LV_3$). Checking all coalition structures leads to brute force search and worst case guarantees are low before huge amount of the space has been searched (as shown in [5]).

*2) Distributed algorithm:* Distributed algorithms for solving CFP are proposed (among others) in [2] and [5]. The solution proposed in [5] (compared to other distributed methods) significantly minimizes efforts on communication between agents.

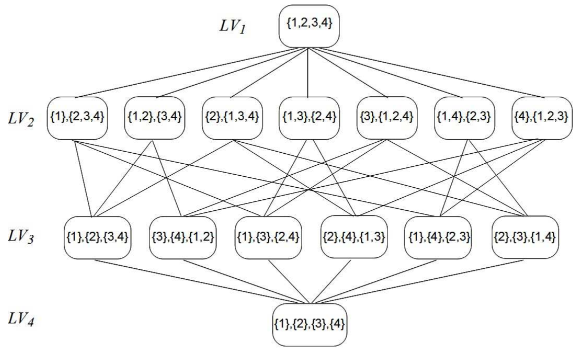

Fig. 1. Coalition structure graph for four agents

*3) Genetic algorithm based method:* In [1] the authors presents a genetic algorithm where two-dimensional, binary chromosome coding is used. The method uses so called *two dimensional "or" crossover operator* that seems to be troublesome, because after using the operator we have to review child chromosome in order to "repair" it when the operator breaks the rules of representation assumed in the method. Inspired by [1] we decided to propose an alternative chromosome coding and operators to solve CFP.

Good introduction to MAS provides [3]. Brief descriptions of organizational paradigms other than coalition of agents are presented in [9]. Environments of self-oriented, conflicting agents are described in [6]. Comprehensive introduction to evolutionary programming is provided in [4].

The main aim of our study is to develop a method of coalitions formation in multi-agent systems using evolutionary approach. The method should combine good efficiency in solving CFP with natural chromosome coding and genetic operators.The paper is structured as follows. Next section will introduce formal representation of agents and coalitions. Third chapter will cover implementation issue and experimental results. The last part of the paper concludes the results and point further research directions.

## II. The proposed method

In this section we present a formal model of our problem and the proposed evolutionary algorithm.

### A. Model

At the beginning we assumed as follows:

1) Agents solve a finite number of tasks,
2) Each agent has some ability (resources) to solve each task,
3) Each task requires some abilities (resources) to be solved,
4) Particular agent may have insufficient abilities (resources) to solve a task,
5) Agents are cooperative,
6) Agents are altruistic—their own good is less important than the good of the system as a whole,
7) Each agent must contribute to exactly one coalition,
8) We want to solve as many tasks as possible with the given set of agents.

According to these assumptions the following model of the problem has been proposed:

Set of tasks is represented as a vector T:

$$T = < T_1, \ldots, T_n >, T_i \in (\mathbb{N}_+ \setminus \{1\}), i > 1$$

Value $t$ at position $T_i$ means that to solve task $i$ $t$ units of resource (ability) are needed. We assume that $i > 1$ because for $i = 1$ the problem is trivial.

Let $A$ be a set of agents:

$$A = \{A_1, \ldots, A_k\}$$

where each agent $A_i$ is represented as:

$$A_i = < U_1, \ldots, U_n >, U_i \in \mathbb{N}, i > 1$$

Value $p$ at position $U_j$ means that agent $i$ has abilities (resources) of $p$ to solve task $j$.

Set $K$ representing partition of set $A$ with properties given below will be the result of proposed algorithm:

- Each element $C_i \in K$ will be a coalition,
- Each element $C_i$ will be a set of agents such that $C_i \subseteq A$ (in particular $C_i$ may be empty),
- For each $C_i, C_k \in K$: $C_i \cap C_k = \emptyset, i \neq k$
- $\bigcup_{i=1}^{n} C_i = A, n = card(K)$
- Membership of an agent in a coalition $i, 1 \leq i \leq n$ means that the agent contributes to solution of task $i$.
- $K$ represents partition that achieved the best (the highest) value of fitness function (described further).

We defined total ability of a coalition $i$ to solve its task as a simple sum of abilities (resources) of its (coalition's) members' abilities to solve the task. Formally total ability $\delta_i$ is given as:

$$\delta_i = \sum_{A_t \in C_i} U_i[A_t]$$

We say that task $i, 1 \leq i \leq n$ is solved in a given partition when (for given $i$) $\delta_i \geq T_i$.

Evolutionary algorithm operates on a set of individuals—$V$—each of them representing some partition of set $A$. Each individual is represented as a vector $v_i$:

$$v_i = < d_1, \ldots, d_q >, \text{ where:}$$
$$d_i \in \mathbb{N} \wedge d_i \in [1, card(T)], q = card(A)$$

All genetic operations are conducted on elements (individuals) from set $V$. Both operators used in our method (crossover and mutation) are presented in next subsection.

### B. Evolutionary algorithm

Evolutionary algorithm that we developed uses $(\mu + \lambda)$ strategy (for detailed information about evolutionary strategies see [4]). We use $\mu = \lambda$. To preserve the best (so far) solution individual with the highest value of fitness function always survives (is added to child population).

Figure 2 presents block diagram presenting main loop of the algorithm.

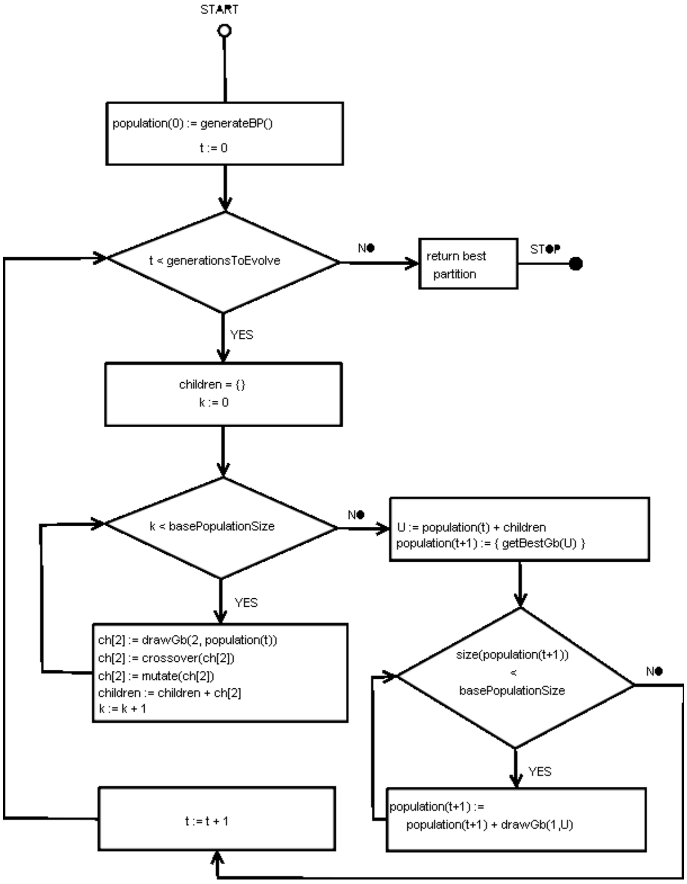

Fig. 2. Evolutionary algorithm block diagram

A few elements on the diagram (Fig. 2) need comment:

- Function drawGb(2, population(t)) draws two individuals from population(t) with returning,
- Function getBestGb(U) gets individual with the highest fitness function value, suffix Gb means that this operation is conducted with returning.

### *C. Operators, fitness function, base population*

*1) Crossover:* We use standard two-point crossover operator. Chromosomes to cross are drawn (chosen stochastically) with giving back with probability proportional to their fitness (fitness and its function are discussed later). Both produced chromosomes are added to child population. Proposed crossover operator preserves the property that each agent (in a child chromosome) belongs to exactly one coalition. Therefore we do not need to repair the chromosome. Two-point crossover (and many more) are discussed in [4].

*2) Mutation:* Mutation is carried out with a given probability $p$ on a single gene. The operator randomly chooses whether to mutate the gene. Mutation randomly changes the coalition to which the agent represented by the gene is assigned. Alike crossover, mutation does not break the chromosome therefore no repairs are needed.

*3) The initial population:* Initial population (the first generation) is generated randomly. Its size is given arbitrarily and all created chromosomes are correct in terms of definitions given in previous chapters.

*4) Fitness function:* A fitness function is essential for the method. As we want to maximize the number of tasks solved by coalitions of agents following assumptions about the function have been made:

- An individual should be punished for non-completion of a task,
- And individual should be punished for exceeding the required abilities (resources) by a coalition ($\delta_i > T_i$),
- Punishment for non-completion of a task should be more harmful than the punishment for exceeding the boundary,
- Fitness function must be non-negative.

Based on the above remarks we designed the following way of fitness calculation (Algorithm 1):

**Algorithm 1** Calculating fitness function value

```
$fitVal \leftarrow numberOfTasks$
for AllCoalitions : Ci do
    if $\delta_i < T_i$ then
        $fitVal \leftarrow fitVal - 1.2 + max(0.2, \delta_i/T_i)$
    else
        if $T_i \neq 0$ then
            $fitVal \leftarrow fitVal - min(0.05, (\delta_i - T_i)/T_i)$
        else
            $fitVal \leftarrow fitVal - 0.05$
        end if
    end if
end for
return fitVal
```

All coefficients in the above algorithm were chosen by manual testing of various values. Given coefficients occurred to be satisfactory in solved problem but should be treated as a hint not as a rule.

At this point it is worth mentioning that the given fitness function is not perfect. It may happen in some situations that some coalition's structure $A$ solving more tasks than coalition $B$ has lower fitness value. It is caused by the punishment for exceeding task's boundary of required resources (abilities). Such a situation usually does not spoil algorithm's results, nevertheless, it is discussed further together with experimental results.

## III. Implementation, results of experiments

Our implementation language was Java. Neither evolutionary algorithm nor MAS frameworks were used. Usage of Strategy pattern occurred to be useful while trying different operators, population generators, etc. See [10] for comprehensive information about design patterns.

Different types of test data have been used. We prepared:

- 2 types of agent populations (random and predefined),
- 2 sizes of agent population,
- 2 sizes of task set,
- 2 sizes of base population.

Brief comment of test data is provided in the next section. After a series of initial test with different values of mutation probability and number of generations we decided to use:

- Probability of mutation: $1\%$,
- Number of generations: $500$.

Given values provided good results, nevertheless, (like for fitness function) they should be treated as a hint.

*5) Agent populations, tasks requirements:* We used two sizes of agent populations containing respectively: 20 agents (solving 5 tasks) and 30 agents (solving 10 tasks). Each population size was tested in two variants: predefined and generated. Predefined population of 20 agents was defined as:

$$\begin{array}{c}
A_{20} = \{ \\
<2,1,1,1,1>, <2,1,1,1,1>, \\
<2,1,1,1,1>, <2,1,1,1,1>, \\
<1,2,1,1,1>, <1,2,1,1,1>, \\
<1,2,1,1,1>, <1,2,1,1,1>, \\
<1,1,2,1,1>, <1,1,2,1,1>, \\
<1,1,2,1,1>, <1,1,2,1,1>, \\
<1,1,1,2,1>, <1,1,1,2,1>, \\
<1,1,1,2,1>, <1,1,1,2,1>, \\
<1,1,1,1,2>, <1,1,1,1,2>, \\
<1,1,1,1,2>, <1,1,1,1,2> \\
\}
\end{array}$$

Set of 30 agents was defined as:

$$\begin{array}{c}
A_{30} = \{ \\
<2,1,1,1,1,1,1,1,1,1>, <2,1,1,1,1,1,1,1,1,1>, \\
<2,1,1,1,1,1,1,1,1,1>, <2,1,1,1,1,1,1,1,1,1>, \\
<2,1,1,1,1,1,1,1,1,1>, <2,1,1,1,1,1,1,1,1,1>, \\
<2,1,1,1,1,1,1,1,1,1>, <1,2,1,1,1,1,1,1,1,1>, \\
<1,2,1,1,1,1,1,1,1,1>, <1,2,1,1,1,1,1,1,1,1>, \\
<1,2,1,1,1,1,1,1,1,1>, <1,2,1,1,1,1,1,1,1,1>, \\
<1,2,1,1,1,1,1,1,1,1>, <1,2,1,1,1,1,1,1,1,1>, \\
<1,1,4,1,1,1,1,1,1,1>, <1,1,4,1,1,1,1,1,1,1>, \\
<1,1,1,4,1,1,1,1,1,1>, <1,1,1,4,1,1,1,1,1,1>, \\
<1,1,1,1,4,1,1,1,1,1>, <1,1,1,1,4,1,1,1,1,1>, \\
<1,1,1,1,1,4,1,1,1,1>, <1,1,1,1,1,4,1,1,1,1>, \\
<1,1,1,1,1,1,4,1,1,1>, <1,1,1,1,1,1,4,1,1,1>, \\
<1,1,1,1,1,1,1,4,1,1>, <1,1,1,1,1,1,1,4,1,1>, \\
<1,1,1,1,1,1,1,1,4,1>, <1,1,1,1,1,1,1,1,4,1>, \\
<1,1,1,1,1,1,1,1,1,4>, <1,1,1,1,1,1,1,1,1,4> \\
\}
\end{array}$$

$T$ vectors for 20 and 30 predefined agents were given as (respectively):

$$T_{20} = <8,8,8,8,8>$$

$$T_{30} = <14,14,8,8,8,8,8,8,8,8>$$

In the case of generated sets of agents we used a generator that (having predefined $T$ vector) prepared such a set that could solve all tasks without a punishment (in terms of fitness function) for exceeding the threshold of needed resources. Each agent in a generated set has positive value of ability to solve any task so it is not obvious to which coalition it should be assigned. Of course the generator does not guarantee that only one optimal solution exists, but it ensures existence of at least one.

We decided to use test data that ensured existence of a solution that solved all tasks. Resources were limited (in fact limits were very rigid) and search spaces were huge (for 10 tasks and 30 agents the whole space consisted of $10^{30}$ possible coalitions!). The choice was suggested by used method which is worth applying to extremely hard combinatorial problems that cannot be solved in acceptable amount of time by deterministic search of the space (e.g. dynamic programming).

*6) The initial population:* We tried two sizes of the initial population for the evolutionary algorithm: 25 and 50 individuals.

*7) Experimental results:* To find optimal parameters for the algorithm we compared four cases:

- Generated test data, base population size: 25/50, number of tasks: 5, number of agents: 20,
- Generated test data, base population size: 25/50, number of tasks: 10, number of agents: 30,
- Predefined test data, base population size: 25/50, number of tasks: 5, number of agents: 20,
- Predefined test data, base population size: 25/50, number of tasks: 10, number of agents: 30.

Results of our experiments are listed in tables I, II, III and IV:

TABLE I

EXPERIMENT I: GENERATED TEST DATA, BASE POPULATION SIZE: 25/50, NUMBER OF TASKS: 5, NUMBER OF AGENTS: 20

| No | Population size | Tasks solved (best) | Fitness function (best) | In generation |
|---|---|---|---|---|
| 1 | 25 | 5 | 4.95 | 16 |
| 2 | | 5 | 4.95 | 35 |
| 3 | | 5 | 5.00 | 22 |
| 4 | | 5 | 4.95 | 17 |
| 5 | | 5 | 5.00 | 17 |
| 6 | | 5 | 5.00 (4.95)[1] | 146 (61)[2] |
| 7 | | 5 | 5.00 (4.90) | 269 (13) |
| 8 | | 5 | 5.00 (4.90) | 46 (8) |
| 9 | | 5 | 5.00 (4.95) | 14 (4) |
| 10 | | 5 | 5.00 (4.85) | 371 (7) |
| 11 | 50 | 5 | 5.00 | 18 |
| 12 | | 5 | 5.00 (4.85) | 55 (6) |
| 13 | | 5 | 5.00 (4.85) | 127 (12) |
| 14 | | 5 | 5.00 (4.80) | 25 (11) |
| 15 | | 5 | 5.00 (4.85) | 54 (13) |
| 16 | | 5 | 5.00 (4.95) | 24 (10) |
| 17 | | 5 | 5.00 (4.90) | 388 (7) |
| 18 | | 5 | 5.00 | 16 |
| 19 | | 5 | 5.00 | 18 |
| 20 | | 5 | 5.00 (4.80) | 35 (8) |

TABLE II
EXPERIMENT II: GENERATED TEST DATA, BASE POPULATION SIZE: 25/50, NUMBER OF TASKS: 10, NUMBER OF AGENTS: 30

| No | Population size | Tasks solved (best) | Fitness function (best) | In generation |
|---|---|---|---|---|
| 1 | 25 | 10 | 9.85 (9.80) | 272 (207) |
| 2 | | 10 | 9.90 (9.80) | 298 (94) |

| 19 | | 5 | 5.00 | 33 |
| 20 | | 5 | 5.00 | 41 |

As we can see after 500 generations of algorithm's work in every test case I-IV we obtained solution no worse than $80\%$ of optimal one. Tests I and III in most cases were solved returning optimal partition. For generated test data we obtained $100\%$ accuracy. Average quality of solution in these cases exceeded $90\%$ Two factors had impact on our results:

1) Search space was relatively small ($5^{20}$ compared to $10^{30}$ makes $2^{20} \cdot 10^{10} \approx 10^{16}$ times smaller search space),
2) In the case of generated data it was not so rigid as predefined so more than one optimal solution might have existed.

In both cases the amount of 500 generations was to big number. For generated data optimal solutions were found in less than 100 generations. For predefined data in most cases 200 generations were enough to obtain comparable results.

In test cases number II and IV we achieved accuracy no worse than $80\%$ of optimal solution. Again generated data occurred to be less rigid and gave better results (exceeding $90\%$ of the best solution). For generated data 250 generations of evolutionary algorithm's work occurred to be enough to provide comparable results. Even after 500 generations our algorithm in most cases did not exceeded 8 solved tasks (only 3 times we achieved 9 tasks solved and it took over 270 generations).

Figures 3 and 4 show algorithm's progress. In both cases we put the number of generation on OX and the value of a given function on OY (3 functions are presented and described on the plots). Both plots show a case where despite the growth of fitness of the best individual the number of tasks solved by (current) best solution is lower (on figure 3 we see this situation between 20-th and 200-th generation; on figure 4 about 50-th generation). As mentioned earlier, this situation is caused by punishment used in fitness function. Despite the fact that such a situation is not frequent it may happen that solution with the highest value of fitness function does not provide partition that solves most tasks (even if such partitions were checked).

## IV. CONCLUSIONS AND FURTHER RESEARCH

Our approach occurred to be efficient in solving CFP. Its power is remarkable especially in huge spaces where brute force search and other regular and deterministic search methods cannot be applied because of limited resources (especially time).

Comparing to [1], implementation of GA presented in this paper uses natural coding of chromosome (simple vector rather than complex 2D structure) which makes it easier to use and preserves classic flow of genetic (evolutionary) algorithm. Simple chromosome coding made it possible to use standard mutation and crossover operators. Both of them create individuals that do not break domain constraints (one agent belongs to exactly one coalition) while *two dimensional "or" crossover operator* proposed in [1] enforced checking of

[1] Value in brackets shows the value of fitness function which provided the same number of solved tasks. The value was achieved in a generation which number is shown in brackets in column "In generation". See [2]. The value is given only when the difference between generations is significant.

[2] Situation symmetric to described in [1].

TABLE IV
EXPERIMENT IV: PREDEFINED TEST DATA, BASE POPULATION SIZE: 25/50, NUMBER OF TASKS: 10, NUMBER OF AGENTS: 30

| No | Population size | Tasks solved (best) | Fitness function (best) | In generation |
|---|---|---|---|---|
| 1 | 25 | 8 | 8.45 | 215 |
| 2 | | 8 | 8.09 (7.95) | 154 (68) |
| 3 | | 9 | 9.00 | 273 |
| 4 | | 8 | 8.09 (7.90) | 260 (154) |

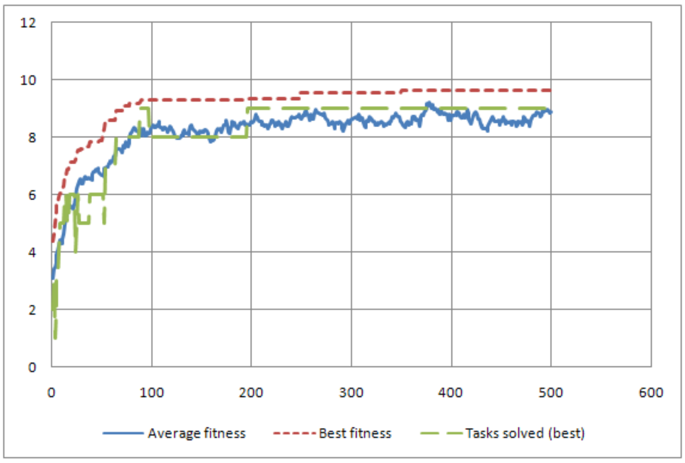

Fig. 3. Algorithm's progress: plot for test II (row number 18)

child chromosomes because they might break the constraint of one-to-one agent to coalition assignment.

Another thing worth mentioning is the initial population. In [1] every coalition structure that does not solve all tasks is assigned fitness of 0. Initial population is generated with revisions whether all tasks are solved and only total efficiency of a whole system (solving all tasks) is being optimized. Such assumption enforces low bounds on available resources (agents may solve all tasks). Our approach does not assume that all tasks must be solved (we do not know whether even a single one can be solved at all). Therefore our initial population is generated randomly, without further revisions. Main optimization target of our method is the number of solved tasks which seems to be very important in real-time, strongly constrained domains.

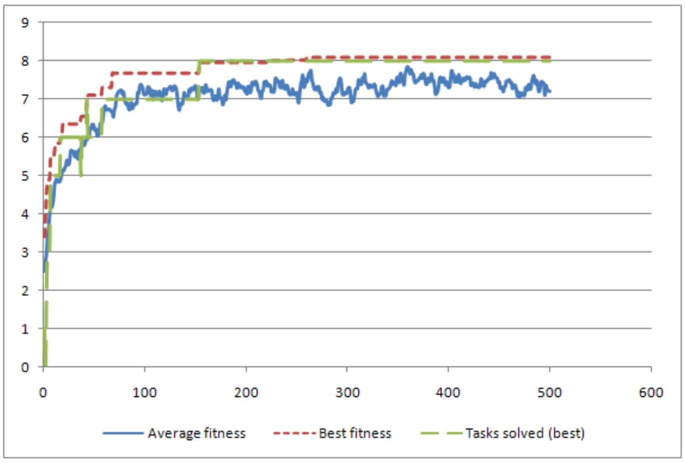

Fig. 4. Algorithm's progress: plot for test IV (row number 4)

The main limitation of our method is its centralization. As we mentioned in the first section, MAS are often distributed (or are at least independent processes or threads). Centralized control must assume that agents are cooperative not competitive. Such an assumption may be acceptable in MAS environments composed of agents belonging to one company. It may be, however, too strong in the case of distributed environments accessible for agents belonging to different companies and having contradictory aims. Therefore we are going to develop a method of coalition formation based on the search of consensus (equilibrium) through negotiation. In such a system the only requirement for agents would be to understand the protocol of communication. Therefore there are no obstacles to make the system fully decentralized and distributed.

***Abstract*—When training machines classifiers, it is possible to replace hard classification targets by their emphasized soft versions so as to reduce the negative effects of using cost functions as approximations to misclassification rates. This emphasis has the same effect as sample editing methods which have proved to be effective for improving classifiers performance. In this paper, we explore the effectiveness of using emphasized soft targets with generative models, such as Gaussian Mixture Models, that offer some advantages with respect to decision (prediction) oriented architectures, such as an easy interpretation and possibilities of dealing with missing values. Simulation results support the usefulness of the proposed approach to get better performance and show a low sensitivity to design parameters selection.**

## I. Introduction

TRAINING machine classifiers with conventional search procedures using hard targets results in minimizing a cost function which is not more than an approximation to the error rate. Fisher type formulations [1] and "decision based" algorithms [2] are also approximations as well as "energy functions" [3], while the Perceptron Rule [4] has convergence difficulties and generalization limitations.

Sample selection or sample editing methods try to compensate the suboptimal character of the conventional approaches by paying more attention to samples that are more important for defining the classification borders. [5] was the first proposal along this line. It was followed by many schemes that were proposed to emphasize sample populations that pay attention to samples lying (approximately) near the borders [6][7][8] or to samples which offer higher errors [9][10]. Some original formulations about boosting schemes to construct classifier ensembles [11][12][13] seem to be rather based on giving importance to erroneous samples, although [14][15] prove that Real Adaboost emphasizes both erroneous samples and those that are near the border; the last reference also propose some generalizations. It is also clear that emphasizing sample populations is very similar to selecting appropiate cost functions. In this sense, the Maximum Margin algorithm used to train Support Vector Machines [16][17][18] can be considered as a procedure which emphasizes both kinds of samples, as well. It is unclear which of these types of samples is more important to get a good design, although the answer seems to be problem dependent [19].

Among other alternatives, the one of substituting the "hard" classification targets for soft versions is interesting, because it leads to an estimation (or regression) problem, in which standard cost functions can be applied without the difficulties mentioned above. This will allow the possibility of directly applying machines that are conceived in order to solve regression problems, such as Gaussian Processes [20][21], for classification tasks. Although there are many forms of generating soft versions of decision targets, such as using convolutional smoothing [22], it seems reasonable to keep the advantages that sample emphasis provides. This was the orientation of [23] and of our previous work [24], in which we demonstrated the effectiveness of using an emphasized combination of the original targets and those provided by an auxiliary classifier to get better classification performance for the most popular family of discriminative (predictive) designs, Multi-Layer Perceptrons (MLP).

In this paper, we extend our studies to generative models, presenting results for the well known Gaussian Mixture Models (GMM), that we apply both in discriminative and soft-target based generative forms to solve classification problems. This study is important not only for the exploration of the general applicability of soft targets approaches, but also because GMM are relatively easy to understand and they accept well principled methods to deal with missing values.

The rest of the paper is organized as follows. In Section 2, we review the basic algorithm that defines the emphasized soft targets. In Section 3, we explain how to solve a classification problem using the soft target definition and GMM models. Section 4 is devoted to check the performance of the proposed approach in a series of experimental settings. We close the paper with the conclusion which emerges from the experiments and some suggestions for further research along this line.

## II. A Method to Construct Emphasized Soft Targets

In order to create soft targets, it is not practical to use the output of a previously trained (auxiliary) classifier, because the

*This work has been partially supported by MEC Pjt. TEC2005-00992. The work of S. El Jelali was also supported by an AECI grant.

decision results of the scheme being trained with these soft targets can be worse than those of the auxiliary machine, because we are trying to repeat its errors. A convex combination of the original (hard) targets and auxiliary machine outputs $\mathrm{o}_{aux}(\mathbf{x})$ can serve to avoid this difficulty; and even more, if we use a well selected local combination parameter $\lambda(\mathbf{x})$ [24], we will have the possibility of applying an emphasis to the samples. A reasonably simple procedure consists on defining soft targets

$$t_s(\mathbf{x}) = \lambda(e(\mathbf{x}))t(\mathbf{x}) + (1 - \lambda(e(\mathbf{x})))\mathrm{o}_{aux}(\mathbf{x}). \qquad (1)$$

where $\mathbf{x}$ is the (training) sample, $t(\mathbf{x})$ is the original (hard) target, $\mathrm{o}_{aux}(\mathbf{x})$ is the output of the auxiliary classifier (in this paper, we will use an MLP for this role), $e(\mathbf{x})$ is the error corresponding to this auxiliary output, and $\lambda(e(\mathbf{x}))$ is a convex combination (emphasis) weight having the form

$$\lambda(e(\mathbf{x})) = \begin{cases} \exp(-\dfrac{(|e(\mathbf{x})| - \mu)^2}{\alpha_1})\text{for} & |e(\mathbf{x})| \leq \mu, \\ \\ \exp(-\dfrac{(|e(\mathbf{x})| - \mu)^2}{\alpha_2})\text{for} & \mu < |e(\mathbf{x})| \leq 2. \end{cases} \qquad (2)$$

$\mu$, $\alpha_1$, $\alpha_2$ being parameters of the Gaussian bells, that must be selected during the design phase.

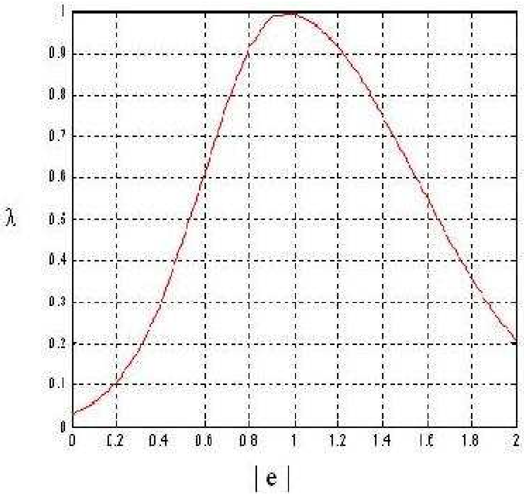

Fig. 1. Form of $\lambda(|e(\mathbf{x})|) : \mu = 1$, $\alpha_1 < \alpha_2$

The form we propose for the convex combination weight is shown in Fig.1. Note that $\mu$ is the value of $|e(\mathbf{x})|$ at which $t_s(\mathbf{x})$ is maximum (unity), and that $\alpha_1$ and $\alpha_2$ control the decay of $t_s(\mathbf{x})$ from this value when samples are clearly well classified ($|e(\mathbf{x})| \to 0$), so they are not very important, or when the samples give highly erroneous results ($|e(\mathbf{x})| \to 2$), in which case they are difficult to classify correctly. So, we can select the value of $|e(\mathbf{x})|$ at which we apply the highest emphasis, and we have flexibility to reduce this emphasis for both "easy" or "impossible" samples.

Although it is obvious that there are many other flexible and reasonable forms for (2), it is easy to verify, as predicted in [25], that the performance of the corresponding designs does not depend critically on the particular emphasis which is employed.

## III. Using GMM

To solve a classification problem by means of GMM models directly, we have to construct these models for both hypotheses, $\widehat{p}(\mathbf{x}|i) = \sum_l \pi_l p_l(\mathbf{x}|i), i = \pm 1$ ( $\{p_l(\mathbf{x}|i)\}$ being Gaussian densities), typically using the Expectation-Maximization (EM) algorithm; then, we construct the approximation to the Maximum A Posteriori (MAP) classifier

$$\widehat{Pr}(1|\mathbf{x}) \underset{-1}{\overset{+1}{\gtrless}} \widehat{Pr}(-1|\mathbf{x})$$

where

$$\widehat{Pr}(i|\mathbf{x}) = \frac{\widehat{p}(\mathbf{x}|i)\widehat{p}(i)}{\sum\limits_{i'} \widehat{p}(\mathbf{x}|i')\widehat{p}(i')}\text{for}i = 1, -1. \qquad (3)$$

$i, i' = 1, -1$; $\{\widehat{p}(i)\}$ can be obtained as relative frequencies.

On the other hand, assuming that we are working with soft target $t_s(\mathbf{x})$, the estimation is addressed under a multidimensional GMM model, first estimating the joint distribution

$$\widehat{p}(t_s, \mathbf{x}) = \sum_l \pi_l p_l(t_s, \mathbf{x}). \qquad (4)$$

with the help of the EM algorithm. After it, since the a posteriori expectation of the target is an estimate of $Pr(1|\mathbf{x}) - Pr(-1|\mathbf{x})$, we look for

$$\begin{aligned} \widehat{t_s}(\mathbf{x}) = \widehat{E}\{t_s|\mathbf{x}\} &= \int t_s \widehat{p}(t_s|\mathbf{x}) dt_s \\ &= \int t_s \frac{\widehat{p}(t_s, \mathbf{x})}{\widehat{p}(\mathbf{x})} dt_s = \sum_l \frac{\pi_l p_l(\mathbf{x})}{\sum\limits_{l'} \pi_{l'} p_{l'}(\mathbf{x})} \int t_s \widehat{p}_l(t_s|\mathbf{x}) dt_s \\ &= \sum_l \frac{\pi_l p_l(\mathbf{x})}{\sum\limits_{l'} \pi_{l'} p_{l'}(\mathbf{x})} \widehat{E}_l\{t_s|\mathbf{x}\}. \end{aligned} \qquad (5)$$

where marginal densities are

$$p_l(\mathbf{x}) = \int p_l(t_s, \mathbf{x}) dt_s \text{for} l = 1, \ldots, L. \qquad (6)$$

It is immediate to check that

$$\widehat{E}_l\{t_s|\mathbf{x}\} = \mathbf{w}_{l,e}^T \mathbf{x}_e = \mathbf{w}_l^T \mathbf{x} + w_{0,l}. \qquad (7)$$

where $\mathbf{w}_l$ is given by the normal equations

$$\mathbf{w}_l = V_{\mathbf{xx},l}^{-1} \mathbf{v}_{t_s\mathbf{x},l}. \qquad (8)$$

$V_{\mathbf{xx},l}$ and $\mathbf{v}_{t_s\mathbf{x},l}$ being the autocovariance matrix of data $\mathbf{x}$ and the cross-covariance vector of target $t_s$ and data $\mathbf{x}$ under (Gaussian) model $p_l(t_s, \mathbf{x})$, that are obtained from the autocovariance matrix of this distribution by deleting its first row and column and as its first column, respectively; finally,

$$w_{0,l} = E_l\{t_s\} - \mathbf{w}_l^T E_l\{\mathbf{x}\}. \qquad (9)$$

where $E_l\{t_s\}$ and $E_l\{\mathbf{x}\}$ are the first element and the remaining vector of the mean vector of $p_l(t_s, \mathbf{x})$, respectively.

Note that $V_{\mathbf{xx},l}$ and $E_l\{\mathbf{x}\}$ are the covariance matrix and mean vector of Gaussian density $p_l(\mathbf{x})$.

The above expressions are formally similar to those corresponding to Mixture of Experts (MoE) ensembles[26][27], as previously mentioned in [28]. However, in our case, we will obtain $\widehat{t}_s(\mathbf{x})$ from the parameters corresponding to the GMM of $p(t_s, \mathbf{x})$ calculated by applying the EM algorithm. Finally, the decision for a new sample $\mathbf{x}_n$ is

$$dec(\mathbf{x}_n) = sgn(\widehat{t}_s(\mathbf{x}_n)). \tag{10}$$

Fig.2 depicts the corresponding decision machine.

## IV. Experiments

### A. Datasets

We have tested the proposed method with six datasets that are frequently used as benchmarks for classification problems. The first is the synthetic bidimensional Kwok problem [29]; the other five are taken from the UCI Machine Learning Repository [30]: Abalone (converted into a binary problem according to [31]), Breast Cancer, Contraceptive, Ionosfera, and Pima Indian. We will refer to them as kwo, aba, bre, con, ion, and pim, respectively. Table 1 shows their main characteristics.

### B. Training

All data were normalized -if not previously done- between -1 and 1.

We use an MLP with $N$ hidden neurons as the auxiliary machine. The number of hidden neurons, as well as parameters $\mu$, $\alpha_1$ and $\alpha_2$, and the number of components of GMM, $L$ for the joint model and $L_1$, $L_{-1}$ for the separate class models, are found by means of a 10-fold cross-validation (CV) using 10 runs, exploring the following values:

-$N$: 4, 6, 8, 10 ,12, 14, 16

-$\mu$: 0.01, 0.1, 0.3, 0.6, 1, 1.2, 1.6, 2

-$\alpha_1$, $\alpha_2$: 0.001, 0.01, 0.05, 0.1, 0.5, 1, 1.5, 2, 3, 4, 5

-$L$: 4, 5, 6, 7, 8, 9, 10

-$L_1$, $L_{-1}$: 2, 3, 4, 5

TABLE I
Characteristics of the test problems

| **Dataset** | **Train** $(\mathbf{C_{+1}/C_{-1}})$ | **Test** $(\mathbf{C_{+1}/C_{-1}})$ | $\#\mathbf{dim}$ |
|---|---|---|---|
| **kw** | 500<br>(200/300) | 10200<br>(4080/6120) | 2 |
| **aba** | 2507<br>(1238/1269) | 1670<br>(843/827) | 8 |
| **bre** | 420<br>(145/275) | 279<br>(96/183) | 9 |
| **con** | 883<br>(506/377) | 590<br>(338/252) | 9 |
| **ion** | 201<br>(101/100) | 150<br>(124/26) | 34 |
| **pim** | 461<br>(161/300) | 307<br>(107/200) | 8 |

These experiments did not present important difficulties due to eventual closeness to singularity of the covariance matrices [32]; when this appears in other cases, the solution proposed in [33] can be applied.

Table 2 presents the results of the experiments, as well as the values of the design parameters that are obtained from applying CV. With respect to direct MLP and MAP GMM designs, the results of our approach (SOFT GMM) show an advantage going from very small for kwo and bre to important for pim, ion, and con. The results are also competitive with those provided by an SVM with a Gaussian kernel whose parameters have also been optimized by a 10-fold CV process (penalty factor $C$ : $[10^{-1}11010^{2}10^{3}10^{4}]$), taking the kernel dispersion as $\sigma = \sqrt{\#dim/2}$. We have used the IRWLS SVM toolbox for Matlab [37] for pattern recognition, with tolerance $\epsilon = 10^{-5}$ to provide the accuracy required for the solution of the Quadratic Programming (QP) algorithm.

To make evident the advantage of the proposed method, Fig. 3 shows the classification boundaries for kwo obtained with the optimal MLP, the MAP-GMM method, and the proposed approach, compared with the theoretical boundary. Note that the greater proximity of the proposed classifier boundary to the optimal boundary means that it correctly classifies some samples that MLP and MAP-GMM place in the wrong decision region.

TABLE II
AVERAGED PERCENTAGES OF CORRECT CLASSIFICATION ± STANDARD DEVIATION AND DESIGN PARAMETERS FOR EACH METHOD (MLP: $N$; MAP GMM: $k_1, k_2$; SOFT GMM: $k, N, \mu, \alpha_1, \alpha_2$; AND SVM: $C$) FOR THE TEST DATASETS WITH A 10-FOLD CROSS-VALIDATION

| **con** | $70.38$<br>$\pm 2.24$<br>$N = 10$ | $62.88$<br>$\pm 1.41$<br>$k_1 = 4,$<br>$k_2 = 4$ | $65.69$<br>$\pm 1.98$<br>$k = 8,$<br>$N = 6,$<br>$\mu = 1.6$<br>$\alpha_1 = 0.1,$<br>$\alpha_2 = 4$ | $70.39$<br>$\pm 0.65$<br>$C = 10,$<br>$\sigma = 2.12$ |
| **ion** | $93.22$<br>$\pm 1.48$<br>$N = 6$ | $93.15$<br>$\pm 2.56$<br>$k_1 = 3,$<br>$k_2 = 3$ | $94.52$<br>$\pm 1.82$<br>$k = 9,$<br>$N = 6,$<br>$\mu = 1.2,$<br>$\alpha_1 = 0.05$<br>$\alpha_2 = 0.5$ | $97.80$<br>$\pm 0.45$<br>$C = 10,$<br>$\sigma = 4.12$ |
| **pim** | $78.33$<br>$\pm 1.33$<br>$N = 6$ | $72.72$<br>$\pm 1.40$<br>$k_1 = 2,$<br>$k_2 = 2$ | $77.37$<br>$\pm 1.50$<br>$k = 6,$<br>$N = 4,$<br>$\mu = 0.3,$<br>$\alpha_1 = 0.01,$<br>$\alpha_2 = 1$ | $75.44$<br>$\pm 0.79$<br>$C = 10^2,$<br>$\sigma = 2.12$ |

Of course, this advantage is obtained at a high training cost, since we need to select the best of $\#N \times \#\mu \times \#\alpha_1 \times \#\alpha_2 \times \#L$ designs, and not just $\#N$ (for a single MLP), $\#L_1 \times \#L_{-1}$ (for the MAP GMM case), or $\#C$ (for SVM schemes). However, once the proposed machine is trained, its application requires a pretty moderate computational effort, equivalent to that of using a GMM for regression.

An additional problem could appear in terms of sensitivity with respect to the values of the design parameters selected by CV. To explore this in a exhaustive form (considering variations of all the design parameters around each optimal design) is too complex. A more reasonable option is to present the results of the so-called “omniscient” designs, those that select the design parameters according to their performances for the test sets. Of course, these omniscient versions are not acceptable as valid designs, but comparing their performances (and the corresponding design parameter values) with those of the optimal CV designs is an indication of the sensitivity of these machines.

Table 3 presents the same values than Table 2, but for the corresponding omniscient machines. Note that, even having to select much more design parameters, the proposed method

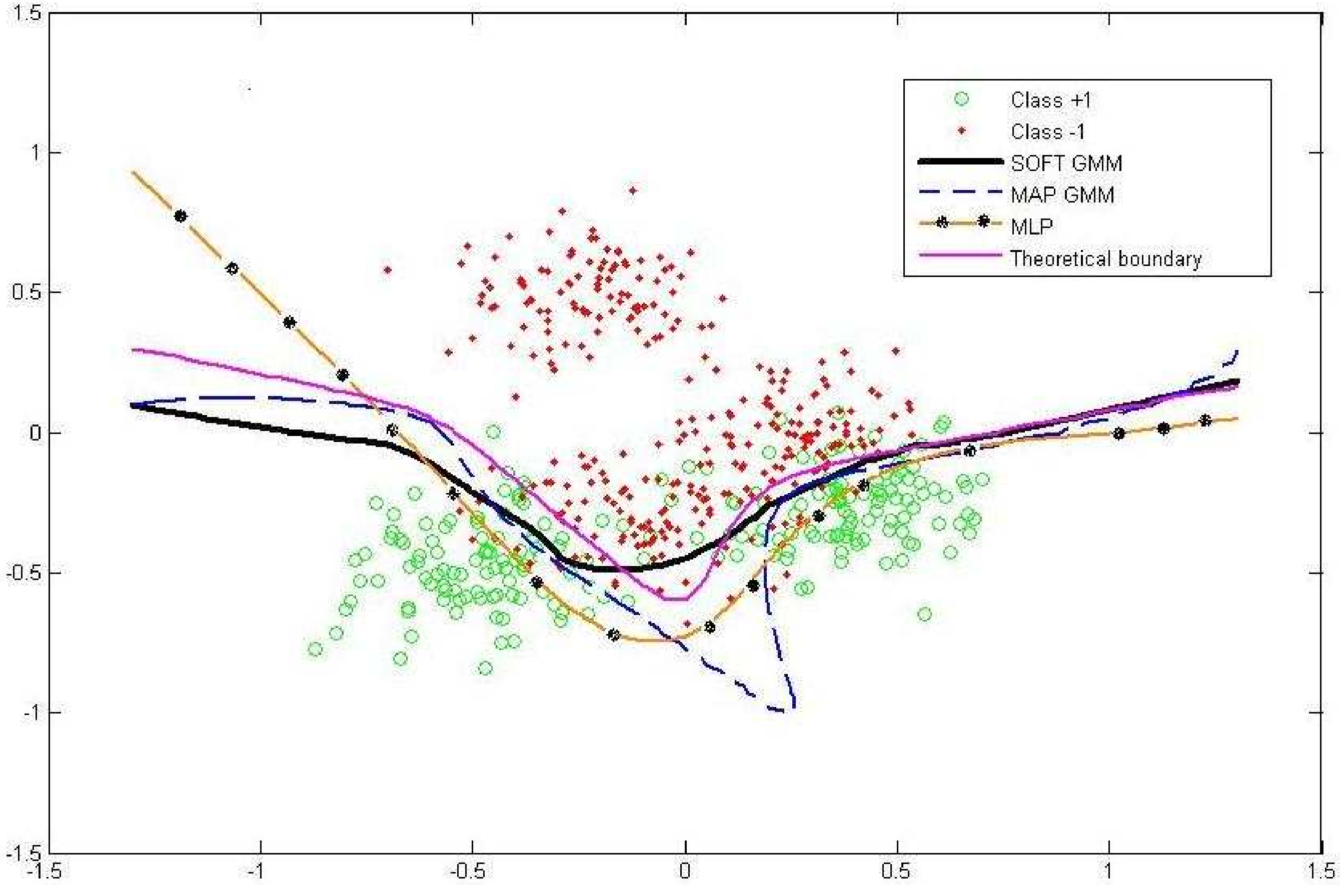

Fig. 3. Boundaries for the three methods mentioned in Table 2 compared with the theoretical boundary for test problem kwo, which is subsampled to 500 samples ($C_{+1} : 200/C_{-1} : 300$)

gets the omniscient result in two problems (aba and con), while the MAP GMM gets it just once (ion). Additionally, even with different design parameters, the CV and omniscient designs for our method show small performance differences for kwo and bre, and significant differences only for pim, just the problem for which the improvement of our proposal with respect to standard designs is the highest. When applying MAP GMM schemes, small differences also appear for kwo and con, and are important for bre. For MLPs, CV offers the omniscient design in ion, and a significant difference in kwo and pim, even $N$ being the only design parameter to be selected. So, it appears that we have a reduced sensitivity when using our designs.

## V. Conclusion

In this work, we have extended the idea of emphasized target smoothing to GMM based decision (it is also possible to extend it to other generative models, such as Parzen windows [34], using Nadaraya-Watson regression [35][36] to deal with soft targets; similar results are obtained). As in the previously studied case of MLP, extensive simulation results allow to conclude that the proposed approach does allow eventual performance improvements with respect to the component standard machines, and it even offers a low sensitivity with respect to the selection of design parameters values. Obviously there is a need for more computational effort to design the proposed classifiers, but their operation is computationally light, and, in the case of being applied to generative models, they have the advantages of allowing a relatively easy interpretation and make it possible to apply principled methods to deal with missing values.

Further research on the extensions of the proposed method will address its use in GP machines, that do not have direct forms for classification purposes because they are based on interpreting targets as Gaussian processes defined on the observations domain.

***Abstract*—In the paper application of Naïve Bayes model, for evaluation of the risk connected with life insurance of customers, is considered. Clients are classified into groups of different insurance risk levels. There is proposed to improve the efficiency of classification by using cluster analysis in the preprocessing phase. Experiments showed that, however the percentage of correctly qualified instances is satisfactory in case of Naïve Bayes classification, but the use of cluster analysis and building separate models for different groups of clients improve significantly the accuracy of classification. Finally, there is discussed increasing of efficiency by using cluster validation techniques or tolerance threshold that enables obtaining clusters of very good quality.**

## I. Introduction

RISK management is one of the most important area of interests in insurance industry. All the activities of insurance companies are usually connected with risk of policyholders claiming for big damages and the necessity of paying them a large amount of money. The level of the risk became the crucial factor influencing insurance company profits and may even decide on prosperity or failure in the industry. Evaluation of the risk level plays an important role in defining insurance companies' strategies. Having data of all the clients together with the historical information of damage claiming, insurers can estimate risk connected with the sale of every insurance policy. Building risk evaluation models may help them to make the decision concerning acceptance or rejection of new insurance applications. There exist different analysis methods that may support that process, as the most important there should be mentioned: predictive modeling, risk modeling, scoring or risk level qualification.

In the paper there is considered using of data mining techniques to classify life insurance applications as good or bad from the point of view of risk undertaken by the company. By examining historical data of insurance company, clients with certain characteristic features, may be qualified into the groups of different risk level. We investigate application of Naïve Bayes classifier for predicting the risk and for assigning every new customer into the proper group. Naïve Bayes algorithm is a very simple tool for machine learning and data mining. Despite of the fact that the conditional assumption, on which it is based, is rarely fulfilled in the real world, it ensures high accuracy of obtained results. The superb performance of its classification effects was explained in [1]. We propose to increase the efficiency of the classification by using clustering techniques in the preprocessing phase. The experiments showed that, however results obtained by building Naïve Bayes models, measured by the percentage of correctly qualified instances, were satisfactory, but application of clustering algorithm in the preprocessing stage improved significantly the accuracy of the classification. What is more using cluster validity measurement techniques enables choosing of optimal clustering schema and the further increase of correctness of classification.

The paper is organized as follows. In the next section some research concerning application of data mining algorithms in insurance industry is presented. In Section 3, data preparation process as well as applied algorithms are introduced. Then in Section 4 experiments and their results are described. Section 5 presents discussion and evaluation of obtained results. Finally some concluding remarks and future work are proposed.

## II. Relevant Research

Analysis of large historical data sets has been used in actuarial investigations that concerns making optimal underwriting and price decisions for many years [2]. Development of data mining techniques enabled to increase an effectiveness of data analysis in insurance area. The main research focus on building predictive and risk evaluation models, that allow for identifying customers' behaviours and supporting insurance decision making. Especially data mining techniques were examined for fraud detection, discovering insurance risk or ameliorating customer services (see [3], [4], [5] for example). Examination of different application areas and their technical challenges are presented in [6]. In [7], author described, how the financial situation of the insurance company, may be improved by using such techniques as: decision trees, generalized linear modeling or logistic regression. In [5], there is considered effectiveness of association rules and neural segmentation for analyzing large data sets collected in health insurance information system. Authors considered detecting patterns in ordering pathology services as well as classifying practitionners, and they concluded that data mining techniques allow to obtain the results that are not achievable by conventional methods. Classification trees were examined in the Worker Compensation insurances area in [8], where CART algorithm [9] was used

978-83-60810-14-9/08/$25.00 © 2008 IEEE

to build a model that classifies each claim as “likely to become more serious” or “not to become more serious”. Comparison of examined algorithm with logistic regression showed that CART model guarantees better classification results. In the same paper, there were also considered classification trees and hybrid modeling for building predictive models of hospital costs in health insurance. Decision trees were also used, in [10], to generate a predictive model, that may help insurance companies in the identification of claims which are the most likely to generate cost savings.

Data mining techniques were also investigated in fraud detection in health insurance area, taking into account such methods as k-Nearest Neighbor [11], multi-layer perceptron network [12] as well as heuristics and machine learning [13]. Broad review of application of neural networks, fuzzy logic and genetic algorithms in insurance industry can be found in [14]. An overview of fuzzy logic applications in insurance is presented in [15], where two approaches were studied: fuzzy logic applied separately and its combination with neural networks and genetic algorithms. The author reported application of fuzzy logic techniques in such insurance areas as classification, underwriting, projected liabilities, pricing, asset allocation, and investments. As the main fuzzy logic tool used in risk and claim classification, there was presented c-means clustering [15], which in turn was recognized, by Derrig and Ostaszewski, who classified insurance claim depending on level of fraud, as valuable addition to other methods but not the best technique (see [16] for example) to use separately.

Performance of Naïve Bayes models was mainly investigated in fraud detection area (see [17], [18]). Many empirical comparisons between Naïve Bayes technique and modern decision trees: C4.5 and C4.4 as well as Support Vector Machine, showed that Naïve Bayes predicts equally well [19]. In comparative study presented in [17], authors concluded that smoothed Naïve Bayes gave better results than C4.5 decision trees in automobile fraud insurance claims. Experimental study in individual disability income insurance fraud detection [20] showed that Naïve Bayes predictive models outperformed decision tree and Multiple Criteria Linear Programming models in terms of classification accuracy.

The accuracy of Naïve Bayes classifier was improved by combining it with other methods in several papers (see [21], [22], [23], [24] for example). Naïve Bayes classifier was enhanced by application of features selection methods, discretization or using boosting procedures. In [21], authors introduced Selective Bayesian Classifier (SBC), which uses only attributes not removed by C4.5 decision trees. They run C4.5 algorithm on the 10% samples of the all data shuffled together. That action was repeated five times, then the set of attributes was built as an union of those appearing only in the first three levels of the simplified decision trees. Created that way set of selected attributes was taken into account by Naïve Bayes classifier. Experiments conducted on the ten data sets showed that SBC learns faster than Naïve Bayes classifier on all the data sets, and the obtained results were improved up to 7.9%.

In [23], there were used together: dicretization, feature selection and boosting procedures, as techniques for Naïve Bayes improvements. Discretization of attributes with continuous values, was done by applying entropy-based method [25]. Features were selected by using filter that computes empirical mutual information between features and discard low-valued features, measured by gain ratio. The gain ratio value of selected attributes were to exceed a fixed threshold. In the proposed algorithm there was included boosting technique Adaboost introduced in [26]. During each iteration of the algorithm, there is applied entropy discretization technique and redundant attributes are removed by using the gain ratio feature selection method. Such defined algorithm is not as easily interpretable as simple Bayes model, but much more comprehensible than neural networks for example. Experiments conducted on 26 data sets showed that the proposed method was more accurate than Bayes algorithm in 12 cases, with the average error rate of about 20% less than that of simple Bayes algorithm. Another improvement of Naïve Bayes model, called hidden Naïve Bayes was proposed in [24]. The main idea of the proposed model consists in creating attribute hidden parents, that represent influence of all the other attributes. Experiments done on 36 data sets showed that considered algorithm outperforms Naïve Bayes, SBC as well as C4.5 decision trees.

## III. Methodology

In considered model risk evaluation is based on classification rules, that may be built by exploring historical data collected in daily activity of insurance companies. Having characteristic features of all customers together with history of their policies and their claims, insurers can determine groups of different risk level. In our research, three groups of clients are distinguished. The first one, containing customers of low insurance risk (the best clients), the second one of medium risk level and the third group, that may be characterized by high risk (clients that should be avoided). The main idea consists in classifying each of new customers to one of the groups to predict the insurance risk. On the basis of information about the potential client, insurers can almost automatically estimate risk and refuse or accept potential customer application.

In our investigations two different approaches are considered: in the first one classification is based on all the data contained in the database; in the second one customers’ data are divided into clusters of certain similarities and different classification rules are built for each segment separately. In that approach the new client is firstly assigned to one of the groups by unsupervised classification and then, the decision rule appriopriate to considered cluster is applied.

### A. Data preparation

In the present study, we will limit our research into life insurance risk evaluation. However, insurance companies are very interested in finding effective risk evaluation models, but they are very sensitive and reluctant in sharing their data publicly, they do not allow for using their data even

TABLE I
ATTRIBUTES OF LIFE INSURANCE DATABASE

| No | Attribute name | Attribute type |
|---|---|---|
| 1 | Sex | qualitative |
| 2 | Profession | qualitative |
| 3 | Region | qualitative |
| 4 | Hobby | qualitative |
| 5 | Drinking alcohol | qualitative |
| 6 | Smoking | qualitative |
| 7 | Disease | qualitative |
| 8 | Weight | quantitative |
| 9 | Age | quantitative |
| 10 | Blood pressure | quantitative |
| 11 | Maritial status | qualitative |

for research goal. Problems connected with that fact, and its consequences were described with details in [10], where the author recognized lack of the access to real data as the main reason of limitations in understanding data mining and predictive modeling in insurance area.

We base our research on artificially generated data sets, with different attributes that may play a crucial role in profitability of life insurance. Considered client features, are strictly connected with medical exams that customers are obliged to fulfill. All the attributes, used in the research represent information required in medical exam of Swiss Life Insurance and Pension Company [27]. Some exemplary tests, containing similar questions, may be also found at [28]. All the attributes are presented in Table I. Most of them are of qualitative type, except of the following: "weight", "age" and "blood pressure".

For the purpose of Naïve Bayes classification all numerical data should be dicretized into ranges partitioned into intervals. In case of the attribute "weight" three ranges defined as underweight, proper weight and overweight, may be distinguished; in case of attribute "age" values may be binned into five ranges and for "blood pressure" we may have three: low, normal and high. Categorical data, in turn, should be binned into meta - classes (for example: region instead of city). This operation is necessary because Naïve Bayes model relies on calculating probability and cardinality of values should be reduced. Since all attributes are used in the classification process, all of them should be binned.

### B. Naïve Bayes classifier

Naïve Bayes models are the simplest forms of Bayesian network for general probability estimation, detailed description of their functionality was presented in [29]. Naïve Bayes classifier, assumes conditional independence of input data. This is the strong assumption, that seems to be unrealistic in the insurance domain, but a history of empirical studies shows that even in such cases the method presented good performance [18].

By application of Naïve Bayesian algorithm, we obtain probability distribution of belonging into classes. In uncertain cases objects may not be assigned into any group (reject option) or similarly to fuzzy logic techniques may be allocated into more than one class. Other advantages of classifier probabilistic output, such as changing utility functions, compensating for class imbalance or combining models, were described in [30]. Naïve Bayesian algorithm also naturally deals with missing values, what is difficult to achieve by decision trees or neural networks methods. What is more, obtained models are very easy to understand, without further investigations, that feature is not valid for all methods, to mention neural networks as an example. Comparisons of the performance of Naïve Bayes classifier and other classification techniques, like decision trees, neural networks, kNN, Support Vector Machine or rule-learners, were presented in [31]. As main features, which allow Naïve Bayes technique to outperform other algorithms, there were mentioned: speed of learning and classification, tolerance to missing values, explanation ability as well as model parameter handling. To increase of the classification accuracy, the author suggested application of ensemble methods [31].

Naïve Bayes model is based on maximum likelihood, that uses very well known Bayes' formula:

$$P(H_j/A) = \frac{P(A/H_j)P(H_j)}{\sum_{i=1}^{n} P(A/H_i)P(H_i)}, \tag{1}$$

where $j \in 1...n$,$P(A/H_j)$ means conditional probability and is defined as:

$$P(A/H_j) = \frac{P(A \cap H_j)}{P(H_j)} \tag{2}$$

$H_j$ is an event, that means belonging to the group of risk. $A$ is a vector of customer attributes. $P(H_j/A)$ is the probability that person described by $A$ belongs to $H_j$; $P(H_j)$ means probability of belonging to group $H_j$. $P(A/H_j)$ is the probability that customer from $H_j$ is described by $A$.

Algorithm compares features' vector of a new customer with all records in the database and computes the probability of memberships of all of the groups, then the considered client is assigned into the group of risk, for which probability of belonging is the highest. Efficiency of the algorithm may be evaluated by checking assignements for test set of customers' data, by comparing of obtained results with real belongings to the group of certain risk level. Assessment of classification accuracy is done by calculating the percentage of correctly classified records. Addidtional advantage of the technique is that it does not have to use all attributes and can work just with few selected ones. The choice of the attributes that guarantee the most accurate results may be done by the use of training data sets in the preprocessing phase.

### C. Clustering

Cluster analysis techniques become very popular in customer segmentation area. One of the main advantage of the clustering technique is that it does not assume any specific distribution on the data. The main disadvantage of the method is the high dependence of experts' opinions in many cases. There exist many clustering techniques that may be used in customer grouping, the broad review of the most popular of them is presented in [32]. In the current research, k-means algorithm has been chosen, because of its simplicity and efficiency. This algorithm performed very well in experiments concerning credit risk scoring [33]. However the method depends significantly on the initial assignments, what may entail in not finding the most optimal cluster allocation at the end of the process, but k-means is very efficient for large multidimensional data sets [32].

Segmentation is done according to attributes that may play the most crucial role in life insurance: “Drinking alcohol”, “Smoking”, “Profession”, for different number of required clusters. The distance between two objects is measured by Manhattan function. As optimal clustering schema may differ depending on data sets, validity measurement techniques are used to evaluate obtained clusters and to make the best choice for their numbers.

Different cluster validity indices were introduced to examine quality of grouping results. All of them and their application for different clustering algorithms are broadly investigated in [34]. To find out the best clustering schema, it has been chosen Davies-Bouldin (DB) index because of its simplicty. It is based on dispersion and cluster distance measures, which means taking into account: internal variance and external similarity. Low $DB$ value means that clusters are compact and well separated. $DB$ is defined as follows [34]:

$$DB = \frac{1}{k}\sum_{i=1}^{k} R_i, \tag{3}$$

where $k$ is the number of clusters, $R_i$ is the ratio of dispersion measures and distance of clusters $C_i$ and $C_j$: $R_i = max\left\{R_{ij}, i \neq j\right\}, R_{ij} = (S_i + S_j)/D_{ij}$. $D_{ij}$ is measured by the distance between centroids $\nu_i$ and $\nu_j$ of $C_i$ and $C_j$ respectively, and dispersion measure of cluster $C_i$ is defined by:

$$S_i = \left(\frac{1}{|C_i|}\sum_{x \in C_i} d^p(x, \nu_i)\right)^{1/p}, p > 0, \tag{4}$$

where $d(x, y)$ is the distance between $x$ and $y$.

## IV. EXPERIMENTS

Experiments were done on artificially generated data sets, with attributes presented in Table I. Two databases were filled with values randomly. The first one contains five hundred records with eight attributes: “sex”, “profession”, “region”, “hobby”, “drinking alcohol”, “smoking”, “disease” and “weight”. The second one, of eight hundred records is characterized by eleven attributes, all of them are presented in Table I. The main aim of the experiments was to examine how the use of clustering techniques in the preprocessing stage may influence classification accuracy. There were compared results of classification done by using all the records of considered data sets, with effects obtained on segments of similar customers. It was also examined how the quality of results changes depending on choice of attributes taken into account during classification in different clusters.

Considered databases contain records that characterize people who bought life insurance policies. All the customers, according to their characteristic features were assigned into one of three groups: of high risk—the ones who cause the biggest financial losses for the company; of low risk—the ones who are expected to be rather profitable than harmful; of medium risk—the ones that do not belong neither to first nor to the second group. Finally there are three groups of customers with different level of risk. During experiments, all records from databases were divided into training and test sets. Records of the first ones took part in classification process, while records of the second ones were to check the classification accuracy, by comparing obtained results with real assignments into the groups of risk.

Experiments were divided into three stages. In the first one classification was made on the entire datasets, during the second stage groups of similar customers were found by clustering, and classification was done on each cluster separately. Finally the role of the attributes in obtaining high accuracy is examined.

### A. *Classification on entire data sets*

Results of the classification process, made on entire data sets, were examined taking into account different combinations of attributes. At the beginning, all the attributes were used. The results were rather poor, only 57% of customers were classified correctly in case of the first database (8 attributes)and 59% for the second database (11 attributes) . Much better effects were achieved taking into consideration different combinations of parameters. For the first database, the best results of 71% of objects classified correctly were obtained for combination of 5 from among 8 attributes: “weight”, “smoking”, “profession”, “region”, “disease”. For the second database, also combination of 5 from among 11 attributes: “drinking alcohol”, “smoking”, “disease”, “blood pressure”, “age”; gave the best results of 76% correctly assigned clients.

The main reason for such an improvement in case of usage of selected attributes is the fact that Naïve Bayes algorithm, contrarily to decision trees, cannot recognize which of features have more influence in the classification process. One attribute cannot affect membership of the object in any of the groups. During experiments, it was noticed that including some of the attributes into the classification process can even decrease its efficiency. If number of attributes is not so big, like in considered cases, there may be tried different combinations of attributes to choose the best ones. Another possibility is to ask experts.

### B. *Classification on clusters*

In this part of the experiments, all customers were grouped by unsupervised classification, before applying Naïve Bayes models. To maintain the proper balance between the weight of each customer features, different attributes were taken into account in every stage of the classification. During the

TABLE II
Classification acuracy for all attributes and 3 clusters

| Data set | Correctly classified |
|---|---|
| Cluster 1 | 51.35% |
| Cluster 2 | 65.21% |
| Cluster 3 | 71.5% |
| All data | 63% |

TABLE III
Classification acuracy for all attributes and 2 clusters

| Data set | Correctly classified |
|---|---|
| Cluster 1 | 63.33% |
| Cluster 2 | 75% |
| All data | 68% |

TABLE VI
Classification acuracy for all attributes and 3 clusters

| Data set | Correctly classified |
|---|---|
| Cluster 1 | 79.31% |
| Cluster 2 | 100% |
| Cluster 3 | 65% |
| All data | 74% |

TABLE VII
Classification acuracy for all attributes and 2 clusters

| Data set | Correctly classified |
|---|---|
| Cluster 1 | 73.33% |
| Cluster 2 | 62.5% |
| All data | 69% |

investigations, there were examined the influence of different combinations of attributes as well as the required number of clusters on the accuracy of obtained results. For both data sets, clustering was done according to three customer features, while the other attributes were used to classify clients into appriopriate groups of risk level. There were considered two different approaches: using the same attributes for all the clusters or distinguishing the choice of attributes depending on clusters.

Some exemplary results for the first database (8 attributes, 500 instances), where clustering was done according to the attributes: “drinking alcohol”, “smoking”, “profession”, for different numbers of clusters, are presented in Table II and Table III. In both of the cases the set of 5 other attributes is used for Naïve Bayes classification.

Table IV and Table V shows percentage of correctly nested instances, when classification rules are built by using different attributes for each cluster. The best choice of attributes, measured by the highest accuracy of classification are presented in the last columns.

Comparison of values presented in Table II, Table III, Table IV and Table V shows that the quality of obtained results is better when different attributes are used to build models for each cluster. For example, if the required number of clusters is equal to 3, total accuracy is increased of 17 percentage points. In the case of two clusters the increase was of 10 percentage points. It can be easily noticed that using of two and three clusters gives very similar effects. For three segments, 2 attributes were used for building classification models in each cluster, while for two segments, in both of them, three of five attributes were used. Results presented in the tables were the best from among those obtained in different experiments. In real databases, with greater number of attributes, the opinion of an expert concerning the feature selection may be very useful.

Exemplary results for the second database (11 attributes, 800 instances) are presented in Table VI and Table VII. Similarly to the first database, customers are segmented according to 3 of the following features: “drinking alcohol”, “smoking”, “profession”, with the required number of clusters equal to 2 or 3 and classification models built on the basis of 8 other attributes.

Results for decision rules built on different attributes in each cluster are presented in Table VIII and Table IX. Also in that case, classification effects obtained by using different attributes in each cluster are better. In case of the segmentation into

TABLE IV
Classification acuracy for different attributes and 3 clusters

| Data set | Correctly classified | Attributes |
|---|---|---|
| Cluster 1 | 72.97% | weight, disease |
| Cluster 2 | 78.26% | weight, disease |
| Cluster 3 | 87.5% | weight, disease |
| All data | 80% | |

TABLE V
Classification acuracy for different attributes and 2 clusters

| Data set | Correctly classified | Attributes |
|---|---|---|
| Cluster 1 | 75% | weight, disease, hobby |
| Cluster 2 | 82.2% | weight, disease, region |
| All data | 78% | |

TABLE VIII
Classification acuracy for different attributes and 3 clusters

| Data set | Correctly classified | Attributes |
|---|---|---|
| Cluster 1 | 84.48% | disease, blood pressure, age |
| Cluster 2 | 100% | disease, blood pressure, age |
| Cluster 3 | 77.5% | hobby, disease, age |
| All data | 82% | |

TABLE IX
Classification acuracy for different attributes and 2 clusters

| Data set | Correctly classified | Attributes |
|---|---|---|
| Cluster 1 | 81.66% | weight, disease, age |
| Cluster 2 | 77.5% | hobby, disease, age |
| All data | 80% | |

TABLE X
CLASSIFICATION ACURACY FOR ALL ATTRIBUTES AND 2 CLUSTERS

| Data set | Correctly classified |
|---|---|
| Cluster 1 | 55% |
| Cluster 2 | 62.5% |
| All data | 58% |

TABLE XI
CLASSIFICATION ACURACY FOR DIFFERENT ATTRIBUTES AND 2 CLUSTERS

| Data set | Correctly classified | Attributes |
|---|---|---|
| Cluster 1 | 66.66% | weight, drinking alcohol, hobby |
| Cluster 2 | 70% | weight, drinking alcohol, hobby |
| All data | 68% | |

two or three clusters, the situation is the same: classification models built for each cluster separately are less complex than the ones obtained for all the data. In all the cases only 3 attributes were used to build models for each cluster. Values of correctly classified instances presented in Table VIII and Table IX, are significantly higher than the ones presented in Table VI and Table VII, where classifications were done on the basis of all 8 attributes.

### C. The choice of attributes

The aim of these investigations, was to check if for all the sets of attributes, segmenting of customers guarantees the improvement of classification results. After several experiments there were indicated attributes: “smoking”, “region”, “disease”, for which results are worse. Table X and Table XI present the effects of classification for the first data set (8 attributes, 500 instances), for clusters built according to those attributes.

It can be easily seen that the results of classification presented in Table X and Table XI are definitely worse than the ones obtained for the entire data set. The accuracy effectively increased after building classification models on different attributes, but it is still worse than the one obtained without using clusters.

## V. EVALUATION

It was shown in the previous section that classification accuracy depends on the choice of attributes as well as the number of clusters. It may be expected that the results of classification should be more accurate for clusters of better quality. Well constructed clusters should have high internal and low external similarity. Calculating of $DB$ index defined by ( 3) allows for choosing the best schema (optimal number of clusters) that will guarantee good quality of obtained clusters. It let us avoid experimental choice of required number of clusters. In considered cases, for the first database Davies Bouldin index is respectively equal to 0.0539 for two clusters and 0.0545 in case of three clusters. Comparisons of Table II and Table III as well as Table IV and Table V show that the effects in both cases are very similar, what is reflected in proximity of $DB$ values. In the case of second database, $DB$ value for two clusters is equal to 0.0547, while for three clusters to 0.0534, which should guarantee the better quality of clusters. Indeed, comparing Table VII and Table VIII as well as Table IX and Table X, it can be easily noticed that the choice of three clusters gives better effects in both cases.

TABLE XII
CLASSIFICATION ACURACY FOR DIFFERENT ATTRIBUTES AND 3 CLUSTERS, AFTER APPLICATION OF THRESHOLD IN EACH CLUSTER

| Data set | Correctly classified | Attributes |
|---|---|---|
| Cluster 1 | 72.97% | weight, disease |
| Cluster 2 | 69.56% | weight, disease |
| Cluster 3 | 90% | weight, disease |
| All data | 79% | |

TABLE XIII
CLASSIFICATION ACURACY FOR DIFFERENT ATTRIBUTES AND 2 CLUSTERS AFTER APPLICATION OF TOLERANT TRESHOLD IN EACH CLUSTER

| Data set | Correctly classified | Attributes |
|---|---|---|
| Cluster 1 | 83.33% | weight, disease, age |
| Cluster 2 | 60% | hobby, disease, age |
| All data | 74% | |

The next issue that should be taken into account is a presence of exceptions in data sets. During the segmentation process, such objects, that do not fit into any of the groups, usually are allocated into one of them. Existence of such elements may decrease quality of clusters and efficiency of the classification process. That situation may be avoided by removing the most distant objects from the clusters. The establishing of tolerance thresholds for each cluster may allow to isolate outliers and not to take them into account during classification process. In the current research as the threshold value for each cluster, the maximum distance between two objects in the generation, divided by the number of clusters, is used.

Table XII presents classification results in case of three clusters, for the first database, after application of tolerance threshold. Comparing Table XII and Table IV we can see that accuracy in Cluster 1 did not change, while in Cluster 3, it efficiently increased from 87.5% to 90%. In Cluster 2, however, we can observe a decrease from 78.26 to 69.56%. Similar situation may be noticed in the case of the second database and segmentation into two clusters. The results are presented in Table XIII

Comparison of Table IX and Table XIII shows that efficiency of classification increased in the first cluster but considerably decreased in the second one. It means that different value of tolerance threshold established for different clusters may give better results. If in the case presented in Table XIII we will use tolerance threshold only in the first cluster, we will obtain results with a general increase in accuracy, what can be seen in Table XIV.

TABLE XIV
CLASSIFICATION ACURACY FOR DIFFERENT ATTRIBUTES AND 2 CLUSTERS AFTER APPLICATION OF THRESHOLD IN FIRST CLUSTER

| **Data set** | **Correctly classified** | **Attributes** |
|---|---|---|
| Cluster 1 | 83.33% | weight, disease, age |
| Cluster 2 | 77.5% | hobby, disease, age |
| All data | 81% | |

## VI. CONCLUSION

In the paper, there is considered application of classification techniques for insurance risk evaluation. The idea is based on dividing clients into three groups of a different risk level. There has been chosen Naïve Bayes model as a classifier. Cluster analysis technique is proposed to improve classification accuracy. Experiments conducted on two data sets, characterised by different attributes of different number of records showed that building classification models for each cluster separately, ameliorates the accuracy of obtained results. For the first database number of correctly classified instances increased from 71% in the case of building the same classification model for all the data to 80%, in the case of differentiating classification models according to clusters, while for the second dataset the growth was from 76% to 82%.

The investigations showed that different results may be received for different number of clusters. To avoid determining a number of clusters experimentally, validation technique, which will indicate optimal schema of clusters of the best quality, may be applied. Classification accuracy can be increased by application of restrictions concerning objects in each cluster. However, experiments showed that establishing of a tolerant threshold, may also bring opposite effects. There should be worked out the strategy, that will allow to differentiate threshold values depending on clusters' properties. The experiments proved that classification process may give much better results by combining Naïve Bayes models with cluster analysis. Taking into account the data that insurance companies possess they may easily segment their customers and build risk models for each of the group separately. The experiments were conducted on artificially generated data sets, in the next step obtained results should be verified on the real data of insurance company.

Future research should also consist of development of the proposed model, by using for example SBC instead of Naïve Bayes classification, as the most crucial problem and the big challenge for researchers, at the same time, is the choice of the optimal combination of features for building classification models.

***Abstract*—Classical convex fuzzy numbers have many disadvantages. The main one is that every operation on this type of fuzzy numbers induces the growing fuzziness level. Another drawback is that the arithmetic operations defined for them are not complementary, for instance: addition and subtraction. Therefore the first author (W. K.) with his coworkers has proposed the extended model called ordered fuzzy numbers (OFN). The new model overcomes the above mentioned drawbacks and at the same time has the algebra of crisp (non-fuzzy) numbers inside. Ordered fuzzy numbers make possible to utilize the fuzzy arithmetic and to construct the Abelian group of fuzzy numbers and then an algebra. Moreover, in turn out, that four main operations introduced are very suitable for their algorithmisation. The new attitudes demand new defuzzification operators. In the linear case they are described by the well–know functional representation theorem valid in function Banach spaces. The case of nonlinear functionals is more complex, however, it is possible to prove general, uniform approximation formula for nonlinear and continuous functionals in the Banach space of OFN. Counterparts of defuzzification functionals known in the Mamdani approach are also presented, some numerical experimental results are given and conclusions for further research are drawn.**

## I. Introduction

CLASSICAL fuzzy numbers are very special fuzzy sets defined on the universe of all real numbers. Fuzzy numbers are of great importance in fuzzy systems. In the applications, the triangular and the trapezoidal fuzzy numbers are usually used.

There are two commonly accepted methods of dealing with fuzzy numbers, both basing on the classical concept of fuzzy sets, namely on the membership functions. The first, more general approach deals with the so-called convex fuzzy numbers of Nguyen [31], while the second one deals with shape functions and $L-R$ numbers, set up by Dubois and Prade [6].

When operating on convex fuzzy numbers we have the interval arithmetic for our disposal. However, the approximations of shape functions and operations are needed, if one wants to remain within the $L-R$ numbers while following the Zadehï¿¡s extension principle [38]. In this representation (in most cases) calculation results are not exact and are questionable if some rigorous and exact data are needed, e.g. in the control or modeling problems. This can be treated as a drawback of the properties of classical fuzzy algebraic operations.

In the literature, moreover, it is well know that unexpected and uncontrollable results of repeatedly applied operations, caused by the need of making intermediate approximations (remarked in [34],[35]) can appear. This rises the heavy argument for those who still criticize the fuzzy number calculus. Fortunately, it was already noticed by both Dubois and Prade in their recent publication [8] that something is missing in the definition of the fuzzy numbers and the operations on them.

In most cases one assumes that a typical membership function ïż¡$\mu_A$ of a fuzzy number $A$ satisfies convexity assumptions requiring after Nguyen [31] all $\alpha$-cuts and the support of $A$ to be convex subsets of $\mathbf{R}$. At this stage it seems necessary to recall both notions used: the $\alpha$-cut of A is a (classical) set $A[\alpha] = \{x \in \mathbf{R} : \mu_A(x) \geq \alpha\}$, for each $\alpha \in [0,1]\}$, and the support of $A$ is the (classical) set $\text{supp}(A) = \{x \in \mathbf{R} : \ \mu_A(x) > 0\}$. One additionally assumes [2], [3], [5], [12], [31], [34] that the convex fuzzy number $A$ has its core, i.e. the (classical) set of those $x \in \mathbf{R}$ for which its membership function $\mu_A(x) = 1$, which is not empty and its support is bounded. Then the arithmetic of fuzzy numbers can be developed using both the Zadeh's extension principle [38], [39] and the $\alpha$-cut with interval arithmetic method [12].

As long as one works with fuzzy numbers that possess continuous membership functions, the two procedures: the extension principle and the $\alpha - cut$ and interval arithmetic method give the same results (cf. [2]). The results of multiple operations on convex fuzzy numbers are leading to a large growth of the fuzziness, and depend on the order of the operations since the distributive law, which involves the interaction of addition and multiplication, does hold there. Moreover, the use of the extension principle in the definition of the arithmetic operations on fuzzy numbers is generally numerically inefficient. These operations cannot be equipped with a linear structure and hence no norm can be defined on them. Standard algebraic operations on fuzzy numbers

978-83-60810-14-9/08/$25.00 © 2008 IEEE

basing on the Zadehïż¡s extension principle and those for fuzzy numbers of $L - R$ type or convex fuzzy numbers (see [5]) which are making use of interval analysis have several drawbacks. They are listed in our previous publications [22],[23], [24],[26], [16].

In our opinion the main drawback is the lack of a solution $X$ to the most simple fuzzy arithmetic equation

$$A + X = C \tag{1}$$

with known fuzzy numbers $A$ and $C$. If the support of $C$ is greater than that of $A$ a unique solution in the form of a fuzzy number $X$ exists. However, this is the only case, since for $A$ with larger support than that of C the solution does not exist. Another drawback is related to the fact that in general $A + B - A$ is not equal to $B$.

The goal of the authors of the previous papers [22], [23], [24], [25], [27] was to overcome the above mentioned drawbacks by constructing a revised concept of fuzzy number and at the same time to have the algebra of crisp (non-fuzzy) numbers inside the concept.

In our investigations we wanted to omit, to some extend, the arithmetic based on the $\alpha$–cut of membership functions of fuzzy numbers (sets), and to be close to the operations known from the real line. It was noticed by Dubois and Prade [7] in 2005, (and repeated recently in [9]) after our definition of the *ordered fuzzy number* [26] had been given, that the concept of fuzzy number is too close to the concept of interval. Our new concept makes it possible to utilize the fuzzy arithmetic in a simple way and to construct an Abelian group of fuzzy numbers, and then an algebra. At the same time the new model contains the cone of convex fuzzy numbers. The definition presented here contains all continuous convex fuzzy numbers, however, its recent enlargement presented in [19] includes all convex fuzzy numbers. Moreover, the new model contains more elements and each convex fuzzy number leads to two different new fuzzy numbers, called here the *ordered fuzzy numbers*, which differ by their orientation. This will become more evident later. Additionally, in turns out that the four main operations introduced are very suitable for algorithmisation. We should stress, however, that the arithmetic of the new model restricted to convex (continuous) fuzzy numbers gives different results in comparison to that of the interval arithmetic. This is evident already in the scalar multiplication and subtraction. However, this gives us the chance to solve the arithmetic equation (1) for any pair of fuzzy numbers $A$ and $C$.

The organization of the paper is as follows. In Section 2 we repeat our main definition and basic properties of extended model of fuzzy numbers presented in the series of papers [15], [16], [21], [22], [23], [24], [25], [26]. Then defuzzification functionals are discussed. First, the linear case, then the nonlinear one. Then a counterpart of the Mamdani center of gravity defuzzification functional is derived. In the final section conclusions together with numerical results of some experiments with implementations of the derived formula are presented.

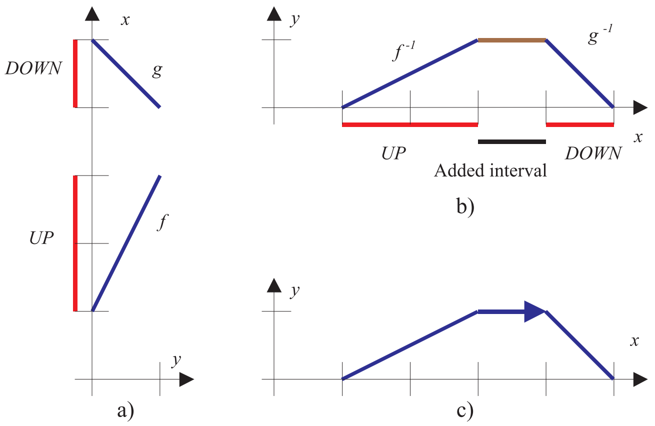

Fig. 1. a) Example of an ordered fuzzy number; b) construction of the membership function; c) the arrow denotes the orientation and the order of inverted functions: first $f$ and then $g$.

## II. Basic Properties of Ordered Fuzzy Numbers

**Definition 1.** By an *ordered fuzzy number* $A$ we mean an ordered pair $(f, g)$ of functions such that $f, g : [0, 1] \to \mathbf{R}$ are continuous.

Notice that in our definition we do not require that two continuous functions $f$ and $g$ are (partial) inverses of some membership function. Moreover, it may happen that membership function corresponding to $A$ does not exist. We call the corresponding elements: $f$—the up-part and $g$—the down-part of the fuzzy number $A$. To be in agreement with further and classical denotations of fuzzy sets (numbers), the independent variable of the both functions $f$ and $g$ is denoted by $y$, and their values by $x$. The continuity of both parts implies their images are bounded intervals, say $UP$ and $DOWN$, respectively (Fig. 1). We have used symbols to mark boundaries for $UP = [l_A, 1_A^-]$ and for $DOWN = [1_A^+, p_A]$. In general, the functions $f$ and $g$ need not to be invertible as functions of $y$, only continuity is required. If we assume, however, that 1) they are monotonous: $f$ is increasing, and $g$ is decreasing, and such that 2) $f \leq g$ (pointwise), we may define the membership function $\mu(x) = f^{-1}(x)$, if $x \in [f(0), f(1)] = [l_A, 1_A^-]$, and $\mu(x) = g^{-1}(x)$, if $x \in [g(1), g(0)] = [1_A^+, p_A]$ and ïż¡$\mu(x) = 1$ when $x \in [1_A^-, 1_A^+]$. In this way we obtain the membership function ïż¡$\mu(x), x \in \mathbf{R}$. When the functions $f$ and/or $g$ are not invertible or the condition 2) is not satisfied then in the plane $x - y$ the membership curve (or relation) can be defined, composed of the graphs of $f$ and $g$ and the line $y = 1$ over the core $\{x \in [f(1), g(1)]\}$.

Notice that in general $f(1)$ needs not be less than $g(1)$ which means that we can reach improper intervals, which have been already discussed in the framework of the extended interval arithmetic by Kaucher [11]. In such case Prokopowicz has introduced in [33] the *corresponding* membership function which can be defined by the formulae:

$$\mu(x) = \max \arg\{f(y) = x, g(y) = x\} \tag{2}$$
$$\text{if } x \in \text{Range}(f) \cup \text{Range}(g) \ ,$$

$$\mu(x) = 1 \quad \text{if } x \in [f(1), g(1)] \cup [g(1), f(1)], \tag{3}$$
$$\text{and } \mu(x) = 0, \text{ otherwise}, \tag{4}$$

where one of the intervals $[f(1), g(1)]$ or $[g(1), f(1)]$ may be empty, depending on the sign of $f(1) - g(1)$, (i.e., if the sign is $-1$ then the second interval is empty).

### A. Norm and partial order

Let $\mathcal{R}$ be a universe of all OFN's. Notice that this set is composed of all pairs of continuous functions defined on the closed interval $I = [0, 1]$, and is isomorphic to the linear space of real 2D-vector valued functions defined on the unit interval $I$ with the norm of $\mathcal{R}$ as follows

$$||A|| = \max(\sup_{s\in I} |f_A(s)|, \sup_{s\in I} |g_A(s)|) \text{ if } A = (f_A, g_A) \ .$$

The space $\mathcal{R}$ is topologically a Banach space. The neutral element of addition in $\mathcal{R}$ is a pair of constant functions equal to crisp zero. It is also a Banach algebra with unity: the multiplication has a neutral element – the pair of two constant functions equal to one, i.e., the crisp one.

A relation of partial ordering in $\mathcal{R}$ can be introduced by defining the subset of 'positive' ordered fuzzy numbers: a number $A = (f, g)$ is not less than zero, and by writing

$$A \geq 0 \quad \text{iff} \quad f \geq 0, g \geq 0 \ . \tag{5}$$

In this way the set $\mathcal{R}$ becomes a partially ordered ring.

## III. Representation of Defuzzification Functional

Defuzzification is a main operation in fuzzy controllers and fuzzy inference systems where fuzzy inference rules appear, in the course of which to a membership function representing classical fuzzy set a real number is attached. We know a number of defuzzification procedures from the literature. Since classical fuzzy numbers are particular case of fuzzy sets the same problem appears when rule's consequent part is a fuzzy number. Then the problem arises what can be done when a generalization of classical fuzzy number in the form of an ordered fuzzy number follows? Are the same defuzzification procedures applicable? The answer is partial positive: if the ordered fuzzy number is *proper* one, i.e. its membership relation is a function, then the same procedure can be applied. What to do, however, when the number is improper, i.e. the membership relation is by no means of functional type?

In the case of fuzzy rules in which ordered fuzzy numbers appear as their consequent part we need to introduce a new defuzzification procedure. In this case the concept of functional, even linear, which maps elements of the Banach space into reals, will be useful.

The Banach space $\mathcal{R}$ with its Tichonov product topology of $C([0, 1]) \times C([0, 1])$, with $C([0, 1])$ the Banach space of continuous functions on $[0, 1]$, may lead to a general representation of linear and continuous functional on $\mathcal{R}$. According to the Banach-Kakutami-Riesz representation theorem any linear and continuous functional $\bar{\phi}$ on the Banach space $C([0, 1])$ is uniquely determined by a Radon measure $\nu$ on $S$ such that

$$\bar{\phi}(f) = \int_{[0,1]} f(s)\nu(ds) \quad \text{where } f \in C([0, 1]) \ . \tag{6}$$

It is useful to remind that a Radon measure is a regular signed Borel measure (or differently: a difference of two positive Borel measures). A Boreal measure is a measure defined on a $\sigma$-additive family of subsets of $[0, 1]$ which contains all open subsets.

However, on the interval $[0, 1]$ each Radon measure is represented by a Stieltjes integral [29] with respect to a function of a bounded variation. Hence we can say that for any continuous functional $\bar{\phi}$ on $C([0, 1])$ there is a function of bounded variation $h_\phi$ such that

$$\bar{\phi}(f) = \int_0^1 f(s) dh_\phi(s) \quad \text{where } f \in C([0, 1]) \ . \tag{7}$$

Hence we may say that due to the representations (6) and (7) *any linear and bounded functional $\phi$ on the space $\mathcal{R}$ can be identified with a pair of functions of bounded variation through the following relationship*

$$\phi(f, g) = \int_0^1 f(s) dh_1(s) + \int_0^1 g(s) dh_2(s) \tag{8}$$

where the pair of continuous functions $(f, g) \in \mathcal{R}$ represents an ordered fuzzy number and $h_1, h_2$ are two functions of bounded variation on $[0, 1]$.

From the above formula an infinite number of defuzzification procedures can be defined. The standard defuzzification procedure in terms of the area under the membership relation can be defined; it is realized by a linear combinations of two Lebesgue measures of $[0, 1]$. In the present case, however, the area is calculated in the $y$-variable, since the ordered fuzzy number is represented by a pair of continuous functions in the $y$ variable (cf. (2)). Moreover, to each point $s \in [0, 1]$ a Dirac delta (an atom) measure can be related, and such a measure represents a linear and bounded functional which realizes the corresponding defuzzification procedure. For such a functional, a sum (or in a more general case – a linear combination $af(s)+bg(s)$) of their values is attached to a pair of functions $(f, g)$ at this point.

For example, if we take the Dirac atomic measure concentrated at $s = 1$, and define

$$\nu_1 = a\delta_1 \text{ i } \nu_2 = b\delta_1$$

where $\delta_1$ is the atomic measure of $\{1\}$, then the value of the defuzzification operator (functional) in (8), denoted here by $\phi_m$ and calculated at $A = (f_A, g_A)$ will be

$$\phi_m(A) = af_A(1) + bg_A(1) \tag{9}$$

and if $a + b = 1/2$, then it is a mean value of both functions (from the core of $f_A$ and $g_A$).

A different choice of the measures may lead to the surface area under the graph of the function, and the first moment of inertia. For example, if

$$\nu_1 = a(s)\lambda \text{ and } \nu_2 = b(s)\lambda$$

where $\lambda$ is the Lebesgue measure of the interval $[0, 1]$ of the real line, and $a(s), b(s)$ are integrable functions on the interval, then in the case of a positive oriented number $A = (f_A, g_A)$ with $f_A \leq g_A$ and

$$b(s) = -a(s) = 1 \tag{10}$$

the defuzzification functional (8) calculated at $A = (f_A, g_A)$ will give the surface area contained between graphs of $f_A$ and $g_A$. If, however, in (10) we put

$$b(s) = -a(s) = s \tag{11}$$

we will get the first moment of inertia of this area.

## IV. Nonlinear Defuzzification Functionals

It is evident that nonlinear and multivariant function compositions of linear functionals will lead to nonlinear defuzzification functionals. For example, a ratio being a nonlinear composition of two linear functionals, where the first one is the first moment and the second . the surface area, discussed in the previous subsection, may lead to the center of gravity known from the Mamdani approach, however, with respect to $s = y$ variable.

Now we can state a uniform approximation theorem concerning the defuzzification operators (functionals). To this end let us use the following denotation. Let $\mathcal{A} \subset \mathcal{R}$ be a subset of all ordered fuzzy numbers $\mathcal{R}$ formed of pairs of functions which are equi-continuous and equi-bounded. Notice that from the theorem of Ascoli-Arzelà [36] it follows that a subset of $C([0, 1])$ is compact if its elements are equi-continuous and equi-bounded. By $\mathcal{G}$ we denote the set of all multivariant continuous functions defined on the appropriate Cartesian product of the set of real numbers. In other words $F \in \mathcal{G}$ if there is a natural number $k$ such that $F : \mathbf{R}^k \to \mathbf{R}$ and $F$ is continuous in the natural norm of $\mathbf{R}^k$. By $\mathcal{D}$ we denote the set of all linear and continuous functionals defined on $\mathcal{A} \subset \mathcal{R}$ (compare (8)). Here we could identify the set $\mathcal{D}$ with the adjoint space $\mathcal{R}^*$ since each continuous (bounded) and linear functional on the whole space $\mathcal{R}$ is a also continuous, linear functional on each subspace, hence on the subset $\mathcal{A}$. Moreover, each continuous, linear functional on a subspace $\mathcal{A} \subset \mathcal{R}$ can be extended to the whole space $\mathcal{R}$, thanks to the Hahn-Banach theorem [36]. Let us use the denotation $\mathcal{R}^\diamond$ for the space of all continuous (not necessarily linear) functionals from $\mathcal{R}$ into reals $\mathbf{R}$. Notice that $\mathcal{R}^\diamond \supset \mathcal{R}^*$.

If a function $F$ of $k$ variables is from $\mathcal{G}$ and $\varphi_1, \varphi_2, ..., \varphi_k \in \mathcal{D}$ then their superposition $F \circ (\varphi_1, \varphi_2, ..., \varphi_k)$ is a function from $\mathcal{D}$ into $\mathbf{R}$, i.e., the functional

$$F \circ (\varphi_1, \varphi_2, ..., \varphi_k) : \mathcal{D} \to \mathbf{R}, \text{ with } F \in \mathcal{G},\ \varphi_1, \varphi_2, ..., \varphi_k \in \mathcal{D} \tag{12}$$

is a defuzzification operator, nonlinear in general. To make the notation short we will write

$$F \circ (\varphi_1, \varphi_2, ..., \varphi_k) =: F(\varphi_1, \varphi_2, ..., \varphi_k). \tag{13}$$

**Theorem.** *Let $\mathcal{A} \subset \mathcal{R}$ be a compact subset of the space of all ordered fuzzy numbers $\mathcal{R}$, and let $\mathcal{D}$ be the set of all linear and continuous functionals defined on $\mathcal{A}$, and let $\mathcal{G}$ be the set of all multivariant continuous functions defined on the appropriate Cartesian product of the set of real numbers. Then the set $\mathcal{H}$ composed of all possible compositions (superpositions) of the type (12) where $F$ is from $\mathcal{G}$ and $\varphi_1, \varphi_2, ..., \varphi_k$ are from $\mathcal{D}$, with arbitrary $k$, is dense in the space $\mathcal{R}^\diamond$ of all continuous functionals from $\mathcal{R}$ into reals* ***R****.*
The proof based on the classical Stone–Weierstrass theorem will be published in another paper.

## V. Center of Gravity

Let us stay with the case of nonlinear functionals. It will be a functional corresponding to that know for convex fuzzy numbers and representing the center of gravity of the area under the graph of the membership function. In the case of OFN the membership function does not exist, in general, however, we may follow to some extend the previous construction.

Let consider an ordered fuzzy number $A = (f, g)$ given in Fig.4. Since $f(g) > g(s)$ for any $s \in [0, 1]$ then by adding an interval (perpendicular to the $s$-axis) which joints the points $(1, f(1))$ and $(1, g(1))$ we get a figure (an area) bounded by the graphs of $f(s)$ and $g(s)$, and the $t$–axis. Our aim is to determine the $t$–th coordinate of the center of gravity of this figure.

Assuming, as it is natural, that the density of each point of the figure is the same and equal to one, first we calculate the moment of inertia of this figure with respect to the $t$–axis. Here $t$ denotes $x$ variable. Let us consider a differential (incremental) element $ds$ situated between the coordinate values $s_1$ and $s_2$ and the corresponding piece of the figure above. Its moment $M_s$ is the product of the area and the length of the arm with respect the $t$–axis, which is the local center of gravity. The (incremental) area is equal to $[f(s_1) - g(s_1)]ds$, while the center of gravity of this area (its $t$–coordinate) can be approximated by the middle point of the interval of $[g(s_1), f(s_1)]$ as $\dfrac{f(s_1) - g(s_1)}{2} + g(s_1) = \dfrac{f(s_1) + g(s_1)}{2}$.

Hence we have for the moment of inertia of this differential (incremental) area element the expression

$$\frac{f(s_1) + g(s_1)}{2}[f(s_1) - g(s_1)]ds\,.$$

Since the point $s_1$ has been chosen quite arbitrarily, the moment of inertia of the whole figure bounded by the graphs of the functions $f$ and $g$, $t$–axis and the interval bounding the points $(1, f(1))$ and $(1, g(1))$, will be the integral

$$M = \int_0^1 \frac{f(s) + g(s)}{2}[f(s) - g(s)]ds \tag{14}$$

Let $P$ be the mass of the figure equal to the area of the whole figure, due to our assumption about the homogeneous distribution of the mass,

$$P = \int_0^1 [f(s) - g(s)]ds\,. \qquad (15)$$

Now we use the classical balance equation of inertial momentum which states that the moment of inertia $M$ is equal to the product of the mass of the figure $P$ and the arm $r$ (of the figure, which is the $t$ coordinate of the global center of gravity),

$$M = P \cdot r\,. \qquad (16)$$

The coordinate $r$ is wanted value of the defuzzification functional representing the center of gravity. Having the expressions (14) and (15) we end up with the following expression for the center of gravity defuzzification functional $\phi_G$ calculated at OFN $(f, g)$

$$\phi_G(f,g) = \int_0^1 \frac{f(s)+g(s)}{2}[f(s)-g(s)]ds\{\int_0^1 [f(s)-g(s)]ds\}^{-1}\,. \qquad (17)$$

We can see that the functional $\phi_G$, denoted on the figures below by COG, is nonlinear. Our derivation is based on the Eq. (16) and the assumption that the function $f(s) \geq g(s)$ which may not be fulfilled in any case. However, if the opposite inequality holds the value does not change. The case when the none of them is true is more complex, we are going, however, to adapt this representation for any ordered fuzzy number $(f, g)$.

## VI. Conclusions

The ordered fuzzy numbers are tool for describing and processing vague information. They expand existing ideas. Their "good"ïż¡ algebra opens new areas for calculations. Beside that, new property – *orientation* can open new areas for using fuzzy numbers. Important fact (in authors' opinion) is that thanks to OFNs we can supply without complication the classical field of fuzzy numbers with new ideas. We can use the OFNs instead of convex fuzzy numbers, and if we need to use extended properties we can use them easily. One of directions of the future work with the OFNs is the construction of new class of nonlinear defuzzification functionals based on required properties. The above problem may have several solutions; however, one can look for one of them with the help of Theorem . Since the Weierstrass theorem states that each continuous function (of many variables) defined on a compact set can be approximated with a given accuracy by a polynomial (of many variables) of an appropriate, i.e., sufficiently high order, then with the use of our final result the family $\mathcal{H}$ may be taken as a set of polynomials of many variables. In the recent papers [18], [20] propositions concerning specially dedicated evolutionary algorithms for the determination of the approximate form of the functional have been discussed. Some interpretations and applications of the present approach to fuzzy modeling, control and finance have been presented in the recent publications [17],[19].

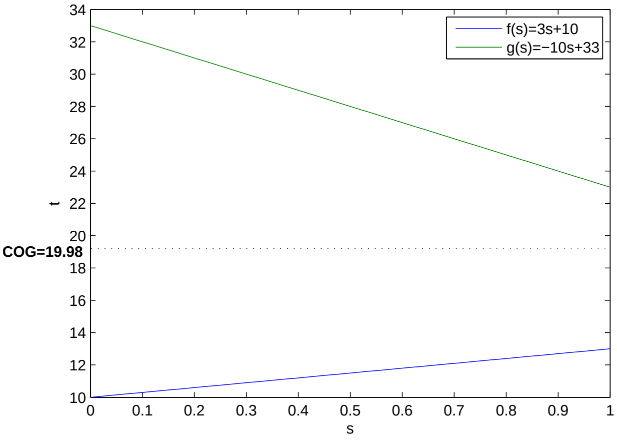

Fig. 2. Ordered fuzzy numbers with affine functions $f, g$ and its center of gravity.

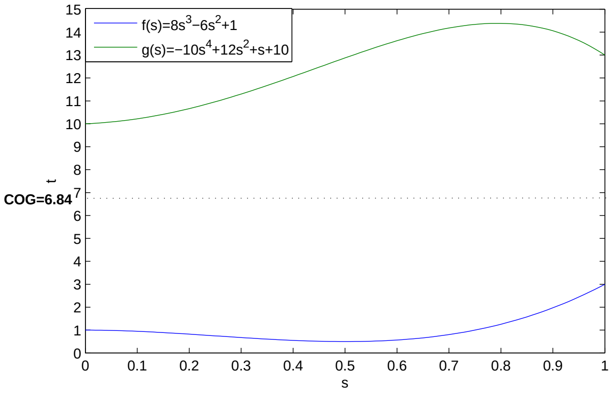

Fig. 3. Ordered fuzzy numbers with polynomial functions $f, g$ and its center of gravity.

Numerical results of implementations of the derived formula for the center of gravity functional $\phi_G$ =:COG from Eq. (17) for two ordered fuzzy numbers, with the functions $f$ and $g$ of the affine type (Fig. 2) and of the polynomial type (Fig. 3), respectively, are presented below. On the figures the variable $t$ corresponds to $x$, and the variable $s$ to $y$, in Fig.1.

***Abstract*—This methodological study demonstrates how to strengthen the commonly used World Health Organization's Quality of Life Index (WHOQOL) by using the consistency-driven pairwise comparisons (CDPC) method. From a conceptual view, there is little doubt that all 26 items have exactly equal importance or contribution to assessing quality of life. Computing new weights for all individual items, however, would be a step forward since it seems reasonable to assume that all individual questions have equal contribution to the measure of quality of life. The findings indicate that incorporating differences of importance of individual questions into the model is essential enhancement of the instrument.**

***Index Terms*—Quality of life, inconsistency analysis, consistency-driven pairwise comparisons**

## I. Introduction

DURING the past three decades, many different quality of life measures have been developed for use as an indicator of patient-focused health outcomes. Commonly used quality of life measures had reported psychometric properties. One measure in particular, the World Health Organization Quality of Life (WHOQOL) measure has been widely field tested since its inception in 1991. This measure was developed to an international cross-culturally comparable quality of life assessment for clinical populations. Its purpose is to assess subjects' perceptions of their quality of life in the context of their personal values and beliefs as well as their social culture. There are three versions of this measure. The first contains 100-items and is commonly used in large clinical trails. The brief version, WHOQOL-BREF, consists of 26-items.

A third version available on the web (www.who.int/mental_health/media/en/76.pdf) seems to be a modification of what was previously published in [9].

To supplement to the WHOQOL User's manual published in 1998, this research will further examine the psychometric properties of the measure by using consistency-driven pairwise comparison. The assumption of this approach is that not all instrument items are of equal importance and including the relative importance in the model contribute to the enhancement of the measure.

## II. The Pairwise Comparison Preliminaries and a Quality of Life Model

From a mathematical point of view, the pairwise comparisons method [2],[3],[4], Appendix A creates a matrix (for example, A) of values $(aij)$ of the $i$-th candidate (or alternative) compared head-to-head (one-on-one) with the $j$-th candidate. A scale $[1/c, c]$ is used for $i$ to $j$ comparisons where $c > 1$ is a not-too-large real number (5 to 9 in most practical applications).

It is usually assumed that all the values $(aij)$ on the main diagonal are 1 (the case of $i$ compared with $i$ and that $A$ is reciprocal: $(aij) = 1/(aij)$ since $i$ to $j$ is (or at least, is expected to be) the reciprocal of $j$ to $i$. (As explained below, the reciprocity condition is not automatic in certain scenarios of comparisons.) It is fair to assume that we are powerless, or almost powerless, as far as inconsistency is concerned. All we can do is to locate it and reconsider our own comparisons to reduce the inconsistency in the next round.

An pioneer of this method is Condorcet [5]. He used the pairwise comparisons in 1785 in the context of counting political ballots. In 1860, however, Fechner provided further yet limited psychometric information about this method. By way of refining the method, Thurstone [7] described pairwise comparisons method as a statistical analysis and proposed a solution. In 1977, Saaty [8] introduced a hierarchy instrumental for practical applications.

The WHOQOL addresses four domains: physical health (PH), psychological health (PSYCH), social relationships (SR), and environment (ENV). Using the Saaty's heuristic approach of having no more than seven items in one group, the ENV domain was mechanically subdivide into ENV1 and ENV2 since it has eight objects. Implementing the Concluder system, the results are shown in Fig. 1. This figure is an illustration of the full model due to screen limitation and scrolling. The items listed on the left-hand side of Fig. 1 should be attached to the first level (groups) to create a hierarchical structure.

Using a scale 1 to 5, the relative importance of each of the five groups were entered and compared objects in the smallest subgroup. For example, SR (social relationships) was compared against each other. For example, "personal relationship" and "sex" are compared to each other in the subgroup SR (social relationship) and given 4 out of 5 (which can be changed for every clinical case to which this instrument is applied). The results are presented in Table 1.

Clearly, the above matrix was not consistent since $a_{13} = 4$. It did not equal to $a_{12} * a_{23}$. To address the inconsistency, ii, the

following formula where: $ii$ =min($|1 - a_{ij}/(a_{ik} * a_{kj})|, |1 - a_{ik} * a_{kj}/a_{ij}|$) for $i = 1, j = 2$, and $k = 3$ (as introduced in [3]). was 0.5 and it was higher than the assumed threshold 1/3. The computed weights (as normalized geometric means of rows) are presented in Table 2. By changing, 4 to 3 for the illustration (rather than clinical), the new inconsistency index ii is computed as 1/3. Alternatively, another approach could have been changing $a_{33}$ to 2 resulting in $ii = 0$. purposes We stress that the changes here have been done for the illustration of the method but in real life, there must be a reason coming from the refined clinical knowledge.

As explained Koczkodaj [[3]], the above values were computed as normalized geometric means of the matrix rows. Figure 1 shows one highlighted subgroup, SR (social relationships), because attaching more subgroups creates a structure that requires additional space. Alternatively, we could show one group in one figure but again, five screen images, which are nearly identical would only make this presentation excessively long so the reader is asked to use his/her imagination as we enter "behind the scene" all objects (listed as unchained on the left hand side margin in Fig. 1) and compare them against each other assigning relative importance and paying attention to inconsistency as it was demonstrated for SR subgroup. Again, the comparisons have been done to illustrate the method, not the real instrument and the overall results for all criteria is presented in Table 3.

## CONCLUSION

Although the method of pairwise comparisons was originally used over 200 years ago, it has not been used to refine the properties of quality of life instruments. The method has strengthened the WHOQOL instrument by adding weights to individual items. Evidently, not all objects on the WHOQOL instrument are of equal importance. Appreciation of their relative differences, adds to the measure's precision. The inconsistency analysis further strengthens the measure by bringing the most problematic but often crucial comparisons of the instrument items. A challenge to the multiple experts in this tool's development can be "averaging" their individual assessments in the assumed model. Clinical trials and statistical analysis

## APPENDIX A BASIC CONCEPTS OF PAIRWISE COMPARISONS

An $n$ by $n$ pairwise comparisons matrix is defined as a square matrix $A = [a_{ij}]$ such that $a_{ij} > 0$ for every $i, j = 1, ..., n$. Each $a_{ij}$ expresses a relative preference of criterion (or stimulus)$s_i$ over criterion $s_j$ for $i, j = 1, ..., n$ represented by numerical weights (positive real numbers) and $w_i$ and $w_j$ respectively. The quotients $a_{ij} = w_i/w_j$ form a pairwise comparisons matrix:

$$A = \left| \begin{array}{cccc} 1 & a_{13} & ... & a_1 \\ & & & n \\ 1/a_1 & 1 & ... & a2 \\ 3 & & & n \\ ... & ... & ... & ... \\ 1/a_1 & 1/a_2 & ... & 1 \\ n & n & & \end{array} \right|$$

A pairwise comparisons matrix $A$ is called *reciprocal* if $a_{ij} = 1/a_{ji}$ for every $i, j = 1, ..., n$ (then automatically $a_{ii} = 1$ for every $i = 1, ..., n$ because they represent the relative ratio of a criterion against itself). A pairwise comparisons matrix $A$ is called *consistent* if $a_{ij} \cdot a_{jk} = a_{ik}$ holds for every $i, j, k = 1, ..., n$ since $w_i/w_j \cdot w_j/w_k$ is expected to be equal to $w_i/w_k$. Although every consistent matrix is reciprocal, the converse is not generally true. In practice, comparing of $s_i$ to $s_j$, $s_j$ to $s_k$, and $s_i$ to $s_k$ often results in inconsistency amongst the assessments in addition to their inaccuracy; however, the inconsistency may be computed and used to improve the accuracy.

The first step in pairwise comparisons is to establish the relative preference of each combination of two criteria. A scale from 1 to 5 can be used to compare all criteria in pairs. Values from the interval $[1/5, 1]$ reflect inverse relationships between criteria since $s_i/s_j = 1/(s_j/s_i)$. The consistency driven approach is based on the reasonable assumption that by finding the most inconsistent judgments, one can then reconsider one's own assessments. This in turn contributes to the improvement of judgmental accuracy. Consistency analysis is a dynamic process which is assisted by the software.

The central point of the inference theory of the pairwise comparisons is Saaty's Theorem, [8], which states that for every $n$ by $n$ consistent matrix $A = [a_{ij}]$ there exist positive real numbers $w_1, ..., w_n$ (weights corresponding to criteria $s_1, .n.., s)$ such that $a_{ij} = w_i/w_j$ for every $i, j = 1, ..., n$. The weights $w_i$ are unique up to a multiplicative constant. Saaty (1977) also discovered that the eigenvector corresponding to the largest eigenvalue of $A$ provides weights $w_i$ which we wish to obtain from the set of preferences $a_{ij}$. This is not the only possible solution to the weight problem. In the past, a least squares solution was known, but it was far more computationally demanding than finding an eigenvector of a matrix with positive elements. Later, a method of row geometric means was proposed (Jensen, 1984), which is the simplest and most effective method of finding weights. A statistical experiment demonstrated that the accuracy, that is, the distance from the original matrix $A$ and the matrix $AN$

reconstructed from weights with elements $[a_{ij}] = [w_i/w_j]$, does not strongly depend on the method. There is, however, a strong relationship between the accuracy and consistency. Consistency analysis is the main focus of the consistency driven approach.

An important problem is how to begin the analysis. Assigning weights to all criteria (e.g., $A = 18, B = 27, C = 20, D = 35$) seems more natural than the above process. In fact it is a recommended practice to start with some initial values. The above values yield the ratios: $A/B = 0.67$, $A/C = 0.9$, $A/D = 0.51$, $B/C = 1.35$, $B/D = 0.77$, $C/D = 0.57$. Upon analysis, these may look somewhat suspicious because all of them round to 1, which is of equal or unknown importance. This effect frequently arises in practice, and experts are tempted to change the ratios by increasing some of them and decreasing others (depending on knowledge of the case). The changes usually cause an increase of inconsistency which, in turn, can be handled by the analysis because it contributes to establishing more accurate and realistic weights. The pairwise comparisons method requires evaluation of all combinations of pairs of criteria, and can be more time consuming because the number of comparisons depends on $n^2$ (the square of the number of criteria). The complexity problem has been addressed and partly solved by the introduction of hierarchical structures [8]. Dividing criteria into smaller groups is a practical solution in cases in which the number of criteria is large.

## Appendix B Consistency Analysis

Consistency analysis is critical to the approach presented here because the solution accuracy of *not-so-inconsistent* matrices strongly depends on the inconsistency. The consistency driven approach is, in brief, the next step in the development of pairwise comparisons.

The challenge to the pairwise comparisons method comes from a lack of consistency in the pairwise comparisons matrices which arises in practice. Given an $n$ by $n$ matrix $A$ that is not consistent, the theory attempts to provide a consistent $n$ by $n$ matrix $AN$ that differs from matrix $A$ "as little as possible". In particular, the geometric means method produces results similar to the eigenvector method (to high accuracy) for the ten million cases tested. There is, however, a strong relationship between accuracy and consistency.

Unlike the old eigenvalue based inconsistency, introduced in [8], the triad based inconsistency locates the most inconsistent triads [3]. This allows the user to reconsider the assessments included in the most inconsistent triad.

Readers might be curious, if not suspicious, about how one could arrive at values such as 1.30 or 1.50 as relative ratio judgments. In fact the values were initially different, but have been refined and the final weights have been calculated by the consistency analysis. It is fair to say that making comparative judgments of rather intangible criteria (e.g., overall alteration and/or mineralization) results not only in imprecise knowledge, but also in inconsistency in our own judgments. The improvement of knowledge by controlling inconsistencies in the judgments of experts, that is, the consistency driven approach, is not only desirable but is essential.

In practice, inconsistent judgments are unavoidable when at least three factors are independently compared against each other. For example, let us look closely at the ratios of the four criteria $A$, $B$, $C$, and $D$ in Figure $C1$. Suppose we estimate ratios $A/B$ as 2, $B/C$ as 3, and $A/C$ as 5. Evidently something does not add up as $(A/B)@\ (B/C) = 2 \cdot 3 = 6$ is not equal to 5 (that is $A/C$). With an inconsistency index of 0.17, the above triad (with highlighted values of 2, 5, and 3) is the most inconsistent in the entire matrix (reciprocal values below the main diagonal are not shown in Figure $C1$). A rash judgment may lead us to believe that $A/C$ should indeed be 6, but we do not have any reason to reject the estimation of $B/C$ as 2.5 or $A/B$ as 5/3. After correcting $B/C$ from 3 to 2.5, which is an arbitrary decision usually based on additional knowledge gathering, the next most inconsistent triad is (5,4,0.7) with an inconsistency index of 0.13. An adjustment of 0.7 to 0.8 makes this triad fully consistent ($5 \cdot 0.8$ is 4), but another triad (2.5,1.9,0.8) has an inconsistency of 0.05. By changing 1.9 to 2 the entire table becomes fully consistent. The corrections for real data are done on the basis of professional experience and case knowledge by examining all three criteria involved.

An acceptable threshold of inconsistency is 0.33 because it means that one judgment is not more than two grades of the scale 1 to 5 away (an off-by-two error) from the remaining two judgments. There was no need to continue decreasing the inconsistency, as only its high value is harmful; a very small value may indicate that the artificial data were entered hastily without reconsideration of former assessments.

***Abstract*—The paper introduces accuracy boosting extension to a novel induction of fuzzy rules from raw data using Artificial Immune System methods. Accuracy boosting relies on fuzzy partition learning. The modified algorithm was experimentally proved to be more accurate for all learning sets containing non-crisp attributes.**

## I. Introduction

FUZZY-BASED data mining is a modern and very promising approach to mine data in an efficient and comprehensible way. Moreover, fuzzy logic [8] can improve a classification task by using fuzzy sets to define overlapping class definitions. This kind of data mining algorithms discovers a set of rules of the form “IF (fuzzy conditions) THEN (class),” whose interpretation is as follows: IF an example’s attribute values satisfy the fuzzy conditions THEN the example belongs to the class predicted by the rule. The automated construction of fuzzy classification rules from data has been approached by different techniques like, e.g., neuro-fuzzy methods, genetic-algorithm based rule selection, and fuzzy clustering in combination with other methods such as fuzzy relations and genetic algorithm optimization (for references see [10]).

A quite novel approaches, among others, integrate Artificial Immune Systems (AISs) [3] and Fuzzy Systems to find not only accurate, but also linguistic interpretable fuzzy rules that predict the class of an example. The first AIS-based method for fuzzy rules mining was proposed in [2]. This approach, called IFRAIS (Induction of Fuzzy Rules with an Artificial Immune System), uses sequential covering and clonal selection to learn IF-THEN fuzzy rules. In [7] the speed of IFRAIS was improved significantly by buffering dicovered fuzzy rules in a clonal selection. One of the AIS-based algorithms for mining IF-THEN rules is based on extending the negative selection algorithm with a genetic algorithm [4]. Another one is mainly focused on the clonal selection and so-called a boosting mechanism to adapt the distribution of training instances in iterations [1]. A fuzzy AIS was proposed also in [6], however that work addresses not the task of classification, but the task of clustering.

This paper seeks to boost an accuracy of IFRAIS approach by exploring the use of fuzzy partitions learning.

## II. IFRAIS

Data preparation for learning in IFRAIS consists of the following steps: (1) create a fuzzy variable for each attribute in data set; (2) create class list for actual data set; (3) and compute information gain for each attribute in data set.

Listing 1. Sequential covering algorithm

```
Input: full training set
Output: fuzzy rules set

rules set = 0
FOR EACH class value c in class values list DO
  values count = number of c in full training set
  training set = full training set
  WHILE values count > number of maximal uncovered
      examples AND
    values count > percent of maximal uncovered
      examples
    rule = CLONAL–SELECTION–ALGORITHM(training set,
      c)
    covered  = COVER–SET(training set, rule)
    training set = training set / covered with rule
      set
    values count = values count – size of covered
    ADD(rules set, rule)
  END WHILE
END FOR EACH
training set = full training set
FOR EACH rule R in rules set DO
  MAXIMIZE–FITNESS(R, training set)
  COMPUTE–FITNESS(R, training set)
END FOR EACH
RETURN rules set
```

IFRAIS uses a sequential covering as a main learning algorithm (see Listing 1). In the first step a set of rules is initialized as an empty set. Next, for each class to be predicted the algorithm initializes the training set with all training examples and iteratively calls clonal selection procedure with the parameters: the current training set and the class to be predicted. The clonal selection procedure returns a discovered rule and next the learning algorithm adds the rule to the rule set and removes from the current training set the examples that have been correctly covered by the evolved rule.

Clonal selection algorithm is used to induct rule with the best fitness from training set (see Listing 2). Basic elements of this method are antigens and antibodies which refers directly to biological immune systems. Antigen is an example from

978-83-60810-14-9/08/$25.00 © 2008 IEEE

data set and antibody is a fuzzy rule. Similarly to fuzzy rule structure, which consists of fuzzy conditions and class value, antibody comprises genes and informational gene. Number of genes in antibody is equal to number of attributes in data set. Each gene consists of a fuzzy rule and an activation flag that indicates whether fuzzy condition is active or inactive.

Listing 2. Clonal selection algorithm in IFRAIS (based on [2])

```
Input: training set, class value (c)
Output: fuzzy rule

CREATE randomly antibodies population with size s
    and class value c
FOR EACH antibody A in antibodies population
  PRUNE(A)
  COMPUTE-FITNESS(A, training set)
END FOR EACH
FOR i=1 TO number of generations n DO
  WHILE clones population size < s-1
    antibody to clone = TOURNAMENT-SELECTION(
        antibodies population)
    clones = CREATE x CLONES(antibody to clone)
    clones population = clones population + clones
  END WHILE
  FOR EACH clone K in clones population
    muteRatio = MUTATION-PROBABILITY(K)
    MUTATE(K, muteRatio)
    PRUNE(K)
    COMPUTE-FITNESS(K, training set)
  END FOR EACH
 antibodies population = SUCCESSION(antibodies
    population, clones population)
END FOR
 result = BEST-ANTIBODY(antibodies population)
RETURN result
```

In the first step the algorithm generates randomly antibodies population with informational gene equals to class value *c* passed in algorithm parameter. Next each antibody from generated population is pruned. Rule pruning has a twofold motivation: reducing the overfitting of the rules to the data and improving the simplicity (comprehensibility) of the rules [11]. Fitness of the rule is computed according to the formula

$$FITNESS(rule) = \frac{TP}{TP+FN} \cdot \frac{TN}{TN+FP} \tag{1}$$

where TP is number of examples satisfying the rule and having the same class as predicted by the rule; FN is the number of examples that do not satisfy the rule but have the class predicted by the rule; TN is the number of examples that do not satisfy the rule and do not have the class predicted by the rule; and FP is the number of examples that satisfy the rule but do not have the class predicted by the rule. Since the rules are fuzzy, the computation of the TP, FN, TN and FP involves measuring the degree of affinity between the example and the rule. This is computed by applying the standard aggregation fuzzy operator *min*

$$AFFINITY(rule, example) = min_{i=1}^{condCount}(\mu_i(att_i)) \tag{2}$$

where $\mu_i(att_i)$ denotes the degree to which the corresponding attribute value $att_i$ of the example belongs to the fuzzy set accociated with the *i*th rule condition, and *condCount* is the number of the rule antecedent conditions. The degree of membership is not calculated for an inactive rule condition, and if the *i*th condition contains a negation operator, the membership function equals to $(1 - \mu_i(att_i))$ (complement). An example satisfies a rule if $AFFINITY(rule, example) > L$, where $L$ is an activation threshold. Next, antibody to be cloned is selected by tournament selection from the antibodies population. For each antibody to be cloned the algorithm produces *x* clones. The value of *x* is proportional to the fitness of the antibody. Next, each of the clones undergoes a process of hypermutation, where the mutation rate is inversely proportional to the clone's fitness. Once a clone has undergone hypermutation, its corresponding rule antecedent is pruned by using the previously explained rule pruning procedure. Finally, the fitness of the clone is recomputed, using the current training set. In the last step the *T*-worst fitness antibodies in the current population are replaced by the *T* best-fitness clones out of all clones produced by the clonal selection procedure. Finally, the clonal selection procedure returns the best evolved rule, which will then be added to the set of discovered rules by the sequential covering. More details of the IFRAIS is to be found in [2].

## III. Fuzzy partition inference

IFRAIS, as an Artificial Immune System evolves a population of antibodies representing the IF part of a fuzzy rule, whereas each antigen represents an example. As was stated, each rule antecedent consists of a conjunction of rule condition. In IFRAIS approach three and only three linguistic terms (low, medium, high) are associated with each continuous attribute. Each linguistic term is represented by the triangular membership functions (see Fig 1). It seems to be purposeful to infer a fuzzy partition for each continuous attribute over the data set instead of stiff, and the same for different attributes partitioning. There exist various methods to learn a fuzzy partions over a set of data [5]. We consider using a clonal selection algorithm to automatic infer partitions for each attribute, both crisp and continuous one. In such an approach a population of antibodies represent a set of partitions, and an antigen is a whole set of data.

### A. Representation

Each partition is represented by two crisp tables: a size table $S$ and a range table $R$. $S$ is one-dimensional table $S = \{s_1, s_2, \ldots, s_{setsCount}\}$, where $setsCount$ is the number of fuzzy sets the partition is consisted of (the number of ligustic terms). $setCount$ is drawn from the range $[3, 12]$ during inference. $s_i$ is a size of a fuzzy set and is expressed in so-called "‘division points"’ $pv$. For a crisp attribute $pv$ corresponds to one attribute value. For an attribute to be fuzzified $pv$ is computed as follows

$$pv = \frac{maxValue - minValue}{apc} \tag{3}$$

where $maxValue$ is a maximal attribute value, $minValue$ is a minimal attribute value, and $apc = setsCount \cdot pc$ defines the number of $pv$-points allocated to the attribute. $pc$ is an algorithm parameter set to 10, and $pc$ is interpreted as a number of $pv$-points assigned to one fuzzy set of the partition. While fuzzy partition infering, the size of one fuzzy set $s_i$ is drawn from a range $[1, apc - apc \cdot apcp]$, where $apcp$ is a percent of $apc$ ($apcp$ is a program parameter set to 10%).

A range table $R$ is two-dimensional table contains pairs $R = \{(r_{l_1}, r_{r_1}), (r_{l_2}, r_{r_2}), \ldots, (r_{l_{setsCount}}, r_{r_{setsCount}})\}$, where a pair $(r_{l_i}, r_{r_i})$ is a range expressed in $pv$ for which triangle fuzzy set (linguistic term) will be created. $r_{l_i}$ is a lower bound and $r_{r_i}$ is upper bound of the $i$th range. For crisp attributes each cell of the $R$ table contains induced list of attribute values. For example, partition of unfuzzy attribute FALLOUT, could be divided to 3 fuzzy sets $S = \{1, 1, 2\}$ with following value list $R = \{(snow), (rain), (hail, nofallout)\}$. The range for triangle fuzzy set is calculated on the basis of a size of fuzzy set $s_i$, $pv$, $minValue$, $maxValue$, $r_{r_{i-1}}$, and point overflow index $oi$. $oi$ is calculated as a difference between a sum of all values in $S$ table and $apc$. In the case when $oi > 0$, an overalap index $ovi$ is randomly generated from the range $[1, oi]$ to prevent lack of attribute full covering by lingustic terms. If $oi > r_{r_{i-1}}$, then $ovi$ is drawn from the range $[1, r_{r_{i-1}}]$.

To the first lower bound $r_{l_0}$ is assigned $minValue$. The first upper bound $r_{r_0}$ equals the size of a fuzzy set $s_1$ multiplied by $pv$ value. Every next pair in the $R$ table is calculated according to the following rules: if $oi > 0$ then draw $ovi$ from $[1, oi]$ or from $[1, r_{r_{i-1}}]$ if $oi > r_{r_{i-1}}$. Otherwise $ovi$ is equal to 0. The lower bound $r_{l_i} = ovi \cdot pv$, whereas the upper bound $r_{r_i} = r_{l_i} + s_i \cdot pv$. If $r_{r_i} > maxValue$ then $r_{r_i}$ is truncated to $maxValue$. Figure 2 illustrates the one of the fuzzy partion learning steps for an attribute TIME. The values from $S = \{15, 20, 5, 10, 25\}$ are represented by double side arrows. $ovi$ values are represented by one side arrows. $R$ table goes as follows $R = \{(0, 15), (5, 25), (23, 28), (25, 35), (25, 50)\}$.

### B. Operations

Fuzzy variables ready to use by IFRAIS are created from the range table $R$. All partition modifications are made over the size table $S$, from which table $R$ is derived according to the mentioned above rules. Fuzzy partitions are evaluated by using following operations:

*strong splitting*—removes randomly number $\chi$ of $pv$-points from randomly chosen cell $s_i$, and creates at randomly chosen position in $S$ new cell including $\chi$-points,

*light splitting*—removes only one $pv$-point form randomly chosen cell $s_i$, and creates at randomly chosen position in $S$ new cell including one point,

*strong joining*—removes randomly number $\chi$ of $pv$-points from randomly chosen cell $s_i$, and adds $\chi$-points to the randomly chosen cell,

*light joining*—removes only one $pv$-point from randomly chosen cell $s_i$, and adds one points to the randomly chosen cell.

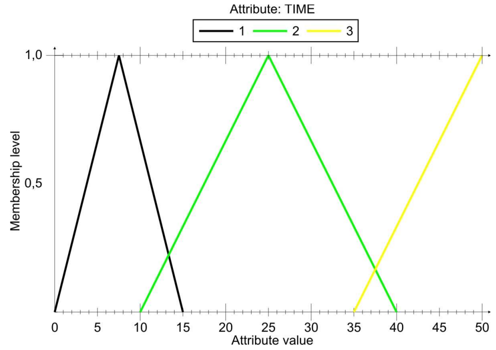

Fig. 1. An example of fuzzy partition for TIME attribute

### C. Inferring

Fuzzy partition inferring is based on clonal selection algorithm (see Listing 3). In this algorithm it is worth underlining a clone mutation which undergoes for all clones in a population. While mutating, only the sizes of fuzzy sets (table $S$) for choosen attribute are generated according to the mentioned above rules, but without changing the number of liguistic terms (the size of table $S$). After a new partition generation, the operations (strong and light splitting, strong and light joining) are fired, each with the probability $muteRatio$

$$muteRatio = min + \frac{(max - min) \cdot (1 - f + No)}{2} \quad (4)$$

where $min$ and $max$ are minimal and maximal probability respectively (algorithm parameters), $No$ is a number taken at random from $[0, 1]$, and $f$ is a normalized clone fitness before mutation.

TABLE I
DATA SETS AND NUMBER OF ROWS, ATTRIBUTES, CONTINUOUS ATTRIBUTES, AND CLASSES

| Data set | #Rows | #Attrib. | #Cont. | #Class. |
|---|---|---|---|---|
| Bupa | 345 | 6 | 6 | 2 |
| Crx | 653 | 15 | 6 | 2 |
| Hepatitis | 80 | 19 | 6 | 2 |
| Ljubljana | 277 | 9 | 9 | 2 |
| Wisconsin | 683 | 9 | 9 | 2 |
| Votes | 232 | 16 | 0 | 2 |

## IV. EXPERIMENTAL RESULTS

In order to evaluate the performance of the speed boosting extensions, both IFRAIS and improved IFRAIS were applied to 6 public domain data sets available from the UCI repository (http://archive.ics.uci.edu/ml/datasets.html):

- Bupa (Liver+Disorders)
- Crx (Credit+Approval)
- Hepatitis (Hepatitis)
- Lubljana (Breast+Cancer)
- Votes (Congressional+Voting+Records)
- Winsconsin (Breast+Cancer+Wisconsin+(Original))

The experiments were conducted using a Distribution-Balanced Stratified Cross-Validation [12], which is a one of the version of well-known $k$-fold cross-validation, and improves the estimation quality by providing balanced intraclass distributions when partitioning a data set into multiple folds. Additionally, both IFRAIS method were compared to C4.5, well-known data mining algorithm for discovering classification rules [9] (results of C4.5 taken from [2]).

Table 1 shows the number of rows, attributes, continuous attributes, and classes for each data set. Note that only continuous attributes are fuzzified. The Votes data set does not have any continuous attribute to be fuzzified, whereas the other data sets have 6 or 9 continuous attributes that are fuzzified by IFRAIS. All experiments with IFRAIS were repeated 50-times using 5-fold cross-validation. Table 2 shows for each data set the average accuracy rate with standard deviations, both for IFRAIS and IFRAIS extended by fuzzy partition learning (boosted IFRAIS), as well as for C4.5 method. As shown in Table 2 the boosted IFRAIS obtained better accuracy rates than standard IFRAIS for all data set but one (the Votes data set comprises only crisp attributes). For Bupa set the average gain is ca 14 %, and for Hepatitis even more (16.6 %)! The improved IFRAIS obtained higher accuracy than C4.5 in five out of the six data sets. C4.5 obtained a higher accuracy than IFRAIS in only one data set (Crx), but the differences in accuracy rate is not significant, since the accuracy rate intervals (based on the standard deviations) overlap.

TABLE II
ACCURACY RATE ON THE TEST SET

| Data set | C4.5 | IFRAIS | Boosted IFRAIS |
|---|---|---|---|
| Bupa | 67.40±1.60 | 58.38±0.78 | 72.34±0.99 |
| Crx | 90.22±1.59 | 86.03±0.26 | 87.37±0.08 |
| Hepatitis | 76.32±2.79 | 77.25±1.71 | 93.87±2.65 |
| Ljubljana | 68.80±4.45 | 69.55±1.09 | 74.70±0.79 |
| Wisconsin | 95.32±1.09 | 94.91±0.39 | 97.39±0.28 |
| Votes | 94.82±0.82 | 96.98±0.00 | 96.98±0.00 |

## V. CONCLUSION

The accuracy boosting extension was introduced to the IFRAIS algorithm—an AIS-based method for fuzzy rules mining. Boosting uses the fuzzy partion learning based on the clonal selection. The partition inferring improves significantly effectiveness of an algorithm. Although the proposed improvements increase the accuracy of the whole algorithm, it is worth noticing that the learning of fuzzy partition is additional time-consuming procedure.

It seems to be still possible to improve the Induction of Fuzzy Rules with Artificial Immune Systems, and not only considering the effectiveness of the induced fuzzy rules but also time of working. These two goals could be achieved mostly by modifying the fitness function to reinforce the fitness of high-accuracy rules, as in [1]. We also consider changing the triangular membership functions to various more sophisticated functions and manipulating all system parameters to obtain higher quality results. We have performed preliminary experiments, in which speed and accuracy boosting IFRAIS with modified fitness function and parameters is trained on well known data sets. The results are very promising.

## ACKNOWLEDGMENT

The authors would like to thank Dr. Robert Alves for making available to them his source code of IFRAIS.

***Abstract*—Some tools to measure convergence properties of genetic algorithms are introduced. A classification procedure is proposed for genetic algorithms based on a conjecture: the entropy and the fractal dimension of trajectories produced by them are quantities that characterize the classes of the algorithms. The role of these quantities as invariants of the algorithm classes is discussed together with the compression ratio of points of the genetic algorithm.**

## I. Introduction

THERE is the so-called "No-free lunch theorem" [10] algorithms and moreover, one cannot find most suitable operator according to which: it does not exist a best evolutionary between all possible mechanisms of crossover, mutation and selection without referring to the particular class of optimisation problems under investigation. Evolutionary algorithms are the methods of optimizations which use a limited knowledge about investigated problem. On the other hand, our knowledge about the algorithm in use is often limited as well [11], [12].

One of the most difficult, however, of practical importance, problems is the choice of an algorithm to given optimisation problem.

The distinguishing between optimisation problem and the algorithm (its choice) leads to the main difficulty. Consequently, the distinguishing is an artificial operation because it abstains from the idea of genetic algorithm (GA), since the fitness function, arises from the cost function (i.e. the function to be optimised) is the main object of the genetic algorithm and it emerges form the formulation of the optimisation problem and it is difficult to speak on genetic algorithm as an operator without the fitness function. However, in our consideration we will simultaneously use the both notions of the genetic algorithms. The first notion as an operator acting on the cost (fitness) function, the second—as a specific (real) algorithm for which the fitness is the main component being the algorithm's parameter.

This dual meaning of the genetic algorithm is crucial for our consideration, because our main aim is to try to classify genetic algorithms. The classification should lead to a specific choice methodology of genetic algorithms understood as operators. It is expected that in terms of this methodology one will be able to choose the appropriate algorithm to given optimisation problem. We aim that using this classification one could improve existing heuristic methods of assortment of genetic algorithms which are based mainly on experiences and programmer intuition.

During the action of genetic algorithm several random operations are performed and each action generates a sequence of random variables, which are candidate solutions. The action of GA could be represented in the solution (or rather—search) space as a random trajectory.

The present paper is an attempt to introduce an enlarged investigation method to the theory of genetic (evolutionary) algorithms. We aim at the development of some tools suitable for characterization of evolutionary algorithms based on the notions of the symbolic dynamics as well as on compression rates.

## II. Classification of algorithms and its tools

The convergence of GAs is one of the main issues of the theoretical foundations of GAs, and has been investigated by means of Markov's chains. The model of GA as a Markov's chain is relatively close to the methods known in the theory of dynamical systems.

In the analysis of GAs regarded as (stochastic) dynamical systems one can use the fact, (proven by Ornstein and Friedman [3], [8]) which state that mixing Markov's chains are Bernoulli's systems and consequently, the entropy of the systems is a complete metric invariant.

Those facts enable us to classify GAs using the entropy. The systems for which the entropies have the same value are isomorphic. Hence the entropy makes it possible to classify GAs by splitting them into equivalence classes. Unfortunately, in many cases the determination of the entropy is very difficult or even impossible. Hence one can try to use as classification

978-83-60810-14-9/08/$25.00 © 2008 IEEE

tools the compression rate and the fractal dimension determined for trajectories of GAs.

## III. Genetic algorithms

Let $X$ be a space of solutions of an optimisation problem characterized by a fitness function $f : X \to \mathbf{R}, X \subset \mathbf{R}^l$ for which a genetic algorithm will be invented. Each element $x \in X$ will be encoded in the form of a binary chromosome of the length $N$. The coding function $\varphi : X \to \{0,1\}^N = B$ maps elements of $X$ into chromosome from the $B$ space.

Let us assume that the genetic algorithm acts on $K$-element populations. Each population forms a multiset $[P^K]$ in the product space $B^K$, for the $i$-th generation we will use the denotation $[P_i^K]$, for the population and each element of this multiset can be identified with a vector

$$P_i^K = [x_1^i, x_2^i, \dots, x_K^i] \tag{1}$$

rembering that a population is an equivalent class of points from the vector space $B^K$. The equivalent relation is defined by the class of all possible permutations of the set of $K$-th numbers $\{1, 2, ..., K\}$.

Let us notice that we can identify points from $X$ with their encoded targets in $B$ under the action of space $X^K$. By a trajectory of the genetic algorithm of the duration $M$ we mean a set

$$T = \bigcup_{i=1}^{M} [P_i^K], \tag{2}$$

where $M$ is the number of steps (generations) of the genetic algorithm which is realized.

Let $p_m$ and $p_c$ be the probabilities of the mutation and crossover, respectively, while $p_s$ is the probability of selection, all independent from the generation.

Then, for such a genetic algorithm the probability of the appearance of the population $[P_{i+1}^K]$ at the generation $i+1$ after the population $[P_i^K]$ at the generation $i$, is the conditional probability

$$\mathcal{P}(P_{i+1}^K | P_i^K \ , f(P_i^K), p_m, p_c, p_s). \tag{3}$$

Here by $f(P_i^K)$ we understand the vector–valued function $[f(x_1^i), f(x_2^i), \dots, f(x_K^i)]$. The initial population $[P_1^K]$ is generated by the use of a uniform probability distribution over the set $B$, i.e. each point from $B$ has the same probability of being selected as a member (component) of $[P_1^K]$. Next populations following that one, are the results of the action of the GA and, hence, may have a non-uniform probability distribution.

Let us notice that in view of our assumptions it follows from (3) that the probability of the appearance of each population depends on the previous population and does not depend on the history (i.e. on earlier population; the probabilities $p_m, p_c$ and $p_s$ can be regarded as parameters of the function $\mathcal{P}$).

Now, if we look at the trajectory of the GA defined by (2), we can see that its generation is an ergodic (mixing) process and Markov's one. Subsequent populations (i.e. points of the trajectory) are states of the process, about which we can say that each state is accessible with the probability 1.

## IV. Entropy of GA

The domain of research of the ergodic theory is a space with measure and mappings which preserve it. Let us denote by $\mathsf{T}_i$ the operator which maps $i$-th generation (point of the trajectory) into the next one. Having the probability distribution (3) characterizing the mapping $\mathsf{T}_i$ from one population to another, we can define the entropy of the mapping

$$H(\mathsf{T}_i) = -\sum_{j=1}^{M} \mathcal{P}(P_{i+1,j}^K | P_i^K, f(P_i^K), p_m, p_c, p_s) \\ \log\mathcal{P}(P_{i+1,j}^K | P_i^K, f(P_i^K), p_m, p_c, p_s) \tag{4}$$

where $[P_{i+1,j}^K]$ is a possible population from $B, j = 1, 2, \dots, 2^{NK}, \dots, M$.

According to our previous proposition the initial population is generated by the use of a uniform probability, and attains the maximal value generated by the GA. In the next step the probabilities of populations are not uniform and differ at each generation; this is the essence of the action of GA. Consequently the entropy of the mapping $\mathsf{T}_i$ decreases. In the limit case when the number of steps tends to infinity one could expect that the terminal population will be composed of $K$ copies (exactly speaking, according to (1) – a cartesian product) of the same element (an optimal solution). However, this case will be possible only in the case of the pointwise asymptotic stability of GA. In general, the entropy will tend to minimum.

Entropy is the function of the probability of mutation and selection; it grows with the growing mutation probability and decreases when the selection pressure grows. Then the entropy could realize a measure of interactions between mutations and selection operators. Entropy also depends on the number of elements in population and it is decreasing when the population grows. The entropy value of the trajectory could be linked with computational complexity of the evolutionary algorithms.

## V. Fractal dimensions

Since the determination of the probability of the mapping $\mathsf{T}_i$, as well as the entropy $H_i$, in an analytical way is rather difficult to be performed, we are proposing to substitute them with a fractal dimension which is related to the entropy [8] and can characterize non-deterministic features of GA. In [7] general statistical and topological methods of analysis of GAs have been introduced. Moreover one can use Hausdorff's dimension or its approximation as an invariant of equivalence of algorithms.

To be more evident, let us recall the notion of the $s$-dimensional Hausdorff measure ([4]) of the subset $E \subset \mathbf{R}^l$, where $s \geq 0$. If $E \subset \bigcup_i U_i$ and diameter of $U_i$, denoted by $\delta(U_i)$, is less than $\epsilon$ for each $i$, we say that $\{U_i\}$ is an $\epsilon$-cover of $E$. For $\epsilon > 0$, let us define

$$H_\epsilon^s(E) = \inf \sum_{i=1}^{\infty} [\epsilon(U_i]^s \tag{5}$$

where the infimum is over all $\epsilon$-covers $\{U_i\}$ of $E$. The limit of $H^s_\epsilon$ as $\epsilon \to 0$ denoted by $H^s(E)$, is the $s$-dimensional Hausdorff measure of $E$.

Let us notice that in the space $R^l$ one can prove that $H^l(E) = \kappa_l L^l(E)$, where $L^l$ is the $l$-dimensional Lebesgue measure and $\kappa_l$ is a ratio of volume of the $l$-dimensional cube to $l$-dimensional ball inscribed in the cube.

It is evident that $H^s_\epsilon(E)$ increases as the maximal diameter $\epsilon$ of the sets $U_i$ tends to zero, therefore, it requires to take finer and finer details, that might not be apparent in the larger scale into account. On the other hand for the Hausdorff measure the value $H^s(E)$ decreases as $s$ increases, and for large $s$ this value becomes 0. Then the Hausdorff dimension of $E$ is defined by

$$\dim(E) = \inf\{s : H^s(E) = 0\}, \tag{6}$$

and it can be verified that $\dim(E) = \sup\{s : H^s(E) = \infty\}$.

The Hausdorff dimension is one of several fractal dimensions. To make the definitions more evident let us notice that for the Hausdorff dimension of the Peano curve has dimension 2 and of the Cantor middle set is $\log 2/\log 3$, while its topological dimension $D_T$ is zero. In most cases Hausdorff dimension $\geq$ the topological one. In its classical form a fractal is by definition a set for which the Hausdorff dimension strictly exceeds the topological dimension.

Topological dimension takes non-negative integer values and is invariant under homeomorphism, while the Hausdorff dimension is invariant under bi–Lipschitz maps (sometimes called quasi–isometries).

As some approximation of the fractal dimension one may consider another dimension known as the packing dimension or the box-counting dimension [4]. To calculate this dimension for a set $S$ imagine this set lying on an evenly-spaced grid. Let us count how many boxes are required to cover the set. The **box-counting** dimension is calculated by observing how this number changes as we make the grid finer. Suppose that $N(\epsilon)$ is the number of boxes of the side length $\epsilon$ required to cover the set. Then the box-counting dimension is defined as:

$$\dim_{box}(S) = \lim_{\epsilon \to 0} \frac{\log N(\epsilon)}{\log(1/\epsilon)} \tag{7}$$

It is possible to define box–counting dimensions using balls, with either the covering number or the packing number. It follows that box dimension of $E$ is always $\geq \dim(E)$.

By inventing the fractal (Hausdorff) dimension the trajectory of GA's or its attractor can be investigated. Algorithms could be regarded as equivalent if they have the same computational complexity while solving the same problem. As the measure of computational complexity of genetic algorithm, we propose a product of population's size and the number of steps after which an optimal solution is reached. This measure of computational complexity of genetic algorithms joins the memory and the temporal complexity.

During the execution of genetic algorithms, a trajectory is realized and should "converge" to some attraction set. It is expected that an ideal genetic algorithm produces an optimal solution which, in the term of its trajectory, leads to an attractor which is one–element set. On the other hand, for an algorithm without selection the attractor is the whole space. Then, we could say that algorithms are equivalent when they produce similar attractors [5].

Hence, instead of the entropy, the fractal dimension will be used as an indicator, or better to say—a measure of the classifications of GAs.

We say that two genetic algorithms are equivalent if they realize trajectories with the same fractal dimension.

## VI. Compression ratio

It is our conjecture that some characteristic feature of the trajectory of GA can be obtained by analysing the ration of the compressed trajectory to itself. We decided to investigate Lempel-Ziv compression algorithm [2] applied to populations executed by various genetic algorithms. We implemented five De Jong's functions with 10 different parameters sets. Each experiment was run 10 times. All together we obtained 500 different trajectories. The following settings of algorithms were considered

| EXP | CROS | PC | PM | SEL |
|---|---|---|---|---|
| 1 | 1 | 0.25 | 0.001 | t |
| 2 | 2 | 0.6 | 0.01 | r |
| 3 | u | 0.95 | 0.05 | p |
| 4 | 1 | 0.6 | 0.05 | p |
| 5 | 2 | 0.25 | 0.001 | r |
| 6 | u | 0.6 | 0.01 | t |
| 7 | 1 | 0.95 | 0.01 | r |
| 8 | 2 | 0.95 | 0.001 | p |
| 9 | u | 0.25 | 0.05 | t |
| 10 | 1 | 0.95 | 0.99 | r |

where EXP is the experiment number; CROS is type of crossover operator (one point, two point, uniform); PC and PM are probabilities of crossover and mutation, respectively; and SEL is type of selection operator (tournament, rank, and proportional). In each experiment the population consisted of 25 points and the genetic algorithm was realized on 100 generations (points).

We performed numerous experiments on compressing particular generations with Lempel-Ziv algorithm of various bit resolution. We measured number of prefixes resulting from compression process and corresponding compression ratio in scenarios of two types. The first one considered single generations, and for each trajectory we obtained corresponding trajectory of number of prefixes used. In the second scenario, each next generation was added to all past generations forming an ascending family of sets of generations. Compressing elements of such family gave an overall picture how number of prefixes used in the compression stabilizes over time.

## VII. Experiments and conclusions

The first experiments with attractors generated by GAs and the expression (8) have been performed by our co-worker in [5]. His results allow us to claim that the present approach can be useful in the GA's dynamics research.

In the recent paper [14] we have used another approach to the approximation. Let $N(T,\epsilon)$ be the minimum number of $K$-dimensional cubes with the edge length equal to $\epsilon$, that covers the trajectory $T \subset X$, and $X$ is a $l$-dimensional search space. To be more evident let us consider the case when $\epsilon = 2^{-k}$ and diminish the length of cube edges by half. Then the following ratio will approximate the box counting dimension of trajectory $T$

$$D_c(T) \approx \frac{\log_2 N(T, 2^{-(k+1)}) - \log_2 N(T, 2^{-k})}{\log_2 2^{k+1} - \log 2^k} = \\ = \log_2 \frac{N(T, 2^{-(k+1)})}{N(T, 2^{-k})}. \qquad (8)$$

The approximated expression (8) of the box dimension counts the increase in the number of cubes when the length of their edges is diminished by half.

In [14] we have included new calculation results. 12 benchmark functions were used (cf. [6]) in the analysis. Experiments were performed for different dimension: 10, 15, 20 bits with operator parameters and Popsize. Then the box counting dimension was used to calculate the trajectory dimension.

As far as the analytical approach and the formal definitions of dimensions (5) and (6) are concerned their computer implementation needs additional investigations. Computer accuracy is finite, hence all limits with $\epsilon$ tending to zero will give unrealistic results. For example, if the calculation drops below the computing accuracy the expression value becomes zero or undefined. It means that we have to stop taking limit values in early stage. Hence, the questions arise: to which minimal value of $\epsilon$ the calculation should be performed and whether and how the relations with limits should be substituted with finite, non-asymptotic, expression? This, however, will be the subject of our further research.

The main idea of our experiments made in [14] was the verification and confrontation of our theoretical considerations and conjectures with real genetic algorithms.The analysis of the experimental result has shown that the value of box-counting dimension of the trajectory of genetic algorithms is not random. When we use the same fitness function and the same configurations, then the box dimensions become clustered near the same value. Whole trials of the independent running attains the same values. Moreover with the different functions but the same configuration we deal with the conservation of box-counting dimension clustering.

Average values of the box-counting dimension for the united trajectories of the algorithms from the same trial were similar to these which were calculated by averaging of the dimension of individual trajectories. This fact acknowledges the conjectures that box-counting dimension could characterize the complexity of algorithms.

Box-counting dimension describes the way of evolution during search. Algorithms which attain the maximum in a wide loose set have bigger dimension than others which trajectories were narrow, with small differences between individuals.

One can say that bigger box dimension characterizes more random algorithms. The main result of the experiments states that fractal dimension is the same in the case when some boxes contains one individual as well as when these boxes contain many elements (individuals). Box dimension does not distinguish the fact that two or more elements are in the same place. They undergo counting as one element. The value of dimension should depend on the number of elements placed in each box. Our main conclusion is that good characterization is the information dimension.

## ACKNOWLEDGEMENT

The research work on the paper done by W.K., S.K., Z.M. and P. S. was supported by the KBN Project No. 3 T11 C007 28 in 2005-2007. The authors are grateful to Dr. J. Socała for valuable discussions.

# Evolution of Strategy Selection in Games by Means of Natural Selection

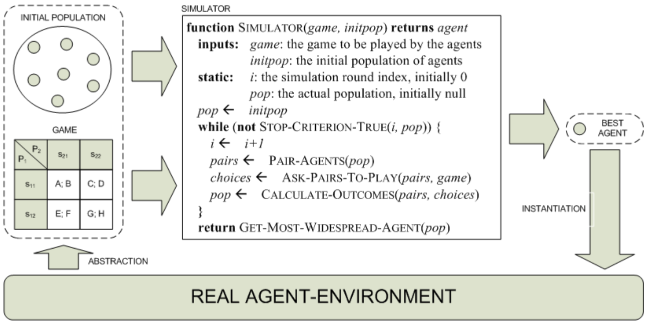
Daniel L. Kovacs, Tadeusz Dobrowiecki
Budapest University of Technology and Economics, H-1117 Budapest, Hungary
Email: {dkovacs, dobrowiecki}@mit.bme.hu

*Abstract*—**In this paper we present a novel agent-based simulation model for the natural selection of replicating agents whose survival depends on their programs for selecting their strategy to interact with each other. Game theoretic models describe this kind of interaction. The simulator can be used both for analysis, design and verification of autonomous systems (by intuitively abstracting them into our model and running the simulation). Good system design can be selected even for difficult, underspecified design problems. Although the inspiration of the model comes from evolutionary game theory, the evolving agents may represent not only biological, but also technical systems (e.g. software agents), and thus in some cases the underlying evolutionary mechanisms and observations differ from the typically published results.**

## I. Introduction

THIS article presents a novel, realistic agent-based simulation model for the natural selection of replicating agents whose survival depends on their programs for selecting their strategy to interact with each other [1]. Compact game theoretic models describe such interaction, masking most low-level details, but nevertheless catching the essential program features, and simplifying simulation [2].

The implementation of the proposed simulation model is a domain-independent problem-solving tool that facilitates not only analysis, but also design and verification of autonomous systems. Assuming that there is a fixed set of different *design alternatives* (e.g. different types of software agents) in the real environment which interact with each other repeatedly and randomly in a pairwise manner, and that their number depends on their success in these interactions, they can be modeled – including their environment – by **(1$^{st}$)** a fixed pool of game playing agents (being able to replicate and terminate) and **(2$^{nd}$)** a 2-person game. These are the two inputs of our simulation model as shown in Fig. 1.



| P₁ \ P₂ | s₂₁ | s₂₂ |
|---|---|---|
| s₁₁ | A; B | C; D |
| s₁₂ | E; F | G; H |

```
function SIMULATOR(game, initpop) returns agent
  inputs:  game: the game to be played by the agents
           initpop: the initial population of agents
  static:  i: the simulation round index, initially 0
           pop: the actual population, initially null
  pop ←  initpop
  while (not STOP-CRITERION-TRUE(i, pop)) {
    i ←  i+1
    pairs ←  PAIR-AGENTS(pop)
    choices ←  ASK-PAIRS-TO-PLAY(pairs, game)
    pop ←  CALCULATE-OUTCOMES(pairs, choices)
  }
  return GET-MOST-WIDESPREAD-AGENT(pop)
```

Fig. 1 The simulation model and its use in system analysis and design

The simulation is boldly as follows: agents are repeatedly and randomly paired to play the 2-person game, and their survival (and chance for replication) depends on the utility they can gather during that process. Thus quantitative aspects enter the simulation via the proportion of subpopulations of these different agents constituting the initial population. Evolution essentially means the dynamics of the distribution of these different agents (species) within the evolving population. This way we intend to find the agent corresponding to the best design alternative even when the under-defined specification (usually due to missing, or uncertain knowledge about the task environment) does not make it possible to pinpoint the optimal design via the traditional design process. The success of this process depends very much on the abstracting phase, where the real problem is represented as an input for our simulation model.

The inspiration for the model comes mainly from evolutionary game theory, and the seminal experiments of Robert Axelrod with the **T**it-**F**or-**T**at (**TFT**) strategy in the repeated **P**risoner's **D**ilemma (**PD**) [3]–[5]. Several other models of program evolution exist, but our approach differs from them mainly in the following [6]–[8].

1. We utilize natural selection as a realistic "driving force", and not some preprogrammed, explicit mechanism, to evolve the population;
2. we do not consider the emergence of new variants, only proliferation, i.e. asexual replication (spreading);
3. we do not impose any formal constraints on the structure and inner workings of the agent programs.

We hope thus to model, predict, and support design in several interesting real world situations (e.g. the success of given software agents managing resources or being engaged in electronic commerce on the Internet).

The rest of the paper is organized as follows: Section 2 introduces the background of the simulator, Section 3 describes its architecture and implementation in detail, Section 4 presents and evaluates some essential experiments, Section 5 contains conclusions and outlines future research.

## II. Background

In the following, we will briefly summarize those approaches, which mainly influenced our model. The purpose of this is to introduce some fundamental concepts, and to enable later discussion of similarities and differences.

### *A. Axelrod's experiments*

The goal of Axelrod's experiments was to find a program which efficiently plays the repeated PD game (cf. Table I). At first 15, then 62 programs were chosen, and pairwise compared. Every program played against each other a fixed number of rounds. In every round they had to choose between two strategies (cooperate or defect), and got their respective payoff according to their collective choice.

TFT, a simple program, which initially cooperates, and then repeats the previous choice of its opponent, won both tournaments by collecting the most at the end. Axelrod concluded, that because of the importance of PD as a model of social interaction, the core characteristics of cooperation in general must be those found in the TFT.

Axelrod then conducted other experiments to confirm the success of TFT, called ecological and evolutionary analysis. In the former he examined the dynamics of a population composed of programs submitted for the second tournament (all having an equal proportion of the initial population). The proportion of a program changed according to the proportion-weighted average of its scores against other programs in the second tournament. The results of this experiment again underpinned the success of TFT. Its proportion was the largest, and it grew steadily.

In the latter experiment Axelrod used genetic algorithms to evolve programs (represented as bit strings) that could play against the programs submitted for the second tournament [9]. Fitness was equal to the then average payoff. The algorithm produced programs that played effectively against the tournament programs, and resembled TFT.

### *B. Evolutionary Game Theory*

Evolutionary game theory, on contrary to the previous simulations, enables formal analysis and prediction of such evolving systems (although only for relatively simple cases).

For example, let's suppose that we have an infinite population of agents, who strive for resources. The game is divided into rounds, and in every round every agent randomly (according to uniform distribution) meets an other agent to decide upon a resource of value $V>0$ . For the sake of simplicity let's say, that there are only two types of agents: hawks (aggressive), and doves (peaceful).

When two hawks meet, they fight, which costs $C$ , and so they get $(V-C)/2$ per head. When two doves meet, they divide the resource equally between each other (they get $V/2$ per head). When a hawk meets a dove, then the hawk takes the resource (gets $V$ ), while the dove is plundered (gets $0$ ).

Table I.
Payoff matrix of the "Prisoner's Dilemma" game used by Axelrod

| Player 2<br>Player 1 | Defect | Cooperate |
|---|---|---|
| Defect | 1; 1 | 5; 0 |
| Cooperate | 0; 5 | 3; 3 |

This situation is simply modeled by the **H** awk- **D** ove (**HD**) game (cf. Table II) [10]. The gained payoffs are collected over rounds, and the proportion of hawks and doves depends on their average collected payoff. Formally this is as follows.

Let $p_H^i$ and $p_D^i$ denote the proportion, while $W_H^i$ and $W_D^i$ the average collected payoff of hawks and doves in round $i$ respectively. For every $i \geq 0$ $p_H^i, p_D^i \in [0,1]$ , and $p_H^i + p_D^i = 1$ is true. The average collected payoff of the whole population in round $i$ , $W^i$ , is

$$W^i = p^i_H W^i_H + p^i_D W^i_D \tag{1}$$

The proportion of hawks and doves in round $i+1$ is calculated according to discrete replicator dynamics.

$$p_H^{i+1} = p_H^i \frac{W_H^i}{W^i} \text{ , and } p_D^{i+1} = p_D^i \frac{W_D^i}{W^i} \tag{2}$$

The average collected payoff of hawks and doves in round $i+1$ is respectively.

$$W_H^{i+1} = W_H^i \left( p_H^{i+1} (V-C)/2 + p_D^{i+1} V \right) \tag{3}$$

$$W_D^{i+1} = W_D^i + p_D^{i+1} V/2 \tag{4}$$

Consequently, for example, it can be simply shown that if $V > C \geq 0$ , $W_H^0 = W_D^0 > 0$ , and $p_H^0 > 0$ , then

$$\lim_{i \to \infty} p_H^i = 1 \text{ , and } \lim_{i \to \infty} p_D^i = 0 \tag{5}$$

This means, that the system converges to a state, where only hawks remain in the population. Many similar, interesting results can be obtained this way, although the necessary assumptions are usually unrealistic, and overly simplified (infinite number of agents; trivial programs, that can be handled analytically; etc) [11]. For more realistic and complex cases, with arbitrary programs (like in the ecological analysis of Axelrod) and finite, overlapping generations of varying size, we need to use simulations.

## III. Simulation Driven by Natural Selection

The proposed simulation model combines the advantages of the previous approaches without their drawbacks. It resembles artificial life in many aspects, but it is different in its purpose (it tries to capture the key features of not only biological, but also technical systems' evolution) [12]. It is an extension to the previous approaches, differing from them in the following.

Table II.
Payoff matrix of the "Hawk-Dove" game

| Player 2<br>Player 1 | Hawk | Dove |
|---|---|---|
| Hawk | (V-C)/2; (V-C)/2 | V; 0 |
| Dove | 0; V | V/2; V/2 |

1. Populations are finite, and vary in size;
2. Generations are overlapping;
3. Agents are modeled individually;
4. The selection mechanism, and the fitness of agents is not explicitly given, but it is a product of agents' features and their interaction;

5. Modeling of not only biological, but also technical systems' evolution is considered.

These differences make the model more realistic, and enable us to use it not only for analysis, but also for design.

### C. Detailed Description of the Simulation Model

The basis of the model is an intuitive combination and extension of the ideas discussed in Section 2. The simulation is divided into rounds. There is a finite number of agents in the population, who are randomly paired in every round (according to uniform distribution) to play a 2-person game in the role of one of the players. Every agent of the population plays the same type of game (e.g. just PD, or just HD) in every round of a run, and each of them has a program (e.g. TFT, Random, Always-Cooperate, Always-Defect) for selecting its strategy in these plays.

After a pair of agents finished to play in a given round, the respective (possibly negative) payoffs are added to their individually cumulated utility. If the utility of an agent gets below a level (e.g. zero), then the agent dies, i.e. it instantly disappears from the population, and won't play in the following rounds; otherwise it may reproduce depending on its reproduction strategy. Every agent has a reproduction strategy (defining how, and when to reproduce), but only asexual proliferation, i.e. replication without change is considered. After every agent finished the given round (died, survived, or even replicated), comes the next round.

It can be seen, that in this model there is no explicit selection mechanism directly controlling the proportion of agents in the population (like replicator dynamics, or roulette wheel), but it is an implied, emergent phenomena. Every agent has its own lifecycle (they are born with given features, interact with each other, change, maybe even reproduce, and then possibly die), and only those are "selected" for reproduction, whose features make them able to survive in the environment up to that moment. In our view this process is real *natural selection*.

Of course there are many other more or less similar definitions in literature originating mostly from Darwin [13]. For instance, it is usual to say that "natural selection is a process that affects the frequency distributions of heritable traits of a population" [14] (page 16), and that "heritable traits that increase the fitness of their bearers increase in frequency in a population" [15] (page 821), etc. These statements do not contradict our views, but they aren't specific enough in the sense, that they allow even the selection behind a genetic algorithm to be called "natural". The reason for that is that these statements stem from biology and genetics, which are concerned with natural systems [16], [17]. This is why we use a "new" definition.

Moreover, we need to differentiate between modeling natural selection of natural, and technical systems. In respect of technical systems, "natural selection" may reflect the "natural" peculiarities of technical application areas, which may be quite far from what can be considered natural in biological, or social science. We differentiate these aspects by introducing agents' *reproduction strategies*.

We'll consider two types of reproduction: type 1 is called "natural", and type 2 is called "technical". Agents with type 1 reproduction can have only a limited number of offsprings in their lifetime (maximum one per round). They replicate, if their utility exceeds a given limit (limit of replication). After replication, their utility is decreased with the cost of replication (which is usually equal to the limit of replication). Offsprings start with zero utility, and the same program, and features, as their parents originally (i.e. the same lower limit of utility necessary for survival, limit and cost of replication, and limit on the number of offsprings).

On the other hand, agents with type 2 reproduction can have unlimited offsprings (maximum one per round). They replicate when their utility exceeds the limit of replication, but this limit is doubled every time an offspring is produced, and their utility does not decrease. Offsprings start with the same utility, program, and features, as their parents at the moment of replication (i.e. the same lower limit of utility necessary for survival, and limit of replication).

The rationale behind the above design choices originates in the following: biological agents can reproduce only a limited number of times during their lifetime, while technical systems (e.g. software agents) usually do not have such limitations. The replication (copy) of a technical system is usually inexpensive compared to the replication of a biological agent. Offsprings of technical systems may be exact copies of their parents with the same level of quality, while offsprings of a biological system usually develop from a lower (immature) level. The level of "maturity", where a biological system can reproduce, may be constant, and the same as its parents', but it may increase in the case of a technical system (to represent the increasing cost of production, or the amount of resources needed, etc).

### D. Using the Simulation Model for Analysis and Design

As mentioned before, the simulation model can be used not only for description, but also for design of technical systems. Let's suppose, for example, that we want to design an efficient software agent (e.g. a broker agent, or a trading agent on the Internet acting on behalf of human users, trying to maximize their profit). Our goal is to make this agent as efficient and useful as possible in hope that in result it will spread better (e.g. more users will start to use it). Of course there are many other factors (like marketing, ergonomics, etc) that may influence the success of such a system, but, as for a Designer, ensuring functional efficiency and usefulness is a primary objective. Nonetheless these properties depend not only on the program of the agent, but also on its environment (e.g. the other concurrent agents), which may be not fully accessible, too complex and dynamic to be modeled and analyzed exactly in order to calculate an optimal system design (e.g. in the case of Internet).

It is inevitable to abstract the problem. We recommend game theory to model the strategic interaction in the real agent-environment. It may mask most of the subtlety of agents' programs, but it catches essential features, and works toward a simpler simulation, which becomes necessary, if – according to the conclusions of Section 2 – agents' programs are too complex to be handled analytically.

For example, let's suppose that software agents participate in electronic auctions on the Internet to acquire goods for their human users. The less they pay for them, the higher their individual utility is (from the perspective of their users). If two agents agree to cooperate (e.g. to raise the bid only until one of them wins and then share equally), then they pay less, than being non-cooperative (e.g. when competing against each other by bidding more and more to win). The best outcome is however for an agent to "cheat" its cooperative partner by defecting (e.g. raising the bid to win while the other is not competing and then not sharing the win). This outcome is the worst for the other agent since it gets nothing. Let's say, that if a software agent is successful, then after it achieves a given profit for its user, then its user invests in another such agent, but if the profit is below a level then she/he stops using it. *What software agent would we design to better survive and proliferate in this scenario?*

The situation can be modeled by the proposed simulation: agents have two strategies (cooperate or defect), and the order of their preferences corresponds to a PD game (cf. Section 4/A). Now we can estimate the distribution of the various software agents in the real agent-environment, and construct an initial population accordingly. Assuming that natural selection is the "driving force" behind agents' evolution, we can give the corresponding PD game and the initial population as an input to the simulation model, and run it. If we run the simulation by injecting several different candidate solutions into that initial population, we can get the most successful variant. This way we can use natural selection to support not only analysis, but also design.

### *E. Some Thoughts About Natural Selection*

But why do we need natural selection? Why don't we use some other, explicit model (e.g. replicator dynamics) for simulating the dynamics of the real environment? – First, we claim that using natural selection instead of some explicitly declared mechanism for evolving the population of agents allows more realistic predictions of several interesting real world phenomena. In Section 4 we'll discuss this in more detail (in relation to experiments concerning replicator dynamics). Second, if the selection mechanism is direct and explicit, then it usually accounts for some kind of fitness to measure the goodness of individuals. Such a value would reflect the goodness of all (maybe even hidden or implicit) features influencing the success of an agent in its environment. The calculation of such a fitness value can be hopeless for complex, dynamic systems and environments.

In the proposed simulation we currently use a cumulated utility value associated with the goodness of an agent. But it is not a fitness value. The fitness of an unvarying individual can change only when its environment changes. But this is not true for the cumulated utility, which is only a parameter of the agent's state, and may change even when the agent, its program, or its environment does not vary. Also, the survival of an agent may depend on much more sophisticated terms than just checking if the cumulated utility value is below a lower limit. This mechanism could be easily exchanged by a much more complex and realistic variant.

### *F. Implementation Issues*

The proposed simulation model was implemented in the **JADE** (**J**ava **A**gent **DE**velopment) framework [18]. It is an open-source, Java-based, platform independent, distributed middle-ware and **API** (**A**pplication **P**rogramming **I**nterface) complying with the **FIPA** (**F**oundation for **I**ntelligent **P**hysical **A**gents) standards [19]. It enables relatively fast and easy implementation of physically distributed, asynchronous, high level multi-agent systems.

The implemented software architecture was aimed to be as simple, as possible. It consisted of only two JADE agents: a `GameAgent` (`GAg`), and a `PlayerAgent` (`PAg`). `GAg` was responsible for conducting the runs of the simulation, and orchestrating `PAg`-s, while `PAg`-s were the actual agents in the population, who were paired in each round to play a given 2-person game.

Each JADE agent had a variety of (mostly optional) startup parameters, which in case of a `GAg` set the type of the game to be played (e.g. PD, or HD, or else), the maximal number of agents in the population, and the maximal number of rounds in the run. The OR-relation of the latter two defined the termination criteria of a run. The startup parameters of a `PAg` set agents' program and reproduction strategy, initial utility, the lower limit of utility, the limit and cost of reproduction, the limit on the number of offsprings, and the capacity of memory. The latter was needed because each agent had to be able to use its percept history in order to decide upon the strategy to be played in a given round. The percept history of an agent associated a series of events (information about past plays) to agent identifiers (ID-s). There was a limit on maximal length of these series and maximal number of ID-s. If any of these limits was exceeded then the oldest element was replaced by the new one.

Now the simulation went as follows. First a given number of `PAg`-s were started on the JADE agent platform (constituting the initial population), followed by a `GAg`, who at the beginning of every round first searched the platform for available `PAg`-s (because later there may have been newly born agents, or some agents terminated), then made a pairing of the `PAg`-s, and informed these pairs about the game to be played (who plays with whom and in what role). The pairs of `PAg`-s then replied to the `GAg` with a chosen strategy ID respectively. The `GAg` then calculated their respective payoff accordingly and informed them about it. This was repeated until the termination criterion was satisfied. Several interesting experiments were conducted this way. Some of them are explained in the next section.

## IV. Experiments

The experiments consisted of running the simulation described above with several different initial populations and games to observe the changes in the number, proportion, and average utility of the different types of agent programs. Since JADE is a distributed framework (and for faster performance) a cluster of 10-13 PC-s (with 1-2 Ghz CPU, 0,5-1 Gb RAM, Win. XP, and JADE 3.5) was used to run the simulations.

Each experiment had its own settings, but a part of them was the same for every experiment. The maximal number of agents was 800; the maximal number of rounds was 250; the maximal number of offsprings was 3; the limit and the cost of reproduction was 20; the lower limit of agents' utility and their initial utility was 0; the maximal number of percept histories (about different opponents) was 1000; and the limit on the length of such a percept history was 4 for every agent in every experiment. Everyone was playing in every round (except when the number of agents was odd).

In the following we will describe these experiments grouped according to the games the agents' were playing. Five games were examined: **P**risoner's **D**ilemma (**PD**), **C**hicken **G**ame (**CG**), **B**attle of **S**exes (**BS**), **L**eader **G**ame (**LG**), and **M**atching **P**ennies (**MP**). The first 4 games are the only interesting (i.e. dilemmas, where the choice is not trivial) between the 12 symmetric out of altogether 78 ordinally different 2×2 games [20]. MP is an addition to these because unlike them it has no pure strategy **N**ash **E**quilibrium (**NE**), and this has some interesting implications (cf. Section 4/E) [21].

During the experiments agent programs were drawn from a fixed set. Only the following programs were studied yet: Always-Strategy1, Always-Strategy2, TFT, and Random. Nonetheless both types of agents' reproduction strategy (cf. Section 3/A) were examined. All in all, this configuration was more than enough to run insightful experiments comparable to the previous results discussed in Section 2.

### *G. Prisoner's Dilemma*

PD is one of the most popular 2-person games in game theory [22]. It is a special case of the HD game, when $V > C \geq 0$ (cf. Table II). The original story of the game is about two prisoners, who are put in separate cells (cannot communicate), and are asked to simultaneously decide, whether to cooperate, or defect. The best outcome is defecting, if the other cooperates, but it is the worst outcome for the other. It is better if both defect, and even better, if both cooperate. The game is called a "dilemma" because its only NE is the sub-optimal Defect-Defect outcome.

Similar situations may arise in the world of artificial systems too (cf. example in Section 3/B). If the payoffs are chosen according to the HD game, where V=4, C=2 (and so it becomes a PD), then if the initial population consists of altogether 6 agents: 3 Always-Cooperate, and 3 Always-Defect agents, then the proportions of the different agent programs change according to Fig. 2, which is in accordance with the formal predictions of Section 2/B (cf. Eq. 5). Defective agents (hawks) infest the population, and the proportion of cooperative players (doves) steadily converges to zero. The reproduction strategy of agents in Fig. 2 is of type 1 ("natural"), but essentially the results are the same in case of type 2 ("technical") reproduction.

Fig. 3-5 show the change of the quantity, and average utility, if the initial population consists of 3 Random, and 3 TFT agents. The quantity of these subpopulations ("species") does not decrease because there are no negative payoffs in the game, and so agents cannot die since their cumulated utility cannot decrease below the lower limit.

Fig. 5 shows the same situation as Fig. 4 except that the reproduction is "technical". A periodical change of the average utility of subpopulations can be observed on Fig. 4, while it is monotonously increasing on Fig. 5. That is because "natural" reproduction has a cost (equal to the limit of reproduction) on the contrary to "technical" reproduction.

According to Fig. 3, Random agents typically outperform TFT agents by far. This is the case with both types of reproduction. Similarly, Always-Defect agents also outperform TFT agents. These observations seem to differ from the results mentioned in Section 2/A, although the latter is not so surprising, since the numerical values of the game are now such, that the defective player gets as much against a cooperating player, as two cooperating players together, and its average income (5/2) is better than by cooperating (2/2).

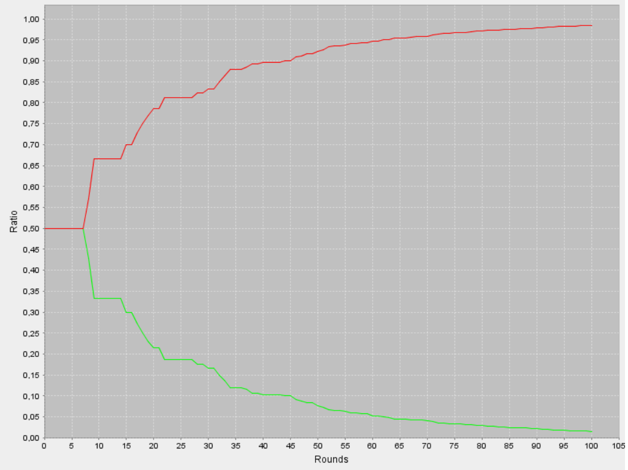

Fig. 2 Typical change of agent programs' proportion in PD, if the initial population consists of 3 Always-Cooperate (green), and 3 Always-Defect (red) agents whose reproduction strategy is "natural".

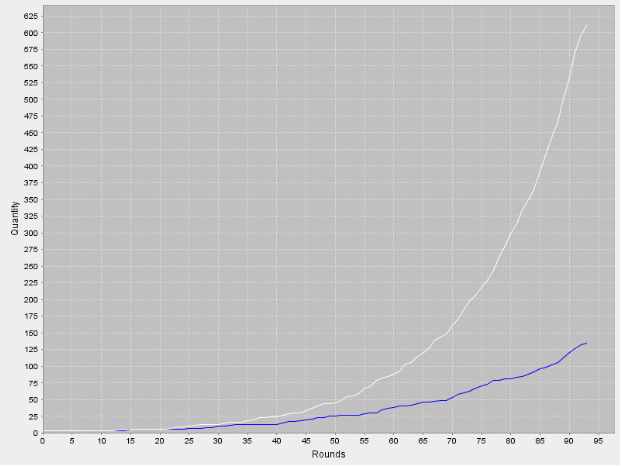

Fig. 3 Typical change of agent programs' quantity in PD, if the initial population consists of 3 Random (white), and 3 TFT (blue) agents whose reproduction strategy is "natural".

Moreover, according to Fig. 3-5, the change of subpopulations' proportion isn't in direct proportionality with the ratio of their average utility and the average utility of the whole population, as predicted by replicator dynamics (cf. Eq. 2). It must be pinned down, that replicator dynamics holds a central role among models of evolutionary dynamics. Some consider it even to be a fundamental theorem of natural selection [23]-[25]. Reference [26] even writes "The dynamics of such replicator systems are described by the fundamental theorem of natural selection". Nonetheless, according to these experiments, replicator dynamics seems to be unable to model such scenarios properly. Thus, in our view, the assumptions behind Eq. 2 are unrealistic.

If, for example, there are two subpopulations, and one of them grows exponentially (which is common in evolution), then after a while their average utility will determine the average utility of the whole population, and so the ratio of these two averages will converge to 1. In this case replicator dynamics would predict that the growth of the large subpopulation stops (cf. Eq. 2). But why should it?

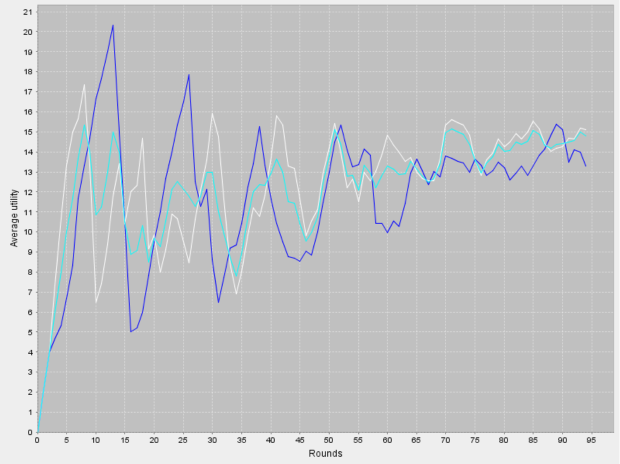

Fig. 4 Typical change of agent programs' average utility in PD, if the initial population consists of 3 Random (white), and 3 TFT (blue) agents whose reproduction strategy is "natural". The average utility of the whole population is also shown (light blue).

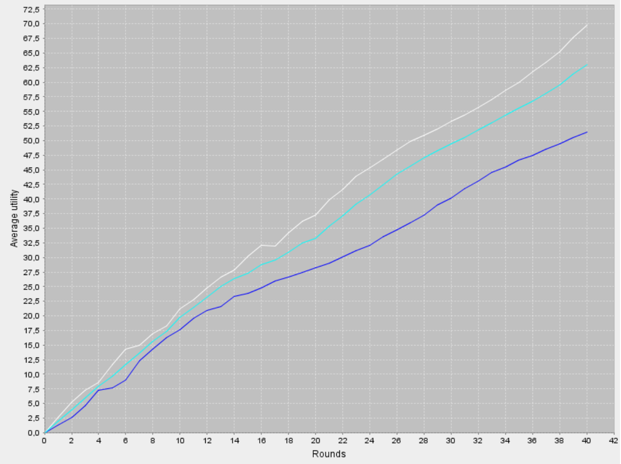

Fig. 5 Typical change of agent programs' average utility in PD, if the initial population consists of 3 Random (white), and 3 TFT (blue) agents whose reproduction strategy is "technical". The average utility of the whole population is also shown (light blue).

The larger the population, the more offsprings are born. The tendency of growth accelerates, if it is not limited by finite resources, or some other way. So maybe there is an implicit assumption (e.g. about finite resources) in Eq. 2. Apparently after a while every evolutionary system should reach its boundaries, but until then their growth must be governed by a dynamics different from replicator dynamics.

The results shown in Fig. 6 utter these concerns further. Axelrod's ecological analysis (cf. Section 2/A), based on replicator dynamics, predicts the extinction of the invading defectors, but our experiments show the opposite is true [7].

All of the above results are typical in a sense that they are indifferent to parameter changes (e.g. changing the size of the initial population; changing the type, the limits, or the cost of reproduction, or the payoff values of the game). TFT agents could be made a little better by increasing their memory, but in the end it doesn't change the overall tendency. These observations may also help to explain the scarce evidence of TFT-like cooperation in nature [27].

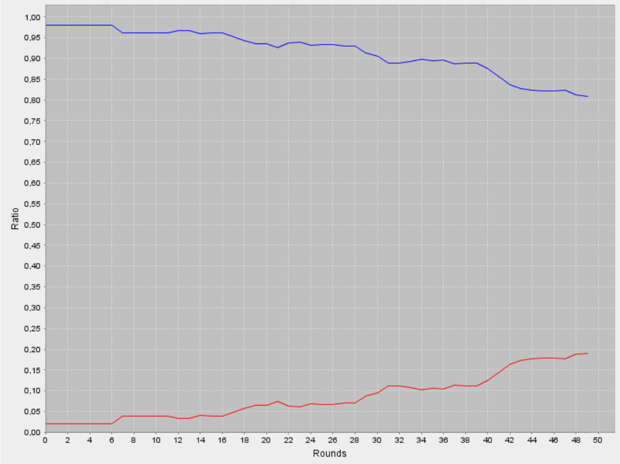

Fig. 6 Typical change of agent programs' proportion in PD, if the initial population consists of 50 TFT (blue), and 1 invading Always-Defect (red) agent(s) whose reproduction strategy is "natural".

### *H. Chicken game*

This game is also a special case of the HD game, when $C > V$ (cf. Table II) [22]. The original story is about two cars driving toward each other. If both drivers are "reckless", and won't swerve away, it is the worst outcome, since they crash. Better is, if one swerves away (being "chicken"), while the other wins (best outcome). But it is better for the former, if the latter swerves away too. This is a mixed motive game, since it has two NE-s (if players do the opposite).

A technical scenario may be the same as in the previous example (cf. Section IV/A) with the exception that if both agents are non-cooperative (reckless), then it is the worst outcome for them (e.g. because if two such cheating bidder agents meet, they disclose each other, and thus are excluded from the auction, and must pay a penalty to the organizers).

Experiments with this game showed different results than in case of PD in Section 4/A. The main reason for that is that the payoffs were chosen according to HD game, where V=2, C=4, and so agents could die because of negative payoffs.

Always-Strategy2 (i.e. Always-Chicken) proved to be the best (most proliferating) program out the four studied alternatives if there were only two types of programs in the initial population. Always-Reckless and TFT claimed the second place, while Random was the worst. This means that if the cost of being mutually defective is beyond the achievable value, then it becomes too risky not to cooperate.

It was interesting to observe, that if Always-Reckless proved to be the winner of a situation (i.e. if it extinguished an other "species"), then it too died out. In this aspect Always-Reckless is "parasite", that exploits the other subpopulations from whom its survival depends.

Experiments with more than two types of agent programs were rather unpredictable. They depended mostly on the actual pairing of the individuals in the first dozen of rounds.

### *I. Battle of Sexes*

This game is also a mixed motive game, like CG, but it differs from it in that it is asymmetric by default (cf. Table III) [2]. The original story is about a husband and wife, who must choose between going to a football match, or an opera. The husband would better like to go to the football match, while his wife would better go the opera. But, in any case, it is more preferable for them to be together, than to be alone.

Cooperation is different in the case of the husband, than in the case of the wife. They cooperate, if they try to do what is best for the other, and if they both do that, it is the worst (husband goes to opera, and wife goes to football).

TABLE III.
PAYOFF MATRIX OF THE "BATTLE OF SEXES" GAME

| Wife<br>Husband | Opera | Football |
|---|---|---|
| Opera | 1, 2 | -1, -1 |
| Football | 0, 0 | 2, 1 |

This means, that Always-Cooperate, and Always-Defect strategies are a bit more complex now, since they depend on the role of the agents too. TFT needs also to be revised.

A corresponding technical scenario could be, when two tasks share the same resource (e.g. CPU, or server). Their user wants them to finish as soon as possible. The worst case is, if they don't access the resource at all (e.g. its availability may have a default cost to the user). If they access it at the same time (both defect), it is better, but it slows their execution too much. So it is better for them to access the resource separately, but the first to access it is the best.

Experiments showed that regardless of the type of reproduction, Always-Cooperate and TFT agents were the worst (others made them die out every time). Always-Defect was the best program, and Random was second (it survived).

### *J. Leader game*

This game is similar to the symmetrical form of BS, with the exception that mutual defection is the worst outcome, and mutual cooperation is better [28].

The name of the game comes from the following situation: two cars wait to enter a one-way street. The worst case is, if they go simultaneously, because they crash. If both wait (cooperate), it is better. But it is even better if they go separately. The one, who goes first, is the best (cf. Table IV) .

A technical scenario could be similar to the previous example in Section IV/C with the exception that if both tasks access the resource at the same time, then it breaks (e.g. the server crashes). So this is the worst outcome. It is better, if they do not access it at all, and even better, if they access it separately. The first agent to access the resource is the best.

According to our experiments, TFT and Always-Cooperate were better, than Always-Defect agents, but Random agents again outperformed TFT agents. The reproduction strategy made a difference in the tendencies, but not in the outcome.

TABLE IV.
PAYOFF MATRIX OF THE "LEADER" GAME

| Player 2<br>Player 1 | Go | Wait |
|---|---|---|
| Go | -1, -1 | 2, 1 |
| Wait | 1, 2 | 0, 0 |

### *K. Matching Pennies*

This game is asymmetric (like BS), with the exception that it has no symmetric form, and cooperation and defection have no meaning in it [29]. Thus the first (hitherto cooperative) choice of TFT doesn't particularly matter now.

The original game is about two players, who both have a penny. They turn the penny secretly to heads or tails, and then reveal their choice simultaneously. If the pennies match, one player gets a dollar from the other, else it is conversely (cf. Table V).

TABLE V.
PAYOFF MATRIX OF THE "MATCHING PENNIES" GAME

| Player 2<br>Player 1 | Heads | Tails |
|---|---|---|
| Heads | 1, -1 | -1, 1 |
| Tails | -1, 1 | 1, -1 |

A corresponding technical scenario can be where two software agents compete for resources (e.g. locks to files), and they have two different strategies to get the resources. One of the agents is faster than the other, so if both choose the same strategy, then the faster agent gets all of the resources. Else the slower agent can also get some of them.

Our experiments showed that in this scenario Random agents were the fittest for survival (playing the only mixed NE of the game), but in case of type 1 reproduction they died out like all the others. However in case of type 2 (technical) reproduction they could cumulate enough utility to ensure their survival, and start proliferating after a while.

## V. CONCLUSIONS

In this article we presented a novel agent-based simulation model for natural selection of programs selecting strategies in 2-person games, and its use in system analysis and design. Our goal was (1) to create a framework enabling agent design for complex, underspecified environments (e.g. Internet); (2) to give a realistic model for the natural selection of not only natural, but also technical systems; and (3) to reproduce some decisive experiments.

The framework facilitates agent design by supporting the choice of agents (from a finite set of alternatives). The distinction between natural and technical systems is made by introducing reproduction strategies of the agents. Natural selection is not explicitly present, but emerges from the inner workings of the agent population. Experiments revealed several interesting aspects of such population dynamics. For example, the assumptions behind replicator dynamics were shown to be inherently unrealistic and simplifying; the fitness of the Tit-for-Tat strategy was the opposite of what was expected according to the previous experiments of Axelrod; not just the Prisoner's Dilemma, but several other fundamental 2-person games were examined, and for every such game a concrete technical analogy was also given.

There are many possible ways to continue this research. For instance the simulation can be further refined by allowing agents to play not only one, but several different games during a run. We currently use only 2-person games for modeling strategic interaction between agents. This can be extended to N-person games. More complex programs could be examined in the experiments. We could introduce sexual reproduction instead of the current asexual replication. A genetic representation of agent programs could be given to enable the birth of new variations. Finally, the limits on the cardinality of the agent population could implicitly depend on environmental resource limitations.

***Abstract*—A method of similarity clusters detection in large visual databases is described in this work. Similarity clusters have been defined on the basis of a general concept of similarity measure. The method is based also on the properties of morphological spectra as a tool for image presentation. In the proposed method similarity of selected spectral components in selected basic windows are used to similarity of images evaluation. Similarity clusters are detected in an iterative process in which non-perspective subsets of images are step-by-step removed from considerations. In the method similarity graphs and hyper-graphs also play an auxiliary role. The method is illustrated by an example of a collection of medical images in which similarity clusters have been detected.**

## I. Introduction

VISUAL data bases (*VDB*) are widely used in various experimental investigation areas [2, 3, 5, 6, 21]. Documents stored in *VDB*s consist of a digital representation of an image (e.g. given in the form of a bit-map), of a sequence of formal data identifying the document and, possibly, of a series of qualitative and/or quantitative attributes characterizing image content. One of the main problems in *VDB* exploration is retrieval of visual documents satisfying the formal and content requirements given by the users. A typical query coming from a *VDB* user concerns all available visual documents satisfying formal (type, source, emission data, etc.) as well as content requirements [5, 20]. However, in certain cases another type of queries concerning visual documents is possible: among a class of visual documents satisfying some general formal requirements, find all subsets of documents forming, in a below-defined sense, *similarity clusters*. In this case it is assumed that a concept of *similarity* has been defined by the user (instead of defining the image content attributes). Moreover, the number of similarity clusters is beforehand neither defined nor limited, single documents as similarity clusters being out of interest. On the other hand, some documents, as it will be shown below, can be included into more than one similarity cluster. We call the above-formulated problem a *similarity clusters detection* (*SCD*) *problem*. It should be emphasized that there is a substantial difference between the well known problem of strong classification of objects [1,16] and this of *SCD*. The difference is caused, in general, by non-transitivity of similarity relation, as it can be illustrated by an example of a dactyloscopic database. The classification problem consists in this case in assigning fingerprints to similarity classes strongly defined on the basis of dactyloscopic patterns and minutes (bridges, meshes, forks, line ends, etc.). Similarity classes are pair-wise disjoint and each object belongs to exactly one similarity class. On the other hand, a *SCD* problem may consists in finding all subsets of fingerprints containing, at least, one subset of minutes of the corresponding types forming the same geometrical configuration. A visual document, due to several types of minutes satisfying the above-formulated similarity criterion, can be included into more than one similarity clusters. Solution of the *SCD* problem, as leading to a class of *NP*-complete numerical tasks, in the case of large visual databases leads to high calculation costs.

The aim of this paper is presentation of a method of reducing the calculation costs of *SCD* due to a multi-step similarity detection strategy. The strategy is based on a concept of a step-wise strengthening of similarity criteria connected with elimination of not satisfying them pairs of documents. This concept is realized due to an additional concept of using *morphological spectra* to image description; the concept was formerly used to partial similarity of documents detection [11].

The paper is organized as follows: in Sec. II basic notions of *similarity measure ε-similarity clusters* (Sec. II *A*), and of *representation of images* (Sec. II *B*) are shortly reminded. In Sec. III the concept of multi-step similarity detection is presented generally (Sec. III *A*) and an algorithm of ε-similarity clusters detection in (Sec. III *B*) is described. An example illustrating using the proposed method to a collection of medical images is presented in Sec. IV. Conclusions are formulated in Sec. V.

## II. Basic Notions

The notion of *similarity* plays a basic role in pattern recognition. In the strongest sense it can be considered as a synonym of *equivalence*, i.e. a binary relation satisfying the reciprocity, symmetry and transitivity conditions [9]. However, such similarity concept does not suit well to a description of similarity of images where the transitivity condition

978-83-60810-14-9/08/$25.00 © 2008 IEEE

is often not satisfied. In a wider sense, similarity is a sort of *neighborhood* relation (reciprocal and symmetrical) rather than this of equivalence.

*I. Similarity measures and similarity clusters*

A numerical characterization of similarity in wider sense is possible due to a *similarity measure c*oncept. This concept can be defined in several ways [9,14]. In pattern recognition similarity measure is usually defined on the basis of a *distance measure* or of a *cosine* (angular) measure [11]. That is why the following definition of similarity measure below is given (see also [9,11]):

*Definition 1.* Let *C* be a set of elements and let *a, b, c* ∈ *C* be any of its members; then a function:

$$\sigma\colon\ C\times C \to [0,\ldots,1] \qquad \textbf{(1)}$$

satisfying the conditions:

I. $\sigma(a,a) \equiv 1$,

II. $\sigma(a,b) \equiv \sigma(b,a)$,

III. $\sigma(a,b)\cdot\sigma(b,c) \le \sigma(a,c)$

will be called a *similarity measure* described on *C* ●

In particular, if *C* is a metric space [8] and *d*(*a,b*) is a distance measure of the given pair of its elements then a function:

$$\sigma(a,b) = exp\,[\,-\alpha\cdot d(a,b)], \qquad \textbf{(2)}$$

$\alpha$ being a positive scaling coefficient, satisfies the conditions of Definition 1.

Another possibility arises if *C* is assumed to be a linear unitary space [19]. In such case ***a**, **b***, etc. are interpreted as *vectors*, (***a**,**b***) denotes their *scalar product*, $\|\boldsymbol{a}\| = (\boldsymbol{a},\boldsymbol{a})^{1/2}$ is a *norm* of ***a*** and the cosine of the angle ∠(***a**,**b***) between the vectors is given by the well-known formula:

$$\cos(a,b)=\frac{(a,b)}{\|a\|.\|b\|} \qquad (3)$$

However, *cos(**a**,**b**)* cannot be used as a similarity measure satisfying the condition III of Definition 1. For this purpose it will be used the following *angular similarity measure*:

$$\sigma(a,b)=1-\sqrt{1\text{-}\cos^2(a,b)} \qquad (4)$$

On the basis of similarity measure a concept analogous to this of *similarity classes* used in equivalence (i.e. strong similarity) relation can be introduced.

*Definition 2.* Let *C* be a set of elements, $\sigma(\,a,b)$ be a similarity measure defined on *C* and let ε such that $0 \le \varepsilon \le 1$ be an arbitrary constant. Then a subset $\Phi_\varepsilon \subseteq C$ such that:

1 st for any pair of its elements $a\,,b \in \Phi_\varepsilon$ it is $\sigma(\,a,b) \ge \varepsilon$, and

2 nd for each element *c* belonging to $C \setminus \Phi_\varepsilon$ there is at least one element *a* in $\Phi_\varepsilon$ such that the inequality $\sigma(\,a,c) < \varepsilon$ is satisfied,

will be called an *ε -similarity cluster* ●

Let us remark that, excepting the case of ε = 1, there is a substantial difference between the strong *similarity class* concept and this of the *ε -similarity cluster* . It is illustrated in Fig. 1 where a set *C* consisting of 4 elements on an Euclidean plane is shown. The elements are located in the vertices of a square of unit edge-lengths. A similarity of vertices has been defined on the basis of their Euclidean distance and the *ε* - similarity clusters consist of subsets of vertices whose distance is not greater than 1. In such case it is clear that two *ε* - similarity clusters can be established in two alternative ways; such situation in strong similarity classes could not arise.

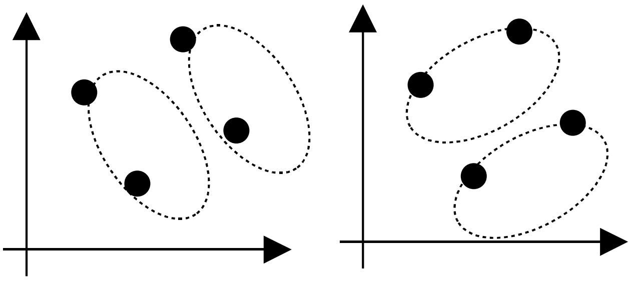

Fig. 1 . Two alternative ways of choosing ε -similarity clusters.

In similarity of objects evaluation a multi-aspect similarity can be taken into consideration by using several similarity measures. For this purpose, if $\sigma_1(a,b),\ \sigma_2(a,b),\ \ldots,\sigma_f(a,b)$ are similarity measures satisfying the conditions of Definition 1 and representing different similarity aspects then it can be shown [10] that

$$\sigma(a,b)=\prod_{\phi=1}^{f}\sigma_{\phi}(a,b) \qquad \textbf{(5)}$$

also satisfies the conditions of Definition 1 and as such it can be used as a mutli-aspect similarity measure of the given objects. This property will be used in *ε - SCD* of images.

*II. Spectral representation of images*

It will be considered representation of monochromatic images in visual databases in a basic form of *bitmaps*, i.e. numerical *I* × *J* rectangular matrices, where *I* and *J* denote, respectively, the number of rows and columns. A bitmap representing an image ***u*** will be denoted by ***U*** while its elements $u_{ij}$, called pixel values, will be assumed to be integers from a finite interval $[0,\ldots,2^k-1]$, *k* being a fixed natural number. Below, expansion of a bitmap ***U*** into a linear *I·J*-component column vector ***V***, as more convenient for calculations, will also be used.

Images can also be represented in several alternative, spectral forms [10,17]. Below, image representation by systems of morphological spectral components will be considered [12,13].

*Morphological spectra* are basically defined for monochromatic images given in the form of $2^m \times 2^m$ - size bitmaps, where *m* is a fixed natural number such that $2^m \le$ *min* ( *I,J* ). Morphological spectra form a hierarchical structure, *m* being the highest level of the hierarchy and the 0 th level being identified with the original image. The *h* -th level spectral components, where $0 \le h \le m$, are calculated on *basic windows* of $2^h \times 2^h$ size. Therefore, it is assumed that for calculation of any *h*- th level morphological spectrum the original bitmap is partitioned into a number of adjacent basic windows covering the image area.

Fig. 2. Partition of an image area into basic windows.

If necessary, the image area can be covered with certain margins as shown in Fig. 2, where an image of a 7×9 (*I*= 7, *J*= 9) size has been covered by basic windows of $2^1 \times 2^1$ (i.e. *h* =1) size, the lacking pixel values in the extreme right column and in the lowest row being filled with 0-s.

In each basic window the values of a fixed *h* -th level spectral component are calculated independently. Therefore, if *p, q* denote, respectively, the number of rows and columns of basic windows covering the image ( *p* =4, *q* =5 in the above-shown case) then the values of each *h* -th level spectral component of a total image can be collected in a $p \times q$ real matrix called a *spectral component matrix* . Any *h* -th level morphological spectrum consists of $2^{2h}$ types of components. For *h* >0, spectral components are labeled by *h*- element strings consisting of symbols *Σ*, *V, H, X* ; the 1 st level morphological spectrum contains four components labeled by single symbols *Σ*, *V, H* and *X* only. The 2 nd level morphological spectrum contains $2^4$=16 components labeled and lexicographically ordered as follows: ***ΣΣ***, *Σ V, Σ H, Σ X, V Σ, VV, VH, VX, H Σ, HV, HH, HX, X Σ, XV, XH* and *XX.* The 3 rd level spectral components are denoted by ***ΣΣΣ***, ***ΣΣ*** *V*, ***ΣΣ*** *H*, … etc . The components of morphological spectra can be thus represented by a regular tree whose nodes on a given level are assigned to the given spectral-level components [17]. The spectral component labels are used to a denotation of spectral component matrices. For example, $\boldsymbol{M}_V$ , $\boldsymbol{M}_{VX}$ , $\boldsymbol{M}_{\Sigma\Sigma H}$ , etc. denote, respectively, the spectral component matrices of the spectra *V, VX* and *ΣΣ H.* For a given image size the size of the corresponding spectral component matrices depends on the spectrum level *h* and is decreasing with it. Hence, the number of elements representing a given image on each spectrum level corresponds to the number of pixels in the original image (it is exactly equal to this number if the image area can be covered without margins by the highest-level basic windows).

Morphological spectra can be calculated by using *spectral matrices* [13] . For this purpose for each (*h*-th) spectrum level it is constructed a matrix $\boldsymbol{M}^{(h)}$ of $4^h \times 4^h$ size whose rows correspond to lexicographically ordered spectral components and columns are assigned to the lexicographically ordered pixels in the basic window. For example, the 1st level morphological spectrum can be represented by a matrix:

$$M^{(1)} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ -1 & 1 & -1 & 1 \\ -1 & -1 & 1 & 1 \\ -1 & 1 & 1 & -1 \end{bmatrix} \qquad (6)$$

Each row of the spectral matrix consisting of the elements +1 and –1 only represents the weights assigned to pixel values whose sum within a basic window should be calculated. Spectral matrices of any level satisfy the following orthogonality condition:

$$\boldsymbol{M}^{(h)} \cdot (\boldsymbol{M}^{(h)})^{tr} = (\boldsymbol{M}^{(h)})^{tr} \cdot \boldsymbol{M}^{(h)} = 4^h \cdot \boldsymbol{I} \qquad \textbf{(7)}$$

where tr denotes matrix transposition and ***I*** is an unity matrix of $2^{2h} \times 2^{2h}$ size. If pixel values of a basic window are presented in the form of a vector:

$$\boldsymbol{V}^{(h)} = [\xi_{1,1}, \xi_{1,2}, \ldots, \xi_{1,K}, \xi_{2,1}, \ldots, \xi_{2,K}, \ldots, \xi_{K,1}, \ldots, \xi_{K,K}] \qquad \textbf{(8)}$$

where $K = 4^h$ , then the morphological spectrum of the basic window can be calculated as:

$$(\boldsymbol{W}^{(h)})^{tr} = \boldsymbol{M}^{(h)} \cdot (\boldsymbol{V}^{(h)})^{tr}. \qquad \textbf{(9)}$$

A formula for reverse bitmap components calculation from the morphological spectral components then takes the form:

$$\boldsymbol{V}^{(h)} = 4^{-h} \cdot \boldsymbol{W}^{(h)} \cdot \boldsymbol{M}^{(h)}. \qquad \textbf{(10)}$$

An important property of morphological spectra as tools for image representation consists in their multi-scalar structure and possibility to focus image description in given regions of interest covered by selected elements of the spectral component matrices. These properties will be used below in a concept of step-wise *ε-SCD* of images.

## III. Multi-step similarity clusters detection

It will be assumed that there is given a finite set *C* of images available in the form of bitmaps and a similarity measure *σ* defined on the Cartesian product *C*×*C*. The problem consists in finding in *C*, for a certain *ε*, $0 \le \varepsilon \le 1$, (usually kept close to 1) all *ε*-clusters. If *N* = |*C*| denotes the number of elements in *C* then the simplest (but very time-consuming) solution method can be based on a direct review of all ½*N*(*N*-1) pairs of analyzed objects (images). The algorithm will then consist of the following (roughly defined) steps:

*Algorithm 1 (naïve)*:

Step 1: take into consideration all unordered pairs of objects $\{ a ,b \} \in C \times C$ ;

Step 2: for each pair calculate its similarity measure $\sigma( a,b )$;

Step 3: accept all pairs for which the condition $\varepsilon \le \sigma( a,b ) \le 1$ is satisfied and reject the other ones;

Step 4: for the accepted pairs construct a set $C^*$ , $C^* \subseteq C$ , of all occurring in them objects;

Step 5: construct a *similarity graph* *G* = [ *C** , *S, φ* ] where *A* is a set of its *nodes, S* is a set of undirected *edges* , and *φ* is a function assigning, in an unique way, to each accepted pair of nodes an edge from the set *S* ;

Step 6: using a standard algorithm of finding *cliques* in graphs find all cliques in *G* ;

Step 7: end ●

The cliques (maximal complete subgraphs) of the similarity graph *G* found by the algorithm are, by the same, the ε-similarity clusters. On the other hand, it should be remarked that if *F* is a family of cliques of the similarity graph *G* then a triple:

$$H = [C^*, F, \psi] \qquad \textbf{(11)}$$

defines a hyper-graph in the Berge sense [7], where $C^*$ is a set of nodes, ***F*** is a set of hyper-edges and $\psi$ is a partial function described on the family $2^{C^*}$ of the subsets of $C^*$, assigning in an unique way the hyper-edges of *F* to selected subsets of nodes. We shall call *H* a *similarity clusters hyper-graph*; its role in *SCD* algorithms will be shown below.

However, reducing a *SCD* problem to this of a classical *cliques* finding problem is practically not a satisfying task solution because of its non-polynomial (*NP*) complexity. Despite the fact that there are several approximate algorithms for it described in the literature [4,15], an approach to the calculation cost reduction based on a step-wise restricting of ε-similar cliques is proposed below.

*I. General concept description*

For the purpose of comparison of images they will be considered as ordered sets of sub-bitmaps according to their partition into basic windows, as shown in Fig. 2. A bitmap ***U*** of a given image ***u*** will be thus represented by a composed matrix of sub-bitmaps:

$$U = [U_{\kappa\lambda}] \qquad (12)$$

where $U_{\kappa\lambda}$ is a sub-bitmap, $1\le\kappa\le p$, $1\le\lambda\le q$ . Similarity of any given pair ***u', u"*** of images means that the pairs of the corresponding sub-bitmaps $U'_{\kappa\lambda}$ , $U''_{\kappa\lambda}$ satisfy some similarity criteria. Similarity of any given pair of corresponding sub-bitmaps can be thus considered as an aspect of similarity of the images ***u', u"*** in the whole. According to (5), their similarity measure can be expressed as

$$\sigma(U',U'')=\prod_{\kappa=1}^{p}\prod_{\lambda=1}^{q}\sigma(U'_{\kappa\lambda},U''_{\kappa\lambda}) \qquad (13)$$

Let us denote by *L* , $L = \{(\kappa,\lambda)\}$, the set of all considered pairs $(\kappa,\lambda)$. It is clear that due to the general properties of similarity measures the inequalities

$$0\le\sigma(U',U'')\le min_L[\sigma(U'_{\kappa\lambda},U''_{\kappa\lambda})] \qquad \textbf{(14)}$$

are held. Therefore, if for a given pair of images ***u', u"*** it is required that $\sigma(U',U'')\ge\varepsilon$ and for a certain pair $(\kappa,\lambda)\in L$ it has been found that $\sigma(U'_{\kappa\lambda},U''_{\kappa\lambda})<\varepsilon$ then there is no reason to prove the similarity condition in other pairs of sub-bitmaps and the given pair ( ***U', U"*** ) can be considered as "non-perspective" from its ε -similarity point of view. Moreover, if we denote by *L'* , $L'\subseteq L$ a certain subset of pairs $(\kappa,\lambda)$ of indices for which it has been found that

$$\sigma(U',U'')=\prod_{(L')}\sigma(U'_{\kappa\lambda},U''_{\kappa\lambda})=\varepsilon' \qquad \textbf{(15)}$$

where $\varepsilon'$ is a number $\ge\varepsilon$ then for satisfying the condition $\sigma(U',U'')\ge\varepsilon$ it is necessary that an inequality

$$\sigma_{L\setminus L'}(U',U'')=\prod_{(L\setminus L')}\sigma(U'_{\kappa\lambda},U''_{\kappa\lambda})\ge\frac{\varepsilon'}{\varepsilon} \qquad \textbf{(16)}$$

is satisfied.

For similar reasons, for a fixed pair of sub-bitmaps ($U'_{\kappa\lambda}$, $U''_{\kappa\lambda}$) their similarity measure can be considered as a multi-aspect similarity measure of the corresponding pairs of morphological spectra

The below-proposed procedure of ε-*SCD* of images is based on a concept of step-by-step strengthening of similarity criteria connected with removing non-perspective pairs of images from considerations and improving accuracy of the *SCD*.

*II. Choosing the ε-similarity thresholds*

At an initial state of the procedure it is posed the following

*Initial working hypothesis*: the similarity measures of the pairs of all corresponding basic windows and spectral components of all pairs (***u', u"***) of images in the analyzed set *C* are equal 1.

By this assumption, the condition $\sigma(u',u'')\ge\varepsilon$ according to (5) and (14) is satisfied and *C* constitutes, as a whole, the first assumed, hypothetical ε -similarity cluster.

In the consecutive iterations of the procedure the working hypothesis by evaluation of similarity measure of selected pairs of basic windows and spectral components (selected similarity aspects) is verified. The condition $\sigma(u',u'')\ge\varepsilon$ is satisfied if it is satisfied by all pairs of corresponding basic windows and spectral components. As a consequence:

i. the objects whose similarity to all other objects does not satisfy the condition $\sigma(u',u'')\ge\varepsilon$ can be removed from considerations as non-perspective ones;

ii. the pairs of perspective (non-removed) objects whose similarity does not satisfy the above-given condition are taken into consideration; however, they bring about a necessity of correction of the currently assumed, hypothetical similarity clusters;

iii. at each iteration of the procedure the similarity threshold levels should be corrected according to the general principle described in Sec. *A* ;

iv. at each iteration the similarity measure of basic windows and of spectral components which yet have not been evaluated remain equal 1;

v. each iteration (excepting the last one) leads to a revised subset of hypothetical similarity clusters which in the next iteration in similar way should be processed.

### *III. The procedure of $\varepsilon$-similarity clusters detection*

For a given initial set $C$ of images and a fixed final similarity measure value $\varepsilon$, $0 < \varepsilon \leq 1$, a morphological spectrum level $h$ determining the size of basic windows should be chosen by taking into account that the larger is this size the higher is the probability that differences between the images, if any exist, by the algorithm in each iteration will be detected. On the other hand, the higher is $h$ the larger is the number of spectral components that should be taken into account in the *SCD* algorithm.

The $\varepsilon$-*SCD* procedure consists of a sequence of iterations, each iteration consisting of two phases:

1st reduction, according to the strengthened similarity criteria, of the set of compared pairs of objects;

2nd decomposition and/or reduction of the similarity clusters inherited from the former iteration.

Each ($i$-th) iteration of the algorithm needs the following data to be entered:

i. a starting threshold level $\varepsilon^{(i)}$, $0 < \varepsilon < \varepsilon^{(i)}$;

ii. a pair$\{(\kappa^{(i)}, \lambda^{(i)})\}$ of addresses of basic windows selected for being used in the current iteration of *SCD* procedure;

iii. a label $\boldsymbol{\Gamma}^{(i)}$ (subset of labels) of the $h$- th level morphological spectrum component selected for being used in the current iteration of *SCD* procedure.

No strong rules of choosing the above-mentioned data exist. However, the following, heuristic recommendations can be taken into account:

a) according to the formula (16), for any $i$ =1,2,… the threshold level $\varepsilon^{(i)}$ should be chosen as $\varepsilon^{(i)} = \varepsilon^{*(i-1)}/\varepsilon$ where $\varepsilon^{*(i-1)}$ denotes the similarity measure of the given pair of images evaluated in the former, $(i - 1)$ iteration;

b) the basic windows selected for analysis should be, if possible, selected with a preference given to the components having the highest discriminative power.

To meet the recommendations the following, auxiliary objects are defined:

* a symmetric square matrix $\boldsymbol{S} = [\sigma^{(i)}_{\alpha\beta}]$ of $N\times N$ size, $N$ denoting the number of elements of $C$; elements $\sigma^{(i)}_{\alpha\beta}$ denote the similarity measures of the pairs of bitmaps $(\boldsymbol{U}^{(\alpha)},\boldsymbol{U}^{(\beta)})$ evaluated at the $i$-th iteration);

* a binary matrix $\boldsymbol{M} = [m^{(i)}_{\beta\gamma}]$, $\beta$ denoting a serial number of basic window (equivalent to its $(\kappa,\lambda)$ address), $\gamma$ being assigned to a serial number of spectral component; $m^{(i)}_{\beta\gamma} = 1$ if the $\beta$-th basic window and the $\gamma$- th spectral component have been already used to the similarity of images assessment, otherwise $m^{(i)}_{\beta\gamma} = 0$.

At the initial state of the procedure all elements of $\boldsymbol{S} = \boldsymbol{S}^{(0)}$ equal 1 and all elements of $\boldsymbol{M} = \boldsymbol{M}^{(0)}$ equal 0.

In the below-presented concept of algorithm a graph representation of the current state of the $\varepsilon$-*SCD* procedure is also useful.

A similarity graph $G$ (see Sec. III) is described by:

a) a subset $C^* \subseteq C$ of nodes representing the images currently considered as "perspective" for $\varepsilon$ - *SCD* ;

b) a symmetrical square sub-matrix $\boldsymbol{S^*} \subseteq \boldsymbol{S}$ containing the rows and columns of $\boldsymbol{S}$ corresponding to "perspective" images, the elements of $\boldsymbol{S^*}$ being interpreted as weighed edges of the graph $G$ . $\boldsymbol{S^*}$ plays the role of an adjacency matrix of $G$ .

At a starting point the similarity graph $G = G^{(0)}$ is assumed to be a complete graph identical to its unique clique.

A current state of the $\varepsilon$ - *SCD* task solution can also be illustrated by an $\varepsilon$ - *similarity cluster hyper-graph $H$* . Its definition is given by the formula (11) excepting that $F$ denotes a family of hyper-edges representing the currently detected, hypothetical $\varepsilon$ - *similarity* cliques $\Phi_s$ , $s$=0,1,2,3,…, in $G$. At a starting point the hyper-graph $H = H^{(0)}$ contains a single hyper-edge: $F^{(0)} = \{\Phi_0\}$, $\Phi_0 \equiv C^*$.

For similarity of pairs of images assessment the similarity measure of spectral vectors based on the formulae (2) or (4) and (5) can be used. A progress index $z$ also will be used to mark the situations when in the $i$-th iteration the necessity of similarity clusters hyper-graph $H$ correction has been detected.

The $i$-th iteration, $i$ = 1,2,3,…, of the *SCD* algorithm applied to a hypothetical $\varepsilon$-similarity cluster detected in a previous iteration has the following structure:

*Algorithm 2 (similarity clusters specifying)*:

```
Step 1: set the initial data values: $\varepsilon^{(i)}$, $z := 0$, $\boldsymbol{S}^{(i)} := \boldsymbol{S}^{(i-1)}$ , $\boldsymbol{M}^{(i)} := \boldsymbol{M}^{(i-1)}$ and $\boldsymbol{F}^{(i)} := \boldsymbol{F}^{(i-1)}$;
Step 2: select the next basic window $(\kappa,\lambda) := (\kappa^{(i)}, \lambda^{(i)})$ and the next spectral component $\boldsymbol{\Gamma} := \boldsymbol{\Gamma}^{(i)}$ from the set of non-zero elements of $\boldsymbol{M}^{(i)}$;
Step 3: according to the selection made in Step 2 set $m^{(i)}_{\beta\gamma} := 1$;
Step 4: for all non-zero elements $\sigma^{(i-1)}_{\alpha\beta}$ of adjacency matrix $\boldsymbol{S}^{(i)}$:
    1) select the sub-bitmaps $\boldsymbol{U}^{(\alpha)}_{\kappa\lambda}$ , $\boldsymbol{U}^{(\beta)}_{\kappa\lambda}$ corresponding to the basic windows $(\kappa^{(i)},\lambda^{(i)})$;
    2) for $\boldsymbol{U}^{(\alpha)}_{\kappa\lambda}$ , $\boldsymbol{U}^{(\beta)}_{\kappa\lambda}$ and the given $\boldsymbol{\Gamma}$ calculate the spectral components $\boldsymbol{W}^{(\alpha)}_{\Gamma;\kappa\lambda}(\alpha)$, $\boldsymbol{W}^{(\beta)}_{\Gamma;\kappa\lambda}$;
    3) calculate the similarity measure values $\sigma^{(i)}_{\alpha\beta} = \sigma[\boldsymbol{W}^{(\alpha)}_{\Gamma;\kappa\lambda}, \boldsymbol{W}^{(\beta)}_{\Gamma;\kappa\lambda}]$ using the formula (2);
Step 4: if $\sigma^{(i)}_{\alpha\beta} = \sigma[\boldsymbol{W}^{(\alpha)}_{\Gamma;\kappa\lambda}, \boldsymbol{W}^{(\beta)}_{\Gamma;\kappa\lambda}] \geq \varepsilon^{(i)}$ then in $\boldsymbol{S}^{(i)}$ set $\sigma^{(i)}_{\alpha\beta} := \sigma[\boldsymbol{W}^{(\alpha)}_{\Gamma;\kappa\lambda}, \boldsymbol{W}^{(\beta)}_{\Gamma;\kappa\lambda}]$, otherwise set $\sigma^{(i)}_{\alpha\beta} := 0$ and $z := 1$;
Step 5: if $z = 0$ then go to Step 8, otherwise:
Step 6: if all elements $\sigma^{(i)}_{\alpha\beta}$ of the $\alpha$ - row (respectively, of the $\beta$-row) of $\boldsymbol{S}^{(i)}$ equal 0 then remove the corresponding row and column and remove $\boldsymbol{u}^{(\alpha)}$ (respectively, $\boldsymbol{u}^{(\beta)}$) from $C^*$, and from all containing it hyper-edges in $\boldsymbol{F}^{(i)}$ , then go to Step 8, otherwise:
Step 7: in the set $\boldsymbol{F}^{(i)}$ of hyper-edges:
    1) find all hyper-edges $\Phi^{(i)}_m$ containing both nodes $\boldsymbol{u}^{(\alpha)}$ and $\boldsymbol{u}^{(\beta)}$;
    2) replace each hyper-edge $\Phi^{(i)}_m$ found in 1)
       by two hyper-edges: $\Phi^{(i)'}_m := \Phi^{(i))}_m \setminus \{\boldsymbol{u}^{(\alpha)}\}$ and
       $\Phi^{(i)''}_m := \Phi^{(i))}_m \setminus \{\boldsymbol{u}^{(\beta)}\}$;
    3) remove $\Phi^{(i)'}_m$ (respectively, $\Phi^{(i)''}_m$) from $\boldsymbol{F}^{(i)}$ if
       it consists of one node only;
    4) assign to the hyper-edges new indexes unifying the enumeration in the set $\boldsymbol{F}^{(i)}$ ;
  Step 8: check whether all elements of $\boldsymbol{M}^{(\mathrm{i})}$
equal 1; if no then go to Step 1, otherwise
  Step 9: end of the algorithm ●
```

Algorithm 2 should be applied to all $\varepsilon$-similarity clusters found in the previous iterations of the ε-*SCD* procedure.

## IV. Application to Medical *VDB* Exploration

Large medical *VDB* s may contain thousands of visual documents of various modalities stored in hospitals, specialized medical clinics or in departments and laboratories of medical universities. The *VDB* exploration problems usually concern retrieval of documents based on their formal features or contents. However, in scientific investigations as well as in difficult diagnostic problems *SCD* can also play a significant role.

### *I. Example*

In Fig. 3 a sample of a large collection of typical human brain images obtained by SPECT (Single Photon Emission Tomography) technique is shown. The images are of 124 × 124 pixels size partitioned into basic windows of 16 × 16 pixels size arranged in columns (denoted by numbers from *1* to *8*) and in rows (denoted by symbols from *A* to *H*). The contents of a single basic window can be represented by an 8 × 8 size bitmap or by its 3rd level morphological spectrum consisting of 64 components.

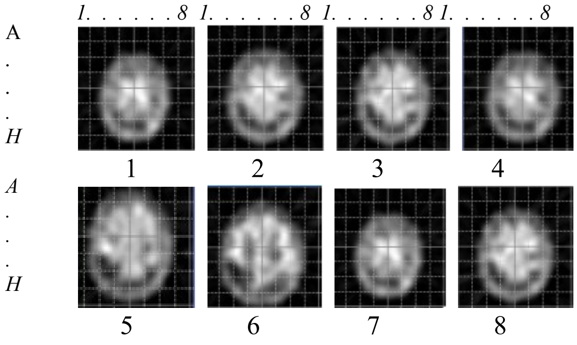

Fig. 3. Cerebral SPECT images stored in a *VDB* .

Fig. 4 shows intensity maps of several spectral components of an image are (symbol *S* stands here for $\Sigma$ ). For comparison of images a region of interest (*ROI*) consisting of *K*, *K* ≤ 64, basic windows not belonging to the background should be considered.

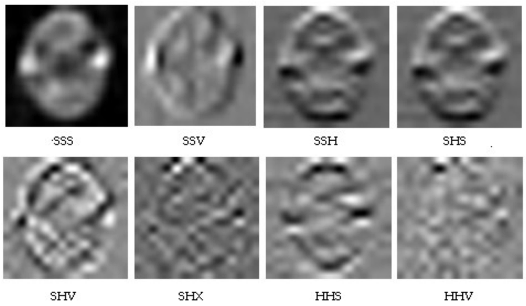

Fig. 4. Selected examples of spectral components' intensities of a given image.

Looking at Fig. 3 it can be remarked that, probably, the subsets of images: {#1, #7} and {#2, #4, #8} form similarity clusters, while images #5 and #6 do not match to any other ones. However, this observation is not based on an objective similarity measure, hence, for a more precise task solution a 0.9-*SCD* problem will be considered.

First, *ROI*s identical in size and form in the set of images should be chosen. Next, a similarity measure based on a distance measure of vectors:

$$d(v', v'') = \sum_{(k)} |v'_k - v''_k| \qquad (17)$$

as the simplest one will be chosen.

In the case of using Algorithm 1 each of *K* (*K* ≤ 64) basic windows containing 64 pixels, should be compared with respective basic windows of all other images. Then, all pairs of vectors not satisfying the inequality $\sigma(\boldsymbol{v'},\boldsymbol{v''}) \geq 0.9$ should be removed, a similarity graph *G* consisting of 8 nodes and of all edges satisfying the given inequality should be constructed and, according to, the cliques finding problem should be solved.

An alternative, on Algorithm 2 based approach to the problem consists in its iterative solution connected with step-wise elimination of non-perspective pairs of vectors.

At the first iteration the basic windows (*D*,*4*) in the images using the $\Sigma\Sigma\Sigma$ (a sum of 64 pixel values filling a single basic window) spectral component will be compared. As a result, it can be established that the similarity between image #6 and all other ones is below the threshold 0.9 and #6 should be removed from considerations. The problem is thus reduced to this of finding cliques in a complete similarity graph $G^{(1)}$ consisting of 7 nodes: #1, #2, #3, #4, #5, #7 and #8. $G^{(1)}$ is by assumption identical to its unique clique; however, this working hypothesis by testing the similarity measure of selected pairs of basic windows and spectral components should verified.

At the second iteration of the procedure for testing there have been selected (in principle, randomly) the (*F,6*) basic windows and the $\Sigma HV$ spectral component. As a result two further dissimilarities between the pairs of vectors corresponding to the images (#1,#2) and (#1,#4) have been detected. Therefore, value 0 should be assigned to the elements $\sigma_{12}$, $\sigma_{21}$, $\sigma_{14}$ and $\sigma_{21}$ of the adjacency matrix $\boldsymbol{S}^{(2)}$ of the similarity graph $G^{(2)}$. Moreover, the non-perspective edges

(#1,#2) and (#1,#4) of the graph lead to its replacement by maximal complete sub-graphs non-containing the prohibited pairs of nodes. This means that $\boldsymbol{S}^{(2)}$ should be replaced by two its sub-matrices $\boldsymbol{S}^{(2,1)}$ and $\boldsymbol{S}^{(2,2)}$ based, respectively, on the following rows (columns): {#2, #3, #4, #5, #7, #8} and {#1, #3, #5, #7, #8}. Consequently, the similarity hypergraph $H^{(2)}$ will consist of the set of 7 nodes:

$$C^* = \{\#1, \#2, \#3, \#4, \#5, \#7, \#8\}$$

and of the set of hyper-edges:

$$F = \{(\#2, \#3, \#4, \#5, \#7, \#8),\ (\#1, \#3, \#5, \#7, \#8)\}.$$

Next iterations will be based on increased threshold levels $\varepsilon^{(i)}$ ; the results will be presented after removing single-node subsets and subsets included by some larger ones. Let us select for being tested the basic windows ( $F$ ,3) and spectral components $\Sigma H \Sigma$. Then dissimilarity of the pairs (#2, #7), (#4, #7), (#5, #7) and (#7, #8) can be detected. This preserves the former set $C^*$ of nodes but it leads to the following hypothetical set of hyper-edges:

$$F = \{(\#2, \#3, \#4, \#5, \#8), (\#1, \#3, \#7), (\#1, \#3, \#5, \#8)\}.$$

Next iteration, based on the components ($D$,6), $\Sigma HX$, detects dissimilarity of the pairs (#1, #3), (#1, #4), (#1, #5), (#1, #8), (#2, #5), (#2, #8), (#3, #5) and (#4, #5). This leads to the set of hyper-edges:

$$F = \{(\#3, \#4, \#8), (\#2, \#3, \#4), (\#1, \#7), (\#3, \#7), (\#3, \#5, \#8)\}.$$

### *II. Comments*

In the above-presented example the results have been reached due to comparison of several basic windows and spectral components only instead of comparing full images.

The procedure is stopped when in an iteration all $\varepsilon$ -similarity clusters disappear or if the number and form of the clusters does not change for several iterations.

## V. Conclusions

The following properties of the above-described method of $\varepsilon$ - $SCD$ should be remarked:

i. Each iteration of the algorithm consists of a finite number of repetitions of a finite sequence of steps.

ii. The number of iterations is finite.

iii. Each iteration leads to an approximation of the solution satisfying more rigid ε-similarity criteria, hence it preserves or reduces the size of formerly found ε -similarity clusters.

iv. Each next iteration consists in finding cliques in a similarity graph $G$ containing a non-increased (in most cases – reduced) set of nodes and set of edges.

v. In the less favorable case the algorithm leads to an exact $\varepsilon$-$SCD$ task solution in a finite number of steps.

Hence, the properties of the Algorithm 2 do not guarantee that the calculation cost of an $\varepsilon$-$SCD$ task solution is in each case lower than if Algorithm 1 type one is used. However, it does guarantee that in most cases it is lower due to the reduction of the number of nodes and edges in the similarity graph $G$ leading to an exponential reduction of the cliques finding calculation cost. An exact The above-presented images are of 124×124 pixels size partitioned into basic windows of 16×16 pixels size arranged in columns (denoted by numbers from *1* to *8*) and in rows (denoted by symbols from *A* to *H*). The contents of a single basic window can be represented by an 8×8 size bitmap or by its 3rd level morphological spectrum consisting of 64 components. evaluation of the real gain in calculation cost reduction is not possible to be done by analytical methods. It needs a series of experiments to be performed on statistically representative sets of large (i.e. hundreds of nodes containing) similarity graphs.

# Automatic Acquisition of Wordnet Relations by the Morpho-Syntactic Patterns Extracted from the Corpora in Polish

Roman Kurc, Maciej Piasecki
Institute of Applied Informatics, Wrocław University of Technology, Poland
Email: maciej.piasecki@pwr.wroc.pl

***Abstract*—In the paper we present an adaptation of the Espresso algorithm of the extraction of lexical semantic relation to specific requirements of Polish. The introduced changes are of more technical character like the adaptation to the existing Polish language tools, but also we investigate the structure of the patterns that takes into account specific features of Polish as an inflectional language. A new method of the reliability measure computation is proposed. The modified version of the algorithm called Estratto was compared with the more direct reimplementation of Espresso on several corpora of Polish. We tested the influence of different algorithm parameters and different corpora on the received results.**

## I. Introduction

STARTING construction of a system from scratch gives much more control over it, but in the case of large, practical systems it usually means that it will never be completed. In current-day software engineering, the component-based architecture and re-usable components became a typical way of construction. In the contemporary Computational Linguistics and Natural Language Engineering a similar role is played by basic language resources and tools. There are attempts to define a basic set of them, e.g. [1][2], or to build architectures supporting their application, e.g. (Clarin). Wordnets[1] built for different languages became commonly applied as the source of linguistic knowledge. The main problem of the basic language resources is that they do not exist for many languages and their construction takes a lot of time and is costly. The construction of the first Polish Wordnet, called *plWordNet* (Polish name: *Słowosieć*) started in the year 2005, and its current version includes 14 677 lexical units (henceforth LUs)—one word or multiword lexemes [4]. In wordnet, LUs which are near synonyms are grouped into synsets, sets of near synonyms, and synsets are linked by lexical relations of several types. In plWordNet, the synset relations can be mapped onto the level of LU relations. One of the most important relations for any wordnet is hypernymy—simplifying, an LU $a$ is the hypernym of the $b$ if $b$ is a kind of $a$ on the basis of their lexical meanings.

The present size of plWordNet is too small for many applications. It could not be larger, since its manual construction was quite expensive. However, knowing that, from the very beginning, we assumed the manual work would be supported by the developed tools for the automatic extraction of instances of lexical semantic relations from corpora. We paid special attention to hypernymy due to its importance, i.e. our aim is to construct a tool acquiring pairs of: hypernym and hyponym from large corpora.

There are two possible paradigms [5]: *pattern-based* and *clustering based* also called *distributional*. The latter results in good recall but there are problems with precision, as its typical product is a *measure of semantic relatedness*, not some lexical semantic relationship itself. For any pair of LUs their level of relatedness can be obtained, but it is very unclear how to perform the identification of an type of relation. In the area of the clustering based paradigm, several works were done for Polish, e.g. [6], [7]. However, the number of works done in the area of pattern-based paradigm is very small, e.g. (Dernowicz, 2007), (Ceglarek & Rutkowski, 2006) the latter one dealing with the machine readable dictionaries, not corpora.

Pattern-based approaches are claimed to express good precision, but very small recall in the case of patterns constructed manually, e.g. [8]. The recall of patterns can be increased by using many or more generic patterns extracted automatically from a corpus, i.e. patterns which have broad coverage but intrinsically low precision. The system Espresso presented by Pantel and Pennacchiotti [5] is so successful an example of such an approach, that it inspired us to adapting this type of approach to Polish.

Our goal was to develop a statistical method of the extraction of lexico-morphosyntactic patterns for the needs of automatic hyperonymy acquisition. Our starting point was the adaptation of the Espresso algorithm to the Polish language, and even more important, to a very limited set of language tools for Polish. In the paper we present the measures introduced in Espresso, elements that should be taken into account when Polish patterns are being extracted and application of Espresso to extracting hypernymy. We also discuss the possibility of acquiring other types of relations. On the basis of the collected experience, an extended version of Espresso is proposed called *Estratto*.

## II. Espresso

Espresso is thought to solve the *bootstrapping* problem [9], [10] i.e. learning the structure of the domain, where

[1] A wordnet is an electronic thesaurus of the structure following the main lines of the Princeton WordNet [3]

> “the phenomena and the rules defined in terms of those categories are learned from scratch [...]”

and

> “the specification of a set of rules presupposes a set of categories, but the validity of a set of categories can only be assessed in the light of the utility of the set of rules that they support.”

So both rules and categories must be derived together. In Espresso rules are patterns and categories are semantic relations represented by *instances* defined as pairs of LUs. The algorithm consist of three phases:

- *construction* of patterns on the basis of *instances* of a relation,
- pattern statistical *evaluation*,
- and *extraction* of instances on the basis of positively evaluated patterns.

Pantel and Pennacchiotti claim [5] that Espresso is characterized by:

- high recall together with a small decrease in precision of extracted instances,
- autonomy of work (weakly supervised algorithm)—only several initial instances of the given relation must be defined at the beginning,
- independence from the size of the used corpus or a domain,
- wide range of relation types that can be extracted.

The small decrease in accuracy results from the application of generic patterns together with specific ones. This balance is achieved by the proposed measure evaluating *reliability* of patterns and instances, explained in Section *Reliability and confidence measures*. *Confidence* of instances extracted by the generic patterns is verified on a large separated corpus. The confidence of an instance originates from its strength of association with reliable patterns and the number of reliable patterns which extract it. Only the best patterns and instances are kept for the following phase of the algorithm

The introduced measure of reliability and confidence reduce the need for manual supervision once Espresso started. The measures are a means of creating rankings of instances and patterns defining the degree to which they express the target relation.

As the system of measure, instances and pattern selection are universal and do not refer to any properties of any particular relation being extracted, Espresso can be applied to a wide range of relation, and was to several, e.g. hypernymy, meronymy, antonymy but also more specific like person—company or person—job title [5].

The characteristics of Espresso inspired us to try to adapt it to Polish. We are going to investigate the key of the algorithm like measures of reliability and confidence, methods of pattern extraction and the usage of verifying corpus for the evaluation of confidence in relation to the characteristic features of Polish.

## III. Reliability and confidence measures

The reliability measure that is applied to construct the ranking of patterns and instances is one of the most important elements of the algorithm and is defined for patterns in the following way:

$$r_\pi = \frac{\sum_{i \in I} \left( \frac{pmi(i,p)}{max_{pmi}} * r_t(i) \right)}{|I|} \tag{1}$$

where $p$ is a pattern, $i$—an instance, $r_t$—measure of reliability for instances, $pmi$—Pointwise Mutual Information, explained below, and $|I|$—the size of the set of instances.

The reliability of instances is defined in a very similar way, but this time the reliability of patterns is utilized in the equation.

PMI measure originates from the Theory of Information and is defined as following:

$$pmi(i,p) = \log \frac{|x,p,y||*,*,*|}{|x,*,y||*,p,*|} \tag{2}$$

where $|x,p,y|$ is the number of occurrences of $x$ and $y$ in contexts matching the pattern $p$, $x,*,y$—the number of co-occurrences of $x$ and $y$ in the corpus regardless the pattern, etc.

The $pmi$ definition given in [5] does not include the constituent: $|*,*,*|$, i.e. the number of contexts. However, the PMI measure should be usually greater than 0, while the one defined in 2 is not. Moreover, the missing constituent is suggested also by the general definition of PMI:

$$pmi(i,p) = \log \frac{p(I,P)}{p(I)p(P)} \tag{3}$$

Because PMI is significantly greater in the situation in which instances and patterns are not numerous (e.g. the size smaller than 10), PMI is multiplied by a factor proposed in [11].

The measure of confidence of an instance extracted by the generic patterns is based on the application of specific patterns of high reliability to a different validating corpus and is calculated in the following way:

$$S(i) = \sum_{p \in P_R} S_P(i) * \frac{r_\pi(p)}{T} \tag{4}$$

$P_R$ is the set of specific patterns, $S_p = pmi(i,p)$ and $T$ is the sum over the reliability of specific patterns.

It is worth to emphasize that patterns are evaluated not on the basis of instances which were extracted by them, but on the basis of instances that were used to acquire these patterns. Instances are evaluated in a similar way. This is a consequence of the method assumed in Espresso: patterns are not matched to the instances but are induced by the instances.

The intuition behind the measures of reliability and confidence is that patterns which well describe the given relation frequently occur with a large number of confident instances of this relation. The same applies in the opposite way. However, in the case of confidence the difference is that instances extracted by generic patterns will obtain high confidence, if they occur in contexts matched by the specific patterns of good reliability in the validating corpus.

There are two unclear issues in the picture presented above. Firstly, even making a draft calculation, we can check, that reliability is sensitive to possible fluctuations in PMI value. Occurrence of higher PMI values (e.g. originating from small frequencies, even after correction by the discounting factor dependent on the number of occurrences) can cause lower assessment of patterns with balanced ratio of co-occurrence with matched instances in relation to the pattern occurrences and occurrences of instances alone. Such a situation results in the artificially increased value of $max_{pmi}$. Thus, we would like to look for a measure which would be more insensitive to the problem of the low frequency of pattern matches or instances matched. Secondly, the reliability measure of the best instance or pattern may take the value lower than one even in a situation in which there is a complete match of all patterns and all instances (or the other way round, depending on which we are calculating the reliability). That is why, the reliability propagation to the subsequent phases causes, that new values calculated for patterns on the basis of instances, and vice versa, will be gradually lower according to the size of the set for which the reliability is computed, i.e. patterns or instances. Thus we want to introduce a new measure of reliability, which returns one as the value for the best patterns or instances in every phase.

$$r_\pi(p) = \frac{\sum_{i \in I}(pmi(i,p) * r_t(i)) * d(I,p)}{max_P(\sum_{i \in I}(pmi(i,p) * r_t(i))) * |I|} \qquad (5)$$

where $d(i,p)$ defines how many unique instances the given pattern is associated with.

PMI in the formula (5) is usually modified by the discounting factor, as well.

## IV. Patterns

As for the Machine Learning methods the choice of features for objects is a very important decision, so is the choice of pattern structure and pattern language for the pattern-based approaches in acquisition of lexical semantics. The majority of approaches take the scheme proposed by Hearst [12] as their reference point, i.e. patterns being a subset of regular expressions, in which the alphabet includes lemmatized word forms and a set of variables for noun phrases matched as an element of a relation instance. An example for hipernymy could be: NP such as NP1*
NP is a/an NP1

We assumed that patterns are a subset of regular expressions with Kleene closure, but without grouping. The alphabet includes morphological base forms of lexical units. Before presenting the scheme of a pattern for Polish, we need to investigate the characteristic features of Polish, which we considered.

### A. Selected aspects of Polish

The vast majority of pattern-based approaches were developed for English. Those approaches base in some extent on the positional, linear syntactic structure of English. It was not clear how one can successfully transform this approach to a language of a significantly diffrent type like Polish.

The basic, unmarked order of a Polish sentence is Subject—Verb—Object, i.e. similarly to English. So, for simple lexico-syntactic patterns based on relative positions of described elements the differences should not be large. However, on the other side, in order to fully explore the potential of pattern-based approach we have to go beyond the analysis of the most simple constructions only. One needs to take into account such phenomena like morphosyntactic agreement of different kinds among word forms and the relaxed order of a sentence, according to which one can use several different orders of a sentence which only slightly changes in meaning. It seems to be reasonable to put more emphasis on the morphological description of pattern elements in terms of scheme introduced in the IPI PAN Corpus of Polish (IPIC) [2]: grammatical class (extended, more fine grained division than Part of Speech) and values of grammatical categories like case, number and gender for nouns and adjectives or aspect and number for verbs. In the case of Polish, the linear positions of LUs in a sentence is not necessarily correlated with their role in a lexical semantic relation when the relation is not symmetrical, e.g. in case of hypernymy most patterns mark hypernym and hyponym by different cases, while their relative positions are changing. Obviously, we can generate many specific patterns for all different combinations, but we can also look for some generalization of a group of patterns on the basis of the morphosyntactic properties.

### B. Scheme of patterns

Patterns have a flat structure and describe a sentence as a sequence of word forms or at most groups of word forms. Patterns are not based on any deeper description of the syntactic structure. The alphabet comprises three types of symbols: an empty symbol `*`, *base form* and *matching place*. The empty symbol represents any LU (represented by any of its word form). The base form is a morphological base form of some LU together with the grammatical class, as the same morphological base form can represent more than one LU. A matching place represents all LUs whose morphosyntactic description matches the partial description encoded in the matching place symbol. As grammatical classes of IPIC are too fine grained we introduced a macro collective symbol, e.g. `noun` joining together: *substantives*, *gerunds*, *foreign nominals* and *depreciative nouns*. A matching place is a reduced version of the IPIC morphosyntactic tag, in which only some grammatical categories are specified.

Following [5], there are always two matching places: one at the beginning and one at the end of a pattern. Patterns do not describe the left and right context of a potential instance.

A pattern also encodes the roles of both LUs identified by matching places, e.g.:

**`(hypo:subst:nom) jest (hyper:subst:inst)`**

—where `jest` is *to be*$_{number=sg,person=3rd}$, `hipo` marks hyponym, and `hiper`—hypernym, `subst`—*substantive*, `nom` and `inst` are case values (all three are from the IPIC descrption)

**(hyper:subst:inst) jest (hypo:subst:nom)**

The described pattern scheme expresses to some extent the characteristic features of Polish. The change of the pattern scheme was the first step leading to an algorithm called Estratto, which is a modification of Espresso that is better suited for an inflectional language like Polish.

## V. Induction of patterns and extraction of instances

According to [5], patterns can be inferred by any pattern learning algorithm. In Estratto the generalisation and unification of patterns is based on the longest common substring algorithm. The algorithm is guided by a predefined list of relation specific LUs, e.g. for hypernymy, *być* (*to be*), *stać się* (*to become*), *taki* (*such*), *inny* (*other*), etc.

In Espresso, the inferred patterns are then generalized by replacing all *terminological expressions* (i.e. a subset of noun phrases) by *terminological labels*. Such an approach to generalization is not applicable for Polish, as a required *chunking parser* (chunker) does not exist. Therefore a slightly different method was proposed. Patterns are grouped and then merged with respect to the significant elements of the patterns: specification of matching places (determining properties of morphological similarity to contexts), and words expected to be related in some way to the semantic relation being extracted.

The instance extraction phase comes after patterns induction and selection. An instance is a pair $\langle x, y\rangle$ of LUs belonging to the set of instances representing the target semantic relation. Authors of Espresso suggest, that if the algorithm is applied to a small corpus, two methods can be used to enrich the instance set. First each multiword LU in an instance can be simplified according to the head of LU. For example *new record of a criminal conviction* is simplified to *new record* and this to *record*. A new instance is created with a simplified LU and the LU that was in the pair together with the original LU. Second an expansion is made by an instantiating pattern only with one of the LUs: $x$ or $y$, and searching if it can extract a new instance from additional corpora, for example, for the instance (*dog*, *animal*) and the pattern expressed in the inflectional format used in Estratto:

**(hypo:subst:nom) is a/an (hyper:subst:inst)**

two queries:

**dog is a/an (hyper:subst:inst)**

and

**(hypo:subst:nom) is a/an animal**

are created.

Instances gathered using both of those methods are added to the instance set. However, it worth of noticing that in all experiments described in [5] only one-word LUs are used and the applied corpora are claimed to be large enough to provide statistical evidence.

Generalized patterns, described above, are not classified as *generic* as long as they do not generate ten times more instances than the average number of instances extracted by specific patterns. However high recall results in loosing some of the precision, that is why every instance extracted by a generic pattern is verified. The verification process starts with instantiating all specific patters with the instance in question. Then the instantiated patterns are queried in a validating corpus and the confidence measure is next computed on the basis of collected frequencies. If confidence is above the defined threshold than the tested instance is considered as representing the target relation.

In Espresso, Internet resources were used as a huge validating corpus for instances extracted by generic patterns. Contrary to this, due to several limitations in searching the Internet in Polish (i.g. limited access to the search engine and inflection of the language), we applied a second large corpus, much smaller the aforementioned one, as a validating corpus in Estratto. The necessary condition is that the validating corpus must be similar in its characteristics to the basic one.

The process of the induction of patterns and extraction of instances is controlled by the following set of parameters:

1) the *number of top* $k$ patterns not to be discarded (preserved for the next iterations),
2) the *threshold* for measure of confidence for instances,
3) the *minimum* and *maximum frequency* values for patterns,
4) the *minimum size* of a pattern— all patterns that consist of only matching places and conjunctions are discarded by the assumption,
5) a *filter* on common words in instances and instances that have identical LUs on both positions,
6) the *size* of the validating corpus.

## VI. Performance measures

A proper evaluation of the extracted lexical semantic resources is mostly a serious problem, e.g. [13], [14]. However, in the case of lists of instances the situation is simpler: we need to verify how many of them are correct. There are only two possibilities to compare the list with: an existing manually constructed resource, i.e. plWordNet in our case or human judgement. The former will introduce some bias as plWordNet is limited in its size, but gives a possibility of testing the whole set of instances, while the manual evaluation is always laborious.

In both types of comparison we applied the standard measures of *precision* and *recall*, e.g. [15]. The F-measure could not be applied, because of the limitations of recall based on plWordnet, which are discussed later.

Precision is defined in a standard way: $P = \frac{tp}{tp+fp}$ where $tp$ is the number of true positives, i.e. extracted pairs of LUs which are instances of the target relation, $fp$—false positives.

True positives are patterns or instances (depending on what we are going to measure) that are correct and marked by algorithms as correct and false positives are those that are incorrect but marked by algorithms as correct.

Recall is defined in a standard way too: $R = \frac{tp}{tp+fn}$

However, it is worthy of note that recall is the ratio between instances or patterns that are correctly marked as correct (true positives) and the sum of true positives and all those that are correct but were either marked as incorrect or not extracted at all. The problem is that we certainly cannot treat the limited plWordNet as the exhaustive description of the subsequent relations. Thus, recall in our approach is only the measure of the ratio of rediscovery the plWordNet structure, it is not a recall in relation to all instances or patterns that can be present in the used corpora.

We extracted a ranked list of possible instances which can be sorted in descending order of their reliability. Its values are real numbers and there is no characteristic point below which we can cut off the rest of pairs according to some analytical properties. Thus, instead of pure precision and recall, we prefer to use *cut off precision* and *cut off recall* calculated only in relation to some $n$ first positions on the sorted list of results (instances or patterns).

Finally, we used the following evaluation measures:

1) *Cut off precision based on plWordNet* - this measure marks as correct only those instances and patterns that were found both in plWordNet and an additional list provided a priori by human judge. It is worth to consider that the limited size of plWordNet can influence precision negatively because some LUs are not present yet or although included into plWordNet, still not connected. This precision is computed for each element on the list of instances.
2) *Precision based on human judgement* is evaluated according to a randomly drawn sample from the list of instances. This evaluation measure was used only for the first group of experiments (ref. Experiments). The error level of sample was 3% and the confidence level was 95%.
3) *Recall based on plWordNet* is evaluated at the set of word pairs generated form plWordNet. However this measure does not describe the recall from corpora

## VII. Experimental setup

The experiments were performed on three datasets corpora:

a) IPIC [2] including about 254 millions of tokens, is not balanced but contains texts of different genres: literature, poetry, newspapers, legal texts and stenographic records from parliament, and scientific texts,

b) 100 millions tokens from Rzeczpospolita [16]—Polish newspaper (henceforth RC)

c) and a corpus of large text documents collected from the Internet, texts including larger numbers of spelling errors and duplicates were semi-automatically filtered out (LC), LC includes about 220 millions of tokens.

We tested several configurations of systems during the experiments, namely:

a) **ESP-** —Espresso without generic patterns,

TABLE I
INFLUENCE OF THE EXTENDED RELIABILITY MEASURE AND CHANGES IN THE FORM OF PATTERNS

| | **Precision levels (plWN)** | Hum. eval | Recall plWN | **Instances** |
|---|---|---|---|---|
| **ESP-** | 36%/50%/75% | 39% | 27% | 3982/903/14 |
| **ESP-nm** | 37%/50%/75% | 47% | 26% | 3784/774/96 |
| **ESP+** | 32%/50%/75% | | 27% | 4221/613/11 |
| **EST-** | 52%/52%/75% | 54% | 18% | 1628/1628/169 |
| **EST-nm** | 16%/50%/75% | 59% | 18% | 1775/1598/120 |

b) **ESP-nm**—Espresso without generic patterns, but with the extended reliability measure 5,

c) **ESP+** Espresso with generic patterns,

d) **EST-** Estratto without generic patterns, exploiting specific features of Polish,

e) **EST-nm** Estratto without generic patterns, exploiting specific features of Polish language and the extended reliability measures 5,

f) **EST+nm** same as VII but using generic patterns.

If not stated otherwise the threshold for confidence is 1.0 for all ESP systems and 2.6 for EST. The *number of top* $k$ patterns was set to $k = 2 + I$, where $I$ is the number of the present iteration. The number of iterations was set to four. In those experiments whose results are presented we focused only on the hypo/hypernymy relation and we selected as the main corpus, on which we performed experiments compared in tables, was IPIC.

## VIII. Experiments

Research on Espresso and Estratto can be divided into three groups. The first one includes experiments, that were designed to analyse the influence of the proposed extended reliability measure 5 and of the form (i.e. if they are improved for using selected aspects of Polish or no) of patterns for the **ESP-**, **ESP-mn** and **EST-**, **EST-nm**. The results are shown in Table I, where values in the column labelled "Precision level" refer to the number of instances in the last column e.g. in the first row **ESP-** extracted 3982 instances with precision of 36%, 903 instances with precision 50% and so on. The column labelled “Hum. eval” refers to the evaluation of the results made by one of the authors.

On the basis of the results of the first group of experiments, Table I, one can conclude, that the use of the original reliability measure 1 results in extraction of more instances. The overall cut-off precision based on plWordNet for 4000 of instances is around 35%. On the other hand, the cut-off precision evaluated for EST suggested, that EST performs worse. However plWN is relatively small, that is why, the evalutation can be misleading. Therefore one of the authors performed manual evaluation. This additional evaluation showed, that in fact the plWN might be used only for a very rough estimation of the precision. The results of the manual evaluation suggest also, that the use of the new measure increases the precision of **ESP-/EST-**. In each case ESP-nm vs. **EST-nm** is better. During experiments it was also observed, that the value of original

TABLE II
DEPENDENCY OF THE ALGORITHMS ON THE VALUES OF PARAMETERS.

| | **Precision levels (plWN)** | Recall plWN | Instances |
|---|---|---|---|
| **EST-nm:th1.0** | | | |
| **EST-nm:th2.6** | 16%/50%/75% | 18% | 1775/1598/120 |
| **EST-nm:th5.2** | **47%/50%/75%** | **20%** | **1907/1736/117** |
| **EST+nm:patt4iter4** | 27%/50%/75% | 27% | 4372/1537/86 |
| **EST+nm:patt8iter4** | 32%/50%/75% | 24% | 3999/1521/47 |
| **EST+nm:patt4iter6** | 17%/50%/75% | 29% | 7265/1505/83 |
| **EST+nm:patt8iter6** | 30%/50%/75% | 27% | 4210/1485/58 |
| **EST+nm:PMI** | **27%/50%/75%** | **27%** | **4187/1505/86** |
| **EST+nm:Tscore** | 6%/- | 25% | 8934/-/- |
| **EST+nm:Zscore** | 34%/50%/75% | 26% | 3563/1419/59 |

reliability (1) decreases very fast and after 6th iteration it is far below 10–12. This is a reason for the drop of newly extracted instances. Applying the extended reliability (5) allows to avoid that problem. Recall based on plWN is comparable, and depends on the number of extracted instances. Another matter of concern is the scheme of the patterns adjusted for Polish. It is clear that the application of the adjusted patterns produces better precision **EST-** and **EST-nm** in comparison to **ESP-** and **ESP-nm**. However the recall is decreased.

Experiments from the second group were performed only for **EST+nm** and **EST-nm**, using suggested measure, and this group was aimed at determining the influence of the algorithm parameters on the result. The following dependencies were investigated:

i) influence of the confidence threshold on the precision of instances achieved within subsequent iterations,

ii) influence of the number of the top $k$ patterns on the stability of the algorithm and the precision of instances,

iii) dependency on the filtering infrequent and very frequent patterns and instances.

iv) influence of the number of initial instances (seeds) on the induced patterns, and then the influence of the ration between instances and patterns inducted by them,

v) a way in which different statistical similarity measures used in reliability calculation change the precision of the results.

In the case of **i)** it seems, that best results are achieved, when the threshold is higher, see Table II. However one must keep a balanced ratio between chosen instances and new patterns. If there is a small number of instances, there is no statistical evidence to induce proper patterns and EST/ESP crawls picking almost random patterns. That leads to the decrease in precision.

Considering **ii)**, on the basis of the obtained numbers, it can be noticed, that using a smaller number of the $k$-top patterns results in higher precision. This is due to the stability of a model, in which semantic relations are generated by a small group of elite patterns. An interesting idea would be to use a dynamic $k$-top factor. Should it be more strict at the begging, the more stable set of patterns would be indicated. Then in the subsequent iterations the $k$-top would grow faster, and as a result more correct patterns could extract instances from corpus in the next phase.

The data for **iii)** are not presented in Table II. However the experiments have shown, that infrequent patterns (occurring less than four times) should be filtered before generalization, because they introduce additional noise, which causes good patterns to be evaluated as worse.

Initial seeds, the point **iv)**, are meant to generate a skeleton of a model of the lexical semantic relation. If the number of seeds is not enough high, the best extracted patterns can be random. Of course, one could collect a small number of seeds, that would indicate only expected patterns. However that would require a precise analysis of the corpus, that would be used for instance extraction. That is pointless, because using more seeds one can acquire the same patterns with less effort.

In the case of **v)**, the data shows, that PMI is better than Z-score and T-score as the measure of similarity in the extraction of lexical semantic relations. T-score results are especially disappointing, and that might be due to the fact of the insufficient statistical evidence (the algorithm very often accepted instances occurring only once).

The third and the last group of experiments was prepared to check the ability of EST and ESP to use a different corpus and extract other relations than hypo/hypernymy. Performed experiments showed that both algorithms: EST and ESP can be applied to different corpora successfully, however it seems, that each time the corpus is changed, a new confidence threshold must be discovered by some method For IPIC the threshold value was 2.6 but in the case of RC we found 0.9 as working fine. Tests performed on the LC corpus appeared to be unsuccessful. But this is a rather special case, as most of the text in LC are written in literary style, so the language expressions are more complex. Moreover, one should expect less defining sentences than in utility texts. It seems that this kind of corpus requires more powerful patterns to catch some syntactic dependencies. The other problem, namely the application of EST to different relation types appeared to be only partially successful. Tests on meronymy ended with a rather poor result, i.e. the estimated precision was lower than 30%. There are at least three main reasons for this failure. Firstly, the expressive power of patterns is too low and some important morpho-syntactic dependencies are missed. Secondly, meronymy is indeed a set of quite varied sub-relations. That is why, it could be reasonable to try to extract each sub-relation separately. Thirdly, the trials were done only on one corpus. On the other hand, initial experiments on extracting antonymy (but only for adjectives) gave promising results. The human-judged cut-off precision reached 39%. Both meronymy and antonymy will be further investigated.

## IX. EXAMPLES

Below we present examples of instances (hyponym; hypernym) extracted by the **ESP-** algorithm from IPIC:

*szkoła*(*school*); *instytucja*(*institution*)
*maszyna*(*machine*); *urządzenie*(*mechanism*)
*wychowawca*(*tutor*); *pracownik*(*employee*)
*kombatant*(*combatant*); *osoba*(*person*)
*bank*(*bank*); *instytucja*(*institution*)
*pociąg*(*train*); *pojazd*(*vehicle*)
*telewizja*(*television*); *medium*(*medium*)
*prasa*(*press*); *medium*(*mass media*)
*szpital*(*hospital*); *placówka*(*establishment*)
*czynsz*(*rent*); *opłata*(*payment*)
*grunt*(*land*); *nieruchomość*(*real estate*)
*Wisła*(*Wisła*); *rzeka*(*river*)
*świadectwo*(diploma); *dokument*(*document*) *opłata*(*payment*); *należność*(*charge*)
*ryba*(*fish*); *zwierzę*(*animal*)
*Włochy*(*Italy*); *kraj*(*country*)
*jezioro*(*lake*); *zbiornik*(*reservoir*)
*jarmark*(*fair*); *impreza* (*entertainment*)
*piwo*(*beer*); *artykuł*(*comestible*)
*zasiłek*(*dole*); *świadczenie*(*welfare, benefit*)
*powódź*(*flood*); *klęska*(*disaster*)
*paszport*(*passport*); *dokument*(*document*)

Examples of patterns extracted by **ESP-** from IPIC and used in the extraction of the above instances are presented below:

```
occ=31 rel=0.26803 (hypo:subst:nom) być
(hyper:subst:inst)
(hypo:subst:nom) is/are (hyper:subst:inst)

occ=20 rel=0.222222 (hypo:subst:nom) i

(hypo:subst:acc) interp which is
(hyper:subst:inst)
```

## X. Conclusions and further work

In the paper we presented a partially successful application of the *Espresso* algorithm [5] to Polish. The modified version of the algorithm was called *Estratto*. Experiments showed that the reliability measure proposed by Pantel and Pennacchoti [5] works usually well as a ranking measure for the extraction of lexical semantic relations. However the plWN-based precision of the Espresso/Estratto algorithm is lower when measured on Polish corpora than the precision reported in [5]. This might be due to a slightly different approach to precision evaluation, which was performed partially on the basis of plWordNet (of a limited size) and combined next with a limited manual evaluation. On the other hand the results of the manual evaluation are similar to the results reported in [5]. Results obtained for different measures of similarity as the basis of the reliability suggest that PMI gives the best results for the given test suit.

The adjustment of the pattern structure to the characteristic features of Polish improved the precision in comparison to patterns using only word forms and Parts of Speech as features.

The extended version of Espresso—namely Estratto showed to be successful in extracting hypernyny and antonymy from the IPI PAN Corpus [2] and the Rzeczpospolita corpus [16]. Unfortunately attempts to extract meronymy did not bring positive results.

During experiments we tested several parameters that have a significant influence on the algorithm. The most important of them appeared to be: the *number of seed instances*, the *confidence threshold* and the *number of the k-top patterns* preserved between the subsequent iterations. The number of seed instances should be more than 10. The confidence threshold depends strongly on a corpus, e.g. for IPIC the best found value was about 0.3. Each time the algorithm is applied to a new corpora both seed instances and the measure of confidence must be reset. The number of the $k$-top patterns should be low i.e. about two. Such a number results in a stable representation of the semantic relation, i.e. by the means of the set of patterns. However, it is still unclear, how to explore patterns, that seem to be correct and are close to the top. Those patterns usually disappear in next iterations and that means that some instances are also excluded from final results.

Espresso/Estratto is an intrinsically weakly supervised algorithm, although the preparation of seeds and setting the initial values of parameters might require even some initial runs of Espresso/Estratto or browsing the corpus.

Additionally it turned out, that in order to maintain a stable representation of relations, the appropriate ratio between patterns and instances must be kept. The ratio was estimated during experiments and equals for patterns vs. instances: 1:15/20. If there are less instances, the algorithm becomes unstable. Using more instances results in a longer time of computation.

An interesting result of experiments is the observation of the “intensifying” patterns. Such patterns do not represent any particular semantic relation and when applied alone they extract instances belonging to relations of multiple types. However when the intensifying patterns are combined with regular ones they deliver additional statistical evidence to correct but infrequent instances and as a result rise the precision of the algorithm, e.g.,

**(hypo/holo:subst:nom) w (hyper/mero:subst:inst)**
where *w* means *in*.

We observed a problem with the number of instances collected by the **ESP+**/**EST+** versions of the algorithms. This number is comparable to the number of instances extracted by **ESP-**/**EST-** while one would expect it to be much higher. This might be a result of the characteristic features of the corpus, namely IPIC, used in the experiments or of the size of the validating corpus. This problem might be partially solved by the use of Google as a validating corpus. Unfortunately, in contrast to English, Polish LUs have multiple word forms. As a result queries issued to Google will have to be more complicated. The other reason might be the limited expressive power of patterns. The expressive power of the patterns is the element of the algorithm that should be investigated. The extended structure of patterns still seems to miss some lexico-semantic dependencies, especially in stylistic reach text. The experiments on extracting hypernymy from the corpus LC, mostly consisting of text in literary style, was unsuccessful. The first step towards strengthening patterns is to take into account possible agreements in elements of the patterns that match the instances. The patterns used in EST are very strict about grammatical categories e.g.,

**(hypo:subst:gen) i inny (hyper:subst:gen)**
(two nouns in the genitive case) is treated as a completely different pattern from:

**(hypo:subst:inst) i inny (hyper:subst:inst)**
which matches two nouns in the instrumentative case. It seems to be helpful to allow merging of such patterns into e.g., the form of:

**(hypo:subst:case1) i inny (hyper:subst:case2)**
where case1 = case2. On the basis of the results for **ESP-** and **EST-**, where in **ESP-** there are no such strict constraints, one can expect the increase in recall. The other way, much more complicated, is to enrich the pattern representation, so that additional syntactic information (at least about nominal phrases) could be used.

Natural extension of present representation of instances for Polish is the introduction of multiword lexical units(LUs). Due to their present form it is sometimes possible to obtain instances consisting of two similar words, e.g., for *word office* and *post office* the resulting instance would be (office, office), as only single words are matched.

The list of acquired instances cannot be easily imported to plWordNet. This is due to the fact that the list is a flat structure. Such a representation cannot indicate, which wordnet classes an instance belongs to and what is the distance between the LU in the instance. This problem has been already addressed by Pantel and Pennacchiotti [5].

***Abstract*—Recently, in response to growing market demand, several different techniques of business rules representation have been created. Some of them try to present business rules in a visual manner. However, due to the complexity of the problem, the graphic representations that are proposed seem to be far from perfection. In this paper we would like to describe how UML state diagrams might be used for business rules formulation and visual modeling. The strength of this approach relies on reusing classical notions provided by UML 2.0, e.g. an action, guard, etc., in a way which is close to theirs original meaning.**

## I. Introduction

RULES constitute a commonly recognized mechanism for representing knowledge about the world. In particular they are suitable for specifying the behavior and properties of different complex artifacts like information systems [1]. The rule-based approach is a foundation of various engineering and business systems. It is helpful for formulating business knowledge about the problem domain, defining the way in which systems interact with the changing environment and performing inference upon the knowledge. With time, rules applied to business problems have gained the name *business rules* and have become a separate notion. From the very beginning, business rules have aimed to be precise enough for professional software engineers and easy to use and to understand for all parties involved in the modeling of business domain concepts [2]. This is especially important since domain experts usually do not have mathematical knowledge indispensable for using formalisms like Prolog, Datalog or Process Algebras, for example.

The simplicity and expressiveness have also been very important for UML's authors. Since UML is perceived as a universal modeling language, in a natural way there is a tendency to use it for rule modeling [3], [4]. Growing popularity of languages like URML [5] proves that UML has been recognized as a very useful platform for business rules modeling. UML, thanks to being popular with the software and business community, has an emerging opportunity to became an everyday language for wide audience of people involved in various kinds of business activities.

The paper is organized as follows: In Sect. II related research in the area of business rules is discussed. Next, in Sect. III, selected rule modeling aspects are summarized. Then, in Sect. IV a new approach to rule representation with UML is proposed. Finally, in Sect. V, concluding remarks, as well as directions for future work are given.

## II. Related Works

The first known usage of the term "Business Rules" comes from 1984 [6]. In fact, applying rules to business logic started in the late 1980s and the early 1990s[7], [8] and focused mainly on using business rules for data base modeling and programming. A serious attempt to make business rules better defined is "The Business Rules Book" written by Ronald G. Ross [9] and the report of the IBM GUIDE "Business Rules" Project [2]. In these works the authors define the scope of the problem domain, and identify core categories and patterns of business rules.

There is no uniform business rule format [10], [11]; however, there are some standardization efforts in this area [12]. Also the idea of using UML together with business rules is not completely new. Usually, UML is treated as a language for expressing facts about terms in a model [13], whilst the rules themselves are not written in UML. In this context, the applying of UML/MOF to modeling rules, not only to the terms or facts, seems to be a very interesting perspective. There are several projects that try to propose UML/MOF representation for rules. One of them is *Production Rules Representation* (PRR) proposed by OMG [10]. PRR has been developed to address the need for a representation of production rules in UML models (business rules modeling as part of a modeling process). It proposes a meta-model for production rules and defines several notions like condition, action, binding and rulesets. The relationship between PRR and OMG model driven architecture is also discussed.

Another interesting initiative developed in order to exchange rules between communities is a general markup framework for integrity and derivation rules (R2ML) [14], [15]. The authors of R2ML define the rule concepts on the basis of RuleML[11] and Semantic Web Rule Language (SWRL) in terms of MOF and UML[15]. On the top of the list of concepts provided by RuleML [16], a UML-Based Rule Modeling Language

978-83-60810-14-9/08/$25.00 © 2008 IEEE

(URML) has been developed. It extends UML meta-model with the notion of a rule and defines new diagram elements supporting visual notations for rules [3], [5]. In this approach, modeling rules is done with the help of a class diagram enriched by one new diagram element called a *conclusion arrow*. A created model must conform to the *URML* meta-model, defining the semantics for all indispensable notions, i.e. rules, conditions, conclusions, etc.

Besides the indisputable benefits like providing visual rule notation in accordance with *UML/MOF*, the relatively high number of classes required for defining a single rule might be a little onerous for people not accustomed to work with large *UML* models. A new diagram elements such as rule's circle requires use of special *UML* tools supporting *URML* syntax.

Business rules express the statements upon the model elements called business vocabulary. Thus it is important to have well formulated business vocabulary with precisely defined semantics. As an example of a standard facilitating business vocabulary formulation may serve SBVR (Semantics of Business Vocabulary and Business Rules) [17]. SBVR defines the vocabulary and rules, which allow to express business vocabulary, business facts and business rules. This standard also provides XMI scheme for the interchange of created artifacts among different software tools. However, SBVR is not an UML based language, since its generality, it might be successfully used in the context of UML model. In such approach detailed semantics of business vocabulary is defined with the help of SBVR in Structured English, whilst some aspects of business vocabulary are also expressed in form of UML class diagram (e.g. EU-Rent Example [17]).

## III. MODELING BUSINESS RULES

Let us take a closer look at the modeling concept first. The situation is as follows: by having a natural language description of a certain problem area, we aim at providing a declarative rule-based description of this area. The rule-based description is then formalized (or at least disciplined) compared to the original one. Rules are a knowledge representation method that captures regularities, constraints and relations. While formalized, this description is a high-level one, close to the original natural language-based one. So the basic sense of rule modeling is to build a rule-based knowledge representation of the problem. It is a classic case of knowledge engineering, where a designer, knowledge engineer has to identify, extract, describe and represent knowledge possessed by domain experts, or possibly embedded in an information system, such as an enterprise.

The rule representation should meet certain requirements. It should:

- be easy to grasp by non-technical individuals,
- be possible to process automatically and to integrate with a certain runtime (rule engine),
- formalized to some degree,
- meet certain quality standards (e.g. completeness, lack of redundancy),
- be suitable for interchanging and integration with other systems,
- be manageable.

The emphasis on these aspects can differ, depending on the goal of providing the rule-based description. This could be describing system requirements, including constraints, or building a complete system from scratch. Rules can also be thought of as a certain means of formalized communication.

Rule modeling methods and approaches should be considered with respect to other modeling methods such as software engineering methods and methodologies (e.g. UML, MDA). Since rules are often an essential part of business systems, business process modeling methods, such as workflows or BPMN, have to be taken into consideration in the chapter.

When it comes to the modeling *process*, different aspects can be pointed out:

- identifying concepts and their semantics,
- determining high-level structure ruleflow, rulebase contexts,
- building rules capturing the knowledge,
- integrating the ruleset,
- analyzing the quality of the model.

A rule-based model representation is expressed by means of a certain rule language.

While modeling rules, some other important factors have to be taken into consideration. These include:

- rule applications and types, e.g. constraint handling, facts, derivation, etc., and
- rule inference model, mainly the forward and backward chaining case.

These issues can have an important influence on the rule language.

### A. MODELING LANGUAGES

Rule modeling is a classic problem in the field of AI (Artificial Intelligence). It is a question of knowledge engineering (KE) and building rule-based expert systems that have strong logical foundations. In this chapter, some fundamental logical rule formats are considered, based upon the propositional or predicate calculus. The formats are a basis for rule languages. Rules can be practically written and processed in the logic programming paradigm, e.g. in Prolog. Even though the language uses a subset of first order predicate logic (restricted to Horn clauses), it is easy to write meta-interpreters working with languages of another order.

Within the AI, a number of *visual* knowledge representation methods for rules have been considered. These methods include:

- decision tables, that help combining rules working in the same context,
- decision trees, that support visualization of the decision making process, and

- decision graphs and lists, a less common but powerful method of control specification.

Two important factors for using these methods are:

1) design support – all of these methods help the designer (knowledge engineer) develop the rule-based model in a more rapid, and scalable manner, and
2) logical equivalence – all of these formally correspond to rules on the logical level.

These methods are used to model rules in practical applications. They also influenced some classic software engineering languages, e.g. UML.

A common approach to model rule-based systems is to use UML, considered by some as a universal modeling language. UML offers a visual or semi-visual method for different aspects of information modeling. By using this, it is possible to model some specific rule types. However, when it comes to practical knowledge engineering, it has some major limitations due to the different semantics of rules and the object-oriented paradigm. In particular cases, some of these shortcomings can be overcome by the use of OCL, which allows for constraint specification for UML classes.

One area where UML or UML-related methods are more useful is the conceptual modeling, which supports practical rule authoring. UML class diagrams are suitable to capture relations between concepts present in rule vocabularies. In this context usage of SBVR from OMG seems to be very interesting.

Since UML is a de facto standard information modeling method in software engineering approaches and tools, it can be treated as a low-level language on top of which a richer semantics is provided. This is possible for the standardized MOF and UML profiles formats. By building upon these, a dedicated rule modeling language can be built, e.g. URML or PRR.

An important community is built around the W3C and the so-called *Semantic Web Initiative*. The methods built on top of XML, RDF and OWL allow also for rule modeling for both web and general purposes. Rule interchange is possible using the XML-based RIF format.

The rule-based model can be used as a stand-alone logical core of a business application. However, in practice, this model should be somehow integrated with other models, and components of a heterogeneous application. Examples of integration discussed in this chapter include integration with business processes described with BPMN, as well as interfaces on the Java platforms. A number of approaches to the integration can be enumerated, with Model-View-Controller being a prime example.

Finally, the multilayer aspect of the rule language should be considered. A useful and expressive rule language should provide:

- rich, but well-defined semantics,
- formally defined syntax with clear logical interpretation,
- scalable visual representation, which allows for the visualization of many rules,
- machine readable encoding for model interchange and integration.

Using this criteria, it is easier to analyze selected languages.

### B. HEKATE APPROACH

Developing new effective rule methods is one of the main goals of the HEKATE project [18]. It aims at providing a complete rule modeling and implementation solution. Some of the main concepts behind it are:

- providing an integrated design and implementation process, thus
- closing the semantic gap, and
- automating the implementation, providing
- an executable solution, which includes
- an on-line formal analysis of the design, during the design.

To fulfill the goal HeKatE uses methods and tools in the areas of:

- knowledge representation, for visual design,
- knowledge translation, for automated implementation,
- knowledge analysis, for formal verification.

Currently, development within the project is focused on the:

- conceptual design method, ARD+ [19], which allows for attribute (vocabulary) specification,
- logical design, XTT+ [20], for rule design using a hybrid decision tables and tree based method.

For project progress see hekate.ia.agh.edu.pl

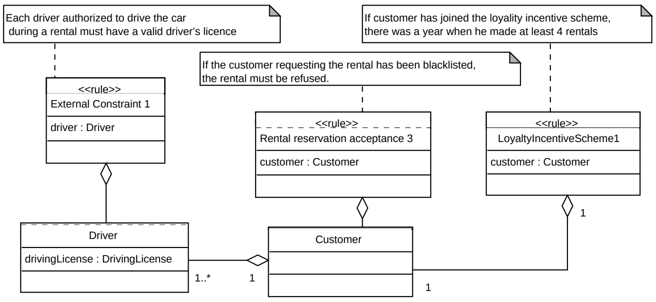
A principal idea in this approach is to model, represent, and store the logic behind the software (sometimes referred to as business logic) using advanced knowledge representation methods taken from KE. The logic is then encoded with the use of a declarative representation. The logic core would be then embedded into a business application or embedded control system. The remaining parts of the business or control applications, such as interfaces or presentation aspects, would be developed with classic object-oriented or procedural programming languages such as Java or C.

The work proposed in this paper aims at developing a UML-based representation for rules describing the logical core of an application. Such a representation would allow for direct rule modeling with standard UML tools.

## IV. REPRESENTING BUSINESS RULES IN UML

Rules are widely recognized as a critical technology for building various types of knowledge-based applications. Rules are also important in information systems engineering, where they constitute a natural way of expressing business application logic. The classical form of a rule is a plain, textual if-then-else statement defining a rule's condition and rule's conclusions. On the other hand, there are a few propositions of visual rules modeling, e.g. URML [3].

In response to the market gap for visual rules modeling and taking into account the great popularity of UML as a general purpose modeling language, we propose another UML-based approach to visual rules modeling. In this approach a rule is



Each driver authorized to drive the car
during a rental must have a valid driver's licence
If customer has joined the loyality incentive scheme,
there was a year when he made at least 4 rentals
If the customer requesting the rental has been blacklisted,
the rental must be refused.
<<rule>>

1
1

Fig. 1. Rules as classes

expressed as a class with a stereotype *rule*. Such a class has its own *state diagram*, which is used for expressing the rule's condition, conclusion and action.

Presented solution does not deal with business vocabulary modeling. It is assumed that all the business artifacts indispensable to business rules formulation are given in form of class diagrams. The precise definition of business vocabulary might be provided in form of other modeling languages e.g. SBVR.

### A. INTERPRETABLE LANGUAGE

In the presented approach, UML is used for modeling a system and creating schemes of the rules. Other important parts of the model, such as events, guards conditions, actions and conclusions, are written in an *interpretable language*. In the context of UML the natural choice of language for expressing e.g. guard conditions is OCL. It has appropriate expression power and proven syntax constructions suitable for expressing statements upon the UML abstracts. Since actions are also important parts of some kinds of rules, there is still a need for another language for actions modeling. OCL as a constraint language does not seem to be the optimal choice for this purpose. On the other hand, a situation in which there are several different languages for modeling several different aspects of the systems is not convenient. The optimal solution should consists of UML and one interpretable language having mechanisms allowing for the expression of all non-UML terms like constraints and actions. Such a language should be easy to use by rule architects, and it also needs to be understood by the rule interpreter. Because people for whom the idea of using UML and state diagrams appears attractive should not be forced to use a certain implementation of a rule engine, the question of an interpretable language to expressing non-UML model elements remains open. Thus, however, the OCL language seems to be useful in the context of specifying logical statements upon the UML terms, in this article, it is treated rather like one possible and well documented proposition, not like a part of the final method's specification.

### B. RULE DIAGRAMS

The rule diagram (Figure 1) is a UML class diagram containing the classes representing rules and some business terms that are directly used by the rules.

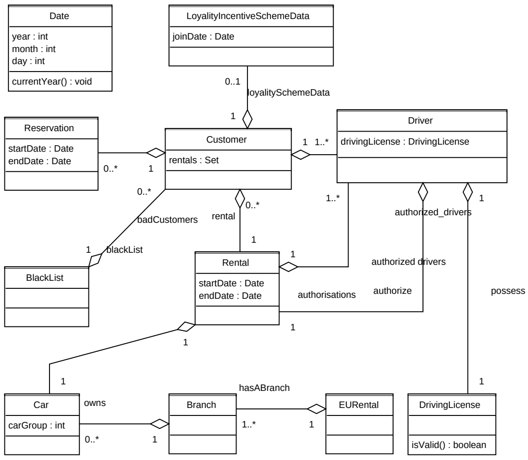

Fig. 2. Business vocabulary diagram

The main role of the rule diagram is to show relationships between rules and business terms. Attributes of the class representing a rule should cover all of the business artifacts indispensable for a condition evaluation, a conclusion drawing or an action being performed. Every rule should have a textual comment informing about its business source.

### C. BUSINESS VOCABULARY DIAGRAMS

Rules express some logical statements about terms and facts [2] that comes from the UML model. The set of all terms and facts will be called the *business vocabulary*. Thus, every UML diagram containing elements of *business vocabulary* which are neither *rule diagrams* nor *rule definition diagrams* associated with a rule will be called a *business vocabulary diagram*. The most popular kind of *business vocabulary diagram* is a class diagram (Figure 2).

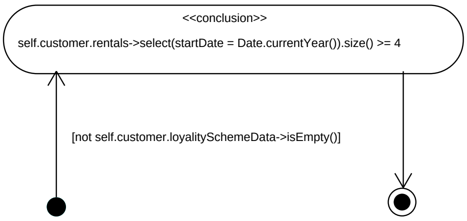
### D. RULE DEFINITION DIAGRAM

The definition of the rule has a form of a state diagram associated with the class representing the rule. This diagram will be called the *rule definition diagram*. The rule can be fired (can be applied) if, according to its *rule definition diagram*, it is able to change the state from a start state to a stop state. If there are some actions defined between a start state and a stop state, all of them have to be executed when the rule is triggered. If it is not possible for the rule to leave a start state, it means that the given rule is not active and cannot be executed at the moment. Following the conceptual rule classification [15], [3] we would like to define three types of business rules: Integrity Business Rules, Derivation Business Rules and Reactive Business Rules. The Reactive Business Rules incorporates Production Business Rules and ECA Business Rules [21].

The integrity rule, represented here as an integrity constraint, consists of a predicate function given producing a boolean value on the output. A very popular language for formulating constraints and expressing business knowledge in UML models is OCL (Object Constraint Language). It allows for precise formulation properties of relations between classes

[self.driver.authorizations->size() > 0 implies self.driver.drivingLicense.isValid]

Fig. 3. Integrity business rule



<<conclusion>>
self.customer.rentals->select(startDate = Date.currentYear()).size() >= 4
[not self.customer.loyalitySchemeData->isEmpty()]

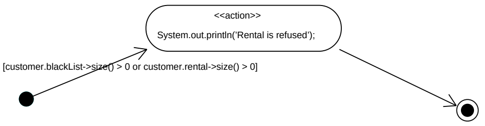
Fig. 4. Derivation business rule

and objects. In fact, a guard condition may be formulated in any language understood by a rule interpreter; however, for the sake of examples' clarity, the OCL language is preferred. In the proposed approach the semantics of an integrity rule is given by a simple start-stop diagram containing one guard condition. Obviously, a condition of the integrity rule is met if the rule object changes its state to stop. On figure 3 an example of integrity rule is shown. The integrity constraint expresses the fact that the driver's driving license is valid if it has at least one authorization. The source of this rule as well as other presented examples comes from broadly known in literature as the EU-Rent case study [17], [15], [3] .

Derivation business rules have conditions and conclusions. Depending on the positive evaluation of the condition, a conclusion is drawn. In our approach, a condition is represented by a guard expression, whilst the conclusion is the action performed in the action state followed by a guard expression. The action state should have a stereotype *conclusion*. The action should have the form of a logical expression in a language understood by a rules interpreter. The action's logical expression represents a new knowledge derived from the existing facts (subjects of conditions) in the system. The presented example (figure 4) shows derivation rule describing the fact that if a customer has joined the loyalty incentive scheme, he must have made four rentals within the year. The same as previously the source of the rule is the EU-Rent case study.

Reactive business rules may have conditions, triggering events and actions. For the given rule, one condition or one triggering event (at least one is obligatory) and one action should be defined. In general, such a kind of rule allows for the modeling of an event-condition-action behavioral pattern, in which execution of the action is preceded by event triggering and guard condition evaluation. The absence of a condition is allowed only if a triggering event is defined, and inversely, a triggering event is not required if only a condition is defined. Thus, there are three possible subtypes of the reactive business rules:

- reactive business rule with a non-empty event and a non-empty condition
- reactive business rule with a non-empty event and an empty condition
- reactive business rule with an empty event and a non-empty condition



<<action>>
System.out.println('Rental is refused');
[customer.blackList->size() > 0 or customer.rental->size() > 0]

Fig. 5. Reactive business rule

The first kind of rule is triggered by the event only if a guard condition is true. The second one models the executing action in response to the raised event, whilst the third kind of rule models the action execution as a result of changes in the system that make the guard condition true. The condition is modeled as a guard expression; thus, it may have any boolean form suitable for a rule interpreter (OCL is the preferred language). The action state in the *rule definition diagram* has a stereotype *action*. Whilst the first two kinds of reactive rules have a semantics of ECA Rules, the third kind of the reactive rules has a semantics borrowed from production rules i.e. an action is executed as soon as the condition becomes true [21]. On figure 5 an example of the third kind of reactive business rule is shown. According to the rule, if a customer is on a black list or he has already a rental, the specified action is executed. In this particular case the action writes the message informing that the rental is (or will be) refused.

## V. CONCLUSIONS

In this paper, the main assumptions of a new approach to representing business rules in UML has been presented. This approach allows for modeling business rules as UML state diagrams. It makes modeling rules similar to modeling system behavior, which may shorten the time required for modeling the system. A rule is represented by a well-known concept of a stereotyped class; thus, there is no need to define any new UML artifacts except for stereotypes. Consequently, almost every UML 2.0 compatible modeler might be used for rule modeling. It is easy to find the business vocabulary since it is explicitly shown in UML diagrams. With the help of stereotyped rules, the well known statechart concepts, such as action, guard and event, retain as much as possible from their original meaning. E.g. since applying the rule is represented by following the transitions of an state diagram, a guard concept remains a kind of expression deciding whether we may apply the rule, i.e. whether we may follow the transition.

Since some of a rule's components are written in OCL or other interpretable languages, rule modeling may seem to be a little bit harder than using a graphical notation. On the other hand, such languages are usually quite simple; e.g. in OCL some more sophisticated constructions like nested collections has been abandoned [22]. Thus, after getting a bit of practice in the chosen language, working with rules written in UML and state diagrams should not be a problem.

Regardless of the lack of a strictly defined language for actions and guards expressions, some experiments in these areas are being conducted. The aim of the authors is to propose a complete *xtUML* solution [23], which would allow to execute rule–based model on appropriate rule–based runtime engine as well as provide model building guidelines to facilitate modeling process. Since key role of UML statecharts in existing *xtUML* solutions [24], [25] a statechart form of a rule cannot be underestimated. A semi–automatic transition from *SBVR* textual form to *business vocabulary diagram* and *rules diagram* is also considered. Using *SBVR* would allow for easy capturing business vocabulary and business rules, and theirs validation and preliminary authorization. In the context of *MDA* [26] such transition will correspond to transformation a computation independent model *(CIM)* to platform independent model (*PIM*). The next transition, i.e. from *PIM* to *PSM*, will be done by rule–based runtime engine.

The work presented here will be integrated within the *HeKatE* approach briefly discussed in Sect. III-B. The basic idea is to model a rule-based logical application core with the visual representation presented here. The OCL expression can be replaced by Prolog-based rules, since Prolog is the language of choice for the HeKatE prototype implementation [27]. Since HeKatE aims at designing applications using the Model-View-Controller pattern, using an UML-based representation greatly improves the possibility of integration with the UML-based view design. Another area of intensive research is the formal analysis of the rule-based model. It is hoped that HeKatE verification methods could be extended to cover the UML-based model.

**Acknowledgements** The paper is supported by the HeKatE Project funded from 2007–2009 resources for science as a research project.

***Abstract*—In this paper our method of discovering data sequences in the time series is presented. Two major approaches to this topic are considered. The first one, when we need to judge whether a given series is similar to any of the known patterns and the second one when there is a necessity to find how many times within long series a defined pattern occurs. In both cases the main problem is to recognize pattern occurrence(s), but the distinction is essential because of the time frame within which identification process is carried on. The proposed method is based on the usage of multilayered feed-forward neural network. Effectiveness of the method is tested in the domain of financial analysis but its adaptation to almost any kind of sequences data can be done easily.**

## I. Introduction

THE issue of discovering data sequences has been heavily investigated by the scientists of different disciplines for many years. Despite this fact there is no doubt the issue is still up-to-date. Statisticians, economists, weather forecasters, operating system administrators – all of them, in their daily routine, deal with many kind of sequences. Specifically, in the domain of finance analysis there are patterns defined by the *Technical Analysis* (TA). Recognition of some of this patterns among quotation data triggers investors buy or sell decisions regarding examined stock. So it is crucial for the people who play the stock exchange to recognize patterns when they are really formed by stock exchange quotations. Because of that there is a need to provide trustworthy method of finding defined sequences. Lately, discovery of patterns in time series plays very important role in the area of bioinformatics [2] also.

In this paper a method of discovering data sequences in the domain of financial analysis is presented but its adaptation to any other kind of sequences data can be easily done. This method uses multilayered feed-forward neural network to recognize the technical analysis patterns. All experiments which aim was evaluation of the method efficiency, are done by the use of data which come from the Warsaw Stock Market.

The paper consists of five sections. The next one describes different approaches to the problem of sequence data discovery. Our method is introduced in the third section. The next one presents the results of the experiments. some of them were performed by the use of the method in artificial environment simulating the Warsaw Stock Market. The final section presents conclusion and future plans.

## II. Related Works

Methods of pattern discovery in time series sequences in the financial analysis are closely connected to econometrics which can shortly be defined as the branch of economy that deals with defining models of different systems by the use of mathematics and statistics. Some of these models are created by economists in order to make analysis of data or to make a prediction of future stock exchange quotations. The problem is to prepare a good model, where ‘good’ means the model which takes into consideration all important relations which can be distinguished in the modeled reality. This is of course not easy. Often some relations become important under certain circumstances when others turn out to be useless. To comply with all defined requirements there is a need to prepare accurate model which can consist of even hundreds of equations. Such approach causes difficulties in its comprehensibility by the user but also in a computer implementation. That is why scientists look for other methods of discovering patterns in time series.

Fu and others [3] describe a method which uses *perceptually important points* (PIPs) of the graph to compare it with other graph. By PIPs are assumed points that are significant for the shape of the diagram to which they belong. Authors presented a method for finding PIPs and algorithms for determining the distance between points from two different graphs. The idea introduced by them reflects the human-like way of thinking (people usually do not remember all the points which build the graph – they keep just more significant ones in mind and then compare them to the other important points). The advantage of this algorithm is its easy implementation. Despite of that fact, there is a big disadvantage of this  method of discovering sequences. A problem is with series which have high amplitude between two adjacent points – higher than some PIPs can place between those two points. It leads to the problem, when we have PIPs identified not among whole series but mainly in some its parts. Similar approach is applied in the paper [1], where a special metrics of similarity between a pattern in question and a given pattern is designed.

978-83-60810-14-9/08/$25.00 © 2008 IEEE

The usage of rules and fuzzy rules in searching time sequence patterns are considered as well. The examples can be found in [7] and [3].

Many researches are made by the use of machine learning methods in order to retrieve some predefined technical analysis patterns within the time series, e.g. [5].

Very popular approach is an application of Kohonen's neural network to cluster patterns retrieved among stock exchange quotations. The examples of SOM networks can be found in [4] and [6]. Authors admitted that this kind of network in their experiments showed good results in searching for patterns of main trend of quotations. They also consider this approach as not ideal for making predictions of turning points among quotations.

Other approach which used neural networks is presented in [5]. The method described in this paper can be shortly characterized as follows. Each of the patterns is memorized as a chart in the computers memory within some specified boundaries. Next, neural network (NN) is trained of chosen pattern. After training, the network is able to recognize whether a given series is similar to the pattern it was trained. To become results more trustworthy the author suggested to use two different NNs for a recognition of one pattern (the average of both results was treated as a final result). What is important, both neural networks had to be trained using different sets of learning patterns. The method based on chart pattern recognition in time sequence is proposed in  as well.

## III. The Details of the Method

Our method of discovering data sequences in time series is also based on the neural network which has feedback connections. It is trained with back propagation learning algorithm. The whole idea is simple. For each pattern of technical analysis one dedicated neural network exists which is trained to recognize it. The architecture of the network used in the experiments is presented in Fig 1. The network is fully connected. Each of the inputs represents exactly one value of a stock exchange quotation. In this figure *N* describes the number of input neurons (which was set to 27 in the experiments), *L* represents the number of hidden neurons (it was equal to 14 in the experiments) and *M* is the number of output neurons (that was set to 1). The response of the output neuron indicates whether a given series is recognized as a pattern that the network was trained to recognize.

To be more precise it is worth mentioning, that sigmoidal function was used as an activation function. This means that the value returned by the output neuron is in the range (0; 1).

The output value closer to the upper bound of the range was interpreted as a given series was similar to the series from training set. When the continuous range of values is allowed the obvious question is how to make a binary decision if the series represents a pattern in question or not? The answer is not so well-defined. It depends on what the parameters of the network training were set, what the stop criteria of learning algorithm were adjusted or what kind of activation function was chosen. In the experiments after preliminary experiments this threshold value was set to 0.85. In the Fig. 2 there are presented main steps of the proposed method of discovering data sequences. In the first step training patterns for neural network are prepared. It is important to provide representative patterns. It is a good practice that some of them should be multiplied within the training set (with added noise).

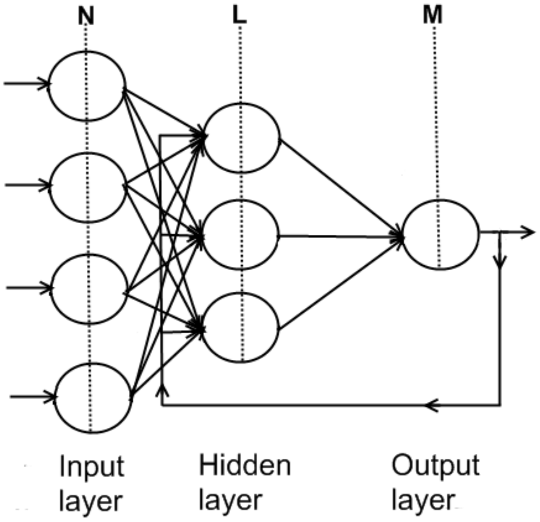

Fig. 1. The neural network architecture used in the experiments

```
PrepareTrainingPatterns()//define training set
NormalizePatterns()//prepare normalization
TrainNeuralNetwork()//training process
SmoothInputSeries()//step is optional
NormalizeInputSeries()//series' normalization
ProceedtheSeries()//Classifying decision
```

Fig. 2. The algorithm of discovering technical analysis patterns in time series

Adding similar learning patterns ensures that the neural network after the training process will have better generalization skills. The next step (normalization of patterns) is needed in order to reduce all defined patterns to a common range. It is important, because in other case series defined on different ranges could favor some patterns with higher values. Each value *s* from a series *S* is normalized according to the equation (1). In the next step the neural network is trained. The training process should be continued until an output value of the network reaches satisfied value (usually below defined threshold).

$$s_{norm,i} = \frac{s_i - \min(S)}{\max(S) - \min(S)}, \qquad (1)$$

where: $s_i \in S$, $\min(S)$ – minimum, $\max(S)$ – maximum.

In the next step a given series, in order to be processed by the neural network, can be smoothed. It is especially essential when a series consists of any abnormal values. The aim of smoothing is to reduce the number of points where the amplitude between two adjacent points in the chart is extremely high. An example of smoothing result is presented in Fig. 3. Because this method changes the original points in a chart it is recommended to use it only if needed.

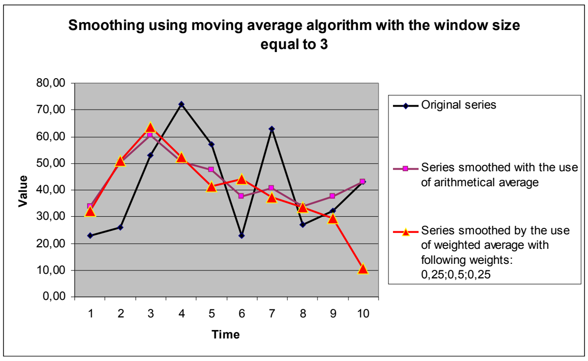

Fig. 3. An example of smoothed series

Because of the fact that patterns used during a training process were normalized, similar action has to be done after an optional smoothing of the series. It is crucial to have series defined on the same range as training patterns are. Otherwise the result cannot be reliable. The final step relies on processing values from the series given to the input layer of the network and calculating its output.

The algorithm shown in Fig. 2 can be easily used when the series (*P*) in question is of the same length as the patterns from the training set (series *S*).

The problem raises when the lengths are different. Having patterns longer than a series in a training set leads to the necessity of expanding a given series (i.e. by adding some additional points between existing ones). Depending on the shape of series which needs to be stretched, different methods should be used. A simple approach can be realized by the use of linear function to calculate values of extra points while more complex can demand the usage of more sophisticated curves in order to determine points values (such as Bezier curves).

The other case that should be considered is when a given series *P* is longer than the number of inputs in the neural network (a length of training patterns). Then a shortening of examined series should be done. In this case to solve this problem the following solutions can be suggested:

a) Shortening by a deletion of surplus points,

b) Shortening by a determining only perceptually important points (based on the idea presented in [3]),

c) Shortening by compressing a series.

The first technique is based on the assumption that some points from a time series can be removed without affecting its shape too much, which is especially true if concerned are series taken from the real stock exchange. In this case each subseries formed as hop or valley on the chart consists of many points which values change gradually. Removing one point from such short subseries will not affect a whole form. The simplest way to determine which points should be removed is to count how many of them is surplus ($s_p$). Afterwards the number of all points ($m$) in the series should be divided by $s_p$ resulting in the steps ($k$) which should be used while designating indexes of surplus points within a given series. Fig. 5 presents the effect of the usage of the mentioned method to the series which is depicted in the Fig. 4.

The second technique is to find within a series exactly $n$ characteristic points (called perceptually important points -*PIP*). Other points, which were not considered as characteristic points should be removed.

The last technique of shortening series of length $m$ to become one with $n$ values is its compressing. The compression can be done by specifying $n$ segments in a given series and all values within each segment are substituted by one value. This value is an arithmetic or a weighted average of the substituted values (this method is a little similar to smoothing). The exemplary results are shown in Fig. 6.

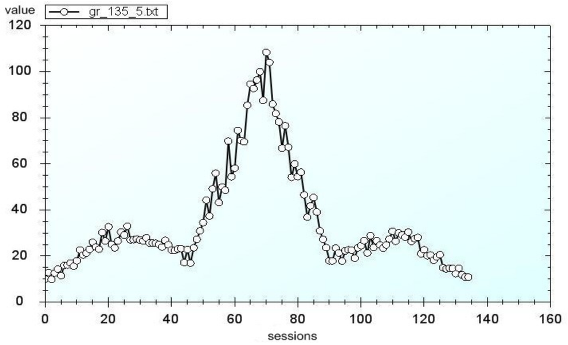

Fig. 4. The chart of 'Head and shoulder' pattern made of 135 points

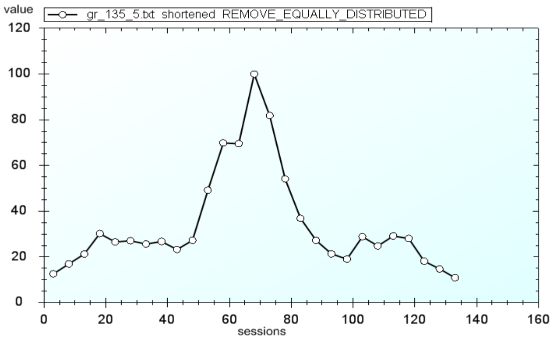

Fig. 5. The chart of 'Head and shoulder' pattern shortened to 27 points using a deletion of surplus points

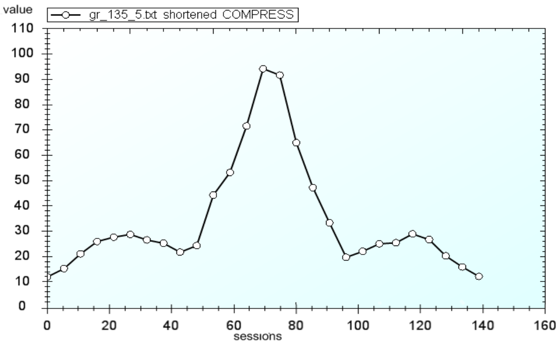

Fig. 6. The chart 'Head and shoulder' pattern shortened to 27 points using a compression

It is important to emphasize that all described previously issues were adequate to recognize a whole series as a pattern. The other case is when we want to find how many times an interesting pattern was repeated among the whole series (this operation can only be done, when a series is longer then training patterns). One approach to this problem is to specify start index and the number which represents a value of length step (which will be used for moving the window from the start index). Next, moving a window (which has the length equal to the number of input neurons of the neural network) the main series can be cut into subseries with a defined step from the start index. Then, each subseries should be checked whether it is similar to the pattern trained by the network. The problem becomes more complex when the length of subseries differs from the length of training patterns. We can consider checking the subseries of length from 2 up to *m* (where *m* represents the length of whole series).

In this case the problem occurs that computational complexity becomes $O(m^2)$ . To reduce the number of subseries that should be checked, similarly to [3] a function *TC* (given by eq. (2)) is used. Its task is to control a length of a series which should be processed. This function returns a smaller value when the length of the series is closer to the preferred length. In eq. (2) *dlen* is the desired length of series (which in our case should be equal to the number of input neurons in the network), *slen* means the series length. Additionally, *dlc* parameter can be adjusted according to the steepy of the function which is used. Only for the points which are below specified threshold (i.e. $\lambda = 0.2$ ) on the *TC* function graph the checking should be performed.

$$TC(slen, dlen) = 1 - \exp^{-(d_1/\theta_1)^2}, \qquad (2)$$

where $d_1 = slen - dlen$ , $\theta_1 = dlen/dlc$

Fig. 7 illustrates how on the basis of *TC* function the lengths of subseries are checked. The following values of parameters were used: $dlen = 180$ , $dlc = 2$ , as *slen* all values of series were provided. For assumed value $\lambda = 0.2$ red bolded line marks the range of the lengths to be checked.

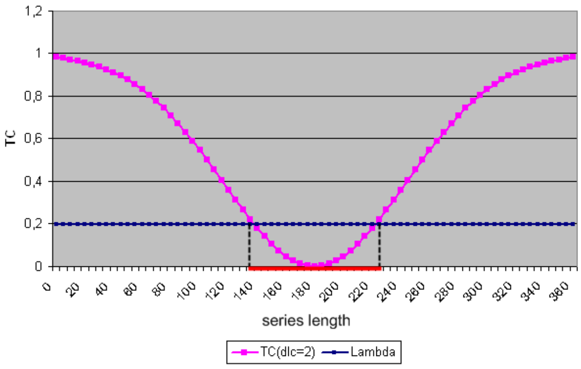

Fig. 7. Example of *TC* function usage

## IV. Experimental Results

In the first experiment the shortening methods of series were evaluated in order to choose the best one. The network was trained to recognize the technical analysis pattern 'head and shoulder'. The training set was prepared where each training pattern had the length 27 (the number of neural network inputs). It consists of positive training patterns (representing 'head and shoulder' form) as well as negative ones (that do not represent this form). The network was trained with an error equal to 0.001.

To evaluate the method of a shortening series the testing set was created. It contained: 30 artificial series of 'head and shoulder' pattern with the length equal to 54; 81 and 135 (10 of each length), 10 series of 'triple top', 'double top' and some randomly chosen patterns, finally some series of archive stock (GPW) exchange quotations (which were manually annotated by the authors whether they represent the pattern in question - 'head and shoulder' form or not. In these annotations the value 1 informs that a given time series represents a given pattern, value 0 means that it does not).

In the test it was arbitrary assumed that the network output equal or greater than 0.9 represents the neural network recognition of the pattern in question.

For each pattern from the testing set an *error* between desired value of the output and the one returned by the network was used to evaluate the results (absolute value of subtraction of mentioned elements). The average error calculated for each method is the basis of comparison. The results are shown in Table I.

Table I
Comparison of shortening techniques

| Shortening technique | Average error | Deviation of average error |
|---|---|---|
| **Surplus points** | 0.0672 | 0.1233 |
| **Compression** | 0.0697 | 0.1409 |
| **PIP** | 0.0936 | 0.1632 |

It is easy to notice that the best results are achieved by the method *surplus points*. The results in Table II show that it performs discoveries of patterns in the best way, as well. Effectiveness of patterns discovering was calculated as a relative number of properly recognized patterns to the number of all patterns.

Table II.
Effectiveness of discovering patterns using different shortening techniques

| Shortening technique | Effectiveness | | |
|---|---|---|---|
| | artificial series | GPW series | All series |
| **Surplus points** | 1.0000 | 0.8730 | 0.9624 |
| **Compression** | 1.0000 | 0.8571 | 0.9577 |
| **PIP** | 0.8400 | 0.8413 | 0.8404 |

Based of an analysis of the results we can draw the conclusion that the proposed method of checking whether a given long series (longer than the number of inputs in the network) is similar to a chosen pattern returns very good outcome. For all presented techniques of shortening we can observe that effectiveness is greater than 80%, considering two best techniques we received even better result (~95% of properly classified series).

The aim of the next experiment was to check whether the methods of discovering patterns are sensitive to the length of tested subseries. For the test purpose one long series was chosen. It was created on the basis of stock exchange quotations of the stock market 01NFI from 150 sessions (from 14 August 2006 till 16 March 2007). The algorithm of discovering patterns has run twice. In the first run the length of the window varied from 2 to 100. In the second one the *TC* function was applied. It allowed to limit the number of time sequence lengths to be checked (the range from 22 to 32 for the network with 27 input neurons). The results are presented in [8]. The blue line represents the widths of window for which patterns could be found in the given series without using *TC* function, while the pink line shows the number of discovered patterns with the use of *TC* function. It can be easily notice that its usage really limits the range of widths to the (21; 32). The fact, that for the widths of window in the range 60 – 69 so high number of patterns were found can be a surprise. But it is nothing extraordinary. We have to keep in mind, that the neural network with well performed preprocessing algorithm (which properly shortens or expands series) can effectively recognize patterns regardless of the length of checked series. The obtained results show that the method is not very sensitive to the length of the tested time series.

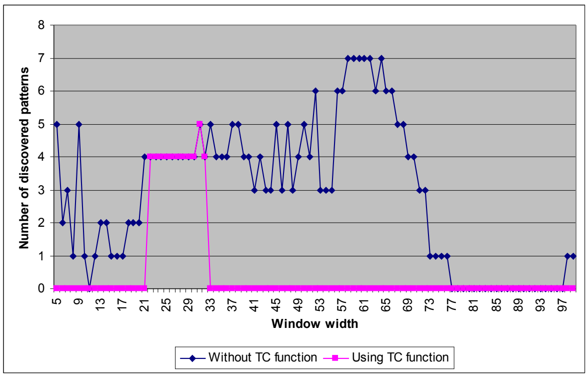

Fig. 8. The number of discovered patterns in relation to the window width

In Fig. 9 and Fig 10 examples of the series found during the experiment are presented (the red line represents a shape of the chart ‘head and shoulder’).

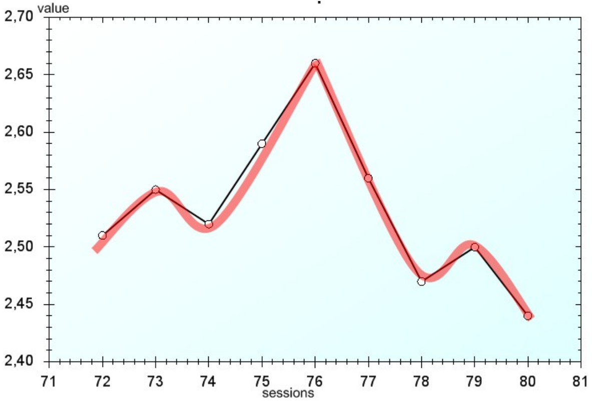

Fig. 9. Stock exchange quotations of 01NFI formed from 9 sessions identified as a 'head and shoulder' pattern

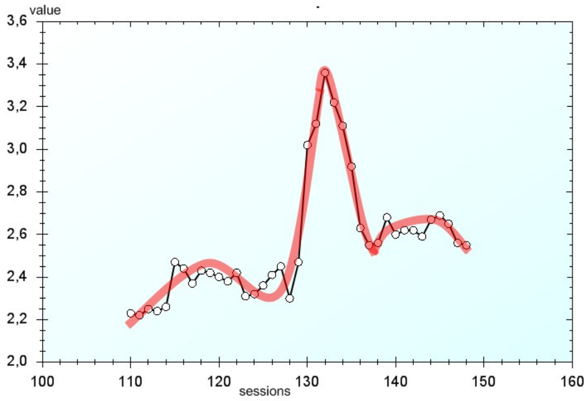

Fig 10. Stock exchange quotations of 01NFI formed from 39 sessions identified as a 'head and shoulder' pattern

As it was mentioned before, the method of discovering data sequences in a time series was tested also in the artificial environment – multi-agent stock exchange system which is presented in . In this system agents representing real investors are evolved by genetic algorithm. Each agent is described by the set of its coefficients defining its behavior. The aim of the system is to find the set of agents (with the best suited values of coefficients) who will be able to generate the stock price movement similar to the existing one in the real stock. Evolution takes place in steps which are called generations. After each generation the individuals (the set of agents in our case) are evaluated in terms of fitness value that informs about a quality of an individual. The better is the fitness value, the better is the set of agents (individual). Originally the system had an naïve algorithm (assigned as *old*) of identification which investments should be done by an agent. Then this algorithm was substituted by the method of discovering time series sequences presented in this paper (called *new*). The comparison of the results with the usage of both methods is shown in Table III.

An analysis of the results in the table clearly shows that the application of the new method improves the value of agents’ fitness. The old algorithm returned good results only in the third test. It means that stock prices generated by the agents using newer decision algorithm are much more similar to the real ones. However, because a genetic algorithm has embedded randomness in its nature, more tests are required to fully evaluate the results which were not possible to perform now because of the duration of one experiment.

TABLE III.
THE COMPARISON OF NEW AND OLD ALGORITHM OF TAKING DECISION BY THE AGENTS

| | **Average fitness of all individuals in all generations** | | **Fitness of the best individual in the experiment** | |
|---|---|---|---|---|
| **Nr** | Decision algorithm | | | |
| | *old* | *new* | *old* | *new* |
| 1 | 0.12 | 0.25 | 0.47 | 0.51 |
| 2 | -0.01 | 0.19 | 0.43 | 0.45 |
| 3 | 0.11 | 0.05 | 0.59 | 0.50 |
| 4 | 0.02 | 0.03 | 0.42 | 0.42 |

It is worth mentioning that the platform on which tests were performed should be upgraded in some places (i.e.

agents should start with an amount of money adequate to the number of stocks which are on the market, genetic algorithm should not create a specified number of new agents as the result of mutation operator after generation, etc.). For the purpose of this test no upgrades were performed (only the mentioned change of the decision algorithm took place). Authors suspect, that even better results could be gained by the use of newer discovering patterns method if some patches to the existing platform were provided. Performed experiment was a first trial of integration and has shown that there is still some place for improvements.

## V. Conclusion and Future Plans

The aim of the research presented in this paper was to design of an effective method which is able to properly recognize a given pattern in the time series data. Based on the results of experiments we can draw the conclusion that the proposed method can properly discover the sequences of data within time series. Moreover, when the network is trained the process of recognition is easy and fast. The network response arrives immediately. The only difficulty can be the network training – the choice of appropriate training patterns and the parameters of training, but after some trials and getting more experience this problem disappears.

However the results are promising, there are still improvements possible, for instance other optimization technique of finding the series of shorter or longer widths than the number of input neurons in the network could be proposed. As it was shown *TC* function limits the number of searched widths but it is not the ideal solution, because some proper patterns can be omitted. Some improvements can be made in the test platform, as well. Some upgrades in this system can have an impact on the trustworthy of the performed tests. All mentioned problems and places where improvements can be made are great opportunity to continue studies on the proposed discovering technical analysis pattern method.

***Abstract*—The Frequency Assignment is a very important task in the planning of the GSM networks, and it still continues to be a critical task for current (and future) mobile communication operators. In this work we present a hybrid Differential Evolution (DE) algorithm to solve a real-world instance of the Frequency Assignment problem. We present a detailed explanation about the hybridization method applied to DE in order to make it more efficient. The results that are shown use accurate interference information. That information was also adopted by other researchers and it represents a real GSM network, granting, therefore, an extremely important applicability. Furthermore, we have analyzed and compared our approach with other algorithms, obtaining good results.**

## I. Introduction

THE Frequency Assignment problem (FAP) represents an important task in the GSM networks *(Global System for Mobile)*. These networks are very used in the telecommunication area (by mid 2006 GSM services were used by more than 1.8 billion subscribers across 210 countries, representing approximately 77% of the world cellular market) [1].

The FAP problem is an NP-hard problem, therefore approaches using metaheuristic algorithms [2] have proven that they are a viable choice in its resolution.

The main goal of this problem is to be able to obtain an efficient use of the scarcely available radio spectrum on a network. The available frequency band is assigned into channels (or frequencies) which have to be allocated to the transceivers (TRXs) installed in each base station of the network. Both these components have an important role in the definition of this problem. This work is focused on the concepts and models used by the current GSM frequency planning [3]. Moreover, we adopted a developed formulation that takes advantage of realistic and accurate interference information from a real-world GSM network [4].

Our approach presented here uses the Differential Evolution (DE) algorithm as the fundamental step to solve this specific problem. Also, this algorithm w as hybridized with a Local Search method, as well as other features. Therefore, several modifications have been proposed to the original DE to improve its performance further. Also, as mentioned previously to this specific problem a Local Search (LS) method was added in order to be possible to obtain better results to solve this specific real-world FAP problem. It was also applied a method to guarantee that all obtained solutions do not have the most severe penalty, which influences the frequencies assignation inside a same sector of the network.

Our study was focused in a real-world instance of a GSM network named Denver which represents the city of Denver in the USA. It uses 711 sectors with 2612 transceivers (TRXs) installed. For each TRX the same 18 channels are available, representing the available frequencies for the assignation. As we have said, both these elements are the key elements of the problem, influencing directly the codification of the problem and the evaluation of the quality of the solutions accomplished. In a GSM network the TRXs give support to communications, making the conversion between the digital traffic data on the network side and radio communication between the mobile terminal and the GSM network [5].

This paper is structured as follows. In the next section we provide some details about the frequency assignment problem in the GSM networks. Section III describes the algorithm proposed and the hybridization methods applied to it. The results of the experiments are analyzed in Section IV. Finally, conclusions are discussed in the last section.

## II. Frequency Assignment in GSM Networks

In the following subsections we will first give a brief description about the elements present in a GSM network that are fundamental to the Frequency Assignment problem (FAP). Finally it will be presented the mathematical formulation followed by this work.

### *A. The FAP Problem within a GSM System*

A GSM network has several components, but the most important ones, to understand the frequency planning, are the antennas, which are more known as base station transceivers (BTSs) and the transceivers (or TRXs). Therefore, transceivers are the main element to be considered. A BTS can be viewed as a set of TRXs, which are organized in sectors. The

978-83-60810-14-9/08/$25.00 © 2008 IEEE

TRX is the physical equipment responsible for providing the communications between the mobile terminal and the GSM network.

The frequency assignment problem arises because the number of available frequencies (or channels) to be assigned to each TRX is very scarce. Therefore, the available frequencies need to be reused by many transceivers of the network [3][6]. The reuse of the frequencies can compromise the quality of the service of the network. Hence, it is extremely important to make an adequate reuse of the frequencies to the several TRXs, in such a way that the total sum of the interferences occurring in the network needs to be minimized.

Consequently, it becomes extremely important to quantify the interferences provoked by an assignation of a frequency to a TRX and its influence on the remaining TRXs of the other sectors of the network. To quantify this value an *interference matrix* is used, denoted *M* [7]. Each element *M(i,j)* of *M* represents the degradation of the network quality if sector *i* and *j* operate with the same frequency value. This represents the *co-channel* interferences. It also need to be considered the *adjacent-channel* interferences, which occurs when two TRXs, in two different sectors, operate on adjacent channels (i.e., when one TRX operates on channel *f* and the other on channel *f+1* or *f–1*). Therefore, the interference matrix assumes an import role in the formulation of the FAP problem, which intents to minimize the sum of interferences occurring in the network. Thus, it is only possible by using the interference matrix to compute the cost function (see Eq. 1).

### B. Mathematical Formulation

Let $T = \{t_1, t_2, ..., t_n\}$ be a set of *n* transceivers (TRXs), and let $F_i = \{f_{i1}, \dots, f_{ik}\} \subset N$ be the set of valid frequencies that can be assigned to a transceiver $t_i \in T, i=1,\dots,n$ (the cardinality of $F_i$ could be different to each TRX). Furthermore, let $S = \{S_1, S_2, ..., S_m\}$ be a set of given *sectors* (or cells) of cardinality *m*. Each transceiver $t_i \in T$ is installed in exactly one of the *m* sectors and is denoted as $s(t_i) \in S.$ It is also necessary the interference matrix, *M*, defined as: $M = \{(\mu_{ij}, \sigma_{ij})\}_{mxm}$. The two elements $\mu_{ij}$ and $\sigma_{ij}$ of a matrix entry $M(i,j) = (\mu_{ij}, \sigma_{ij})$ are numerical values and they represent the mean and standard deviation respectively, of a Gaussian probability distribution used to quantify the interferences on the GSM network when sector *i* and *j* operate on a same frequency. Therefore, the higher the mean value is, the lower interferences are, and thus it will have a superior communication quality.

A solution to the problem lies in assigning to all the TRXs $(t_i)$ a valid frequency from its domain $(F_i)$, in order to minimize the following cost function:

$$C(p) = \sum_{t \in T} \sum_{u \in T, u \neq t} C_{sig}(p, t, u) \qquad (1)$$

where $C_{sig}$ will compute the *co-channel* interferences $(C_{co})$ and the *adjacent-channel* interferences $(C_{adj})$ for all sector *t* and *u*, in which the transceivers *t* and *u* are installed, that is, *s(t)* and *s(u)*, respectively. $p \in F_1 x F2 x \dots x F_n$ denotes a solution (or frequency plan), where $p(t_i) \in F_i$ is the frequency assigned to the transceiver $t_i$. Moreover, $\mu_{s_t s_u}$ and $\sigma_{s_t s_u}$ are the interference matrix values at the entry $M(s_t,s_u)$ for the sectors $s_t$ and $s_u$ . In order to obtain the $C_{sig}$ cost from equation 1, the following conditions are considered:

$$\begin{cases} k & if\ s_t = s_u, |p(t) - p(u)| < 2 \\ c_{co}(\mu_{s_t s_u}, \sigma_{s_t s_u}) & if\ s_t \neq s_u, \mu_{s_t s_u} > 0, |p(t) - p(u)| = 0 \\ c_{adj}(\mu_{s_t s_u}, \sigma_{s_t s_u}) & if\ s_t \neq s_u, \mu_{s_t s_u} > 0, |p(t) - p(u)| = 1 \\ 0 & otherwise \end{cases} \qquad (2)$$

where *K* is a very large value, defined in the configuration files of the network. The *K* value makes it undesirable to allocate the same or adjacent frequencies to TRXs that are installed in the same sector. In our approach to solve this problem, this restriction was incorporated in the creation of the new solution (frequency plan) produced by the DE algorithm. Therefore, we assure that the solution does not have this severe penalty, which causes the most undesirable interferences (see section III).

## III. Differential Evolution Algorithm

This section is devoted to present the DE algorithm and also its hybridization made by applying a Local Search (LS) method. We also explain the optimization made in the assignment of frequencies to TRXs that are inside the same sector.

### A. Original DE Algorithm

Differential Evolution is an Evolutionary Algorithm proposed by Storn and Price, and has been used successfully to solve optimization problems [8]. The DE has three major steps which are executed in each generation. They are the generation, evaluation and selection, each one involving different operations. These three steps are performed until a stop criterion is not reached. In DE each individual of the current population (named $x_{target}$ or $x_i$) will compete with a new individual $(x_{trial})$ generated by a mutation factor. An individual represents a solution, and it is encoded as a vector of integer values (of frequencies in our case). The DE starts with the creation of an initial population, normally at random.

New individuals are created applying the mutation and the recombination operators. At each generation, for each individual of the population is created a new solution $(x_{trial})$, using a weighted vector difference between two other individuals, selected randomly from the current population. This new individual is obtained e.g. using the equation 3, whose DE scheme name is DE/rand/1/$\beta$, where $\beta$ represents the crossover scheme that can be binomial *(bin)* or exponential *(exp)*. Different classifications of DE schemes are also available [9]. The available schemes use the notation DE/α/γ/β. The α represents the way in which individuals (necessary to obtain the new weighted differences vector, that is, the *trial* individual) are selected from the current population. They can be selected randomly *(rand)* or as the best individual from the current population *(best)*. The γ is the value of difference vector pairs used, which normally are 1 or 2.

$$x_{trial}=x^{t}_{r3}+F\left(x^{t}_{r1}-x^{t}_{r2}\right) \qquad (3)$$

Equation 3 is used to create a new solution, where *r1≠r2≠r3≠i* are used as indices to index each parent vector. F value is the scaling factor, which controls the differential variation (mutation).

Besides the F parameter, it is also necessary the crossover parameter (CR). This last parameter represents a probability that influences the generation of the *trial* individual, by controlling the amount of genes which will be changed from the *target* individual to the new one (after apply the equation 3). It is also necessary to guaranty that all the genes changed will have a value inside the permitted limits. This corresponds to a very important step, in order to guaranty the creation of a valid solution. This characteristic was implemented by using a list of frequency values, containing all the ones that are not been used. Therefore they are available to be assigned to other TRX inside the same sector (each sector of this network problem has one list). Therefore, every time a TRX value is changed, its new value, which is generated by the DE (line 10, Fig. 2), is selected from that list containing the frequencies. This way we guaranty that the values are always inside the valid boundary values.

Table I.
Formulation for the different schemes of the DE algorithm

| Sheme Name | DE mutation definition |
|---|---|
| DE/Rand/1/*β* | $x^{t}_{i}=x^{t}_{r3}+F\left(x^{t}_{r1}-x^{t}_{r2}\right)$ |
| DE/Best/1/*β* | $x^{t}_{i}=x^{t}_{best}+F\left(x^{t}_{r1}-x^{t}_{r2}\right)$ |
| DE/Rand/2/*β* | $x^{t}_{i}=x^{t}_{r5}+F\left(x^{t}_{r1}+x^{t}_{r2}-x^{t}_{r3}-x^{t}_{r4}\right)$ |
| DE/Best/2/*β* | $x^{t}_{i}=x^{t}_{best}+F\left(x^{t}_{r1}+x^{t}_{r2}-x^{t}_{r3}-x^{t}_{r4}\right)$ |
| DE/RandToBest/1 | $x^{t}_{i}=x^{t}_{r3}+F\left(x^{t}_{best}-x^{t}_{r3}\right)+F\left(x^{t}_{r1}-x^{t}_{r2}\right)$ |

The creation of the trial individual is the main characteristic of DE. As we have mentioned previously, several schemas are available [8][9]. The main difference between them is the fact that: they can use different vectors pairs; and also that they could use only randomly-selected individuals or choose to use the best individual obtained so far. Table 1 summarizes the several available schemes, where *t* represents the *t*<sup>th</sup> generation and *r1, r2,* etc. are randomly selected individuals from the population. Steps from line 6 to line 14 (see Fig. 2) may vary depending on the scheme which is being used.

### *B. Hybrid Characteristics*

In order to optimize the results (the frequency plan) two methods have been implemented on the original DE. The first optimization consisted in guarantying that for all the TRXs inside the same sector will not be assigned the same or an adjacent frequency value, because it will provoke severe penalties – these co-channel and adjacent-channel interferences are the highest-cost interferences, as shown in Eq. 2). The second method consisted in applying a Local Search (LS) method, which was adapted to this FAP problem [10]. As described above, this method permits to optimize the assignment of frequencies to every TRX in each sector of a given solution. Also, a more detailed explanation about the LS applied to the FAP problem can be consulted in the reference [10].

The first optimization is used in the creation of the initial population (line 2, Fig. 2) and every time a new solution is created. That occurs every time some of the genes of the solution are changed (line 10 and line 11, Fig. 2). We have optimized this implementation through the incorporation, for each solution, of a dynamic list containing all the available frequencies in each sector. Also, in the LS method we guaranty that the same frequency value or an adjacent frequency is not assigned to two TRXs within the same sector. Therefore, any time a change is made in a solution it is assured that the co-channel and the adjacent-channel interferences are not present. This requires that every time there is made a change to the frequency assigned to a TRX, the list of available frequencies to which belongs the TRX need to be updated (each sector of the network has is one list of available frequencies). Assigning a frequency value *f* to a TRX, originates that also the *f-1* and *f+1* values will be eliminated from the list of available frequencies in the sector of the TRX. To the reverse process (release a frequency value from a TRX) it is necessary to verify that no others TRXs in the same sector are using the *f+1* and *f-1* frequencies values.

Using this approach it is no longer necessary to verify, for each sector, which are the frequencies that are not been used. All that information is always updated in the list of the available frequencies of that sector. Using this approach it was possible to make the process much more efficient.

The second optimization consists in apply the LS method to a solution (frequency plan). Therefore, in a previous work we have conducted several experiments in order to identify what is the most efficient way to apply the LS in the DE [11]. Two hypotheses were considered. The first one consisted in applying the LS to all individuals in the initial population (line 2, Fig. 2) and also after creating every $x_{trial}$ individual (apply the DE scheme, line 10, Fig. 2). The second approach consisted in only applying the LS method after creating every $x_{trial}$ individual.

Due to the experiments carried out the selected strategy was the second approach, because it was the one that permitted obtain the most successfully results, that is solutions with a lower cost [11]. To accomplish these results, and as mentioned previous, several runs using the same DE parameters, were performed in order to identify the location to apply the LS method into the DE algorithm. This experiments were made using a common set of configuration parameters of DE (NP=10; CR=0.4 and F=0.5 and the scheme *DE/Rand/2/Bin*).

```
generation t = 0
population $P_t$ = createInitialPopulation(NP)
evaluate($P_t$)
while (not reached stop criterion)
   for $i$ = 0 to NP do
      select randomly $r1 \neq r2 \neq r3 \neq i$
      $x_{target} = x_i$
      for $j = 1$ to D do //dimension of the problem
         if ($randj[0,1] < CR$ or $j = j_{rand}$) then
            $x_{trial,j} = x_{r3,j} + F\,(x_{r1,j} - x_{r2,j})$          //DE scheme
            $x_{trial,j}$ = applyLocalSearch( $x_{trial,j}$ )
         else
            $x_{trial,j} = x_{i,j}$
         end if
      end for
      if ($f(x_{trial}) < f(x_i)$) then
         $x_i = x_{trial}$
      else
         $x_i = x_i$
      end if
   end for
   t = t + 1
end while
```

Fig 1.DE algorithm with the LS method, using the DE/Rand/1/Bin schema. NP, CR and F are user-defined parameters. NP is the population size.

### C. Solution Encoding

The solution encoding carried out to this problem incorporates the characteristics of this instance of the FAP problem. Therefore, a solution has a dimension equal to the total number of TRXs of the GSM network instance used (in this case 2612, representing the number of TRXs from the network). For every TRX, a frequency (also named channel) has to be assigned. Each TRX has a set of available frequencies. Hence, a solution plan is encoded as a list of integers values *p,* where *p(t)* is the frequency value assigned to TRX *t*.

Each time the DE algorithm changes the value assigned to a TRX, it ensures that the new value is inside the set of the available frequencies for that specific TRX. It also assures that the new value is not assigned to other TRXs installed inside the same sector. According to the made experiments, with this approach it was possible to achieve better results because it is always available an updated list of the unused frequencies.

## IV. Experiments

Our algorithm was implemented in C# using also the Microsoft .NET Framework 3.5. Results were obtained on a PC with a Pentium-4 CPU at 3.2GHz and with 2 GB of RAM, running Windows XP.

The experiments were developed over a real-world instance, named Denver, which has 711 sectors with 2612 TRXs to be assigned a frequency. Each TRX has 18 available channels (from 134 to 151). We only use this dataset in order to be able to compare our results with the results already accomplished for this problem. At this moment is only available this single instance. In future work, when available more real-world instances of the problem we intent to use them.

Fig. 2 displays the network topology, and every triangle represents a sectorized antenna in which operate several TRXs. The interference matrix is the one also used by [4] [10].

All the available information about this instance problem is available in separated configuration files.

### A. Parameterization

Several user-defined parameters are necessary and in the following we present the results achieved with experiments that were performed in order to identify the best configuration parameters to be used by DE. In a previous work [11], we have identify what were the best parameters to be used bt the DE algorithm. The parameters used are the population size (NP), crossover probability (CR), mutation factor/weighting factor (F) and the the DE strategy/scheme. Also, we have determined the best way to apply the local search method in the DE.

The best parameter settings used are a population size (NP) of 10 individuals, a crossover probability (CR) of 0.2, a mutation factor (F) of 0.1, the DE/Rand/2/bin scheme and applying the LS method after the creation of every $x_{trial}$ individual.

We specified as stopping criterion a 30 minutes of execution. In order to provide the results with statistical confidence, we have considered 30 independent runs for each experiment. For each run, and also at every 2 minutes, we have obtained the average, best and standard deviation values.

### B. Results

In order to provide results to be compared with other authors, we have focused on three different time limits (120, 600 and 1800 seconds). Therefore, it is possible to compare different algorithms within short and long time ranges.

According to previous results [10] the more efficient way to create the initial population is randomly but removing the most costly interferences (co-channel and adjacent-channel) within the same sector. After proving the efficiency of this approach to the DE, we used it to initiate the DE algorithm. Initially, without using this approach the accomplished results were not so satisfactory.

After tuning the DE parameters [11] and incorporating also some optimized methods, the conducted experiments showed that using the Local Search method within the algorithm has a very important role in its performance.

According to the formulation presented in section II, the results are given by using the cost function, meaning that a frequency plan with a small value cost is a better frequency plan.

Our results were obtained with the hybrid version of the DE algorithm, which has been described in section III. The best result obtained was 87845.9 cost units (after 30 independent runs, each one with 30 minutes).

Table 2 shows a resume of the results accomplished for this problem by other algorithms with similar characteristics (implemented by other authors), and also our DE algorithm. Here, we show the Ant Colony Optimization algorithm (ACO) and the Scatter Search (SS) [10]. Both have already

TABLE II.
EMPIRICAL RESULTS OF THE METAHEURISTICS FOR 3 DIFFERENT TIME LIMITS. IT SHOWS THE BEST, AVERAGE AND STANDARD DEVIATION OF 30 EXECUTIONS

| Time Limit | 120 seconds | | | 600 seconds | | | 1800 seconds | | |
|---|---|---|---|---|---|---|---|---|---|
| | Best | Average | Std. | Best | Average | Std. | Best | Average | Std. |
| **ACO** | **90736.3** | **93439.5** | 1318.9 | 89946.3 | 92325.4 | 1092.8 | 89305.9 | 90649.9 | 727.5 |
| **SS** | 91216.7 | 94199.6 | 1172.3 | 91069.8 | 93953.9 | 1178.6 | 91069.8 | 93820.4 | 1192.3 |
| **DE** | 92145.8 | 95414.2 | 1080.4 | **89386.4** | **90587.2** | 682.3 | **87845.9** | **89116.8** | 563.8 |

been tested to solve the FAP problem, and they have shown a good performance for this problem.

Analyzing these results, we can conclude that DE obtains the best results for 600 and 1800 seconds, although it is not the algorithm with the best start. Furthermore, with our approach it was also possible to improve the results obtained in [4][12] (where other metaheuristics were used: (1,10) Evolutionary Algorithm, PBIL –Population Based Incremental Learning-, …). In conclusion, the results are quite better that others already achieved for this instance of the problem.

## V. CONCLUSION

In this paper we present a hybrid Differential Evolution (DE) algorithm for solving the frequency assignment problem (FAP) for a real GSM network. It was used a mathematical formulation adopted by other researchers [4]. In this way, it is possible the make comparisons between the results accomplished by this algorithm and others.

In this work, DE was modified to incorporate a Local Search method (i.e., optimizing the assignment of frequencies to every TRX in each sector of the solution).

The results have shown that this hybrid version of the DE algorithm, with the additional features incorporated, clearly makes possible to obtain a viable solution, when compared with other algorithms proposed by other authors. It also shows that the results of the modified DE are better compared to the original one. The proposed modifications have improved the computational efficiency of the DE algorithm to solve the approached problem.

Therefore, it is possible to conclude that the results evolution and the final results for the DE algorithm are very positives.

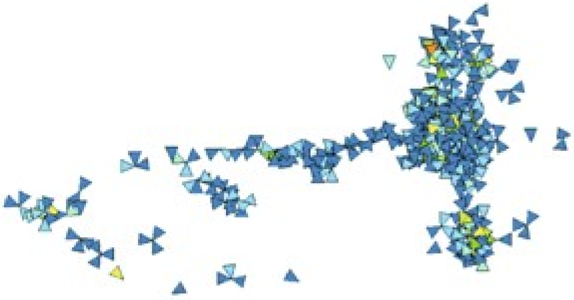

Fig 2.Topology of the GSM instance used

Future work includes the study of other evolutionary algorithms (like VNS -Variable Neighborhood Search-) to make deeper analysis with more different metaheuristics. Furthermore, we will work with more real-world instances, in order to evaluate the algorithms using different instances. Finally, the formulation of the FAP problem as a multiobjective optimization problem will be investigated as well.

## ACKNOWLEDGMENT

This work was partially funded by the Spanish Ministry of Education and Science and FEDER under contract TIN2005-08818-C04-03 (the OPLINK project). Thanks also to the Polytechnic Institute of Leiria, for the economic support offered to Marisa Maximiano to make this research.

***Abstract*—A hierarchical approach to decision rule design in the HeKatE project is introduced in the paper. Within this approach a rule prototyping method ARD+ is presented. It offers a high-level hierarchical prototyping of decision rules. The method allows to identify all properties of the system being designed, and using the algorithm presented in this paper, it allows to automatically build rule prototypes. A practical implementation of the prototyping algorithm is discussed and a design example is also presented. Using the rule prototypes actual rules can be designed in the logical design stage. The design process itself is supported by HaDEs, a set of of design tools developed within the project.**

## I. Introduction

DESIGNING a knowledge-base for a rule-based system is a non-trivial task. The main issues regard identification of system properties, based on which rules are subsequently specified. This is an iterative process that needs a proper support from the design method being used, as well as computer tools supporting it. Unfortunately there are not many well-established tools for providing a formalized transition from vague concepts provided by the user or expert, to actual rules [1]. Quite often regular software engineering [2] methods are used [3] which are subject to so-called semantic gaps [4].

This paper focuses on transition from system properties to rule prototypes. In the paper ARD+ (Attribute Relationship Diagrams) [5], [6] a design method for decision rules is discussed. The method allows for hierarchical rule prototyping that supports the actual gradual design process. A practical algorithm providing a transition from the ARD+ design to rule design is introduced. Using ARD+ and the algorithm it is possible to build a structured rule base, starting from a general user specification. This functionality is supported by the VARDA design tool implemented in Prolog [7]. A next step is design actual rules which is aided by HQEd [8]. Both tools (VARDA, HQEd) constitute the Base of HaDEs, the *HeKatE Design Environment*.

The paper is organized in the following manner. In Sect. II the most important aspects of rule design are summarized, then in Sect. III the hierarchical approach to rule design in the *HeKatE* project is introduced. Within this approach the rule prototyping method *ARD+* is presented in Sect. V. Using the algorithm presented in Sect. VI it is possible to automatically build decision rule prototypes. A practical implementation of the prototyping algorithm is discussed in Sect. VII, with a design example in Sect. VIII. The paper ends with the concluding remarks and directions for future work in Sect. IX.

## II. Rule Design

The basic goal of rule design is to build a rule-based knowledge base from system specification. This process is a case of knowledge engineering (KE) [1], [9]. In general, the KE process is different in many aspects to the classic software engineering (SE) process. The most important difference between SE and KE is that the former tries to model how the system works, while the latter tries to capture and represent what is known about the system. The KE approach assumes that information about how the system works can be inferred automatically from what is known about the system.

In case of rules, the design stage usually consists in writing actual rules, based on knowledge provided by an expert. The rules can be expressed in a natural language, this is often the case with informal approaches such as business rules [10]. However, it is worth pointing out that using some kind of formalization as early as possible in the design process improves design quality significantly.

The next stage is the rule implementation. It is usually targeted at specific rule engine. Some examples of such engines are: *CLIPS*, *Jess*, and *JBoss Rules* (formerly *Drools*). The rule engine enforces a strict syntax on the rule language.

Another aspect of the design – in a very broad sense – is a rule encoding, in a machine readable format. In most cases it uses an XML-based representation. There are some well-established standards for rule markup languages:, e.g. *RuleML* and notably *RIF* (see www.w3.org/2005/rules).

The focus of this paper is the design stage, and the initial transition from user-provided specification that includes some *concepts*, to rule specification that connects rules with these concepts. This stage is often referred to as a *conceptual design*. It is also addressed with some recent representations, such as the *SBVR* [11] in the OMG and business rules communities.

The research presented in this paper is a part of the *HeKatE* project, that aims at providing an integrated rule design and

The paper is supported by the *HeKatE* Project funded from 2007–2009 resources for science as a research project.

implementation method for rule-based systems. The HeKatE approach to the design is briefly introduced in the next section.

## III. Hierarchical Design Approach

An effective design support for decision systems is a complex issue. It is related to design methods as well as the human-machine interface. Since most of the complex designs are created *gradually*, and they are often *refined* or *refactored*, the design method should take this process into account. Any tools aiding such a process should effectively support it.

It is worth noting that UML, the most common design method used in the SE, does not support the process at all. The process should not be mistaken with version or revision control. Simple cases of revision control are undo features, provided by most of UML tools (which is very rarely combined with real project versioning). More complex version control is usually delegated to some other, external tools in the userspace, such as CVS, Subversion, etc. But a tool supported even by a version control system is still unable to actually *present*, and *visualize* changes in the design, not mentioning its refinement or refactoring. This is related to the fact, that UML has no facilities to express the design process.

In real life the *design* support (as a process of building the design) is much more important then just providing means to visualize and construct the *design* (which is a kind of knowledge snapshot about the system). Another observation can be also made: *designing* is a knowledge-based process, where the *design* is considered a structure with procedures needed to build it (it is often the case in the SE).

In order to solve these problems, the HeKatE project aims at providing both design methods and tools that support the design process. They should be integrated, and provide a hierarchical design process that would allow for building a model, containing the subsequent design stages. Currently HeKatE supports the *conceptual design* with the ARD+ method (*Attribute Relationships Diagrams*) [5]. The main logical design is conducted with the use of XTT method (*eXtended Tabular Trees*) [12], [13].

The ARD+ design method is shortly presented in the subsequent section. It serves as a rule prototyping method for rules. The ARD+ method is a supportive design method for XTT, where the knowledge base is designed using a structured representation, based on the concept of tabular trees [14]. The XTT representation is based on the principle that the rule base is decomposed into a set of decision tables, grouping rules that have the same sets of conditional and decision attributes. It makes the knowledge base hierarchical, combining decision tables and decision trees approaches. While the use of ARD+ is aimed at XTT rules,it is a much more generic solution, allowing for prototyping different types of decision rules.

The HeKatE design process is supported by a dedicated toolchain presented in the next section.

## IV. HADES, the HeKatE Toolchain Prototype

The toolchain in the HeKatE project is composed of several elements. Currently two main design tools are available. They are integrated using XML for knowledge representation.

VARDA [7] is an ARD rule prototyping tool. It provides a basic command line interface (CLI) for design creation, refinement and visualization. The CLI is based on the Prolog interactive shell which allows calling application programming interface (API) responsible for design manipulation. It includes system modelling, input/output operations and spawning a visualization tool-chain.

The modelling is provided through several predicates performing property and attribute manipulation, as well as the transformations. The input/output operations regard storing the design as a Prolog knowledge base or exporting it into XML-based format suitable for further processing, which also serves as HQED input. It also allows to spawn the visualization toolchain based on GraphViz and ImageMagick which graphically presents the design.

VARDA is a crossplatform tool written in pure ISO Prolog, that depends only on the Prolog environment and GraphViz library. It is available under terms of the GNU GPL from https://ai.ia.agh.edu.pl/wiki/hekate:varda.

### A. HQEd

*HQeD* [8] is a CASE tool for the XTT design. The tool supports the visual design process of the XTT tables. Using the rule prototypes generated from the ARD+ design with VARDA, HQEd allows for the actual logical rule design grouped with the XTT tables.

The editor allows for gradual refinement of rules, with an online checking of attribute domains, as well as simple table properties, such as inference related dead rules. In case of simple tables it is possible to emulate and visualize the inference process step-by step. However, the main quality feature being developed is a plugin framework, that allows for integrating Prolog-based analysis plugins to check formal properties of the XTT rule base, including completeness, redundancy, or determinism.

HQEd is a crossplatform tool written in C++, that depends only on the Qt library. It is available under terms of the GNU GPL from https://ai.ia.agh.edu.pl/wiki/hekate:hqed.

The output from the editor is a complete rulebase encoded in Prolog. It can be executed using a Prolog-based inference engine. The rulebase and the inference engine can be integrated into a larger application as a logical core.

### B. XML Markup

Knowledge in the HeKatE design process is described in HML, a machine readable XML-based format. HML consists of three logical parts: attribute specification (ATTML), attribute and property relationship specification (ARDML) and rule specification (XTTML).

The attribute specification regards describing attributes present in the system. It includes attribute names and data types used to store attribute values. The attribute and property relationship specification describes what properties the system consists of and which attribute identifies these properties. Furthermore, it also stores all stages of the design process. The rule specification stores actual structured rules.

These logical parts: ATTML, ARDML and XTTML can be used in different scenarios as:

- pure ATTML – to describe just attributes and their domains,
- ATTML and ARDML combined – to describe the system being designed in terms of properties and dependencies among them,
- ATTML, ARDML and XTTML combined – attributes, dependencies and rules combined, a complete description of the system,
- ATTML and XTTML combined – just rules which are not designed out of properties, it could be used to model ad-hoc rules, or systems described by some predefined rules.

The HML, being an XML application, is formally described through a Document Type Definition (DTD). Its full specification and examples are available at https://ai.ia.agh.edu.pl/wiki/hekate:hekate_markup_language.

## V. Introduction To ARD+

The ARD+ method aims at capturing relations between *attributes* in terms of *Attributive Logic* [15]. *Attributes* denote certain system *property*. A *property* is described by one or more attributes. ARD+ captures *functional dependencies* among these *properties*. A simple property is a property described by a single *attribute*, while a complex property is described by multiple *attributes*. It is indicated that particular system property depends functionally on other properties. Such dependencies form a directed graph with nodes being properties.

A typical atomic formula (fact) takes the form $A(p) = d$, where $A$ is an attribute, $p$ is a property and $d$ is the current value of $A$ for $p$. More complex descriptions take usually the form of conjunctions of such atoms and are omnipresent in the AI literature [16], [9].

*Definition 1:* Attribute. Let there be given the following, pairwise disjoint sets of symbols: $P$ – a set of property symbols, $A$ – a set of attribute names, $D$ – a set of attribute values (the *domain*).

An attribute (see [15], [17]) $A_i$ is a function (or partial function) of the form

$$A_i\colon P_j \to D_i.$$

A generalized attribute $A_i$ is a function (or partial function) of the form $A_i\colon P_j \to 2^{D_i}$, where $2^{D_i}$ is the family of all the subsets of $D_i$.

*Definition 2:* Conceptual Attribute. A conceptual attribute *A* is an attribute describing some general, abstract aspect of the system to be specified and refined.

Conceptual attribute names are capitalized, e.g.: `WaterLevel`. Conceptual attributes are being *finalized* during the design process, into, possibly multiple, physical attributes, see Def. 8.

*Definition 3:* Physical Attribute. A physical attribute *a* is an attribute describing an aspect of the system with its domain defined.

Names of physical attributes are not capitalized, e.g. `theWaterLevelInTank1`. By finalization, a physical attribute origins from one or more (indirectly) conceptual attributes. Physical attributes cannot be finalized, they are present in the final rules.

*Definition 4:* Simple Property. $PS$ is a property described by a *single* attribute.

*Definition 5:* Complex Property. $PC$ is a property described by *multiple* attributes.

*Definition 6:* Dependency. A dependency $D$ is an ordered pair of properties $D = \langle p_1, p_2\rangle$ where $p_1$ is the independent property, and $p_2$ is the one that dependent on $p_1$.

*Definition 7:* Diagram. An ARD+ diagram $G$ is a pair $G = \langle P, D\rangle$ where $P$ is a set of *properties*, and $D$ is a set of *dependencies*.

*Constraint 1:* Diagram Restrictions. The diagram constitutes a *directed graph* with certain restrictions:

1) In the diagram cycles are allowed.
2) Between two properties only a single dependency is allowed.

Diagram transformations are one of the core concepts in the ARD+. They serve as a tool for diagram specification and development. For the transformation $T$ such as $T : D_1 \to D_2$, where $D_1$ and $D_2$ are both diagrams, the diagram $D_2$ carries more knowledge, is more specific and less abstract than the $D_1$. Transformations regard *properties*. Some transformations are required to specify additional *dependencies* or introduce new *attributes*, though. A transformed diagram $D_2$ constitutes a more detailed *diagram level*.

*Definition 8:* Finalization. The finalization $TF$ is a function of the form

$$TF : PS \to P$$

transforming a simple property $PS$ described by a conceptual attribute into a $P$, where the attribute describing $PS$ is substituted by one or more conceptual or physical attributes describing $P$. It introduces more attributes (more knowledge) regarding particular property.

An interpretation of the substitution is, that new attributes describing $P$ are more detailed and specific than attributes describing $PS$.

*Definition 9:* Split. A split is a function $TS$ of the form:

$$TS : PC \to \{P_1, P_2, \ldots P_n\}$$

where a *complex property* $PC$ is replaced by some number of *properties* ($\{P_1, P_2, \ldots P_n\}$), each of them described by one or more attributes originally describing PC. This transformation introduces more properties and defines functional relationships among them.

*Constraint 2:* Attribute Dependencies. Since $PC$ may depend on other properties $PO_1 \ldots PO_m$, dependencies between these properties and $P_1 \ldots P_n$ have to be stated.

During the design process, upon splitting and finalization, the ARD+ model grows. This growth is expressed by consecutive diagram levels, making the design more and more specific. This constitutes the *hierarchical model*. Consecutive

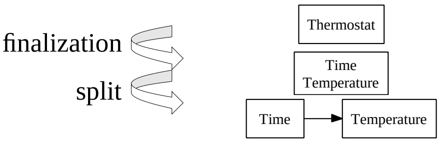

Fig. 1. Examples of finalization and split

levels make a hierarchy of more and more detailed diagrams describing the designed system. The implementation of such a hierarchical model is provided through storing the lowest available, most detailed diagram level at any time, and additional information needed to recreate all of the higher levels, the so-called *Transformation Process History* (TPH). It captures information about changes made to properties at consecutive diagram levels, carried out through the transformations: *split* or *finalization*. A TPH forms a tree-like structure then, denoting what particular property is split into or what attributes a particular property attribute is finalized into.

In Fig. 1 the first and second ARD+ design level of the thermostat example discussed in Sect. VIII are presented. These are examples of finalization and split transformations.

## VI. Rule Prototyping Algorithm

The goal of the algorithm is to automatically build prototypes for rules from the ARD+ design. The targeted rule base is structured, grouping rulesets in decision tables with explicit inference control among the latter. It is especially suitable for the XTT rule representation, however, this approach is more generic, and can be applied to any forward chaining rules.

The input of the algorithm is the most detailed ARD+ diagram, that has all of the physical attributes identified (in fact, the algorithm can also be applied to higher level diagrams, generating rules for some parts of the system being designed). The output is a set of *rule prototypes* in a very general format (`atts` stands for attributes):

```
rule: condition atts | decision atts
```

The algorithm is *reversible*, that is having a set of rules in the above format, it is possible to recreate the most detailed level of the ARD+ diagram.

In order to formulate the algorithm some basic subgraphs in the ARD+ structure are considered. These are presented in Figs. 2,3. Now, considering the ARD+ semantics (functional dependencies among properties), the corresponding rule prototypes are as follows:

- for the case in Fig. 2: `rule: e       | f, g, h`
- for the case in Fig. 3: `rule: a, b, c | d`

In a general case a subgraph in Fig. 4 is considered. Such a subgraph corresponds to the following rule prototype:

```
rule: alpha, beta, gamma, aa | bb
rule: aa                     | xx, yy, zz
```

Analyzing these cases a general prototyping algorithm has been formulated. Assuming that a dependency between two properties is formulated as: $D(IndependentProperty, DependentProperty)$, the algorithm is as follows:

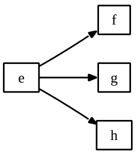

Fig. 2. A subgraph in the ARD+ structure, case #1

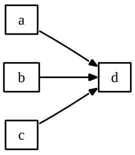

Fig. 3. A subgraph in the ARD+ structure, case #2

1) choose a dependency $D : D(F, T), F \neq T$, from all dependencies present in the design,
2) find all properties $F$, that $T$ depends on: let $F_T = \{F_{T_i} : D(F_{T_i}, T), F_{T_i} \neq F\}$,
3) find all properties which depend on $F$ and $F$ alone: let $T_F = \{T_{F_i} : D(F, T_{F_i}), T_{F_i} \neq T, /\exists T_{F_i} : (D(X, T_{F_i}), X \neq F)\}$
4) if $F_T \neq \emptyset, T_F \neq \emptyset$ then generate rule prototypes:
```
rule: F, FT1, FT2,... | T
rule: F              | TF1, TF2,...
```
5) if $F_T = \emptyset, T_F \neq \emptyset$ then generate rule prototypes:
```
rule: F | T, TF1, TF2,...
```
6) if $F_T \neq \emptyset, T_F = \emptyset$ then generate rule prototypes:
```
rule: F, FT1, FT2,... | T
```
7) if $F_T = \emptyset, T_F = \emptyset$ then generate rule prototypes:
```
rule: F | T
```
8) if there are any dependencies left goto step 1.

Rule prototypes generated by the above algorithm can be further optimized. If there are rules with the same condition attributes they can be merged. Similarly, if there are rules with the same decision attributes they can be merged as well. For instance, rules like:

```
rule: a, b | x  ;  rule: a, b | y
```

can be merged into a single rule: `rule: a, b | x, y`

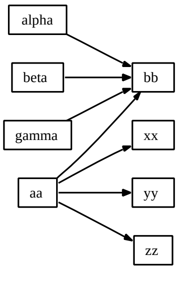

Fig. 4. A subgraph in the ARD+ structure, general case

```
ax :-
   ard_depend(F,T),
   F \= T,
   ard_xtt(F,T),
   fail.
ax.

ft(F,T,FT):- ard_depend(F,T),
   ard_depend(FT,T), FT \=F.

tf(F,T,TF):- ard_depend(F,T),
   ard_depend(F,TF), TF \= T,
   \+ ( ard_depend(X,TF), X \= F).

% generate xtt from a dependency: F,T

   assert(xtt([F],[T|ListTF])),
   ard_done([F],[T|ListTF]).
ard_xtt(F,T):-
   ard_depend(F,T),
   findall(TF, tf(F,T,TF),ListTF),
   findall(FT, ft(F,T,FT),ListFT),
   assert(xtt([F|ListFT],[T])),
   assert(xtt([F],ListTF)),
   ard_done([F|ListFT],[T]),
   ard_done([F],ListTF).
% retract already processed dependencies
ard_done(F,T):-
   member(FM,F),
   member(TM,T),
   retract(ard_depend(FM,TM)),
   fail.
ard_done(_,_).
```

Fig. 5. Algorithm implementation in Prolog

The rule prototyping algorithm has been successfully implemented in Prolog, as presented in the next section.

## VII. Algorithm Implementation

The ARD+ is a visual design method, so an appropriate computer tool supporting it should be developed. VARDA is a prototype ARD+ design tool written in Prolog. It is purely declarative and supports automated visualization at any design stage (diagram level) using *GraphViz* (graphiz.org). The prototype consists of an API for low-level ARD+ handling primitives such as defining attributes, properties and dependencies, and high-level primitives supporting the transformations, and visualization primitives as well. The algorithm presented here has been implemented as a part of VARDA.

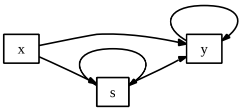

Fig. 6. Factorial, ARD+

Fig. 7. Factorial, XTT prototype

The algorithm implementation (see Fig. 5) consists of: a predicate `ax/0` which spawns the search process, browsing all dependencies (implementing the first step of the algorithm), `ard_xtt/2` predicate which implements steps four through seven, and helper predicates `ft/3`, `tf/3` providing steps two and three. Additional predicate `ard_done/2` removes dependencies which have already been processed. Dependencies are given as `ard_depend/2`.

In addition to the rule prototypes some higher-level relationships can be visualized on the final design. If attributes within a set of XTTs share a common ARD+ property, such XTTs are enclosed within a frame named after the property. It indicates that particular XTTs describe fully the property. Application of this feature is subject to further research, but it seems that it is suitable for establishing rule scope, implementing the XTT *Graphical Scope* feature proposed elsewhere.

The rule generation is reversible. Having rule prototypes it is always possible to recreate the original, most detailed ARD+ level (i.e. for redesign purposes). This functionality is fully implemented in VARDA.

The algorithm has been successfully tested on several examples, including the classic *UServ Product Derby 2005* case study from the Business Rules Forum [18]. This case study includes over 70 rules.

The algorithm covers even more complicated dependencies such these in Fig. 6, including self-dependencies. This example is a model for calculating factorial iteratively. Factorial of $x$ is calculated and its value is stored in $y$, $s$ serves as a counter. The diagram could be read as follows: $y$ depends on $x$ and $s$, in addition it also depends on itself, $s$ depends on $x$ and itself.

Using the above algorithm appropriate rule prototypes is generated:

```
rule: x, y, s | y  ; rule: x, s | s
```

which can be read, that a value of $y$ is calculated based on values of $x$, $y$, and $s$. A value of $s$ is calculated based on values of $x$ and $s$.

These prototype rules are visualized in Fig. 7. Dashed arrows between XTTs indicate, in this case, that a value of $s$ is needed in order to calculate a value of $y$.

This algorithm can be applied to a design case which is presented in the next section.

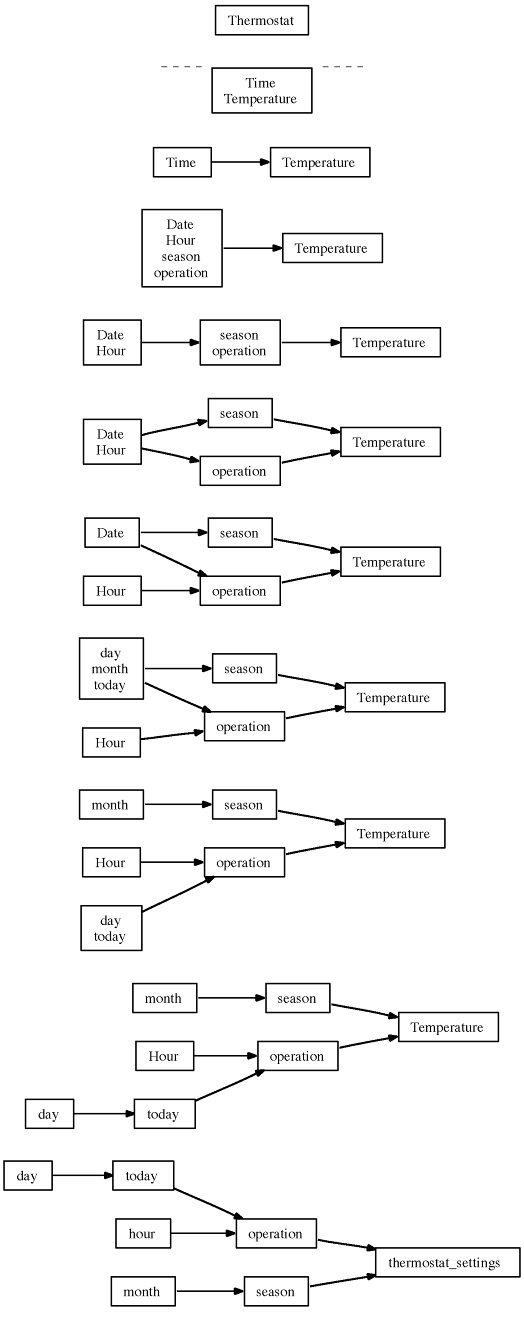

Fig. 8. Thermostat design stages, ARD+

## VIII. Design Example

A simple thermostat system is considered, see [19]. It regards a temperature control system which is to be used in an office. It controls heating and cooling which depends on several time oriented aspects. These include time of the day, business hours, day of week, month and season. Output of the system (a decision) regards what particular temperature the cooling/heating system should keep.

### A. Conceptual Design

The design process includes system property identification and refinement including property relationships, and conceptual and physical attribute identification. The design stages, consecutive ARD+ diagrams, at more and more detailed levels, are given in Fig. 8 with the most detailed diagram at the bottom. Furthermore, the example shows rule prototypes (see Sec. VIII-B) and finally the rules to control the temperature (see Sec. VIII-C). Its TPH, regarding the most detailed level, is given in Fig. 9.

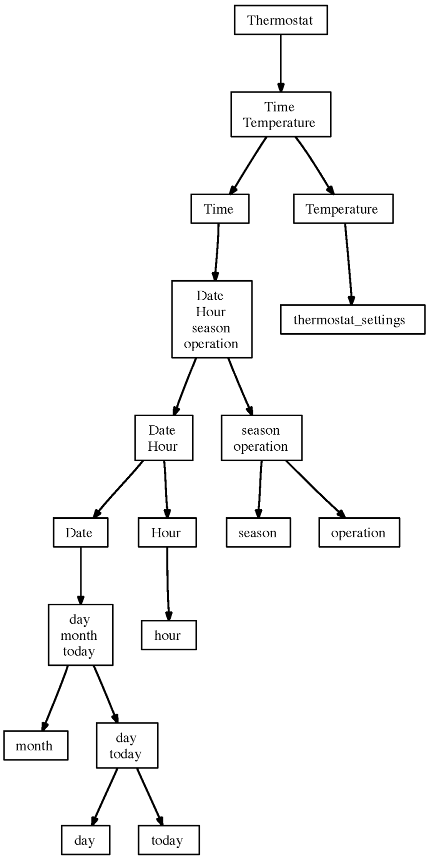

Fig. 9. The thermostat, TPH

### B. Rule Prototyping

A corresponding XTT prototype is given in Fig. 10. Higher level relationships are visualized as labeled frames, i.e.: `rule: day | today` originates from a property `Date`. Similarly, the set of XTT rule prototypes:

```
rule: day          | today
rule: month        | season
rule: today, hour | operation
```

regards `Time` property. All the prototypes regard `Thermostat`, since it is the top most system property.

Dashed arrows between XTT prototypes indicate functional relationships between them. If there is an XTT with a decision attribute and the same attribute is subsequently used by other XTT as a condition one, there is a dashed arrow between such XTTs. These relationships also represent mandatory inference control, in terms of XTT approach.

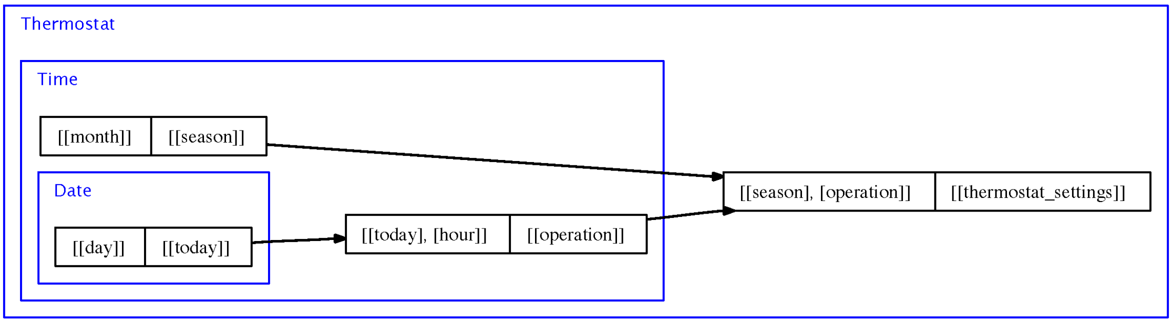

Fig. 10. The thermostat, XTT prototype

### C. Rule Design

The main logical rule design stage using HQEd is presented in Fig. 11, where the actual XTT tables corresponding to the prototypes generated using VARDA are visible.

## IX. Concluding Remarks

In the paper the hierarchical HeKatE design process is discussed. The process is supported by tools constituting the HADEs environment, these are: VARDA and HQED. VARDA is be used to assist a designer with system property identification. It can be applied as early as requirement specification, even to assist in gathering requirements. VARDA output is subsequently used as HQEd input being a template for rules. The actual rules are formulated using HQED.

The focus of the paper is on the ARD+, a hierarchical design method for rule prototyping. The original contribution of the paper is the introduction of the automatic rule prototyping algorithm based on the ARD+ design process.

Applying ARD+ as a design process allows to identify attributes of the modelled system and refine them gradually. Providing the algorithm, which builds an XTT prototype out of ARD+ design, binds these two concepts together resulting in an uniform design and implementation methodology. The methodology remains hierarchical and gradual, the algorithm works both ways: it generates rule prototypes and it is also capable of recreating the most detailed ARD+ level. Combining the most detailed ARD+ level with the TPH allows to recreate any previous ARD+ level, which provides refactoring capabilities to an already designed system.

Future work focuses on the formal definition of the inference process within XTT. There is an initial XTT inference model which requires some extensions and adaptation to cover different use scenarios. A more tight integration of the tools within HADEs is anticipated. Upon finishing it and implementing a prototype run-time environment, HADEs will provide a uniform environment for design and implementation of rule-based systems. Applications being currently considered include business applications logic [20] as well as control applications for mobile robots.

***Abstract*—During recent years a number of medical diagnosis support systems have been presented. Such systems are important from medical point of view, because they aid physicians in their daily work. Some of those systems, like *Computed tomography* support systems (CT) rely on image data analysis, making it an interesting research topic from pattern recognition point of view. The paper presents a practical realization of a medical support system, including segmentation, feature extraction and decision processes. Various techniques are used within the system: fuzzy logic, shape descriptors, classifiers and automatic image annotation framework. Series of 2D CT images are an input of the system. As a result, a patient's diagnosis is presented.**

## I. Introduction

IN THE paper we present an approach to introduce automation of brain CT image analysis. Our goal is to support physicians (radiologists) in their daily work. In the first step of authors' research, the system has to classify a set of 2D CT images with respect to the presence or absence of brain atrophy. To be able to support radiologists, the constructed system has to generate diagnoses which are as similar as possible to expert's ones. To comfortably support radiologists, the system has to work within limited, reasonable time constrains. Analysis of brain CT images can be helpful in diagnosis of many diseases, including dementive diseases. Diagnosing process of dementive diseases is complicated. Although brain lesions appear 10–20 years prior to clinical manifestation, they are subtle and unavailable for standard diagnosing methods. Thus there are many researches during last few years trying to use neuroimaging procedures for diagnosing dementive diseases, such as Alzheimer's disease.

Several pattern recognition and machine vision techniques are used in the presented approach. A single 2C CT image is segmented using a fuzzy logic based algorithm.Afterward, feature vectors are calculated on the basis of extracted brain fluid segments. Classification of a patient's state is the final step. Several approaches to classification are examined. The first one is a classic multilayer perceptron (MLP). The second and the third ones are two automatic image annotation methods. Those methods are: *Binary Machine Learning* [6] using a set of *C4.5* decision trees and *Continuous Relevance Model* [4] using Gaussian kernel distance calculation. One of authors' goals during the research is to evaluate the usage of automatic image annotation framework for the stated classification problem.

The article is organized in the following manner. Next section states the problem from a medical point of view. The proposed approach is described in the third section. A brief description of all used algorithms and methods is presented. The fourth section presents performed experiments. The last section summarizes the article.

## II. Problem Statement

The most common dementia diagnosis method is visual evaluation of brain fluid spaces done by radiologist. It is quick and hardware-independent, however not perfect: it requires experienced specialist, and is descriptive and subjective [2]. More objective method is making planimetric measurements, but this is time-consuming, both during evaluation and generating results, which are relative to brain volume [5].

The most advanced method is automatic volumetric measurement of intracranial fluid. Programs used to evaluate cerebral fluid volume work on a semi-automatic basis—the specialist selects region of interest, and the specified volume is measured [7]. The next step is to make the diagnosis quicker by introduction of a fully automated method.

The automation of brain atrophy evaluation in patients with dementia on the basis of brain CT images analysis can be performed using different approaches. One is developing an effective and precise method of region of interest automatic segmentation.Afterward, region of interest volume can be measured. The second approach, proposed in this paper, is based on applied automatic annotation method which classifies brain CT images as *brain atrophy* or *no brain atrophy*. Such a method is evaluated by physicians as very helpful in dementia diagnosis process, because brain atrophy suggests dementive diseases. Taking into account above statements, the goal of this paper can be defined as follows: **To introduce a method of automatic patients discrimination with and without brain atrophy.**

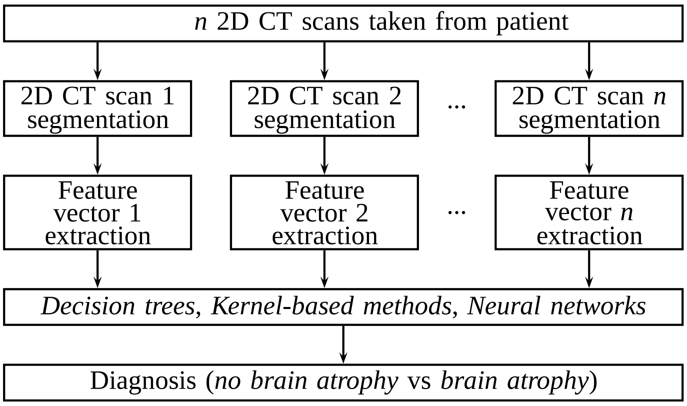
The presented results are a part of wider research on CT image analysis, including image segmentation, feature generation and diagnosis support. Apart of the main goal, following research goals are defined:

- Determination if it is possible to build CT decision support system using features based on intracranial fluid area.
- Evaluation of the proposed architecture and all its components as a whole system.
- Evaluation of classification quality using features other than volume (area) of intracranial fluid.

- Evaluation of classification quality based on automatic image annotation framework in simplest 2 word case, for further research on larger dictionaries (more detailed patient's state description).

## III. Proposed approach

The goal of the proposed method is to automatically discriminate between patients with brain atrophy, which might suggest dementive disease. To achieve this a series of CT images is gathered and processed. A series of 2D CT images are used as an input of the method. Images represent brain slices, gathered during the scanning process. Together, they form a 3D CT brain image. The system output is the patient's state diagnosis.



*n* 2D CT scans taken from patient
2D CT scan 1 segmentation
2D CT scan 2 segmentation
...
2D CT scan *n* segmentation
Feature vector 1 extraction
Feature vector 2 extraction
...
Feature vector *n* extraction
*Decision trees*, *Kernel-based methods*, *Neural networks*
Diagnosis (*no brain atrophy* vs *brain atrophy*)

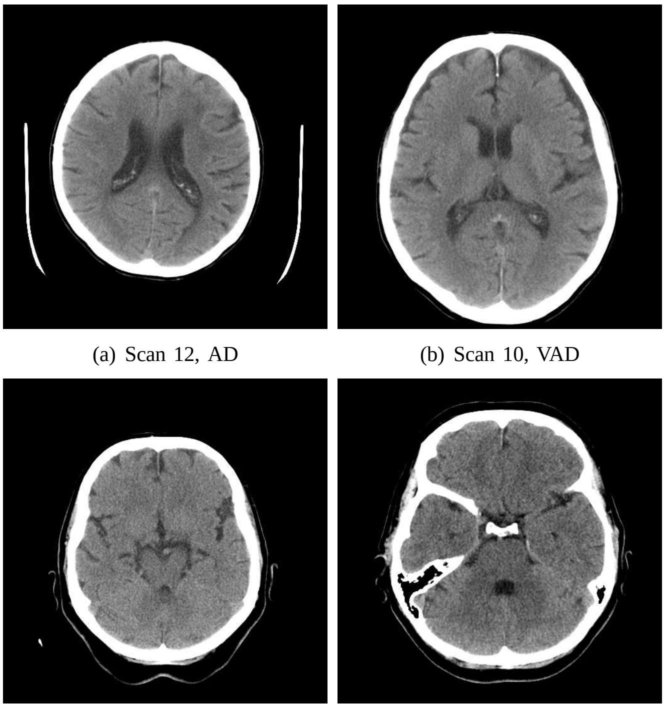
Fig. 1. Process of patients discrimination with and without brain atrophy

The proposed approach utilizes segmentation, feature vectors extraction and various classification techniques. Each of those steps is described in detail in this section. The whole process is visualized in Fig. 1. The goal of segmentation is to extract the *region of interest*, abbreviated *ROI*. Feature vectors are calculated on the basis of *ROI*. They are a set of synthesized, numerical values describing series of 2D CT scans. A set of classifiers is responsible for the final diagnosis.

### A. Image acquisition

CT scans are acquired using two-slice helical General Electric (GE) CT/e Dual scanner. Patient's head is located between X-ray source and the rows of detectors. Detectors and the lamp are rotating by 360 degrees for each scan. Acquired raw data are transformed, using Fourier transformation to 2D images. Each scan is 7 mm thick and there's no gap between the slices, so put up together all scans show complete volume of the brain and intracranial fluid. Every single pixel of 2D picture is described by value known as density, measured in Hounsfield Units (HU) and may vary between -3000 (air), through 0 (water) to 3000 (bones, metals). Only a fraction of the density range is important from the diagnostic process point of view. Original images are rescaled to the important density range and then discretized to 8-bit grayscale. As a result of image acquisition series of 512x512 8-bit grayscale images are produces.

Exemplary CT scans for four different patients are shown in Fig. 2. The first image from the left shows the 12-th scan with diagnosed *Alzheimer disease* (abbreviated *AD*). The second image shows the 10-th scan with diagnosed *Vascular Dementia* (abbreviated *VAD*). The third and the fourth scans are taken for healthy patients.



(a) Scan 12, AD
(b) Scan 10, VAD

(c) Scan 9, no disease
(d) Scan 8, no disease

Fig. 2. Exemplary CT scans for various patients. Patient (a) has *Alzheimer disease*, (b) has *Vascular Dementia*. patients (c) and (d) have no disease.

Analyzed CT scan range is also an important topic and requires discussion. As mentioned before, for each patient a series of scans is performed. CT scans taken from the bottom of the head have the lowest indexes and from the top of the head—the highest indexes. However, scans with the same indexes do not relate between patients. Differences can be quite large, mostly because of the scanning process itself. Patient's head position is one of the most problematic factors. Additionally, scans from the bottom of the head contain many artifacts, due to bone presence and scanning process. It is worth to mention, that scans do not contribute to brain atrophy analysis, equally.

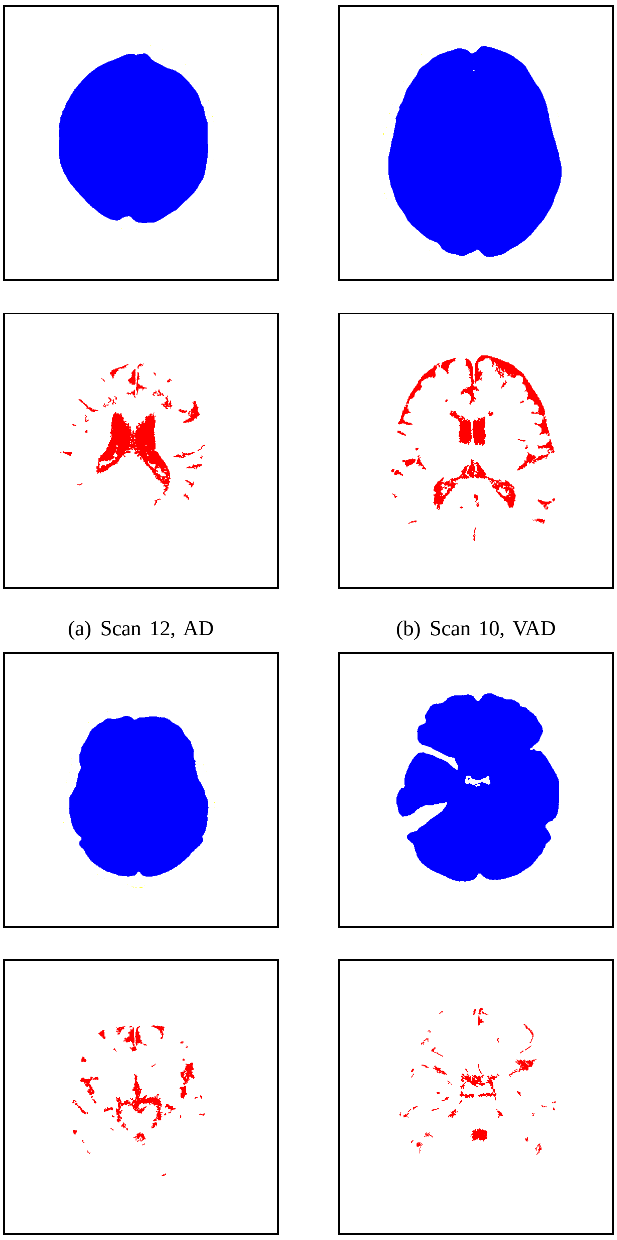
### B. Image segmentation

Acquired 2D CT scans are processed by a specialized segmentation algorithm.The segmentation process extracts *cerebrospinal fluid area*. The method emulates the complexity of the standard radiological and neurological recognition, by definition of appropriate linguistic variables in accordance with a priori introduced fuzzy rule base. In the used method the Mamdani model [1] and the Larsen implication are considered. The COA (center of area) is applied as defuzzification method.

The key point of the proposed segmentation method (considered as a region growing segmentation technique) assumes homogeneity segmentation criteria that are defined upon a fuzzy control system, dedicated to computed tomography imaging. The growing process is controlled by a fuzzy control system and thus it classifies a pixel to a certain region (defined by a *seed*) if and only if the corresponding pixel characteristics are greater than or equal to some a priori given threshold value (denoted by T), considered as an output value of the fuzzy system. A formal treatment of the growing process is given below:

Let $P$ be the set of all image pixels for a given image of size $M \times N$, $P =_{df} \{p(m,n)|m = 1,2,...,M; n = 1,2,...,N\}$ and let $P_s \subset P$ be the subset of all seeds generated for the considered image. Any neighbor pixel of a seed $p_k(x,y) \in P_s$, i.e. $p_k(x+i, y+j)$, where $i,j \in \{-1,0,1\}$ (excluding $i = j = 0$) belong to a region determined by the seed if and only if the output of the fuzzy system corresponding to this neighbor pixel is $\geq T$. In our experiments the possible primary input states for the fuzzy system (the characteristics considered for any pixel) are interpreted as the pixel colour and its localization on the image. This is because the radiological knowledge of the issue (the dementia problem) assumes that pixel represents cerebrospinal fluid if it is *dark* and it is *close* to the cranium or it is *dark* and it is *close* to the central parts of the image.

Results of the segmentation process for exemplary CT scans are presented in Fig. 3. Brain tissue is marked with blue in upper images. Cerebrospinal fluid is marked with red in lower images. The same CT scans are used as in Fig. 2.



(a) Scan 12, AD

(b) Scan 10, VAD

(c) Scan 9, no disease

(d) Scan 8, no disease

Fig. 3. Segmentation of exemplary CT scans for various patients. Upper row, blue images show the brain tissue area. Lower row, red images show the cerebrospinal fluid area.

### C. Feature vectors calculation

Feature vectors calculation is necessary for further decision process. They are one of the method's key components, because they represent the synthesized form of patient's CT image scans. A set of geometrical, real valued features is selected [3]. Feature values are calculated using extracted cerebrospinal fluid area and brain tissue area.

Two feature sets are considered. The first one, named *FS1*, contains information only about area (volume) of the cerebrospinal fluid. Absolute and relative area of the fluid is taken from each scan. This method resembles manual, volumetric approach to patient's examination (cerebrospinal fluid volume calculation). In this approach, cerebrospinal fluid areas are the basic data for the decision process.

The second one, named *FS2*, consists of many other, shape related features. Absolute and relative circumference and center of mass are taken into account. Additionally, a series of shape coefficients are used. All used features are presented in Tab. I.

Patient's examination results in a series of 2D CT scans. On the basis of acquired and segmented CT scans a set of feature vectors is calculated. Each feature value is calculated for the whole CT image using the segmentation output. The process results in a non-square matrix of values generated for one patient. The following symbols are used in the given definitions:

– $i$—number of pixel within object,
– $L$—circumference of cerebrospinal fluid,
– $S$—area of cerebrospinal fluid,
– $L_B$—circumference of brain tissue,
– $S_B$—area of brain tissue,
– $r_i$—distance of a pixel from the center of the mass,
– $d_i$—distance of a contour pixel from the center of the mass,
– $l_i$—minimum pixel distance to the object contour,

TABLE I
FEATURES CALCULATED FOR A SINGLE, SEGMENTED CT SCAN. *FS1* REPRESENTS THE FIRST USED FEATURE SET, *FS2* REPRESENTS THE SECOND ONE.

| *Feature* | *Definition* | *FS1* | *FS2* |
|---|---|---|---|
| Number of scan | $n$ | yes | yes |
| Absolute circumference | $L$ | no | yes |
| Absolute area | $S$ | yes | yes |
| Relative circumference | $L_{rel} = \frac{L}{L_B}$ | no | yes |
| Relative area | $S_{rel} = \frac{S}{S_B}$ | yes | yes |
| Malinowska Coefficient | $R_M = \frac{L}{2\sqrt{\pi S}} - 1$ | no | yes |
| Modified Malinowska Coeff. | $R_{mM} = \frac{2\sqrt{\pi S}}{L}$ | no | yes |
| Blair-Bliss Coefficient | $R_B = \frac{S}{\sqrt{2\pi(\sum_i r_i)^2}}$ | no | yes |
| Blair-Danielsson Coeff. | $R_D = \frac{S^3}{\left(\sum_i l_i\right)^2}$ | no | yes |
| Haralick Coefficient | $R_H = \sqrt{\frac{(\sum_i d_i)^2}{n \sum_i d_i^2 - 1}}$ | no | yes |
| Feret Coefficient | $R_F = \frac{L_h}{L_v}$ | no | yes |
| Circularity Coefficient 1 | $R_{C1} = 2\sqrt{\frac{S}{\pi}}$ | no | yes |
| Circularity Coefficient 2 | $R_{C2} = \frac{L}{\pi}$ | no | yes |
| Center of mass in X | $R_{mx} = \frac{\sum_i x_i}{\sum_i 1}$ | no | yes |
| Center of mass in Y | $R_{my} = \frac{\sum_i y_i}{\sum_i 1}$ | no | yes |

– $L_h$—maximum width of the object,
– $L_v$—maximum height of the object.

$L$ and $L_B$ values are calculated using the following approach. Each pixel in the image, excluding image boundary pixels, is analyzed if it is a ROI boundary pixel. Only ROI boundary pixels are considered in the circumference value calculation. The process is a lookup procedure using a $3 \times 3$ pixels mask. A pixel is ROI boundary if and only if the center pixel is lit and at least two pixels in the masked area are not lit. In case not lit masked pixels are placed on the diagonal, the pixel contributes $\sqrt{2}$ to the circumference value, in all other cases it contributes $1$.

Normalized feature vectors are required by classification methods. All presented features are normalized using linear transformation to $\langle 0; 1\rangle$ interval. Each feature's lower and upper normalization bound is selected as the lowest and highest value from the available data.

### D. Decision making

The last step performed by the proposed medical support system is decision making. Three approaches are presented and evaluated. The first one is a classic multilayer perceptron neural network. The second and the third methods are based on automatic image annotation framework. All used methods are supervised machine learning and require a training set. Training examples are a set of manually diagnosed CT images. Manual diagnoses are performed by the radiologist and thus they represent medical domain knowledge.

*1) Classification using multilayer perceptron:* The first approach to decision making is a classic multilayer perceptron. In the presented approach, 3-layer perceptron is used. Number of neurons in the input layer is equal to the number of features in a single feature vector. Number of neurons in the output layer is equal to the number of output classes. Size of the hidden layer is calculated using a standard rule and is equal to the average size of input and output layer. Number of training epochs is equal to 500, learning rate is equal to 0.3 and momentum coefficient to 0.2.

Final decision process is the following. Each feature vector is classified using the neural network. Results are aggregated and the dominant class in all classification runs is selected.

*2) Classification using automatic image annotation approach:* In general, an automatic image annotation method describes an input image (represented as a set of feature vectors) with a subset of words from the given *dictionary*. Input of image annotation is a set of feature vectors and a dictionary. Output of automatic image annotation is a subset of dictionary. The goal of the method is to select the subset in best possible way, according to presented *training examples*. In this case, the dictionary is reduced to only two possible choices: *brain atrophy* and *no brain atrophy* (*brain atrophy* is treated as a single word, similarly as no brain atrophy). Output of the method is also reduced to only one word, being the diagnosis. Our goal is to verify if automatic image annotation framework can be used for the stated classification problem. Successful verification will lead to further research, with larger dictionaries.

Two automatic image annotation methods are examined for the stated problem. The first one is *Continuous Relevance Model* [4], abbreviated *CRM*. It is based on distance calculation between processed feature vector and feature vectors from the training set. This method uses distance measure based on *Gaussian kernel*. Words are propagated from the training set into the processed feature vectors with respect to the measured distance. The farther the feature vectors are, the lesser the influence is.

The second method is *Binary Machine Learning* [6], abbreviated *BML*. It employs a series of decision trees, constructed using *C4.5* algorithm. Each decision tree relates to one class from the dictionary and is responsible for generation of positive or negative answers. A positive answer given by a decision tree contributes to the word the tree represents. If the tree gives a negative answer, no word contribution is made. In case of $n$ words (in this case $n = 2$), $n$ decision trees is required.

## IV. EXPERIMENTS

The goal of conducted experiments is to show the method's ability to automatically discriminate between *brain atrophy* and *no brain atrophy* CT images. Experiments are performed on a set of CT images acquired from patients with various types of brain disorder and with no disorder. Segmentation and feature calculation are performed according to the presented routines. Three methods of patients discrimination are tested: *Multilayer perceptron neural network*, *Continuous Relevance Model* and *Binary Machine Learning*.

### A. Medical data and quality evaluation

Available medical data are divided into four categories according to the disease type (Tab. II). In each category a number of patients are examined. There are total 72 examinations available. Patients with three disease types are included in the performed experiments: *Alzheimer disease, Mixed Dementia* and *Vascular Dementia*. Patients with no brain atrophy are the fourth group. Examined patients are in different age and have different education level.

TABLE II
NUMBER OF PATIENTS ACCORDING TO THE DISEASE TYPE. CLASSIFICATION USED IN THE AUTOMATED PROCESS IS PRESENTED IN THE THIRD COLUMN.

| *Disease type* | *Number of patients* | *Class* |
|---|---|---|
| No disease | 20 | no brain atrophy |
| Alzheimer disease | 35 | brain atrophy |
| Mixed Dementia | 12 | brain atrophy |
| Vascular Dementia | 5 | brain atrophy |

Results quality evaluation is done with respect to manually prepared diagnoses. Those diagnoses are the reference point both in training and testing processes. All experiments are performed using *leave-one-out* validation procedure. The following values are calculated to evaluate quality: true positives, false positives, true negatives, false negatives, false positives ratio, false negatives ratio and overall accuracy.

To make this discussion more complete, we also address the accuracy baseline. Baseline value for accuracy is equal to 72% and it is calculated for a naive approach. To maximize accuracy, every case is classified to the most common class, without any feature consideration. For the presented data, the most common class is *brain atrophy*. This means that there are only positive answers (true positives and false positives) and no negative answers.

### B. Results

Manual diagnosis is performed by medical doctors, radiologists specialized in CT image analysis. This approach is the reference one. It requires a lot of manual labor, thus is expensive and prone to potential errors. Automated diagnosis is performed using the proposed method. Detailed information on classification results are presented in Tab. III. True positives, true negatives, false positives and false negatives are listed. Selection of feature set (*FS1* or *FS2*) has the largest influence on the achieved results. Selection of scan range and classification method have smaller influence. According to the performed experiments, usage of *FS2* results in much higher quality of results than usage of *FS1*. *BML+FS1* gives a large number of type II errors (false negatives). *CRM+FS1* gives a large number of type I errors (false positives). In one case, true negatives and false negatives have not been generated at all, which means that the method have not generated any negative answer. *MLP+FS1* approach fails on generation of negative answers and proves to be unusable.

As mentioned before, usage of *FS2* results in much better results. Number of true positives for both combinations (*CRM+FS2* and *BML+FS2*) is comparable or larger than for *CRM+FS1*, and number of true negatives is comparable to *BML+FS1*.

TABLE III
BRAIN ATROPHY VERSUS NO BRAIN ATROPHY DETAILED CLASSIFICATION RESULTS FOR EXAMINED APPROACHES. TP STANDS FOR TRUE POSITIVES, TN—TRUE NEGATIVES, FP—FALSE POSITIVES, FN—FALSE NEGATIVES.

| *Used approach* | *TP (correct)* | *FP (type I error)* | *TN (correct)* | *FN (type II error)* |
|---|---|---|---|---|
| Scan range: All | | | | |
| CRM+FS1 | 30 | 10 | 10 | 22 |
| BML+FS1 | 35 | 2 | 18 | 17 |
| MLP+FS1 | 51 | 16 | 4 | 1 |
| CRM+FS2 | 49 | 4 | 16 | 3 |
| BML+FS2 | 51 | 6 | 14 | 1 |
| MLP+FS2 | 48 | 3 | 17 | 4 |
| Scan range: 5-15 | | | | |
| CRM+FS1 | 52 | 20 | 0 | 0 |
| BML+FS1 | 33 | 2 | 18 | 19 |
| MLP+FS1 | 52 | 20 | 0 | 0 |
| CRM+FS2 | 50 | 5 | 15 | 2 |
| BML+FS2 | 52 | 13 | 7 | 0 |
| MLP+FS2 | 49 | 7 | 13 | 3 |
| Scan range: 10-15 | | | | |
| CRM+FS1 | 42 | 13 | 7 | 10 |
| BML+FS1 | 32 | 4 | 16 | 20 |
| MLP+FS1 | 52 | 20 | 0 | 0 |
| CRM+FS2 | 46 | 5 | 15 | 6 |
| BML+FS2 | 50 | 6 | 14 | 2 |
| MLP+FS2 | 49 | 8 | 12 | 3 |
| Scan range: 12-15 | | | | |
| CRM+FS1 | 50 | 20 | 0 | 2 |
| BML+FS1 | 35 | 4 | 16 | 20 |
| MLP+FS1 | 52 | 20 | 0 | 0 |
| CRM+FS2 | 47 | 2 | 18 | 5 |
| BML+FS2 | 49 | 7 | 13 | 4 |
| MLP+FS2 | 50 | 4 | 16 | 2 |

Achieved accuracies and negative rates are presented in Tab. IV. Averaged results are the confirmation of the discussion, presented above. Usage of *FS2* in general leads to better results, comparing to *FS1*. In terms of accuracy, selection of the annotation method do not have large influence on the quality. Presented results suggest that *MLP+FS2* with scan range *12-15* should be selected as the best approach. Usage of *MLP+FS2* with scan range *12-15* results in accuracy equal to 92%. *CRM+FS2* approach also provided good results. Accuracy is equal to 90% (only 1 more patient is incorrectly classified, compared to *MLP+FS2*), false positives and false neatives rates are both equal to 10%.

### C. Discussion

Achieved results are satisfying and can be viewed as a good basis for further research. When provided with a proper feature set, all three approaches to classification give similar results. There is a large difference in results quality between tested feature sets. The first one, which is based only on cerebrospinal fluid areas, provides unsatisfactory results. However, when the feature vector is extended, quality is increased. Examined scan ranges do not influence the results quality in a large manner. Best results are achieved for scan range 12-15, however usage of all scans gives only very minor decrease in quality (1 more patient is misclassified).

TABLE IV
BRAIN ATROPHY VERSUS NO BRAIN ATROPHY AVERAGED CLASSIFICATION RESULTS FOR EXAMINED APPROACHES.

| *Used approach* | *FP rate* | *FN rate* | *Accuracy* | *Relation to baseline* |
|---|---|---|---|---|
| Scan range: All | | | | |
| CRM+FS1 | 0.50 | 0.42 | 0.56 | below baseline |
| BML+FS1 | 0.10 | 0.33 | 0.74 | above baseline |
| MLP+FS1 | 0.80 | 0.02 | 0.76 | above baseline |
| CRM+FS2 | 0.20 | 0.06 | 0.90 | above baseline |
| BML+FS2 | 0.30 | 0.02 | 0.90 | above baseline |
| MLP+FS2 | 0.15 | 0.08 | 0.90 | above baseline |
| Scan range: 5-15 | | | | |
| CRM+FS1 | 1.00 | 0.00 | 0.72 | baseline case |
| BML+FS1 | 0.10 | 0.37 | 0.71 | below baseline |
| MLP+FS1 | 1.00 | 0.00 | 0.72 | baseline case |
| CRM+FS2 | 0.25 | 0.04 | 0.90 | above baseline |
| BML+FS2 | 0.65 | 0.00 | 0.82 | above baseline |
| MLP+FS2 | 0.35 | 0.06 | 0.86 | above baseline |
| Scan range: 10-15 | | | | |
| CRM+FS1 | 0.65 | 0.19 | 0.68 | below baseline |
| BML+FS1 | 0.20 | 0.38 | 0.67 | below baseline |
| MLP+FS1 | 1.00 | 0.00 | 0.72 | baseline case |
| CRM+FS2 | 0.25 | 0.11 | 0.85 | above baseline |
| BML+FS2 | 0.30 | 0.04 | 0.89 | above baseline |
| MLP+FS2 | 0.40 | 0.05 | 0.85 | above baseline |
| Scan range: 12-15 | | | | |
| CRM+FS1 | 1.00 | 0.04 | 0.69 | below baseline |
| BML+FS1 | 0.10 | 0.33 | 0.74 | above baseline |
| MLP+FS1 | 1.00 | 0.00 | 0.72 | baseline case |
| CRM+FS2 | 0.10 | 0.10 | 0.90 | above baseline |
| BML+FS2 | 0.35 | 0.06 | 0.86 | above baseline |
| MLP+FS2 | 0.20 | 0.04 | 0.92 | above baseline |

Let us relate to the stated research goals, now. Construction of a CT decision support system is possible, however great care has to be made during feature selection process. Areal features seem to be insufficient and other shape related features must be introduced. The presented support system architecture gives satisfactory results. Having the accuracy baseline value equal to 72%, authors have achieved maximum classification accuracy reaching 92%. Verification of automatic image annotation framework is also positive. Achieved results are similar to those with standard classification approach.

## V. SUMMARY

A method for automatic discrimination of brain-atrophic patients with possible dementive disease and patients with no brain atrophy is proposed. A series of 2D CT scans, representing the 3D brain image is given as input. Each scan is segmented by a specialized routine, extracting the cerebrospinal fluid and nervous tissue. A set of feature vectors is calculated on the basis of segmentation and they are input of a classification method. Afterward, feature vectors are processed and a diagnosis is generated.

Achieved results are very promising. For the best presented combination of feature set, scan range and classification method, accuracy reaches 92%. It means that the automatic method is able to repeat expert's manual diagnoses in most cases. Additionally, the automated process is not time consuming and can be used as a live aid in medical doctors daily work.

The proposed method could be also used for prospective and populational researches due to its speed and repeatability of output scores. Another possible usage is the evaluation of possible changes in atrophy degree, e.g. during treatment—especially in experimental methods of treatment. Further research will be focused on introduction of new, shape related features characterizing the cerebrospinal fluid. Additionally, a larger dictionary (with more detailed diagnoses) will be proposed for the image annotation approach.

## ACKNOWLEDGMENT

This work is financed from the Ministry of Science and Higher Education resources in 2006 – 2008 years as a research project N518 022 31/1338.

***Abstract*—Recent development of various domains of *Artificial Intelligence* including *Information Retrieval* and *Text/Image Understanding* created demand on new, sophisticated, contextual methods for data analysis. This article formulates *Neuronal Group* and *Extended Neuron Somatic* concepts that can be vastly used in creating such methods. Neural interrelations are described using graphs, construction of which is done in parallel with neural network learning. Prototype technique based on *Growing Neural Gas* is also presented to give more detailed view.**

***Index Terms*—neural networks, pattern recognition, structural pattern recognition, pattern classification.**

## I. Introduction

IN GENERAL, modern research on classifiers tends to develop into three non excluding directions. The first one, commonly known as *Kernel Methods* performs kernel based indirect mapping to possibly unknown feature space, known as *kernel trick*. The most notable representatives of this group are *Support Vector Machines* [1]. The second direction makes use of *classifier committee* concept, giving *AdaBoost* and others [2], [3] as well recognized examples.

These techniques can with some success be applied also to structural pattern recognition task next to dedicated solutions. Commonly considered tasks of this family are text and image segmentation. The one plays vital role in *Information Retrieval* field, the other in dynamically developing *Image Understanding* [4] paradigm. New tasks in these fields, like *Opinion Mining* [5] and *Image Symbolisation* [4] prove the amount of work that is still to be done, yielding new models, concepts and techniques that would face problem complexity.

Modern probabilistic models of structural pattern recognition, namely family of methods referred to as *Conditional Random Fields* [6] prove vitality of contextual approach to these problems [7]. Advances made in this field in recent years encourage exploration of possible expert knowledge and context utilisation. What is important, this is done outside *vector space* model of object representation, often referred to as *feature space*, that is the most widely used in *Artificial/Computational Intelligence* community.

Section II contains general discussion about data handling different kinds of knowledge utilization while computing object representation. Section III describes conceptual model of *neuronal group* and *graph based description* of *neuronal interrelations*. This kind of knowledge about data is inferred during neural network learning, building a context that can be used during the rest of learning phase as well as can form part of the solution to the addressed problem.

A prototype method taking benefits from *Neuronal Group Learning* concept is defined in section IV using *Adaptive Active Hypercontour* [8] frame. Other possibilities and promising learning process duality considerations are presented in section V. Supervised classification task will be referred to as an example field of applications.

## II. Extended Neuron Somatic Description

Analysing most of contemporary *pattern analysis* methods one can come to the conclusion, that in almost all cases input space definition plays crucial role in entire process.

### A. Object space transformation

Construction of *input space* $\mathcal{X}$ can be usually described as object transformation from domain space $\mathcal{O}$ to $\mathcal{X}$, here denoted as a function $\phi : \mathcal{O} \rightarrow \mathcal{X}$ [9]. It often includes sophisticated, domain dependent feature extraction and selection techniques. It is typically required, that $\mathcal{X}$ fulfils all requirements of the algorithm we wish to use to analyse it. This usually means, that $\mathcal{X}$ is either *inner product*, *normed* or *metric* space. Various types of elements' *similarity* can also be found in literature and are enough for some methods.

Meaningful construction of $\mathcal{X}$ together with target operations on space elements (e.g. metric) are hard tasks, requiring substantial domain knowledge. Their vitality in entire process can additionally be emphasised by the fact, that mistakes done on this phase of research usually cannot be overcome by choosing more powerful algorithms which operate on $\mathcal{X}$, as they cannot supplement the knowledge that has been lost during transformation $\phi$ (if it was not redundant).

One of the most popular approach to input space definition is so called *vector space model* (VSM) - considering $\mathcal{X} = \mathbb{R}^n$ for some natural $n$. Its usefulness cannot be underestimated, especially that its properties have been subjected to many research initiatives and successfully applied to many tasks. The most important benefit of *VSM* usage is availability of numerous standard operation definitions (including sophisticated inner products and metrics) that can be directly used on input space elements regardless $\phi$ actual definition. On the other hand, this model puts extreme importance on feature extraction, selection and informative power of feature set. The other approach considers more complex representation domains, e.g. including graph structures. It aims to preserve more information stored in original object representation in set $\mathcal{O}$. However, more sophisticated and tightened to $\mathcal{X}$ operations are required. In the end, this approach needs similar infield expert knowledge level, which is introduced in $\mathcal{X}$ operation level rather than in $\phi$ transformation definition. Last years of research on *structural kernels* replacing inner products brought huge progress in this field.

Even though vital to final results, *input space* definition utilises mostly expert/engineer knowledge and experience. It is worth mentioning, that $\phi$ usually consists of subsequent steps. Basic feature extraction can, and usually is followed by operations like weighting, normalization, feature selection or chained feature extraction. This transformations often utilise additional knowledge coming not only from expert, but also from data. It is usually inferred from some set of objects accompanied by additional information, e.g. considering supervised classification task this role is typically played by training set, or elements of specially prepared tuning set. It is surprising, that extraction and utilisation of knowledge about interrelations of different areas of $\mathcal{X}$ did not find equally big interest among research teams. One of the efforts worth mentioning are contextual textual document processing ideas presented in [10]

### *B. Extensions In Neuron Somatic Description*

Let the input space be real vector space, to comply with classic *Hebb*'s model of neuron [11]. Somatic parameters of neuron are also required to be real numbers, with additional parameter—*bias weight*. However, other phenomena can have impact on neuron excitement (see *lateral feedback* example in section III). The biggest potential lies in sensor neurons, which operate directly on input data. Currently, somatic information (parameters) stored by neuron are the one required to compute its activity after input presentation. Reminding *Hebb*'s model these are weights (one value for each input including *bias*). There are also other factors that directly or not can influence neuron's behaviour, like position in neural cortex (absolute or relative to neighbouring neurons), activation function parameters not related to input etc. Neuron potential used in *Kohonen* networks to deal with dead neuron problem shows commonness of this approach, which capabilities seems to be underestimated by the researchers.

Only some of these additional parameters can properly be considered *somatic* in biological meaning of this word. Nevertheless, it is proposed to extend somatic description of neuron by data that not necessarily, as input weights or even mentioned *potential*, have direct influence on excitement computation. In contrast, they may play important role during network model adaptation or final result formulation, e.g. by defining context of computation. See sections III and V for more details.

## III. Neuronal Groups

Let neural network be seen as a set of neurons $V$, their parameters and some kind of its architecture description $A$, that defines *synaptic* neuronal interconnections. These connections meet reflection in somatic description of adjacent neurons. In the concept presented it is proposed, that every set $G \subseteq V$ can form a *neuronal group*. Internal relations between group members and with other groups can be used in both network output computation and its learning.

### *A. Neurophysiological Background: Neuronal Group Selection Theory (NGST)*

Rapid development of neurophysiology in $20^{th}$ century brought numerous theories about how brain is organised and cognitive process proceed. One of the most interesting and revolutionary ones is called *Neural Darwinism* [12]. Even though concepts presented do not refer directly to evolutionary process proposed by *Edelman*, it may be considered a neurophysiological and, more notably, *philosophical* analogy to the presented work.

The *Neuronal Group Selection Theory* states [12], that brain is dynamically organised into (sub)networks, structure and function of which arises from its development and behaviour. These networks, consisting of thousands of strongly interconnected neurons, are called *neuronal groups* and considered as *functional units*. *Edelman* considers three phases/processes during neural map development. The first one, aimed to build *primary repertoire* of *neuronal groups*, is done within neurobiological ant anatomical constraints dictated by genotype. *Primary variability* of neurons and their synaptic connections form a basis to further process of self-organisation. This phase takes place mostly during foetal life and infancy, when neural system is mainly exposed to self-generated activity and consequently self-afferent information. Subsequent experiment based selection catalyses development of best performing *group prototypes*, leading to formation of primary *functional units* (*primary neural repertoire*). Even though genetically and anatomically determined, adaptation and selection process is itself epigenetic and it is extremely improbable for two organisms to have identical neural structure- this is called *primary variability*.

Development of neural system unavoidably leads to increase of quantity and variability in information processed by it. During postnatal life an epigenetic process of synaptic weight adaptation takes place, leading to composition of *primary groups* into more complex structures resulting in forming *secondary neural repertoire* in a subsequent selective process. This phase is even more ontogenetic, as it bases on individual experiences which create different predicates for *neuronal group selection*. Temporal correlations between various groups leads to creation of dynamically emerging neural maps, whose re-entrant interconnections maintain spatio-temporal continuity in response to re-entrant signals. A resulting neural maps can be considered an effective functional units of brain.

Seeking for a more detailed and intuitive example, please refer to *Mijna Hadders-Algra*'s article [13], which presents human motor development in light of *NGST*.

The idea presented in this article is convergent with *Neuronal Group* concept presented by *Edelman* and thus shares its name. However, at least two important differences must be outlined. The first one is that in the concept presented *neuronal groups* do not have to reflect degree of interconnection between neurons from the group; various approach to group distinguishing was presented in subsection III-C. The second difference is related to network and group development. Evolutionary process analogous to *NGST* might be considered as one of numerous possible algorithms and does not exhaust concept perspectives.

### B. Lateral Feedback

An other inspiration for presented model was *lateral feedback* mechanism and facts about formation of cortical map [11]. *Lateral feedback* refers to observed impact which activity of latent neurons have on other neuron excitement and plays important role in topographic organisation of cerebral cortex. Depending on selected interaction model we generally can have positive and negative influence (increasing and decreasing neuron activation), which usually reflects distance between neurons. Dynamical properties lead to formation of bubbles-groups of neurons that tend to recognise similar signals.

This very simple mechanism, although impractical from computational point of view because of dynamical stability problems, focuses on cooperation of neurons and group (bubble) activity as potential research field. This biological motivation can be presented as inspiration of widely used self-organising neural networks called *Self Organising Feature Maps*, *Kohonen networks* [11] and similar derivative models. However, the approach presented addresses different aspects of neural interactions, possibly receding physiological inspirations.

### C. Neuronal Group concept

Let $\mathbb{S}$ denotes a set of *neuronal groups*, which can also be considered as a set of group labels. In the concept presented all neurons $n \in V$ have associated set of groups to which they belong, here denoted as function $l : V \to 2^{\mathbb{S}}$, also referred to as *labelling of neurons*. It can be considered *somatic description extension* (see section II-B) but this is not crucial to the expression of the idea. Limitations on $l$'s codomain can be imposed to simplify model or tune it to specific needs. For instance, condition

$$\forall_{n\in V}\overline{\overline{l(n)}} = 1 \qquad (1)$$

enforces mutual exclusions of groups and can also be described functionally as $\hat{l} : V \to \mathbb{S}$. In practice, it is desired to introduce or infer groups of different kinds, playing different roles in algorithms that can utilise information coming from grouping of neurons. As it will be shown later, mutual exclusion condition is important tool, but to avoid tainting the concept it should be imposed only on subsets of $\mathbb{S}$, in cases when these group distinguishing policies exclude themselves.

In general we can consider three possible approaches to group identification:

1) predefined groups—identified by an expert/engineer contexts in which interrelations of neurons should be considered.
2) supervised group identification—in which an external premise/knowledge to distinguish groups or perform neuron grouping; this is typical situation in supervised classification tasks, where category labels can act as group descriptors.
3) unsupervised group identification—possibly the most interesting approach; similarly to object grouping tasks, the number of groups can be predefined or not.

*Predefined* groups might be intentionally compared to *primary neuronal repertoire* included in *NGST*, whereas the other two corresponds to *secondary repertoire*. *Unsupervised group identification* is in general correspondence with *NGST* in approach and philosophy, as premises to groups selection are formed by *internal* relations between neurons and inputs (experiences) related phenomena. However, logical weakness of such analogies should be emphasised.

### D. Neuronal interrelations and their descriptions

The most natural way to describe relations between neurons is using graphs of different kind. Obviously, entire network architecture $A$ can be described as weighted, directed graph. Another example of the often analysed relation type would be topological neighbourhood, utilised by self-organising neural networks during learning process, naming *Growing Neural Gas* algorithm (*GNG*) as most straightforward implementation of this idea.

Going further, let us consider set $\mathcal{G}$ as set of available graph interrelation descriptions. Graphs $G \in \mathcal{G}$ can differ on type. They can be either directed or not, allow multiple edges and loops, be weighted ore edge-labelled graphs etc. All depending on characteristics of described relations and how knowledge carried by such description is later used. Similarly to three approaches to groups identification also graph descriptions can be defined according to analogous premises. In this cases however, graphs of predefined interpretation or the one distinguished through supervised process seem to be more natural.

It is worth mentioning that presence of a bijective mapping between neurons and nodes from all graphs is meant. Thus sometimes we will refer to neurons as nodes, or even use set $V$ having set of nodes in mind. However, this is not a requirement.

### E. Dualism of inference process

During a network inference phase three processes are taking place in parallel. The first consists of neurons somatic parameters adaptation, namely reference points change or weight adaptation, network reorganisation, etc. The second process is an inference of neurons labelling, which covers label set and neuron membership management. The third, possibly the most challenging one, is inference of interrelation descriptions. This itself can be considered some kind of structural pattern analysis problem.

Although using the word “duality” in the following context may be seen as misuse, it intuitively describes character of relations between the inference of neural network and other two mentioned parallel processes. What is more, neuronal groups and interrelation graphs can be integral part of final result, not only the neural network structure and standard somatic parameters themselves.

## IV. Labelled Growing Neural Gas

To keep the presentation clear an example usage of *neuronal group* concepts will now be presented. Consequently, supervised single-label classification of $\mathcal{X} = \mathbb{R}^n$ elements will be analysed. To avoid misunderstanding, this problem can be defined as finding classifying function $h : \mathcal{X} \to \mathcal{L}$, where $\mathcal{L}$ denotes set of labels. In general $h$ of the form $h : \mathcal{X} \to 2^{\mathcal{L}}$ could be discussed (multi-label classification), but here we focus on simpler model for clarity and compactness reasons.

### A. Classifier model

Let $G = (V, E)$ be a strict (simple) graph, where $V$ and $E$ denote the node and the edge set respectively, and

$$\forall_{e \in E} \exists_{v_1, v_2 \in V} \; e = \{v_1, v_2\}$$

As it was suggested in section III we will consider $V$ as neuron set. Let each neuron $n \in V$ has associated element $w(n) \in \mathcal{X}$ here called node's *position* or *reference element*. Each $w(n)$ describes some or all somatic parameters (here weight vector) of a neuron associated with $n$.

Let $\tau : \mathcal{X} \to \mathbb{R}$ be a transmission function (composition of an *activity* and an *output* (activation) functions) of every neuron from $V$. We will restrict to $\tau$ being of the form $\tau = \sigma \circ \rho$, where $\rho : \mathcal{X} \times \mathcal{X} \to \mathbb{R}$ is linear metric in $\mathcal{X}$, $\sigma$ is non-increasing function. These imply

$$\forall_{c \in V} \; \tau_n(\mathbf{x}) = \sigma(\rho(w(n), \mathbf{x})) \tag{2}$$

Metric can easily be exchanged with inner product without significant influence on other parts of presentation. In such case $\sigma$ should be non-decreasing function, as interpretation of inner product result is opposite to distance.

In addition, let $\mathbb{S} = \mathcal{L}$ and mutual group exclusion restriction (1) be imposed. To simplify notation $l(n)$ will denote the label of the group to which $n$ belongs (instead of a set having exactly one element- adequate group label).

Classifying function generated by such network can be defined in the following way:

$$\forall_{x \in \mathcal{X}} \; c_V(x) = l\left(\operatorname*{arg\,max}_{n \in V} \tau(x)\right) \tag{3}$$

It is worth explicit mentioning, that this model is equivalent to Nearest Neighbour algorithm, if one neuron would be constructed for every element $x$ in training set, with reference point and labelling set accordingly.

Graph $G$ will store topological neighbourhood interrelation information in context of input distribution of labelled points or training set. This will be the only description used in the prototype presented.

### B. Supervised Neuron Labelling

In the presented solution supervised neuron labelling is used. Policy must reflect the fact that it is not only used in learning phase (see section IV-C) but also for construction of final functional classifier hypothesis. The most straightforward and also effective supervised node labelling strategy is called *precision labelling*. It basically chooses the label that maximises hypothesis *precision* inside its *Voronoi* cell. Neurons *precision* is evaluated using training set or its subset/detached part. Obviously, *recall* and especially *F*-measures can be utilised as well.

*Activity labelling* can be seen as an alternative to *precision labelling*. While computing new label of neuron it takes also activity of neuron inside its *Voronoi* cell, choosing the *most active* group.

Labelling policy selection should reflect a general aim set to learning process. Referring to *Adaptive Active Hypercontour* techniques of classifier inference, an *energy* function can be used to estimate classifier quality during its inference. Let additionally $c_i$ be the classifier hypothesis in $i$-th classifier step, regardless step division meaning. The very simple energy function might be any measure of $h(c_i)$ *imprecision*. Minimising energy over training set is equivalent to maximising its precision. However, its true power depends on informative relation between training and test set. Other policies are possible and interesting, depending on entire process definition and its aims. The most promising one would be *contextual labelling*, taking advantage of hypothesis about labels of other nodes. Research about such technique is in progress.

Neuron labelling plays important role in adaptation phase, implying neurons reference points strategies. In this case, effective relabelling strategy is vital. Below the most notable approaches to this problem are listed.

1) Constant labelling—we assume that neuron's labelling is not altered during neural network learning. In this case overall algorithm efficiency depends on ability to generate new neurons belonging to a specific group. What is more, mislabelled node can be erased from $V$. In certain conditions, constant network with set labelling can also be used.
2) Off-line relabelling—in this case nodes' labellings do not follow dynamical changes in network structure and parametrisation. Relabelling is done using selected policy once for cone time, e.g. after each epoch (processing of entire training set).
3) On-line relabelling—where labelling policy is applied after every change in current process description.

Although on-line relabelling seems the most powerful and meaningful, it is also the most computationally expensive. Trade-off between effectiveness and efficiency of inference process should be analysed while planning to follow this way.

### C. Adaptation process

As mentioned earlier, the current labelling hypothesis can be used to drive network adaptation. A classic approach did not use such kind of information. Even considering *RBF network* setting, in which a sensor layer's aim is to decrease the space quantisation error rather than to find optimal quantisation for the second layer (learned in supervised process). One of problems addressed by this prototype implementation is to drive network inference in such a way, that would increase quantisation accuracy along surfaces dividing classes (areas surrounding contours).

Let the concept of *Adaptive Active Hypercontour* be presented in short, to build a frame for further considerations

Let $\mathcal{H}^{\mathcal{X},\mathcal{L}} = \{h : \mathcal{X} \to 2^{\mathcal{L}}\}$ denotes the set of (classifier) hypothesis over $\mathcal{X}$ and $\mathcal{L}$; it will be referred to as $\mathcal{H}$. As (in most cases) function realized by the classifier is considered *a solution*, a distinction is made between classifier $c \in C^{\mathcal{H}}$ referred as *hypothesis* and the classifying function $h(c) : \mathcal{X} \to 2^{\mathcal{L}}$ realized by $c$, which will be referred as *function hypothesis*.

Let $\kappa^p$ be parametrised by $p$ a task oriented classifier induction function, $C^{\mathcal{H}}_{\kappa}$ be classifier space (the domain of $\kappa$), such that $\forall_{c \in C^{\mathcal{H}}_{\kappa}} h(c) \in \mathcal{H}$. *AAH* solves classifier inference through optimisation process, which target function $E$ is commonly called *energy*. $E$ can be considered as function $\mathcal{H} \to \mathbb{R}$, but it is usually desired that it operates on $C^{\mathcal{H}}_{\kappa}$ directly, as various aspects of classifier parameters should be evaluated to achieve valuable solution.

*Adaptive Active Hypercontour* algorithm consists of the following steps [14]:

1) **Initialization**: during this phase the choice of initial classifier model and subordinate inference method ($\kappa$) is made. An initial classifier hypothesis $c_o \in C^{\mathcal{H}}_{\kappa}$ is then generated and its *energy* computed.
2) $\boldsymbol{\alpha - phase}$: This step mainly consists of subordinate algorithm invocation which generates new classifier hypothesis:
$$c_{i+1} = \kappa_p(c_i)$$
3) $c_{i+1}$ ***energy*** **estimation**
4) $\boldsymbol{\beta - phase}$: The subordinate algorithm ($\kappa$) is very often optimisation process itself. However, its target function usually is compatible, but different than $E$. In this phase **any** change in current process may be performed to ameliorate $E$ optimisation state modification, like:
   - unwarranted current hypothesis change, usually $\kappa$ and $E$ oriented, like restoring the previous classifier (in case of significant optimisation regression, or its structural change that bypasses $\kappa$ shortcomings).
   - $\kappa$ reparametrisation or replacement with different algorithm.
   - classifier model change.

The solution presented will now be described as an instantiation of presented meta-algorithm. Initialisation of the process consists of creating initial neurons with random reference points. Initial neuron labelling must also be performed; neuron interrelation graph has empty edge set $E$.

### D. Phase $\boldsymbol{\alpha}$

During $\alpha$ phase all inputs from training set or $\lambda$ random points generated according to training distribution are processed. On-line adaptation using all inputs is considered as one, atomic $\kappa$ invocation. For each input $\mathbf{x}$ having associated training label denoted as $l_{\mathbf{x}}$ the following steps are performed:

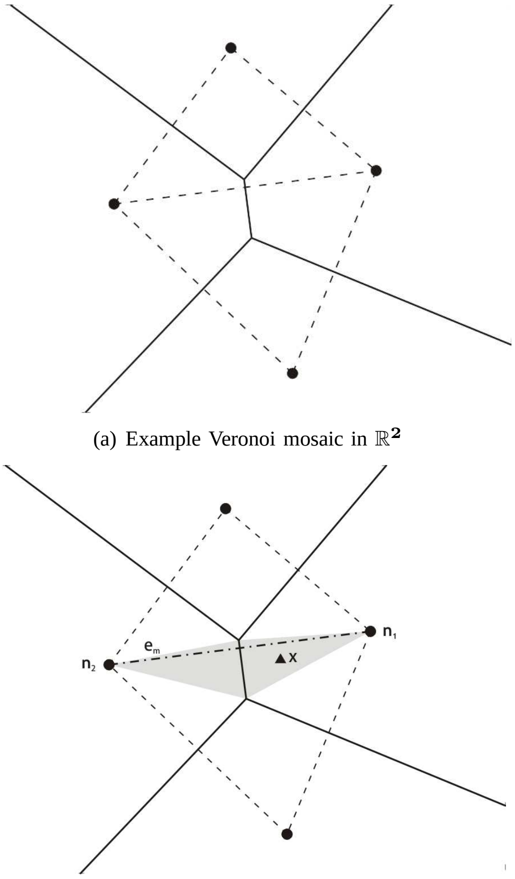
1) Find most active and second-most active neuron from $V$ for given $\mathbf{x}$, let them be $n_1$ and $n_2$ respectively.
2) Increase the age of all edges emanating from $n_1$ in $G$ by 1.
3) If $n_1$ and $n_2$ are connected with an edge $e_m$, set its age to zero. Otherwise, create edge $e_m = \{n_1, n_2\}$.
4) Apply neuronal position adaptation strategy. Few situations can be considered, presented here form "a straightforward example"
   - $\boldsymbol{l(n_1) \neq l(n_2)}$. In this case $e_m$ crosses the surface separating differently labelled areas of $\mathcal{X}$ according to the present function hypothesis. If one of the labels matches $l_{\mathbf{x}}$, then we perform a single-side surface approximation by adapting reference points of matching neuron using standard Kohonen rule:
   $$\Delta w_{n_1} = \alpha_1(\mathbf{x} - w(n_1)) \qquad (4)$$
   and its adjacent nodes in G using same rule with different, smaller step:
   $$\Delta w_a = \alpha_a(\mathbf{x} - w(n_1)) \qquad (5)$$
   If neither $l(n_1)$ nor $l(n_2)$ are equal to $l_{\mathbf{x}}$, then we perform adaptation of $n_1$ (together with its neighbourhood).
   - $\boldsymbol{l(n_1) = l(n_2)}$. In this case, $\mathbf{x}$ lays in "internal" region of label $l(n_1)$. If $l(n_1) = l_{\mathbf{x}}$, then no adaptation, or adaptation with negative steps should be performed. Negative learning is optional and, if enabled, should be used only when all neighbours of $n_1$ and $n_2$ have the same label equal to $l_{\mathbf{x}}$. If $l(n_1) \neq l_{\mathbf{x}}$ then standard adaptation of $n_1$ is applied.
5) Remove edges from $E$ with an age larger than $a_max$. If this results in neurons having no adjacencies—remove them from $V$.

To illustrate a typical situation during adaptation figures 1(a) and 1(b) are supplied, depicting a typical *Voronoi* cells structure and the active area of one of the edges.

### E. Phase $\boldsymbol{\beta}$

Once every phase $\alpha$, or rarely if desired, additional steps should be taken, e.g. to add new neurons to $V$. To enforce generation of new neurons in areas of our interest, namely along class discriminating surfaces, two following strategies are proposed.

**Intermediate node generation** is similar to the node generation mechanism used in *GNG* method. It can be done according to the subsequent steps:



(a) Example Veronoi mosaic in $\mathbb{R}^2$

(b) Example edge activity area

- Determine node $p$ of lowest precision in training set or randomly generated representative set of labelled inputs (if distribution is analysed).
- Insert new node $q$ with $w(q) = \frac{1}{2}(w(p) + w(r))$ where $r$ is neighbour of $p$ in $G$ having lowest precision.
- Insert edges $\{p, q\}$, $\{q, r\}$ into $E$ and remove edge $\{p, r\}$ from it.
- Relabel all neurons from $V$

This strategy requires global node relabelling. We can avoid it by using different policy of similar power called **node replication**. It simply replicates neuron of lowest precision, thus not altering Voronoi cell distribution.

### *F. Summary and possible extensions*

Presented *Labelled GNG* algorithm uses few concepts presented in previous section. At first, it uses supervised neuron labelling to infer classifying function of simple single-layer neural network. Although such network can be used as classifier (with formulae 3), its output can also be processed by other chained classifier model. In this case we will benefit from increased quantisation rate along decision surfaces.

The second important extension is *Neuronal Group Learning*, which utilises information about inferred *neuronal groups* during network adaptation process. This is used in both $\alpha$ and $\beta$ phases of the prototype method presented.

Empirical results and their analysis will be presented during the conference.

## V. NEURONAL INTERRELATIONS AS INFERRED KNOWLEDGE

The previous section presented method of *Labelled Growing Neural Gas* inference that can later be used as classifier. However, parallel inference of *neuronal groups* and *neuronal interrelation descriptions* can be the true problem solved by this method. At first, some other concept presented in [14] will be considered.

### *A. Neuronal Group Activity*

As suggested at the beginning, a formation of neuronal group does not have to be used only to facilitate learning process. Neurons can cooperate within one group and even compete with neurons from other groups during both learning and use stages.

This was first used in [14] in the concept of competitive learning of neural networks. Although differently described in original paper, let the concept of *neuronal group activity* be here introduced.

Let $\mathbb{F}$ be a common codomain of all neurons' transmission function, later referred as *field* or *output space*. In addition, let $\mathcal{L} \subset \mathbb{S}$, and $\forall(s \in \mathbb{S})V(s)$ denote all neurons from group $s$. Function hypothesis generated by neural networks with *neuronal group* information can be defined using the following formulae:

$$c(\mathbf{x}) = \arg\max_{l \in \mathcal{L}} \ \Psi_l(\mathbf{x}) \tag{6}$$

where $\Psi_l$ is activity of group $l$. It was proposed in [14] that $\Phi_l$ was of the form

$$\Psi_l(\mathbf{x}) = norm^{|V(l)|} \ (\Phi_{V(l)}(\mathbf{x})) \tag{7}$$

where $\Phi_{V(l)} : \mathcal{X} \to \mathbb{F}^{|V(l)|}$ be group activation function returning a vector of activations of neurons from specified group and $norm^k : \mathbb{F}^k \to \mathbb{R}$ be a proper norm (or semi-norm) in $\mathbb{F}^k$ space.

Interpreting set $\{(v, l(v)) : v \in V\}$ as a set of labelled control points, an appropriate definition of $\tau$ and $norm$ will result in classifier model equivalent to the one introduced be *potential method* and used in *Adaptive Potential Active Hypercontour* technique. Its properties allows efficient *energy* driven network inference, a solution to some optimisation problems faced during work presented in [9].

### *B. Structural Knowledge Acquisition*

One of the most promising fields of application of presented concepts are those connected with structure discovery and relation recognition, in which neural network is a backbone of *structural pattern analysis* process. Node distribution in space $\mathcal{X}$ induce some Voronoi cell structure. In described parallel processes relations among these cells can be recognised and inscribed in graphs of *neuronal interrelations*. Some of used graphs may have special meaning and can even form solution of *structural pattern analysis* problem.

To present an example, perspectives in the field of my special interest, data segmentation, will be analysed. Considering two dimensional segmentation problem (as image segmentation is) let neuron reference points lie in space $N \times N$ (as pixel coordinates do). It is quite natural, that neuron distribution in pixel coordinates space together with neuronal groups and labellings reflecting output labels forms a solution. However, additional somatic parameters and/or interrelation information may be needed during network learning.

Willing to provide argument proving potential of the concept presented it this field a straightforward image segmentation or contour inference algorithm can be defined in two simple ways.

The first uses concept of group activity and possibility to define them so as to get model equivalent *potential method*. In conjunction with meaningful definition of *energy* function, a *Potential Active Contours* are obtained. The other, better suited in neural network backbone of the method presented is known as *Kohonen Snakes*.

## VI. Conclusions and further work

The article presents *Neuronal Group* concept accompanied with based on graphs *neuron interrelation description* as a method of enriching neural network inference models. If properly defined *Neuronal Group Learning* can also lead to solution of *structural pattern analysis* tasks. Group descriptions and interrelations between neurons can explicitly be defined by a researcher. However, the widest perspectives are given by automatic, supervised or unsupervised interrelation inference.

Apart from extending existing methods, the one presented in this article can be used in advanced *structural pattern analysis* problems. Recent development and new tasks of *Information Retrieval* and *Text/Image Understanding* fields created a huge demand on contextual methods that would be flexible in utilisation of any kind of human knowledge about problem domain. What is more, automated knowledge inference from data is of increasing importance in all *Artificial Intelligence* domains. Future work on presented concepts will focus on these demanding task, especially that they proves to be much more difficult and requiring more sophisticated computational and analysis models than many currently considered.

## Acknowledgments

***Abstract*—Upon developing an information system, establishing an effective information retrieval method is the main problem along with the management of the information. With ontologies, the semantic structure of knowledge can be represented and the resources can be managed along with their context information. Observing that within this knowledge space, resources are not isolated but connected to each other by various types of relations, we believe that utilising those relations can aid information provisioning. In this paper, we explore the concept of the *semantic relevance* between resources and the semantic structure of a knowledge space, and present a relevance measuring algorithm between resources based on a graph structure, with two implementation examples.**

## I. Introduction

IN ANY knowledge space, each information resource does not exist in isolation but is connected to other resource(s) in many different types of relations. The relation may be explicitly represented or can be inferred, and resources can be directly linked or their relations may be indirect via another resource(s). Also, even two resources seem to have no relation whatsoever in a certain environment, they may have a contextual relation within another knowledge space. Concerning that the vast amount of readily available information in not only the Web but also in a limited knowledge space such as a single organisation, the information retrieval has been a challenging problem, and we believe that finding the semantic relevance between resources can contribute to effective information provisioning. To find the semantic relevance, the knowledge space needs to be semantically structured and represented, and a method in finding and measuring the relevance is also required.

In our earlier work [1], we presented our semantic relevance measure that calculates the relevance value between objects in a graph structure. In this paper, we enhance our initial approach by further discussing the meaning of the semantic relevance and describing the knowledge management within an information system with a knowledge model and an ontology, and creating the *Relevance Graph*, an interpretation of a knowledge model and the base structure of the relevance calculation, is explained in more detail. In addition, the relevance calculation algorithm is improved by adapting the *Edge Scaling* method presented in [2], and two systems which utilises this semantic relevance measure are introduced to describe examples of how this method can be implemented.

## II. Semantic Similarity and Semantic Relevance

There have been various different views and approaches to discover the similarity or relatedness among information objects. One of the most obvious relation that can be discovered between resources is the *semantic similarity*, which is the likeness between objects. For textual information such as documents, it means the similarity of their contents, and this similarity can be measured by lexical matching methods. One of the traditional methods is the TF-IDF(term frequency-inverse document frequency) [3] based comparison, and the LSA(latent semantic analysis) [4] provides an automatic way of organising documents into a semantic structure for information retrieval. The semantic similarity can also be found between terms as well as textual documents. Within a set of structured terms, as a tree-based hierarchy, several approaches have been introduced including an edge-based method [5] which measures the similarity from the number of edges between terms, a node-based methods [5], [6] that claim to be more accurate than the edge-based measure, and hybrid methods [7], [8] that overlay the edge-based approach with the node-based one.

From a different point of view, the similarity or relation between resources can be measured based on the links that connect the resources, and the *PageRank* [9] is possibly the most well-known link analysis algorithm. In [10], the links in the blogosphere are interpreted into an influence model and the *spreading activation technique* [11] is applied on the influence graph. Another approach is finding the relevance between objects based on tags by users, and a relevance measuring method based on tagging has been introduced in [12] for pictogram retrieval.

Now, let us describe our point of view on semantic relevance. We have discussed the semantic similarity between documents above, but sometimes it may be necessary to find more than the simple similarity of contents. Two documents can be related even though they do not contain similar contents or have links to each other, and such relation may be affect the resource ranking. For instance, suppose we have a document

This work is partially sponsored by the Korea Institute of Science and Technology (KIST) with the project TSI(Tangible Space Initiative).

describing an interface design methodology and another document explaining a data mining algorithm. In this case, these two documents are not considered to be similar, since their contents are about two different topics. However, if there is a research project developing a recommender system, where its user interface is designed following the methodology described in the first document and the recommendation algorithm is implemented based on the contents of the second document, then these two documents now have an indirect relation between each other within this project. Here, the fact that the methods described in both documents are utilised in the same project is the context information, and the two documents are related to each other in the given context although they are neither similar nor directly linked.

The semantic relevance can also be found between two objects which have completely different nature. For example, a person and a document are semantically related if the person is the author of the document. This can be further extended if the document has a topic and there exists a research project which is related to the topic, then in this case, a relation between the person and the project is discovered even if the person does not know the project exists.

Therefore, the *semantic relevance* we are exploring in this paper is based on any kinds of relations that can be represented in a knowledge space, and we are also considering indirect relations via context information. Now, to utilise such relevance in an information system, the degree of importance that each relation represents is considered as a numeric value, in other words, the closeness between two objects in the given knowledge space, and those values are then analysed to calculate the relevance value between any two objects. The relevance value calculation algorithm is described later in this paper.

## III. Semantic Knowledge Management

### A. Semantic Knowledge Space

Within an information system, there exists a set of information, and not only the information objects but also the relations among them are important for effective information provisioning. These information objects and their relations form a *knowledge space*, and its structure needs to be represented semantically to build a semantic knowledge space. The simplest form of a knowledge space consists of a set of information (or data) that is to be provided to users - in other words, *resources* - without any semantic annotations. Then, links between those resources can be included in the knowledge space to represent relations among those resources. An intuitive example of this would be a set of documents where each document contains links to other document(s). In this knowledge space, the connections between the resources are described, but this structure still does not have semantic meanings as the relations are represented only via *syntactic links*. To describe the semantics of the resources, the meaning of each relation needs to be assigned to those links so that they become *semantic links*. In addition to those semantically linked resources, context information can be added to the knowledge space to represent richer semantic meanings of those resources within a certain context.

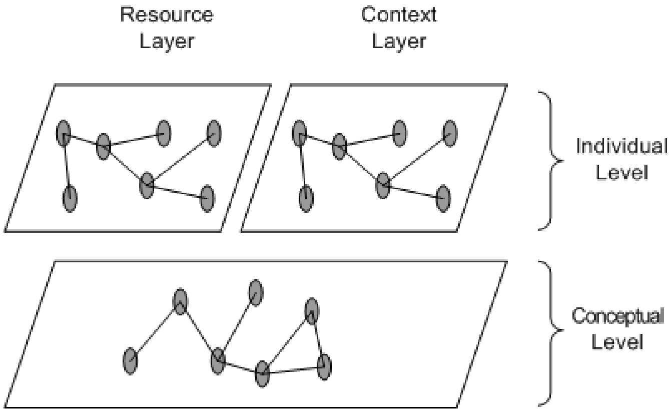

Fig. 1. Knowledge Model

Therefore, a *semantic knowledge space* is a semantic structure of information which contains resources, context information, and relations between them where each relation has its own meaning. We will now describe the structure of a semantic knowledge space in detail with a knowledge model and an ontological representation.

### B. Knowledge Model and Ontology

In our point of view, a semantic knowledge space consists of two types of information, context information and resources. As discussed above, resources are the information objects that are to be provided to users, and context information is the additional environmental or domain information. For effective knowledge management, before describing each individual information objects and their relations, a structure of knowledge space needs to be designed in conceptual level first, then the individual information objects can be represented within the conceptual structure. To represent such semantic knowledge, ontology provides a suitable formal structure, and we will now discuss the ontological representation of a knowledge space along with a knowledge model view, with a simple example ontology of a research organisation. Note that the example ontology presented in this section is severely simplified mainly to support explaining the knowledge structure and relevance calculation. This example will be used throughout the rest of this paper.

The structure of our knowledge model is shown in Fig. 1 to describe the overview of a semantic knowledge space from our point of view. First, in the *Conceptual Level*, the structure of concepts, the relations between them, and additional attributes are defined. Suppose we want to manage and provide information on people and documents within a research organisation, then four concepts may be defined in this level, *Project*, *Topic*, *Person*, *Document*, and the relations between these concepts can also be specified. Therefore, the *Conceptual Level* can be seen as a base structure of an ontology specifying the concepts and their properties, without individual instances. Fig. 2 presents our example ontology.

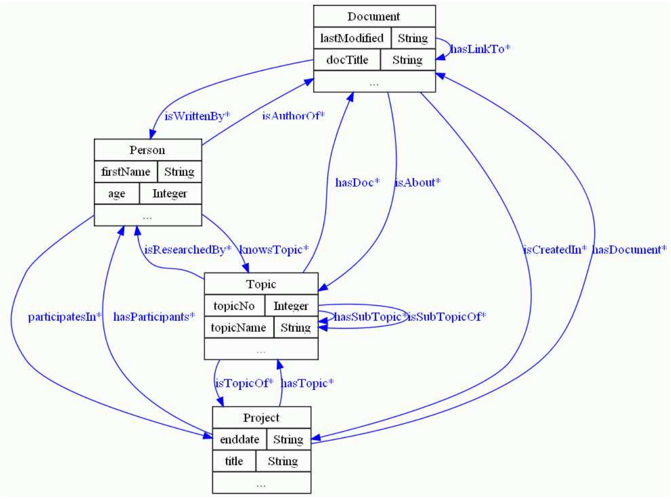

Fig. 2. An example ontology

The *Individual Level* contains the resources and context information represented as instances of the ontology defined in *Concept Level*, and it is divided into two layers - the *Resource Layer* and the *Context Layer*. The *Resource Layer* contains the information to be provided to users, and in our example, a set of documents and a set of people can be regarded as the contents of this layer. The *Context Layer* contains the domain and context knowledge, and a hierarchy of topics and a list of projects are stored in this layer in our example. The contents of these layers are semantically linked to each other based on the relations defined in the *Conceptual Level*.

## IV. Relevance Graph

Having the structured knowledge space, our next objective is measuring the semantic relevance between resources, represented in the *Resource Layer*. To discover their relevance, we interpret the knowledge space (i.e. ontology) into a graph structure where the relevance can be calculated as a numerical value. A *Relevance Graph* is an interpreted semantic knowledge model based on a knowledge structure, or ontology, representing the information objects and their relations. It is defined as a directed labelled graph $G = (V, E)$ where:

- $V$ is a set of nodes, representing individuals;
- $E$ is a set of edges, representing relations between individuals.

Note that our *Relevance Graph* does not have any restrictions in its structure. It is not limited to a tree structure, and different edges can represent different relation types. There may be multiple edges between two adjacent nodes, and the graph can contain cycles. Also, depending on each implementation and their purposes, a whole ontology can be interpreted into a graph, or only a part of an ontology can become the relevance graph. Or, even multiple ontologies can form a single relevance graph, although an ontology matching would be required in this case, and it is not discussed in this paper. The creation of the *Relevance Graph* includes node creation, edge creation, and edge labelling.

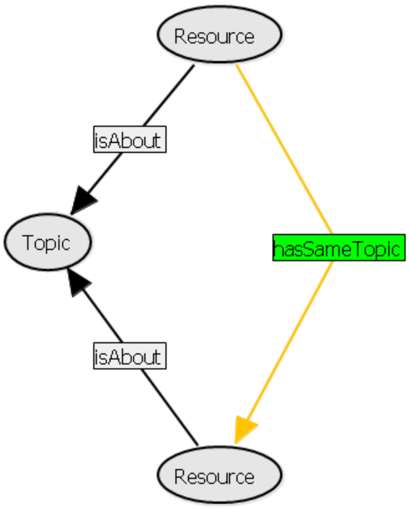

Fig. 3. An example rule

### A. Node Creation

There can be two different ways of creating nodes in our *Relevance Graph*. First, all instances of an ontology can become nodes, or second, only the instances representing *resources* can be created as nodes. The former is simpler way, but the result graph become bigger so it requires more computational time in the relevance calculation phase. The latter requires defining additional rules to clarify the relations between resources via context information since those relations may disappear upon graph creation as individuals representing context information is not included in the graph. For example, upon creating the nodes based on the example ontology described in the previous section (Fig. 2), each instance representing a `Document` or a `Person` becomes each node, but the individuals of `Topic` or `Project` do not appear on the graph, hence indirect relations between resources via these two conceptual information can be lost. Therefore, additional rules need to be defined to keep the meaningful indirect relations, and one example rule may be representing ‘a document is about the same topic as another document.’ This example rule is shown in Fig. 3 and this can be represented in SWRL [13] as follows:

```
<ruleml:imp>
  <ruleml:_rlab  ruleml:href="#sametopic"/>
  <ruleml:_body>
    <swrlx:individualPropertyAtom
      swrlx:property="isAbout">
       <ruleml:var>d1</ruleml:var>
       <ruleml:var>t1</ruleml:var>
    </swrlx:individualPropertyAtom>
    <swrlx:individualPropertyAtom
      swrlx:property="isAbout">
       <ruleml:var>d2</ruleml:var>
       <ruleml:var>t1</ruleml:var>
    </swrlx:individualPropertyAtom>
  </ruleml:_body>
  <ruleml:_head>
    <swrlx:individualPropertyAtom
      swrlx:property="hasSameTopic">
```

```
        <ruleml:var>d1</ruleml:var>
        <ruleml:var>d2</ruleml:var>
      </swrlx:individualPropertyAtom>
    </ruleml:_head>
  </ruleml:imp>
```

However, finding all meaningful indirect relations between resources and defining them as rules may not be a trivial task, hence in practice, the recommendable method is combining both ways of node creation depending on the characteristics of each application—creating all resources and 'some' context instances as nodes, and adding additional rules.

### B. Edge Creation

The next step is creating edges between the nodes in the *Relevance Graph*. The edges represent the relations between nodes, and they can be created from the relations (or object properties in OWL) defined in the ontology. Not only explicit relations but also inferred ones between resources by the additional rules become edges. Depending on the knowledge structure and application, all such relations in the ontology can become edges or only the relations which represent meaningful relevance in the system can be selected. Note that any reflexive relations are ignored hence do not become edges, since they have no significance in measuring relevance between nodes:

$$\forall x \in V : \qquad e(x,x) \notin E$$

### C. Edge Labelling

The edges in our *Relevance Graph* represent various relations defined in the ontology, and each relation has different importance in terms of representing the 'closeness' or 'relevance' between objects within a knowledge space. For instance, if we have two relations `hasSameTopic` and `hasSameAuthor` representing relations between documents, `hasSameTopic` can be regarded to be more important than `hasSameAuthor` because having the same topic means the contents of the two documents are very likely to have a close relationship whereas an author may write two different articles in two completely different area. Based on this assumption, each relation on the ontology can be weighted with a different value representing its importance within the system, and these values become the labels of the edges in the *Relevance Graph*. Note that, the value we are assigning here is the 'distance' value, which is defined as the inverse of the relevance value:

$$Distance = \frac{1}{Relevance} \tag{1}$$

Upon implementation, the distance value assignment can be included in the ontology (as in [14] and [2]) or in the graph creation module (as in [15]). Currently, we do not have an automated way of assigning the relevance value to each relation, so it needs to be done manually by the ontology developer and/or a domain expert. Practically, all distances can be instantiated with a single value, and the value for each relation can then be updated by applying the developers' domain knowledge and throughout testing, which was the initial implementation approach in [15] and was also followed in [2]. Also, there can be a (semi-)automatic way of updating the distance value via historical evaluation methods based on the system usage and explicit/implicit feedback, and this will be explored and experimented further in our future work.

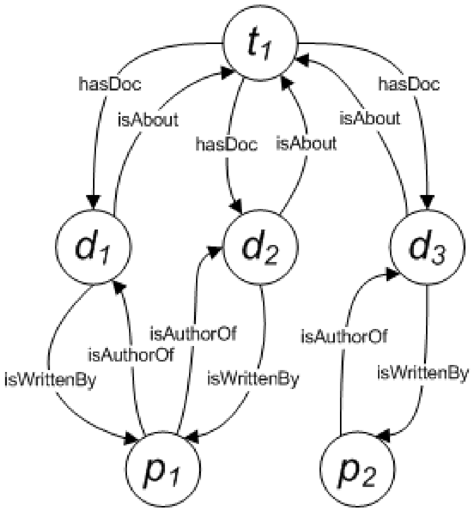

Fig. 4. An example illustration of relations among instances

## V. Relevance Calculation

Having created the *Relevance Graph*, the relevance value between two nodes in the graph can now be calculated by a relevance calculation algorithm, which is based on our earlier work [1]. Before we proceed further, let us elucidate the assumptions of our algorithm and define the terms to clarify their meanings and avoid possible confusion. The two fundamental assumptions are as follows:

1) Each relation has different importance, and it can be represented as a numeric value.
2) Having more relations between two resources means that they are closer(more relevant).

The assumption 1) is already discussed in Section IV-C, and the assumption 2) can be explained with an example case presented in Fig. 4. In this figure, we have a graphical representation of relations among a topic($t_1$), persons($p_1$, $p_2$), and documents($d_1$, $d_2$, $d_3$). Considering the relevance between documents $d_1$ and $d_2$, and between $d_2$ and $d_3$, it is safe to say that—it may not be true in all cases but has high probability—$d_1$ is likely to be more relevant to $d_2$ than $d_3$ is, as $d_1$ has the same topic($t_1$) and the same author($p_1$) as $d_2$ while $d_3$ has the same topic($t_1$) but a different author($p_2$). Based on this assumption, the merging algorithm is developed instead of taking a shortest(or longest) edge(or path) or taking the mean value (see Section V-B and V-D).

The terms used in the rest of this paper is defined as follows:

- *Relevance* represents the closeness between two entities. Each relation has its own relevance value.
- *Distance* represents how far two concepts are away from each other. The distance value is the inverse of the relevance value (see equation (1)).

- *Weight* represents the closeness between two entities in individual level. The weight value (0,1) is used to scale the distance (or relevance) value appropriately to each individual.

Now, the relevance values between the nodes in our *Relevance Graph* are measured by the following four steps.

### A. Edge Scaling

The first step is individualising each edge's label (i.e. distance). It was not included in our original work [1] but developed while implementing the relevance calculation method in a *duty-trip support system* [2]. The edge label is set based on the importance of a certain relation in comparison to other relations in conceptual level(see Section IV-C), hence all instances connected by the same relation have the same distance value. However, depending on the application and its knowledge structure, it might be desired to represent the different degree of relevance to certain relations in individual level. For example, in Fig. 2, we defined the `isAbout` relation that connects `Document` and `Topic`, and the `isAbout` relation has a certain *distance* value. However, there can be two different documents related to the same topic but with different degree. Here, the degree of relevance can be defined in the ontology as following:

```
onto:Doc1
  a onto:Document ;
  onto:isAbout
    [ a onto:DocTopic ;
      onto:relatedTopic onto:Ontology ;
      onto:weight ”0.90”^^xsd:float
    ] .

onto:Doc2
  a onto:Document ;
  onto:isAbout
    [ a onto:DocTopic ;
      onto:relatedTopic onto:Ontology ;
      onto:weight ”0.25”^^xsd:float
    ] ;
  onto:isAbout
    [ a onto:DocTopic ;
      onto:relatedTopic onto:Java ;
      onto:weight ”0.40”^^xsd:float
    ] .
```

The above example presents two documents `Doc1` and `Doc2` which are both related to a topic `Ontology` with different weight values. To apply this in our relevance graph, we multiply the initial *relevance value* by this *weight value* and obtain the scaled distance value.

$$newRelevance = relevance \times weight \tag{2}$$

Therefore, from the equation (1), for an edge $e(x,y) \in E$ where $x$ and $y$ are two adjacent nodes $x, y \in V$, its initial distance value $D_{e(x,y)}$, and the weight value $w_{xy}$, the scaled distance value $D'_{e(x,y)}$ is:

$$D'_{e(x,y)} = (\frac{1}{D_{e(x,y)}} \times w_{xy})^{-1} \tag{3}$$

We can regard this process as *individualisation* of the edge distance since the initial distance was determined in conceptual level and it is scaled by the weight value assigned in individual level. This step is optional part in relevance calculation since it can only be applied when the *weight* values are defined between instances in the knowledge structure (i.e. ontology).

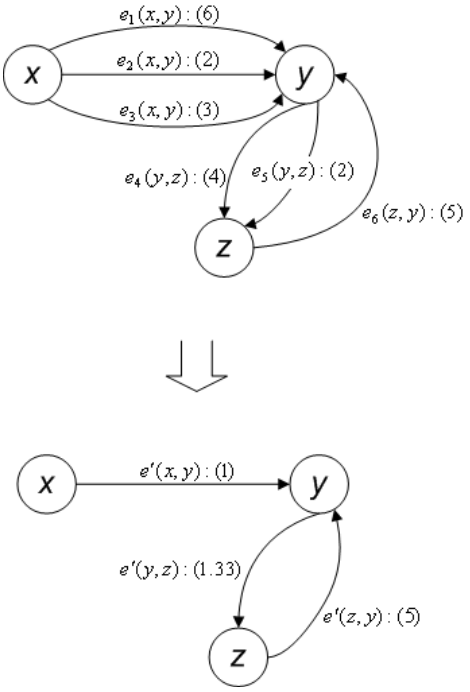

Fig. 5. Edge Merging

### B. Edge Merging

In our *Relevance Graph*, there may be multiple edges with the same direction between two adjacent nodes, since two resources can be connected via more than one relation. Therefore, from our second assumption of the algorithm described at the beginning of this section, we merge those edges into a single one so that we can obtain a simpler graph where there is only a single edge with the same direction between two adjacent nodes. To calculate the distance value of the merged edge, we first calculate the relevance between two adjacent nodes. For two adjacent nodes $x, y \in V$, and edges $e_1(x,y), e_2(x,y), \ldots, e_n(x,y) \in E$ from node $x$ to node $y$ with the distance value $D_{e_i(x,y)}$ for edge $e_i(x,y)$ where $1 \leq i \leq n$, the semantic relevance value $r_{xy}$ from node $x$ to node $y$ by direct relations(edges) is as follows:

$$r_{xy} = \sum_{i=1}^{n} \frac{1}{D_{e_i(x,y)}} \tag{4}$$

Therefore, from the equation (1), the new distance value $D_{e'(x,y)}$ of the merged edge $e'(x,y)$ is:

$$D_{e'(x,y)} = \frac{1}{r_{xy}} = (\sum_{i=1}^{n} \frac{1}{D_{e_i(x,y)}})^{-1} \tag{5}$$

By merging edges, we can now obtain a simpler graph where there is only a single edge with the same direction between adjacent nodes. Fig. 5 describes an example illustration of edge merging.

### C. Path Distance Calculation

Now we need to consider the relevance between non-adjacent nodes. For two non-adjacent nodes, there may or may not exist a path. In our algorithm, a path is valid if and only if it contains no repeated nodes (i.e. simple path). If there does not exist a path between them, it means that they are not related and we can consider their relevance value as $0$. If there exist one or more paths, we first need to calculate the distance value of each path.

In graph theory, the weight(or distance) of a path in a weighted graph is the sum of the weights of each edge in the path. Following this, for a path $P(a_1a_n)$ that visits $n$ nodes $a_1, a_2, \ldots, a_n \in V$, the path distance $D_{P(a_1a_n)}$ is:

$$D_{P(a_1a_n)} = \sum_{k=1}^{n-1} D_{e'(a_ka_{k+1})} \tag{6}$$

However, instead of selecting a single path, we consider all relations in our relevance calculation, and it is discovered that this can produce undesirably close relevance results for between two nodes which are connected via long paths. Precisely, from a node $x$, a node $y$ should be closer than a node $z$ but the result can be the opposite because of the number of paths from $x$ to $z$ even though each path is very long. Hence, it is necessary to make the distance value between indirectly related nodes higher than the simple sum, and this is done by multiplying the edge count $k$ to the distance value of each edge. Therefore, the above equation (6) is replaced with the following:

$$D_{P(a_1a_n)} = \sum_{k=1}^{n-1} (k \times D_{e'(a_ka_{k+1})}) \tag{7}$$

### D. Path Merging

The last step of the relevance calculation is handling multiple paths between two nodes, and this is done by following the same principle as edge merging. For $n$ paths $P_1, P_2, \ldots, P_n$ from node $x \in V$ to node $y \in V$, the relevance value $R_{xy}$ is:

$$R_{xy} = \sum_{k=1}^{n} \frac{1}{D_{P_k(xy)}} \tag{8}$$

$R_{xy}$ represents the final semantic relevance value of node $y$ from node $x$.

## VI. Implementation Examples

The semantic relevance measure introduced in this paper has been implemented in two systems—RIKI and SPIP.

### A. RIKI

RIKI[15] is a Wiki-based portal supporting group communication and knowledge sharing within a collaborative research project. Unlike other *Semantic Wikis*[16][17][18], ontological knowledge management is applied in RIKI mainly to provide easier knowledge access within a specific project's context, rather than rich semantic annotation. Its knowledge space is developed following the knowledge model and structure introduced in this paper (Section III), and the knowledge space is structured in F-Logic[19] ontology. Two top-level concepts are defined in this ontology, the `Resource` containing the Wiki articles and the `Context` representing the context information. These are further divided into four sub-concepts, classifying the article types and describing different types of the contexts. The overview of this structure is depicted in Fig. 6.

RIKI provides two ways of navigating the articles—the *Structured Browsing* and the *Article Recommendation*. The *Structured Browsing* provides a tree-based structure of the contexts, so that users can see the overall structure of the information in RIKI and reach the desired article(s) related to a certain topic, task, event, or person. By the *Article Recommendation* function, while a user is viewing an article, the system generates and displays a list of its relevant articles. To create the *Relevance Graph* from the ontology, first, all the instances of the `Resource` concept and its subconcepts (i.e. articles) are created as nodes. Then, for edge creation, we defined 50 rules representing the indirect relations between those articles via the given contexts, and those rules became edges of our graph. From this *Relevance Graph*, when a user opens an article, the system finds the top 10 relevant articles from the current article by the algorithm presented in this paper. The *Edge Scaling* part is not included in this RIKI implementation. Fig. 7 presents the RIKI interface, with the *Structured Browsing* on the top-left and the *Article Recommendation* on the bottom-left. The details of the overall system can be found in [15].

### B. Smart Personalized Information Provider

Another implementation example of the semantic relevance measure is the *Smart Personalized Information Provider*, which is sponsored by the KIST-SRI PAS "Agent Technology for Adaptive Information Provisioning" grant. It aims for adaptive information provisioning in an agent-based virtual organisation, and provides a personalised information by ontological resource matching. The knowledge space is developed in OWL (details in [20]), and it provides two different services—the *Grant Announcement Service* and the *Duty Trip Support*. In both services, for resource matching, the relevance calculation algorithm is utilised, along with a SPARQL[21] engine for resource filtering and the *GIS Subsystem* for geospacial information management. The matching process is described in detail in [14] for the *Grant Announcement Service* and also in [2] for the *Duty Trip Support*.

## VII. Concluding Remarks

In this paper, we discussed our view of the concept *semantic relevance* and presented a structured view of a semantic knowledge space, with the semantic relevance measure algorithm between the resources based on a graph structure. The relevance measure algorithm can be implemented on its own, but the efficiency will be more evident when it is combined with existing searching or matching algorithms, such as the text-based comparing methods and/or tagging-based relevance measure. Our future work will include the integration of our method with those other techniques, as well as exploring a semi-automatic method of initiating and updating the edge labels, experimenting with various implementations and evaluating throughout extensive testing.

***Abstract*—The *exclusion rule-based system*, proposed in the paper, is an alternative method of designing a rule-based system for an expert or a control system. The starting point of the approach is the set of all possible decisions the considered system can generate. Then, on the basis of the exclusion rules, the set of decisions is limited to the ones permissible in the current state.**

**A railway traffic management system case study is used in the paper to demonstrate the advantages of the new approach. To compare the exclusion rule-based systems with the decision tables both solutions are considered.**

## I. Introduction

ALTHOUGH rule-based systems are widely used in various kinds of computer systems, e.g. expert systems, decision support systems, monitoring and control systems, diagnostic systems etc., their encoding, analysis and design can be a time-consuming, tedious and difficult task ([1], [2], [3], [4]). Their expressive power, the scope of the potential application and very intuitive form, make them a very handy and useful mechanism. However, if more complex systems are considered, it is difficult to cope with the number of attributes or/and the number of decision rules.

Rule-based systems can be represented in various forms, e.g. decision tables, decision trees, extended tabular trees (XTT, [5]), Petri nets ([6]), etc. Decision tables seem to be the most popular form of rule-based systems presentation. Depending on the way the condition and decision entries are represented, a few kinds of decision tables can be distinguished ([7], [8], [3]). The simpler ones are decision tables with atomic values of attributes. However, encoding decision tables with the use of atomic values of attributes only is not sufficient for many real applications. On the other hand, tables with generalised decision rules ([9]) use formulae instead of atomic values of attributes. Each generalised decision rule covers a set of decision rules with atomic values of attributes (simple decision rules). Therefore, the number of generalised decision rules is significantly lower than the number of the simple ones.

In spite of this, it can be really hard to cope with the design of such a decision table if it contains a dozen or so condition attributes or/and each of them can take a few different values. It appears that it is simpler to point out one or two values of some condition attributes that disqualify some decisions, than to point out values of dozen attributes that determine a single decision.

This observation provides the basis for the approach presented in the paper. We start with the set of all possible decisions the considered system can generate. Then, instead of constructing the precondition of a decision rule that usually contains most of the condition attributes, we construct the precondition of an exclusion decision rule that usually contains a single attribute. Thus, instead of pointing out a single decision permissible in the current state, we point out a set of impermissible ones.

In most basic versions, a rule-based system consists of a single-layer set of rules and a simple inference engine. It works by selecting and executing a single rule at a time, provided that the preconditions of the rule are satisfied in the current state. Thus, such a system generates a single decision, even if there are a few suitable ones. On the other hand, when an exclusion rule-based system is used, then executing a single exclusion rule removes some impermissible decision from the set of all possible ones. After executing all exclusion rules with satisfied preconditions, the set contains all decisions permissible in the considered state.

The paper presents the idea of *exclusion rule-based systems* (shortly ExRBS). To point out the main differences between generalised decision tables and exclusion rule-based systems, we describe the two forms of rule-based systems for a railway traffic management system. The system uses a rule-based system to choose routes for trains moving through a train station.

The paper is organized as follows. The railway traffic management system is described in Section II. The generalized decision table is presented in Section III. The exclusion rule-based system is described in Section IV. The paper ends with a short summary in the final section.

## II. Railway traffic management system

A description of a railway traffic management system for a real train station is discussed in this section. To present complete rule-based systems, a small train station, Czarna Tarnowska, belonging to the Polish railway line no 91 from Kraków to Medyka, has been chosen. This example seems to be suitable for the presentation of an exclusion rule-based system. However, it will be shown that the approach can also be applied to more complex systems.

| N1D | xx | | | | | | | | x | x | x | – |

The considered system is used to ensure safe riding of trains through the station. It collects some information about current railway traffic and uses a rule-based system to choose routes for trains.

The topology of the train station with original signs is shown in Fig. 1. The letters A, B, D, etc. stand for color light signals, the symbols Z3, Z4, Z5, etc. stand for turnouts and JTA, JTB, JT1, etc. stand for track segments. Some simplifications have been introduced to reduce the size of the model. We are not interested in controlling the local shunts so the track segment JT6 will not be considered. We assume that the light signals display only two signals: *stop* and *way free*. Moreover, outside the station the trains can ride using the right track only.

A train can ride through the station only if a suitable route has been prepared for it i.e., suitable track segments must be free, we have to set turnouts and light signals and to guarantee exclusive rights to these elements for the train. Required position of turnouts for all possible routes are shown in Table I, where the used symbols stand for:

- + closed turnout (the straight route);
- – open turnout (the diverging route);
- o+ closed turnout (for safety reasons).

For example, the symbol B4 stands for the input route from the light signal B to the track no. 4. The symbol F2W stands for the output route from the track no. 2 (from the light signal F) to the right (to Wola Rzędzińska), etc. The route B4 can be used by a train only if: turnouts 7, 8, 15, 16 are closed, turnouts 3, 4, 6 are open, and the track segments JTB, JT4, JZ4/6 (a segment between turnouts 4 and 6), JZ7 (diagonal segment leading to the turnout 7) and JZ16 are free.

Some routes cannot be set at the same time because of different position of turnouts or for safety reasons. Mutually exclusive routes are presented in Table. II, where the used symbols stand for:

- x – mutually exclusive (different position of turnouts);
- xx – mutually exclusive (safety reasons).

The system is expected to choose suitable routes for moving trains. It should take under consideration that some trains should stop at the platform, while others are only moving through the station and two routes (an input and an output one) should be prepared for them. In such a case, if it is not possible to prepare two routes, only an input one should be prepared.

## III. DECISION TABLE

Decision tables are a precise and compact form of rule-based systems presentation. They vary in the way the condition and decision entries are represented. The entries can take the form of simple true/false values, atomic values of different types, non-atomic values or even fuzzy logic formulas [3].

To construct a decision table, we draw a column for each condition (or stimulus) that will be used in the process of taking a decision. Next, we add columns for each action (or response) that we may want the system to perform (or generate). Then, for every possible combination of values of those conditions a row should be drawn. We fill cells so as to reflect which actions should be performed for each combination of conditions. Each such a row is called a *decision rule*.

A kind of decision tables with generalized rules is used in this section [9]. Systems with non-atomic values are considered since their expressive power is much higher than the one of classical attributive decision tables. Each cell of such a decision table should contain a formula which evaluates to a boolean value for condition attributes, and to a single value (that belongs to the corresponding domain) for decision attributes.

Let us focus on the railway traffic management system. The rule-based system is to be used to determine which routes should be prepared depending on the data collected from sensors. The decision table contains 20 condition and 2 decision attributes. The condition attributes stand for information about:

- current position of the train (attribute JT) – before the light signal B, F, G, etc.;
- type of the train (attribute TT) – only moves through the station (1) or must stop at the platform (2);
- current status of track segments (attributes JT1, JT2, JT3, JT4, JOA, JOP) – a segment is free (0) or it is taken (1);
- already prepared routes (attributes B1, B2, B3, etc.) – a route is already set (1) or not (0).

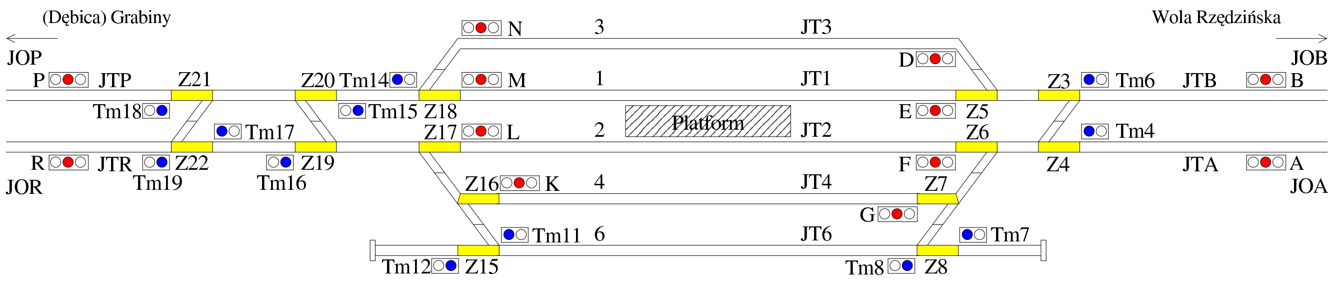

Fig. 1. Czarna Tarnowska – topology of the train station

The decision attributes In and Out represent the input and output routes (that will be prepared for the train) respectively. Domains for these attributes are defined as follows:

$D_{\mathrm{JT}} = \{\mathrm{b}, \mathrm{f}, \mathrm{g}, \mathrm{k}, \mathrm{l}, \mathrm{m}, \mathrm{n}, \mathrm{r}\}$,
$D_{\mathrm{TT}} = \{1, 2\}$,
$D_{\mathrm{JT1}} = D_{\mathrm{JT2}} = D_{\mathrm{JT3}} = D_{\mathrm{JT4}} = D_{\mathrm{JOA}} = D_{\mathrm{JOP}} = \{0, 1\}$,
$D_{\mathrm{B1}} = D_{\mathrm{B2}} = \ldots = D_{\mathrm{N1D}} = \{0, 1\}$,
$D_{\mathrm{In}} = \{\mathrm{b1}, \mathrm{b2}, \mathrm{b3}, \mathrm{b4}, \mathrm{r2}, \mathrm{r4}, \mathrm{none}\}$,
$D_{\mathrm{Out}} = \{\mathrm{f2w}, \mathrm{g2w}, \mathrm{k1d}, \mathrm{l1d}, \mathrm{m1d}, \mathrm{n1d}, \mathrm{none}\}$.

The decision table is presented in table III. Each row represents one decision rule. Let us consider the first rule. It can be represented as follows:

$$\begin{aligned}&(\mathrm{JT} = b) \wedge (\mathrm{TT} = 1) \wedge (\mathrm{JT1} = 0) \wedge (\mathrm{JOP} = 0)\\ &\wedge (\mathrm{B1} = 0) \wedge (\mathrm{B2} = 0) \wedge (\mathrm{B3} = 0) \wedge (\mathrm{B4} = 0)\\ &\wedge (\mathrm{K1D} = 0) \wedge (\mathrm{L1D} = 0) \wedge (\mathrm{M1D} = 0)\\ &\wedge (\mathrm{N1D} = 0) \Rightarrow (\mathrm{b1}, \mathrm{m1d})\end{aligned} \tag{1}$$

It means that if:

- a train of type 1 is approaching the light signals B (or stands before it), and
- track segments JT1 and JOP are empty, and
- routes B1, B2, B3, B4, K1D, L1D, M1D and N1D are not set,

then routes b1 and m1d should be prepared for the train. It is also worth mentioning that in the considered state other decision are also possible. For example, the following pairs of routes can be used: (b2, l1d), (b3, n1d) or (b4, k1d).

If a row contains empty cells, it means that the values of some attributes are not important for the rule. For example, when rule R1 is considered, it makes no difference what the value of attribute JT2 is.

### A. *Adder DT Designer*

The presented rule-based system has been used in an RTCP-net (Petri net) model of the railway traffic management system. A description of the model can be found in [10]. The decision table has been designed using *Adder DT Designer* ([9]). The tool supports design and analysis of generalised decision tables. It supports three types of attributes' domains: integer, boolean and enumerated data type. The verification stage is included into the design process. At any time, during the design stage, users can check whether a decision table is complete, consistent (deterministic) or if it contains some dependent rules.

Fig. 2. Adder DT Designer

An example of *Adder DT Designer* session is shown in Fig. 2. The tool is a free software covered by the GNU Library General Public License. It is being implemented in the GNU/Linux environment by the use of the Qt Open Source Edition. More information about *Adder DT Designer* and the current version of the tool can be found at *http://fm.ia.agh.edu.pl*.

## IV. Exclusion rule-based system

To apply the rule R1 considered in the previous section, it is necessary to check twelve conditions. Further to that, to apply any of the rules presented in Table II, at least seven conditions must be checked. Let us consider Table II that presents mutually exclusive routes. If route B1 is already set, then it cannot be set once again at the same time and also none of routes B2, B3, B4 and N1D can be set.

Suppose the current state is defined as follows: JT $= b$, TT $= 1$, $B1 = 1$ and all other attributes are equal to zero. Let $\mathcal{D}_0$ denote the set of all possible decisions:

$$\begin{aligned}\mathcal{D}_0 = \{&(\mathrm{b1}, \mathrm{m1d}), (\mathrm{b2}, \mathrm{l1d}), (\mathrm{b3}, \mathrm{n1d}), (\mathrm{b4}, \mathrm{k1d}),\\ &(\mathrm{r2}, \mathrm{f2w}), (\mathrm{r4}, \mathrm{g2w}), (\mathrm{b1}, \mathrm{none}), (\mathrm{b2}, \mathrm{none}),\\ &(\mathrm{b3}, \mathrm{none}), (\mathrm{b4}, \mathrm{none}), (\mathrm{r2}, \mathrm{none}), (\mathrm{r4}, \mathrm{none}),\\ &(\mathrm{none}, \mathrm{k1d}), (\mathrm{none}, \mathrm{l1d}), (\mathrm{none}, \mathrm{m1d}),\\ &(\mathrm{none}, \mathrm{n1d}), (\mathrm{none}, \mathrm{f2w}), (\mathrm{none}, \mathrm{g2w}), \}\end{aligned} \tag{2}$$

If attribute $B1$ is equal to 1, then the following decisions are impermissible in the considered state: $(\mathrm{b1}, \mathrm{m1d})$, $(\mathrm{b2}, \mathrm{l1d})$,

TABLE III

Fig. 4. Comparison of rule-based systems

$(\mathrm{b3},\mathrm{n1d})$, $(\mathrm{b4},\mathrm{k1d})$, $(\mathrm{b1},\mathrm{none})$, $(\mathrm{b2},\mathrm{none})$, $(\mathrm{b3},\mathrm{none})$, $(\mathrm{b4},\mathrm{none})$, $(\mathrm{none},\mathrm{n1d})$.

For simplicity, the asterisk $(*)$ will be used to denote any value the corresponding entry can take. Thus, the first exclusion rule $E1$ takes the following form:

$$E_1\colon (\mathrm{B1}=1) \Rightarrow \{(\mathrm{b1},*),(\mathrm{b2},*),(\mathrm{b3},*),(\mathrm{b4},*),(*,\mathrm{n1d})\} \tag{3}$$

Each row of Table II generates an exclusion decision rule. Thus, the constructed exclusion rule-based system will also contain next eleven rules (see Fig. 3, rules from $E_2$ to $E_{12}$).

Let us focus on the train station topology (see Fig. 1). If a train position (attribute TJ) is equal to $b$ and track segment JT1 is taken by another train, then any route leading through the track segment cannot be taken under consideration. Thus, we have the following exclusion rule:

$$E_{13}\colon (\mathrm{JT}=b) \wedge (\mathrm{JT1}>0) \Rightarrow \{(\mathrm{b1},*)\} \tag{4}$$

Similarly, we can investigate situations when one of track segments JT2, JT3, JT4 is busy, or a train position is equal to $r$ and track segment JT2 or JT4 is busy – see rules from $E_{14}$ to $E_{19}$.

If a train type (attribute TT) is equal to 2, then it should stop at the platform. In such a case only an input route must be prepared and routes leading through track segments JT3 and JT4 cannot be taken under consideration – see rules $E_{20}$ and $E_{21}$. Moreover, an output route can be prepared only if the corresponding output track segment is free (track segments JOA and JOP) – see rules $E_{22}$ and $E_{23}$.

The last group of exclusion rules corresponds to the direction of trains moving. If a train position is equal to $b$, then the train moves from 'east' to 'west' and first of all an input route for the train must be prepared. Thus, any decisions with the input route equal to *none* or with routes leading to east are impermissible in such a situation. Therefore, the ExRBS must contain the following exclusion rule:

$$E_{23}\colon (\mathrm{JT}=b) \Rightarrow \{(\mathrm{r2},*),(\mathrm{r4},*),(\mathrm{none},*)\} \tag{5}$$

In a similar way, the other seven train positions can be investigated. Finally, the ExRBS must be extended with seven exclusion rules (see Fig. 3, rules from $E_{23}$ to $E_{30}$).

Executing a single exclusion rule removes some impermissible decisions from the set of all possible ones. The set of decision excluded by an exclusion rule will be denoted by $\mathcal{E}(E_i)$. Hence, for example, the set $\mathcal{E}(E_1)$ contains the following elements:

$$\begin{aligned}\mathcal{E}(E_1) = \{&(\mathrm{b1},\mathrm{m1d}),(\mathrm{b2},\mathrm{l1d}),(\mathrm{b3},\mathrm{n1d}),\\ &(\mathrm{b4},\mathrm{k1d}),(\mathrm{b1},\mathrm{none}),(\mathrm{b2},\mathrm{none}),\\ &(\mathrm{b3},\mathrm{none}),(\mathrm{b4},\mathrm{none}),(\mathrm{none},\mathrm{n1d})\}\end{aligned} \tag{6}$$

Let $\mathcal{D}_i$ denote the set of permissible decisions after executing the rule $E_i$. The following equality holds:

$$\mathcal{D}_{i+1} = \mathcal{D}_i - \mathcal{E}(E_{i+1}) \tag{7}$$

After executing all exclusion rules with satisfied preconditions, the set contains all decisions permissible in the considered state.

For the state considered in this section, rules $E1$ and $E23$ can be applied. The final set of permissible decisions $\mathcal{D}$ is empty. It means that at the moment no route for the train can be prepared. Another example—a state and decisions generated by the decision table and the exclusion rule-based system—is presented in Fig. 4.

The decision table presented in the previous section is complete and deterministic. It means that if it is possible to generate a decision for any acceptable state, then only one decision is generated. To compare the two presented rule-based systems, a Java software has been implemented and decisions generated by the systems for any acceptable state have been compared.[1] For any state the ExRBS generates at least the same decision as the decision table (for many states ExRBS generates more than one possibility).

## V. Conclusion

The idea of exclusion rule-based systems has been given in this paper, and a comparison has been made between decision tables and exclusion rule-based systems. The latter ones can be treated as an alternative method of designing rule-based systems. The presented approach has been illustrated by the use of an example of a railway traffic management system. In this case, ExRBS is significantly more readable and adaptable. In contrast to decision tables, an ExRBS for a train station with different topology and size can be easily constructed in a very similar way. Moreover, the exclusion rule-based system contains less decision rules then the corresponding decision table and the design of the ExRBS was significantly less time-consuming.

***Abstract*—In our work, an agent-based system supporting workers in fulfilling their roles in a virtual organization has as its centerpiece ontologically demarcated data. In such system, ontological matchmaking is one of key functionalities in provisioning of personalized information. Here, we discuss how matchmaking will be facilitated in a *Duty Trip Support* application. Due to the nature of the application, particular attention is paid to the geospatial data processing.**

## I. Introduction

CURRENTLY, we are developing an agent-based system supporting resource management in a virtual organization. While it is often assumed that the notion of virtual organization should be applied when workers are geographically distributed ([1]), we do not make this assumption. Instead, we consider as "virtualization" process in which a real organization is "mapped" into a virtual one, where virtual can be understood as "existing electronically" (see, also [2]). In such virtual organization (1) its structure is represented by software agents and their interactions, while (2) the organization itself and its domain of operation are ontologically described. Here, we recognize need for (i) an ontology of an organization (e.g. specifying who has access to which resource, or which department does a given person work for), and (ii) a domain specific ontology (e.g. ontology of a car repair shop, specifying areas of expertise and skills of individual workers); see [3], [4], [5], [6] for summary of results obtained thus far.

One of main reasons for utilizing ontologies is that they allow for application of semantic reasoning. The aim of this paper is to describe how a specific type of such reasoning—ontological matching—can be used in the context of an applications currently under development. While in [7] we have considered matchmaking involved in the *Grant Announcement Support*, here we consider a *Duty Trip Support*. One of the key concepts that we will explore is geospatial matchmaking. To this effect, in the next section, we introduce the *Duty Trip Support* (*DTS*) application, following with an introduction to matchmaking processes that take place in the system. Next, we discuss specific matchmaking taking place in the *DTS*. In this section we also present in detail our ontological matchmaking algorithm.

## II. *Duty Trip Support* application

In our earlier work [5] we have introduced a scientist, Mr. Jackie Chan, employed in a Science Institute in Aberdeen, Hong Kong, China, who goes on a duty trip to Finland and will utilize a *Duty Trip Support* (*DTS*) application. It is expected that the *DTS* will be able to suggest to travelers places to stay and eat (based on their personal preferences and experiences of other travelers, e.g. from the same institution). This is an example of personalized information delivery that takes into account cultural and dietary differences between, for instance, Japan and Germany. A complete description of proposed functionalities and processes involved in the *DTS* application (including a complete UML sequence diagram) can be found in [8], [4], [5]. Here we focus our attention on ontological matchmaking utilized in the *DTS*. Note that majority of examples listed here (ontology classes and properties, in particular) are based on our previous work (see, [4], [5] for more details). Doing so, allows us to shed more light on these examples and matching processes taking place in the system, which were only outlined before, while preserving continuity and building a complete picture of the process.

Let us now reintroduce ontology class instance samples and start from a listing of *City* and *Country* instances which include geospatial information. Two countries (China and Finland) and three cities (Aberdeen, Oulu and Rovaniemi) are listed (each city located in one of the two countries).

```
geo:FinlandCountry a onto:Country;
        onto:name "Finland"^^xsd:string.
geo:ChinaCountry a onto:Country;
        onto:name "China"^^xsd:string.
geo:OuluCity a onto:City;
        onto:name "Oulu"^^xsd:string;
        onto:long "25,467"^^xsd:float;
        onto:lat "65,017"^^xsd:float;
        onto:isInCountry :FinlandCountry.
geo:RovaniemiCity a onto:City;
        onto:name "Rovaniemi"^^xsd:string;
        onto:long "25,8"^^xsd:float;
        onto:lat "66,567"^^xsd:float;
```

        onto:lat "22,25"^^xsd:float;
        onto:isInCountry  :ChinaCountry.
```

Next, let us recall the sample employee (Mr. Chan). As discussed in [4], [5], each employee is associated with several profiles. Note, however, that some resources introduced in this document have only a single profile assigned. In general, resource detailed information is stored in its profile in order to facilitate adaptability in the system, which assumes that profile extensibility, robustness and resource access control are required. Therefore, saving resource attributes within profiles allows to easily extend and adapt individual resource records (see, also [9]). Below we present a snippet based on the *Employee Profile*, which consists of a *Personal Profile* and an *Experience Profile*:

```
:Employee\#1 a onto:ISTPerson;
    onto:id "1234567890"^^xsd:string;
    onto:hasProfile (:Employee\#1PProfile,
                     :Employee\#1EProfile),
    onto:belongsToOUs (:GOU).
:ResearchOU a onto:OrganizationUnit;
    onto:name ‘‘Researchers Organization
                        Unit’’^^xsd:string.
```

In this example the *Employee#1PProfile*—the *Personal Profile*, presented next—describes the “human resource (HR) properties” of an employee. In what follows we use only basic properties: *fullname*, *gender* and *birthday*; as well as the *belongsToOUs* property, which indicates Mr. Chan’s position in the organization (the *Organizational Unit* he works for). Let us stress that a complete list of HR properties is organization-dependent and is instantiated within the ontology of a given organization.

```
:Employee\#1PProfile a onto:ISTPersonalProfile;
  onto:belongsTo :Employee\#1;
  person:fullname ‘‘Yao Chan’’^^xsd:string;
  person:gender person:Male;
  person:birthday
        ‘‘1982-01-01T00:00:00’’^^xsd:dateTime.
```

The second profile of *Employee#1* (Mr. Chan) that we have introduced, is the *Experience Profile* that demarcates his specialization in terms of fields of knowledge and project experience. Here, codes for the fields of knowledge specification originate from the KOSEF (Korea Science and Engineering Foundation) [10]. Obviously, *any* classification of fields of knowledge/expertise could be applied here (appropriately represented within the ontology of an organization).

```
:Employee\#1EProfile a onto:ISTExperienceProfile;
  onto:belongsTo :Employee\#1;
  onto:doesResearchInFields
    scienceNamespace:Volcanology-13105,
    scienceNamespace:Paleontology-13108,
    scienceNamespace:Geochronology-13204;
  onto:knowsFields
    [a onto:Knowledge;
    onto:knowledgeObject
        scienceNamespace:Volcanology-13105;
    onto:knowledgeLevel "0.25"^^xsd:float],
    [a onto:Knowledge;
    onto:knowledgeObject
        scienceNamespace:Paleontology-13108;
    onto:knowledgeLevel "0.15"^^xsd:float],
    [a onto:Knowledge;
    onto:knowledgeObject
        scienceNamespace:Geochronology-13204;
    onto:knowledgeLevel "0.90"^^xsd:float];
  onto:managesProjects (:Project1).
```

According to the *ISTExperience profile*, Mr. Chan specializes in *Volcanology*, *Paleontology* and *Geochronology*. Level of knowledge in each of these areas is expressed as a sample real value; respectively: 0.25, 0.15, 0.9. Here, we assume that values describing the level of knowledge in specific fields are a result of self-assessment of an employee. However, in [11] we have proposed mechanisms for human-resource adaptability, which can be utilized to automatically (or semi-automatically) adapt level of knowledge on the basis of, for instance, work and training history of the employee. Furthermore, note that professional test (existing in most fields) can also be directly used as a method for knowledge level assessment. Now, *Employee#1* who is described with that profile manages project *Project1*. It is a scientific project in *Volcanology* (see below).

```
:Project1 a onto:ISTProject;
 onto:managedBy :Employee\#1;
 onto:period
 [a onto:Period;

 onto:fieldsRef scienceNamespace:Volcanology-13105;
 onto:projectTitle ‘‘Very Important Volcanology
               Scientific Project’’^^xsd:string.
```

To be able to illustrate matching processes taking place within the *Duty Trip Support* application, we will now introduce instances of a *Contact Person* (*:ContactPerson#1*) and a *Duty Trip Report* (*:DTR#1*); see [5], [7] for additional details).

```

```

As we will see, *Contact Person*s will be suggested (though for a different reason) by our system as someone who Mr. Chan should visit. First, Mikka Korteleinen, is defined through the *ContactPerson#1* and the *ContactPersonProfile#1* objects. The latter object defines Mr. Korteleinen's field of specialization to be *Paleontology* and *Volcanology*. Here, the level of expertise of Mr. Korteleinen is not specified, because it is assumed that such data is a result of self-assessment of the person, or processes taking place internally in her/his organization (see above); and as such is not available to the *DTS* of Mr. Chan's organization. However, note that the very fact that a potential contact person is in a system is very likely going to be a result of a personal meeting with her/him, followed by an employee introducing the contact information into the system. Such employee, could potentially assess not only area(s) of expertise, but also level of knowledge in each one of them. This possibility will be explored in the future. Now, we can observe that the profile of Mr. Korteleinen informs us that he can be reached in Rovaniemi, Finland. Second, the profile of Mr. Juno Viini was defined. According to this example he can be found in Rovaniemi as well, while his research interest is *Geochronology*. Separately, note that the *Duty Trip Report* is a basic resource associated with any *Duty Trip*. It is defined through the *DTR#1* and the *DTRProfile#1* objects and represents a required set of information associated by the organization with a *Duty Trip*. It describes travel details details, such as:

```
destination: Oulu, Finland,
status: application,
purpose: a conference.
```

Here, we can see that Mr. Chan plans to travel to Oulu, Finland to a conference and he has applied for this *Duty Trip* (in the case his travel is approved, the field *status* will change its value to *approved*). Our aim in this paper is to show how ontological matchmaking can be used to find cities near-by the city where Mr. Chan is to travel to, and person(s) that he may want do consider visiting during his trip.

## III. Matching in the system

### A. General idea

What is needed to achieve our goal is to be able to establish measure of distance (similarity) between two (or more) instances of ontologically demarcated data (here, between researchers considered in the context of cities they reside in). Before proceeding, let us note first that in our work we have made an important simplifying assumption. Across all currently developed applications (which are to work *within* an organization), a single ontology is used. Therefore, we do not have to deal with problems related to *ontology matching/integration* (where an attempt is made to establish "common understanding" between two, or more, ontologies; see, for instance [12], [13], [14]). Since our goal is to establish if specific instances of an ontology are "close enough," our objective should be to define a measure of distance representable as a single number (among others, for ease of comparison). This number can be then compared against a threshold to make a decision if objects are relevant to each-other. Note also that for each application there is a specific *Matching Criteria* that represents the "focus" of the matching process (e.g. research interests, eating preferences, or location). In [7] we have described in general terms process of measuring closeness of objects—*Calculating Relevance*, and presented it in the context of the *Grant Announcement Application*. Here a modified version of that algorithm will be proposed. However, we can use the same point of departure and define the *Matching Criteria* as a tuple (quadruple in this case) $\langle x, q, a, g \rangle$, where:

- $x$ is the selected ontology class instance (source object)
- $q$ is a SPARQL query ([15]) which defines a subset of objects that are considered potentially relevant (this is the above mentioned focus of the matchmaking process) and will be matched against the source object $x$
- $a \geq 0$, specifies threshold of closeness between objects to be judged actually relevant to each-other
- $g$ is a sub-query processed by the GIS subsystem (in general, this parameter can be omitted—if there is no geospatial query involved; or it can be replaced by one or more different criteria; thus the notion that the *Matching Criteria* is a tuple); this part of the system is responsible for finding cities which are located within a specified distance to a specified city; this sub-query is a triple $\langle gr, gc, ga \rangle$, where:
  - $gr$ is an operator which allows to either limit returned number of cities of possible interest (*AMOUNT* condition) or to specify the maximum distance between the $gc$ and the returned cities (*RADIUS* condition)
  - $gc$ is an URI of a city demarcated with properties of the *City* class of the system ontology
  - $ga$ is the parameter of the $gr$ operator ($gr(gc, ga)$); it either specifies the limit of the number of returned cities or the maximum distance between the $gc$ and the returned cities

### B. Relevance graph

Calculation of "distance" between instances of ontology is based on a graph structure that represents the underlaying *Jena Ontology Model*. Specifically, this *Model* is interpreted as a directed graph $G = (V, E)$ such that (here, reflexive relations are ignored):

$$V: \text{set of nodes, representing all instances,}$$

$$E: \text{set of edges, representing all object properties.}$$

Upon creating edges, the value of the annotation property *voPropertyWeight* of each object property becomes the label of the edge, representing the "distance between two nodes" ("importance of the relationship between two nodes") in the ontology. This concept comes from work of S. Rhee and collaborators (see, [16], [17] for more details), where it was shown how connections between nodes in the graph representing concepts in the ontology can be weighted according to the importance of their relationships. For instance, suppose for a given researcher we have two relations `doesResearchInFields` and `worksForProjects`; and the system attempts to recommend an additional contact person based on those two relations. Here, `worksForProjects` can be regarded to be more important than `doesResearchInFields` because the fact that two persons work at a given time for a similar project can be considered more important for recommending them to eachother than the situation when two persons declare that they have same (or similar) research interests. Currently, in our system we do not have an automatic way of assigning weights to edges in an ontology, and thus weights equal to 1 will be initially used as a default (which is also the approach suggested in [16], [17]). However, we assume that different weights can (and will in the future) be used in the graph representing the proposed ontology. It is also worthy stressing that such values allow us to naturally deal with concepts that are not directly connected in a directed graph (see, [6] for more details). For the sake of precision it can be thus stated that the relevance graph $G = (V, E)$ becomes $G = (V, E, W)$,

$V$ : set of nodes, representing all instances,

$E$ : set of edges, representing all object properties.

$W$ : "importance weights" assigned to all edges

Let us now observe that while weight values assigned to each edge represent the distance between two nodes in the *Model*, some instances connected by a certain relation (i.e. having the same "importance weight") may not have the same "importance" on the level of individuals. For example, a person may have knowledge/interest in three different subject areas, while his/her knowledge/interest level in each area may be different (see the *ISTExperience profile* example in Section II).

Therefore, we can distinguish two levels of "scaling" of importance of ontological relationships. The first one is "within the ontology" and involves relationships between concepts (nodes in the relevance graph). The second one is on the "level of instances" and specifies importance of specific properties to an individual. Therefore, when the ontological distance is calculated, first we have to take into account ontological distance between concepts and, second, to scale it according to individual "interests" of resources involved in matching. As an example of such process, delivery of personalized information is depicted in figure 1.

Here, we can see an employee within an organization. The ontology of an organization and the domain ontology provide us with a (weighted) relevance graph ($G = (V, E, W)$). At the same time, an ontological instance—the employee profile—allows us to scale specific relations in the ontology according to the employees' interests. Both the relevance graph and the individual profile, together with resources, closeness to which is to be established (selected according to the *Matching Criteria*), are the input to the matching algorithm. As an output we obtain list of resources that are relevant to the employee.

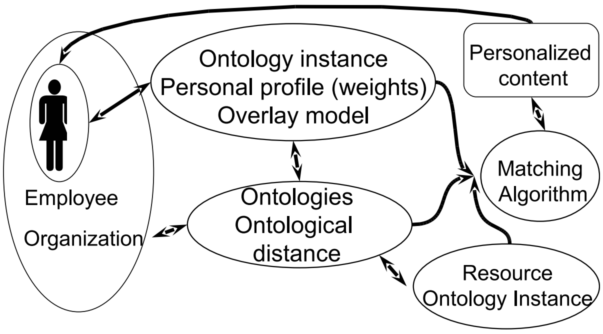

Fig. 1. Top level overview of matchmaking

### C. Geospatial Information Subsystem

Before proceeding to describe in detail the matchmaking algorithm and its utilization in the *Duty Trip Support* application, let us make the following comment on the (optional) GIS sub-query. In general, the first four terms of the *Matching Criteria*, above, allow one to find objects relevant to the given *source object* assuming that there is a (directed) path between these objects in the *Relevance Graph* (these objects are linked with each other). However, one of basic requirements of the system under development is that it will provide geospatial information-based recommendations. Observe that the *Relevance Graph* does not provide natural support for distance calculation in terms of geographical localization (as it is represented in our ontology). Specifically, the *Relevance Graph* is built on the basis of nodes that represent ontology class instances, which in turn are linked by edges that represent properties. In our ontology, geospatial attributes are: *longitude*, *latitude*, *altitude* and *inCountry*. While meaning of the first three is obvious, the latter is a relation between instances of the *Country* and the *City* classes that allows us to model "cities being in a country" property.

SPARQL seems to be most recommended technology for querying the RDF demarcated data and it provides support for computing results of mathematical calculations on *Datatype Properties* values of objects defined in the RDF [18]. The latter functionality is necessary for finding RDF demarcated *City* class instances which meet certain distance criteria in terms of geospatial localization. However, designing full GIS support to be performed by the SPARQL engine would require full information about countries and cities of the world to be stored in the semantic storage. Such an approach would overload the semantic storage and severely influence other SPARQL operations which have to be performed on the RDF demarcated data. On the other hand, distances between nodes of the *Relevance Graph* correspond to (scaled) weights of ontology properties that reflect the semantic distance of certain concepts. This distance is not the geospatial distance. Therefore, in order to avoid semantic storage replication/clustering, which would be necessary if we stored all GIS information in the semantic storage, we decided, for the time being, that the GIS sub-query is going to be processed by a dedicated subsystem that allows us to select only related objects which meet criteria defined in the sub-query. This subsystem returns as a result a list of *City* object URIs which represent cities that meet the geographical localization criteria and, in the case that a particular *City* object does not exist in the semantic storage, it creates the necessary RDF statements. This subsystem is simple and independent and it reduces the volume of the RDF demarcated data stored in the system. Please note that this solution is temporary as we experiment with an alternative that allows to utilize full computational possibilities of SPARQL and keeps RDF data volume as small as possible.

## IV. *Duty Trip Support*-based Matching Example

As noted, one of important functionalities of the *Duty Trip Support* subsystem is to suggest optional activities of an employee who plans a duty trip. In order to give Mr. Chan advice about possible extensions of his duty trip, first, it is necessary to define appropriate *Matching Criteria*. Next, the delivered advice is a result of matching between the *DTR#1* object and instances of the *ContactPerson* class ([19], [7]). Note that in the future such matching will involve also information about food and accommodations (while other features can also be naturally selected). Overall, the matching process in the *DTS* involves the following steps:

1) Construct Matching Criteria $\langle x, q, a, g \rangle$:
   a) $x = DTR\#1$
   b) $q =$

```
PREFIX onto:
<http://rossini.ibspan.waw.pl/
            Ontologies/KIST/KISTVO>
SELECT ?person
WHERE {?person isa onto:ContactPerson.}
 FILTER (onto:locatedAt
                 temp:gisResults-multi).
```

   c) $a = \frac{1}{40}$
   d) $g = [gc, gr, ga]$ :

$$gc = OuluCity,$$
$$gr = RADIUS,$$
$$ga = 200.$$

   The *Criteria* defined above can be stated as: find a potentially interesting (in terms of professional interests) person who resides not further than 200 km away from Oulu.
2) Execute the GIS query $g$. To do this, invoke the GIS interface method which returns references to objects which represent (known to the system) cities located within 200 km distance from the city of Oulu. Results are chosen from all cities for which at least one RDF object in the semantic storage exists. The result in our example is: RovaniemiCity for which the distance from *OuluCity* equals to 173.168 km.
3) Execute an appropriate SPARQL query. In case of the duty trip based advisory [5] this query should limit sought objects only to *ContactPerson* class instances (obviously, in the general case, such a query could seek other entities, e.g. golf courses, or historic castles).

   An additional SPARQL filter is applied according to the respective *Matching Criteria* part: *onto:locatedAt temp:gisResults-multi*. The matching request processing engine transforms the GIS sub-query results to a valid SPARQL filter and executes the query. In our example the final SPARQL query has the following form:

```
PREFIX onto:
<http://rossini.ibspan.waw.pl/
            Ontologies/KIST/KISTVO>
SELECT ?person
WHERE {?person isa onto:ContactPerson.}
FILTER (onto:locatedAt :RovaniemiCity).
```

   In our example, results of this query are *ContactPerson#1* and *ContactPerson#2* object references. Note that the proposed order of the GIS and the SPARQL query execution may change in the final version of our system, as it largely depends on results of our experiments with designing optimal SPARQL support for the, described above, GIS calculations.
4) Having merged results returned by the GIS component and the SPARQL engine, the relevance can be calculated. Note that the above proposed threshold value $R = \frac{1}{40}$ is a sample value only and is used to illustrate the process; an actual value will be a result of experimental calibration of the system. Specifically, to be able to actually establish a reasonable threshold value, a number of experiments have to be performed. Such experiments require a complete implemented system running and providing explicit and/or implicit user feedback. However, the question of tuning the performance of the proposed approach to a given institution is out of scope of this contribution. Thus the matching process involves:
   a) source instance $URI = DTR\#1$
   b) target objects $URI's = [ContactPerson\#1, ContactPerson\#2]$
   c) relevance threshold: $R = \frac{1}{40}$.

   If the relevance value for any object is above the relevance threshold, such object(s) will be suggested.

### A. Calculating relevance

Let us start from considering Figure 2 which presents the overview of relations between *Employee1* and two contact persons *ContactPerson#1* and *ContactPerson#2* via three research fields: *Volcanology*, *Paleontology*, *Geochronology*. These relations are represented in our ontology, as shown in Figure 3 (note that a figure which would include all relations would be too complex to be explanatory).

Figure 2 includes scaling factors (related to professional interests of the *Employee#1*), represented as $W1$, $W2$, and $W3$, which in the proposed algorithm, are used in order to calculate relevance between objects. The values of $D$ represent the ontology property weights for each relation, defined by an annotation property `voPropertyWeight`. On the other hand, Figure 3) presents in some detail links between the *Employee#1* and *ContactPerson#1* resources depicted from the perspective of ontology concepts.

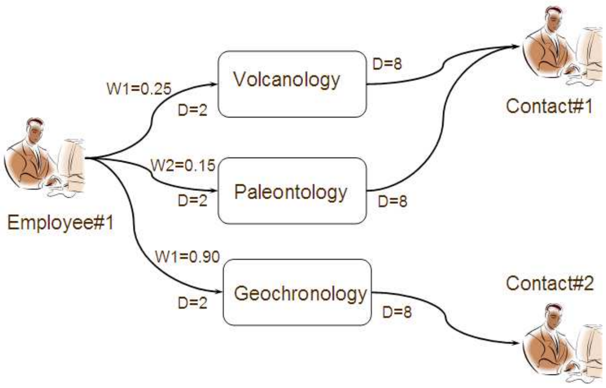

Fig. 2. Employee and foreign contacts

Therefore, based on Figure 2 and the above discussion, we can define three paths from *Employee#1* to the selected contact persons:

*Path* 1: *Employee#1* → *Employee#1Profile* → *Volcanology* → *ContactPerson#1Profile* → *ContactPerson#1*
*Path* 2: *Employee#1* → *Employee#1Profile* → *Paleontology* → *ContactPerson#1Profile* → *ContactPerson#1*
*Path* 3: *Employee#1* → *Employee#1Profile* → *Geochronology* → *ContactPerson#2Profile* → *ContactPerson#2*

Let us assume (see above) that ontology property weights are defined as follows:

$$\begin{aligned} voPropertyWeight(doesResearchInFields) &= 2\\ voPropertyWeight(isResearchedBy) &= 8\\ voPropertyWeight(hasProfile) &= 1\\ voPropertyWeight(belongsToResource) &= 1 \end{aligned}$$

Now, let us recall the fact that the *Employee#1* has different level of knowledge of these research fields, and the knowledge level (i.e. *weight*) can be applied to the `voPropertyWeight(doesResearchInFields)` value (i.e. *distance*) to obtain a scaled distance value for each individual. Precisely, the scaled relevance value is obtained by multiplying the individual weight value by the inverse of the distance value (i.e. the relevance value):

$$newRelevance = relevance \times weight$$

Since the *relevance value* between two nodes is the inverse of the *distance value*, the new distance is as follows:

$$newDistance = (\frac{1}{distance} \times \texttt{weight})^{-1}$$

This scaling provides personalized relevance results for the *Employee#1*. Here, scaled distance values from *Employee#1* to the three research fields (*Volcanology*, *Paleontology*, *Geochronology*) are 8, $\frac{40}{3}$, $\frac{20}{9}$, respectively. Now, the relevance value for each path is calculated as follows:

$$Rel_{path} = (\sum_{k=1}^{n}(k \times D_k))^{-1},$$

where $n$ is the number of edges in the path and $D_k$—distance of $k$-th edge. Thus the relevance result for each path is:

$$\begin{aligned} Rel_{path1} &= \frac{1}{45} = 0.022\\ Rel_{path2} &= \frac{3}{167} = 0.018\\ Rel_{path3} &= \frac{9}{301} = 0.030 \end{aligned}$$

Both $Rel_{path1}$ and $Rel_{path2}$ represent the relevance between *Employee#1* and *ContactPerson#1*, hence we can establish the final relevance value between the two objects by adding relevances of each path. Therefore, the final value of relevance between *Employee#1* and the two contact persons is:

$$\begin{aligned} &Rel_{ContactPerson\#1} = Rel_{path1} + Rel_{path2} = 0.040,\\ &Rel_{ContactPerson\#2} = 0.030. \end{aligned}$$

Note that the calculation process is presented in a simplified way in this paper, however, the detailed algorithm can be found in [16], [17], [20]. Based on the result and the proposed *Criteria*=$\{R \geq \frac{1}{40}$, where $R$ is the relevance threshold$\}$, both *ContactPerson#1* and *ContactPerson#2* will be recommended for *Employee#1*. Let us stress that *ContactPerson#2* is recommended via a single research field (*Geochronology*) whereas *ContactPerson#1* is recommended via combined strength of two research fields, even though the relevance value of each single path is below the threshold. Thus, the relevance measure considers not only a single research field match but also the "multidisciplinary" case. In the future we may consider making the threshold for the multi-pathway relevance to be different than the single-pathway one; as a single strong link is more important than a number of weaker links, but this will be done as a part of system calibration. Overall, as a result of the matching, the following additional duty trip activity is to be suggested:

```
:AdditionalDuty\#1 a onto:ISTDuty;
        onto:destination geo:RovaniemiCity;
        onto:madeContact :ContactPerson\#1.
:AdditionalDuty\#2 a onto:ISTDuty;
        onto:destination geo:RovaniemiCity;
        onto:madeContact :ContactPerson\#2.
:DTRProfile\#1 onto:duty :AdditionalDuty\#1.
:DTRProfile\#1 onto:duty :AdditionalDuty\#2.
```

The *:AdditionalDuty#1* and *:AdditionalDuty#2* objects define activities which are suggested to Mr. Chan who is planning his duty trip represented in the system as the *DTR#1*. Figures 3 and 4 present relations between objects included in the example in this section. Note that these figures omit *ContactPerson#2* and *AdditionalDuty#2* due to the fact that relations of these resources with *Employee#1* are analogical to the relation between *Employee#1* and *ContactPerson#1* and *AdditionalDuty#1*. In Figure 3 we present a path between the *Employee#1* and the *ContactPerson#1* and including them would only make both figures less legible. Finally, in Figure 4 we depict the final relations between the *Employee#1*, the *ContactPerson#1* and the *DutyTrip#1*, after the suggested *AdditionalDuty* is accepted.

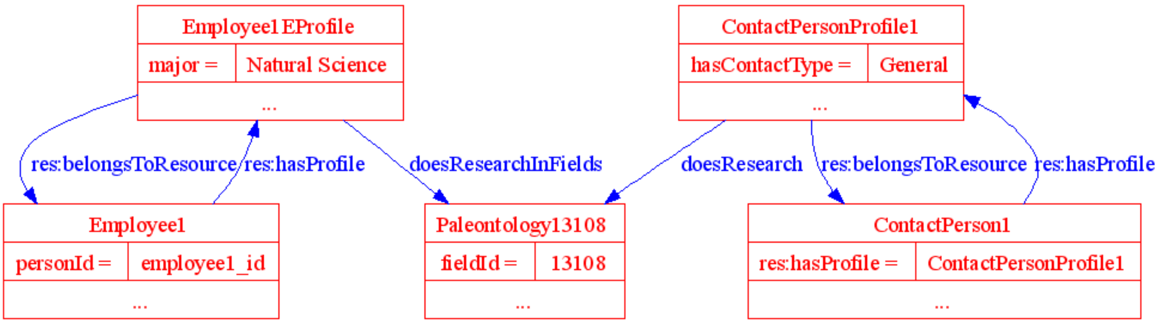

Fig. 3. Employee and foreign contact

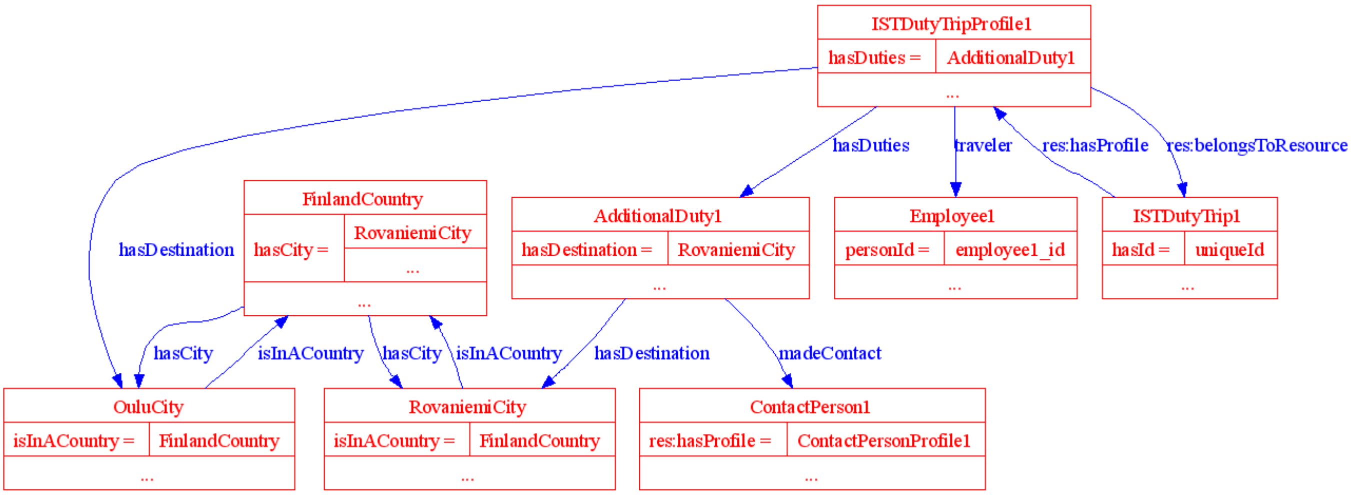

Fig. 4. Duty Trip related objects

## V. System building blocks

In [7] we have described in some details two main building blocks of the system: the *Relevance Calculation Engine* and the *Relevance Calculation Interface*. Therefore, here, we discuss only the *GIS subsystem*.

### A. The GIS Subsystem

In [6], [5], [7] we have outlined utilization of the GIS module—it is queried in case objects which have geospatial location properties that are involved in the matching operation. The state of the art research has shown that we can provide a reliable geospatial backend for our system by using the following components: (1) the GeoMaker [21] for collecting geographic coordinates of cities in the world, (2) the PostgreSQL database [22] for storing that information and for caching the result, and (3) Java *GIS—coordinates and distance cache* for calculating distance between cities, populating distance calculation results cached in the PostgreSQL database and interfacing the GIS module with the rest of the system. In Figure 5, which represents the GIS subsystem, these elements are placed on its bottom.

In the system that is supposed to communicate with the *GIS component*, the *GIS data consumer* is an interface that is responsible for requesting new data from the *GIS component*. On the system side, data is going to be stored in the semantic data storage that is based on the *JENA Model* [23]. We assume that the semantic data storage and *GIS component* share city instance identifiers in order to communicate in an optimal way in terms of performance.

For the purpose of calculating distance between two cities we utilize an implementation of the *Great Circle Distance Formula* [24]. This formula uses spherical trigonometry functions. Although relatively high precision of this method is not required in the system for the purpose of calculating distance between cities we apply it because the distances are calculated only once for each pair of cities.

$$\begin{aligned} result = 69.1 * \frac{180}{\pi} * \arccos\Big(\sin LAT1 * \sin LAT2 + \\ + \cos LAT1 * \cos LAT2 * \cos(LONG2 - LONG1)\Big) \end{aligned}$$

As it was pointed in previous sections, the *GIS component* is still under development and changes in its design (performance-related changes in particular) may be introduced as a result of further experiments.

## VI. Concluding remarks

In this paper we have presented a novel ontological matching algorithm in which we have combined matching based on

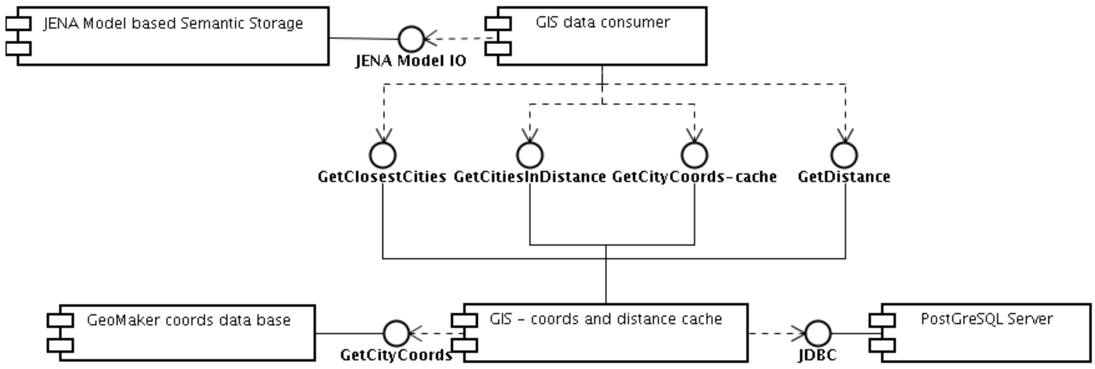

Fig. 5. The GIS subsystem; UML component diagram

ontological distance with filtering based on individual profiles. The proposed algorithm was illustrated in the context of a *Duty Trip Support* application. Across the paper we have identified a number of research questions, especially those related to an efficient implementation of geospatial data processing. We are currently implementing the proposed algorithm and the GIS subsystem as a part of the *DTS* application. Completing the initial implementation will allow us to start experimentally investigating all efficiency related questions. We will report on our progress in subsequent publications.

***Abstract*—This paper presents an easy way of finding strokes on computer tomography images. By calculating a cohesive rate (CR) of suspicious pixels on a series of CT images there is a possibility of calculating a general probability of a stroke. In a difficult case there is always an opportunity to generate a graph of all stroke probabilities interposed on the original image. It is a very helpful tool for specialists and neurologists working in emergency situations . Supported by grant N518 022 31/1338 (Ministry of Science).**

## I. Introduction

A STROKE is a rapidly developing loss of brain functions due to a disturbance in the blood vessels supplying the brain. This can be due to ischemia (lack of blood supply), or due to a hemorrhage which is caused by a blood vessel that breaks and bleeds into the brain. The most common kind an is ischemic stroke. It is /found in about 85% of all the patients with strokes. This kind of disease is very serious and without suitable treatment it leads to death or long term disability.

The availability of treatments, when given at an early stage, can reduce stroke severity. Early diagnosis of acute cerebral infraction is critical due to the timing of thrombolytic treatment.

The clinical diagnosis of an ischemia stroke is difficult and it has to be supported by brain imaging. There are new effective methods for detecting strokes based on the images, but in most cases, a CT remains the most important and the most popular brain imaging tool. It is vital that no longer than 3 hours elapse between diagnosis and action planning that the appropriate treatment is given. During the initial 3 hours the area's ischemia CT attenuation decreases by 2-3 HU (Hunsfield Unit)[1]. The distinction of the colors on the CT images is so small that even a neurologist with great experience cannot see it.

After a few days damaged tissue is very noticeable, but it is too late for effective treatment. Because of the great importance of an early detection of the stroke, many authors presented various approaches to that problem [2-4].

The aim of this paper is to present a self-constructed, effective algorithm to support ischemic stroke detection based on CT images.

## II. Algorithm

The proposed heuristic algorithm analyzes a series of CT images of a brain. As a result algorithm generates graphs of the suspicious areas of the brain. Parts of the brain tissue which have the biggest probability of a stroke are highlighted. There is also a possibility to generate a full graph which contains the probabilities of a stroke in a colorful version. The algorithm also calculates a general probability of a stroke. Calculation are based on the patient's CT images. The method is based on a few important statements.

The first of them is about colors which represent the area of the probable stroke's location. According to [2] the area of ischemia CT attenuation decreases by 2-3 HU which means that the suspicious part in the CT image are a little darker than the common tissue of the brain.

The second statement is that strokes have a volume. It gives a possibility of seeing a stroke on more than one image.

The next statement is that strokes are solid structures. The lack of blood supply on the CT image looks like a large, solid and rounded figure.

The probability of a stroke happening on both sides of the brain is almost zero. The algorithm uses this fact and assumes that a stroke can be found only on one side of the brain[1].

The stroke detection contains four main stages.

### A. Preprocessing

An image has to be prepared by separating the brain tissue from the scan, finding a symmetry of the brain and selecting suspicious points of the CT image where a stroke can be found. . Preprocessing is extremely important because it shows significant features of the analyzed case.

Firstly, non-brain tissue must be removed from a CT image. It may be done through region growing. The skull surrounding the brain has an uninterrupted, rounded shape and on image it has a white color. That is why extraction of the brain tissue can be done by using simple figure filling algorithm (e.g., Smith's algorithm[5]).The starting point for extraction algorithm is the center of image and the filled colors have to be other than white (the skull is represented by a white color).

978-83-60810-14-9/08/$25.00 © 2008 IEEE

The second preparation step is to find a color which is the most common in the image. Using this information the suspicious point of the image can be found. Creating a histogram H where $i \in \langle 0;255 \rangle \wedge i \in N$ and $H_i$ is a number of pixels where color is *i* makes it easy to find and set $C_{max}$ as the most common color [6].

With this information the suspicious pixels are easily found. According to statements and experimental study colors which may represent a stroke are in range $K \in \langle C_{\max} - g ; C_{\max} \rangle$ where g is a precision property.

Searching the symmetry line of the brain is a really important step. It can be found by rotating the image and looking for two parallel straight lines with the smallest distance between them. The $J_R$ and $J_L$ contain pixels which are on the right and left side of the brain.

Using the previous calculation suspicious areas of pixels can be found. Taking into consideration the symmetry line and points which have colors from the range K, two subsets $T_R \subset J_R$ and $T_L \subset J_L$ are created.

### B. Cohesive rate(CR)

The main part of the algorithm is to calculate the cohesive rate of suspicious pixels. CRs value represents the summary relative locations of one suspicious pixel to the rest of them. It is the key to this algorithm. CR is defined by a formula:

$$\forall\, p \in T_V \left( cohesive_{rate}(p) = \sum_{i=1}^{T_V} \left| 1/distance(p, p_i) \right| \right)$$ where

V={R,L}. The distance means distance in Manhattan's metric. Value $P_{max}$ is set as maximum cohesive rate from both $T_V$ subsets. According to statements the stroke is a solid structure which means that CR gets high values for stroke pixels.

### C.Probability of a stroke

The algorithm calculates a general probability of a stroke for a series of CT images by taking under consideration the single scans stroke risk.

For selected $k \in (0;1)$ calculate number of pixels $U_V$ which cohesive rate is from range (k $P_{max}$; $P_{max}$) and are in set $T_V$, where V={R,L}. *k* is a kind of a sensitivity property. A bigger k causes a bigger probability of a stroke. On the other hand a minor k causes a lesser probability of a stroke

According to statements and taking into consideration that stroke is only on one side of the brain the probability of a stroke for left and right side can be calculated by a formula: $P_V=U_V/(U_R+U_L)$, where V={R,L}. The formula which describes calculations uses the information about number of selected pixels generated is previous step. Using this calculations it is easy way to estimate general stroke risk.

Simply taking all $P_R$ and $P_L$ for a series of CT images and calculating average values of them gives the probability of a stroke for left $P_{AVGL}$ and right $P_{AVGR}$ side of the brain.

General probability of a stroke for a series of CT images is defined by a formula: $P = \dfrac{|P_{AVGR} - P_{AVGL}|}{P_{AVGR} + P_{AVGL}}$ .

### D. Visualization

Visualization [6] is the final step which is not necessary but extremely important in difficult cases. There are two types of visualization. The first is to generate an original image with selected pixels by sensitivity factor. The second type shows all suspicious pixels but the color of the pixels depends on the CR for that point. For this one there is no need to specify sensitivity property.

## III. Experimental Study

Experimental tests were performed to verify the efficiency of the algorithm for the various values of parameters g and k. Tests were carried out on 23 CT images specially selected to represent different positions of the stroke in the brain as well as images of a healthy brain. Among the images chosen there are 3 series of scans and the rest are single representations. Results were very optimistic. First tests revealed the potential of the algorithm, the marking was clear and accurate. Sometimes it seemed to show details that were not noticeable in the original image. After comparison of processed images of a healthy brain and one with a stroke the difference was obvious even for someone with no experience in this kind of analysis.

All of the strokes were pointed correctly with their placement and size. As an example 3 CT images were chosen (Fig. 1) and tested with different parameters. The first pair presents a healthy brain. To show how it works in different cases other two pairs of the images show a brain attacked by the disease.

Every presented case contains a table with algorithm results for the various sensitivity and precision Parameters. There is also a figure of visualizations for each factor combination. The shortcuts used in the tables mean:

*I. g – precision factor,*
*II.k – sensitivity property,*
*III.* $U_L$ *– number of selected pixels on the left side*
*IV.* $U_P$ *– number of selected pixels on the right side*
*V.* $CR_L$ *– maximum cohesive rate for the left side*
*VI.* $CR_R$ *– maximum cohesive rate for the right side*

Fig 2. shows screenshots of a healthy brain with different parameters values set. For different factors the algorithm calculates the probability of a stroke. All of the calculated values are combined in Table I and for all of the different values set the probability is very low. It is because cohesive rates for left and right side are almost equal which leads to a conclusion that there are no suspicious areas.

Following images in Fig. 3 and Fig. 4 are very difficult for neurologists to analyze. Strokes are hard to notice because the difference between pixels representing the stroke and normal tissue is very small. This algorithm helps to separate the stroke by finding even a small change between pixels and calculating cohesive rate. Table II and III show calculated values due to differently set parameters. Unlike previous analysis these two cases show high probability of a stroke in every combination of the variables. There are certain adjustments that make the probability go high, even up to 1,00. In both cases the algorithm has highlighted the suspicious areas and clearly announced that a stroke has been found in the image.

ALGORITHM RESULTS FOR THE VARIOUS SENSITIVITY AND PRECISION FACTOR FOR SECOND DIFFICULT CASE

| g | k | $U_L$ | $U_R$ | $CR_L$ | $CR_R$ | Fig | Probability |
|---|---|---|---|---|---|---|---|
| 20 | 0,95 | 788 | 0 | 60 | 50 | 4.a) | 1,00 |
| 20 | 0,90 | 1618 | 0 | 60 | 50 | 4.b) | 1,00 |
| 20 | 0,80 | 2809 | 234 | 60 | 50 | 4.c) | 0,85 |
| 20 | 0,70 | 3596 | 1367 | 60 | 50 | 4.d) | 0,45 |
| 40 | 0,90 | 2084 | 0 | 94 | 80 | 4.e) | 1,00 |
| 60 | 0,90 | 2187 | 0 | 97 | 86 | 4.f) | 1,00 |

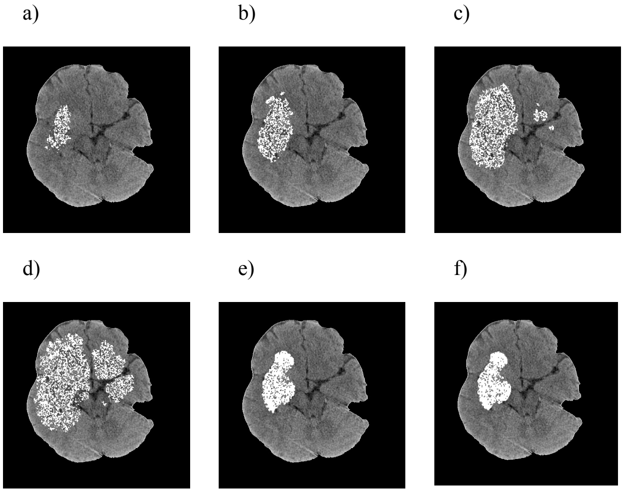

Fig. 4 Visualization for Table III – stroke on the left side.

For the sensitivity factor set to 0.9 and precision property to 20, average probability of a stroke in 8 series has been calculated and it is 0,70%. Standard deviation for these cases is 0,20. It is because some of the CT images contains very dark strokes and for precision property set to 20 it is hard to find it. Changing it to 60 or higher gives better results.

## IV. CONCLUSIONS AND DISCUSSION

The presented method gives satisfying results. The quality of results given by the algorithm and its performance can be set by the sensitivity factor and the precision parameter. The optimal values were found experimentally by analyzing series of CT images. The best settings are 0.9 for the sensitivity factor and 20 for the precision parameter. The precision parameter is most important for the performance of the method and has a minor influence on quality which can be changed by adjusting the sensitivity factor. Although both parameters can be set manually, it is better to use their optimal settings or to change them only in difficult cases to estimate the volume of a stroke

The presented test sets do not include series. It is because it will take up much space. The series were tested on 11 people with strokes and on 15 healthy people and results were very optimistic. The probability for different cases were from 0.6 to 0.95 for CT images with a stroke and 0.0 to 0.5 without a , stroke, the sensitivity factor having been set at 0.9 and precision property at 20.

Another interesting option is that a cohesive rate graph can be displayed and it can be useful for additional analysis of the brain. There is an example of the graph in this paper shown in grayscale instead of a colored one. In the colored graph the highlighted areas have different colors and intensity. Colors are specially chosen to attract human eyes. Red represents the areas which have the biggest probability of being a stroke, green marks the areas with medium danger and blue is reserved for the less suspected parts of the brain. Thanks to this color palette the graph shows a general view of the brain tissue separated from any distractions from the original image.

There are possibilities to improve this algorithm. Better optimalization can be done by rewriting it in Assembler. There is also an idea to use folds analysis by using the fact that in the area where the stroke is the folds are smaller or not noticeable. The changes proposed here can be very useful to improve the algorithm effectivness and performance.

New discoveries can bring new facts to light about the anatomy and characteristic of a stroke. They can also improve the method by taking them into consideration if possible. There is no possibility for a computer program to replace a good specialist but it can be useful for faster diagnosis because it shows by means of a number the probability of a stroke.

# Computer Aspects of Numerical Algorithms

NUMERICAL algorithms are widely used by scientists engaged in various areas. There is a special need of highly efficient and easy-to-use scalable tools for solving large scale problems. The workshop is devoted to numerical algorithms with the particular attention to the latest scientific trends in this area and to problems related to implementation of libraries of efficient numerical algorithms. The goal of the workshop is meeting of researchers from various institutes and exchanging of their experience, and integrations of scientific centers.

## Topics

- Parallel, distributed and grid numerical algorithms
- Data structures for numerical algorithms
- Libraries for numerical computations
- Numerical algorithms testing and benchmarking
- Analysis of rounding errors of numerical algorithms
- Optimization of numerical algorithms
- Languages, tools and environments for programming numerical algorithms
- Paradigms of programming numerical algorithms

# A Numerical Algorithm of Solving the Forced sine-Gordon Equation

Alexandre Bezen
School of Life and Physical Sciences, RMIT University, Melbourne, GPO Box 2476V, Melbourne VIC 3001,
Australia, Email: *abezen@unimelb.edu.au*, and Department of Mechanical and Manufacturing Engineering,
University of Melbourne

***Abstract*—The numerical method of solving the problem of small perturbations of a stationary traveling solution (soliton) of well-known in physics sin-Gordon equation is presented. The solution is reduced to solving a set of linear hyperbolic partial differential equations. The Riemann function method is used to find a solution of a linear PDE. The value of the Riemann function at any particular point is found as a solution of an ordinary differential equation. An algorithm of calculation of a double integral over a triangular integration area is given.**

## I. Introduction

THE RIEMANN method is an important technique for solving Cauchy problems for partial differential equations. However, it does not yield closed form solutions except in few cases of equations with constant coefficients [1]. A typical example of such an equation is the forced sine-Gordon equation

$$\frac{\partial^2 u}{\partial t^2} - \frac{\partial^2 u}{\partial x^2} + \sin u = \varepsilon\Phi(t) \qquad (1)$$

where $\varepsilon = 1$ is a small parameter, $t$ is a time variable, $x$ is a space variable, and $\Phi(t)$ is a deterministic or random external force with known statistics. Equation (1) with zero right-hand side possesses stationary traveling solutions depending on a variable $\chi = x - Vt$ $(-1 < V < 1)$. The particular solution that is of great physical interest is the kink or soliton [2] (Fig. 1)

$$u_0(\chi) = 4\operatorname{atan}\left[\exp\left(\chi/\sqrt{a}\right)\right] \qquad (2)$$

where $a = 1 - V^2$. The problem of deterministic or stochastic perturbations of the kink solution is important in physical applications.

The approximate solution of the equation (1) with non-zero function $\Phi(t)$ can be constructed by the asymptotic method using a smallness of the parameter $\varepsilon$:

$$u(\chi,t) = u_0(\chi) + \varepsilon u_1(\chi,t) + \varepsilon^2 u_2(\chi,t) + \mathrm{K} \qquad (3)$$

where $u_0(\chi)$ is the solution (2). The functions $u_1, u_2, \ldots$ are solutions of linear hyperbolic equations.

Apparently, Walsh's papers [3], [4] were the most remarkable first investigation of stochastic processes described by the second order partial differential equations. In particular, a weak solution of a stochastic partial differential equation was defined as a solution of an integral equation. Walsh in [2] applied the Green's method to simple linear hyperbolic and parabolic equations in case of the white noise, and Carmona and Nualart in [5] proved that the weak solution exists and it is unique.

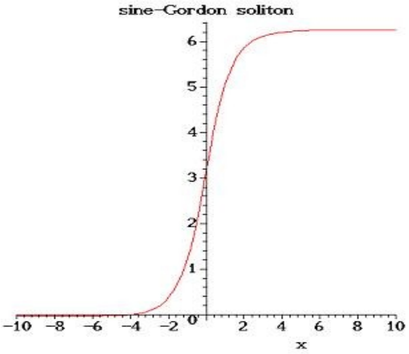

Fig. 1. The sin-Gordon soliton.

In this paper, the Riemann function method is used to find a solution of linear hyperbolic equations (4) and (5). The algorithm is numerical and can be divided into two parts. First, the Riemann function at each point of the integration area is found as a solution of an ordinary differential equation. Second, the triangular integration area is transformed into a rectangle. This allows simplifying and improving considerably calculation of a double integral. Initially the method was described in [6] and [7] and was applied in a case of stochastic perturbations. In the current paper, the proposed method has been improved. The physical part of the method and some numerical results were described in [8].

## II. The Solution Form of the Eequation (1)

In the new variables $(\chi, t)$ the equation (1) becomes

$$\frac{\partial^2 u}{\partial t^2} - 2V\frac{\partial^2 u}{\partial\chi\partial t} - a\frac{\partial^2 u}{\partial\chi^2} + \sin u = \varepsilon\Phi(t) \qquad (4)$$

Expanding $\sin u$ in power series in $\varepsilon$

$$\sin u(\chi,t)=\sin u_0(\chi)+\varepsilon u_1(\chi,t)\cos u_0(\chi)+$$
$$\varepsilon^2\left[u_2(\chi,t)\cos u_0(\chi)-\frac{u_1^2(\chi,t)}{2}\sin u_0(\chi)\right]+\ldots \qquad (5)$$

Substituting (3) and (5) into (4) in the first order on $\varepsilon$ we obtain

$$\frac{\partial^2 u_1}{\partial t^2}-2V\frac{\partial^2 u_1}{\partial\chi\partial t}-a\frac{\partial^2 u_1}{\partial\chi^2}+\cos u_0(\chi)u_1=\Phi(t) \qquad (6)$$

In the second order

$$\frac{\partial^2 u_2}{\partial t^2}-2V\frac{\partial^2 u_2}{\partial\chi\partial t}-\left(1-V^2\right)\frac{\partial^2 u_2}{\partial\chi^2}+\cos u_0(\chi)u_2=$$
$$\frac{1}{2}u_1^2\sin u_0(\chi) \qquad (7)$$

To apply the Riemann's method of solving (6) and (7) [1] we need to transform these equations to the standard form which does not contain the second mixed derivative. To get rid of the mixed derivatives let us make a transformation $\chi=\chi$ and $\tau=t-\dfrac{V\chi}{a}$. In the new variables equations (6) and (7) read

$$\frac{\partial^2 u_1}{\partial\tau^2}-a^2\frac{\partial^2 u_1}{\partial\chi^2}+a\cos u_0(\chi)u_1=a\sin\left(\tau+\frac{V\chi}{a}\right) \qquad (8)$$

and

$$\frac{\partial^2 u_2}{\partial\tau^2}-a^2\frac{\partial^2 u_2}{\partial\chi^2}+a\cos u_0(\chi)u_2=$$
$$\frac{1}{2}au_1^2\sin u_0(\chi) \qquad (9)$$

with trivial initial conditions over the straight line $C$

$$C:\tau=-\frac{V}{a}\xi \qquad (10)$$

## III. The Riemann Function

Equations (8) and (9) have the same left-hand side and can be presented as

$$\frac{\partial^2 u_1}{\partial\tau^2}-a^2\frac{\partial^2 u_1}{\partial\chi^2}+a\left[1-f(\chi)\right]u_1=a\Phi\left(\tau+\frac{V\chi}{a}\right) \qquad (11)$$

$$\frac{\partial^2 u_2}{\partial\tau^2}-a^2\frac{\partial^2 u_2}{\partial\chi^2}+a\left[1-f(\chi)\right]u_2=\frac{a}{2}u_1^2\sin u_0(\chi) \qquad (12)$$

where $f(\chi)=2/\cosh^2(\chi/\sqrt{a})$ since

$$\cos[4\arctan(e^{\frac{1}{\sqrt{a}}\chi})]=1-\frac{2}{\cosh^2(\frac{1}{\sqrt{a}}\chi)}$$

The graph of the function $f(\chi)$ for the value $V=0.5$ is shown in Fig. 2.

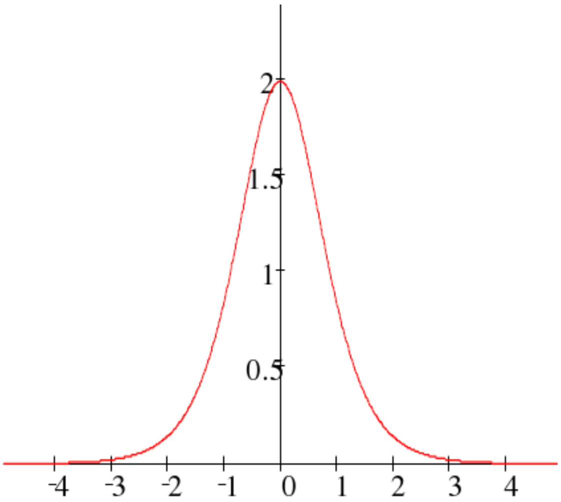

Fig .2. The function $f(\chi)$ , $a=1$ .

The corrections $u_i(\chi_0,\tau_0)$ ,$i=1,2$ to the kink solution $u_0(\chi_0)$ at a point $(\chi_0,\tau_0)$ can be presented through the Riemann function $\omega(\chi,\tau)$ [1]:

$$u_1(\chi_0,\tau_0)=a\iint_A\Phi\left(\tau+\frac{V\chi}{a}\right)\omega(\chi,\tau)d\chi d\tau \qquad (13)$$

$$u_2(\chi_0,\tau_0)=\frac{a}{2}\iint_A u_1^2(\chi,\tau)\sin u_0(\chi)\omega(\chi,\tau)d\chi d\tau$$

(14)

where $A$ is the characteristic triangle in the plane $(\chi,\tau)$, bounded by the straight line $C$ given in (10) and the characteristics WA$_{□}$ $:\tau\quad\frac{1}{a}(\chi-\chi_0)=\tau_0$ (Fig. 3).

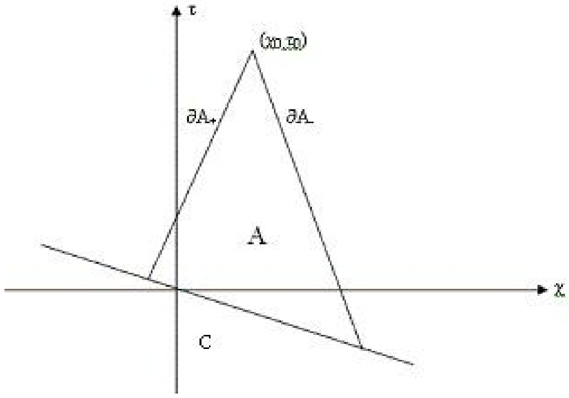

Fig. 3. The characteristic triangle $A$.

The Riemann function $\omega(\chi,\tau)$ satisfies the equation

$$\frac{\partial^2\omega}{\partial\tau^2}-a^2\frac{\partial^2\omega}{\partial\chi^2}+b^2(1-f(\chi))\omega=0 \qquad (15)$$

with $\omega=1/(2a)$ over the characteristics and $b=\sqrt{a}$ .

Since $f(\chi) \to 0$ outside of a finite interval $(-\chi_{\lim}, \chi_{\lim})$ then one can expect that the solution of (15) can be close to the solution of the telegrapher's equation [1]:

$$\frac{\partial^2 \omega}{\partial \tau^2} - a^2 \frac{\partial^2 \omega}{\partial \chi^2} + b^2 \omega = 0$$

which is $\omega(\chi, \tau) = \frac{1}{2a} J_0(b\gamma)$ and $\gamma = \sqrt{(\tau - \tau_0)^2 - \frac{1}{a^2}(\chi - \chi_0)^2}$ . The variable $\gamma$ is a hyperbolic distance in the characteristic triangle $A$ . The distance $\gamma$ is positive inside $A$, i.e. $(\tau - \tau_0)^2 > \frac{1}{a^2}(\chi - \chi_0)^2$ , and imaginary when $(\tau - \tau_0)^2 < \frac{1}{a^2}(\chi - \chi_0)^2$ . It vanishes when $(\tau - \tau_0)^2 = \frac{1}{a^2}(\chi - \chi_0)^2$ .

The equation (15) in the variables $(\chi, \gamma)$ has the form

$$\frac{\partial^2 \omega}{\partial \gamma^2} - a^2 \frac{\partial^2 \omega}{\partial \chi^2} + 2\frac{\chi - \chi_0}{\gamma} \frac{\partial^2 \omega}{\partial \chi \partial \gamma} + \frac{1}{\gamma}\frac{\partial \omega}{\partial \gamma} + \\ b^2(1 - f(\chi))\omega = 0 \qquad (16)$$

Let's look for the solution of (16) in the form

$$\omega(\chi, \gamma) = \frac{1}{2a} J_0(b\gamma) + \Phi(\chi)\sum_{n=1}^{\infty} A_n (b\gamma)^n \qquad (17)$$

where the first term of the sum is the solution of the telegrapher's equation and the second term must be small for a finite value of $\chi_{\lim}$ .

Since

$$J_0''(b\gamma) + \frac{1}{b\gamma} J_0(b\gamma) + J_0(b\gamma) = 0$$

then substitution of (17) into (16) gives

$$\Phi(\chi)\sum_{n=1}^{\infty} n(n-1)A_n b^2 (b\gamma)^{n-2} - a^2\Phi''(\chi)\sum_{n=1}^{\infty} A_n (b\gamma)^n + \\ 2(\chi - \chi_0)\Phi'(\chi)\sum_{n=1}^{\infty} nA_n b^2 (b\gamma)^{n-2} + \Phi(\chi)\sum_{n=1}^{\infty} nA_n b^2 (b\gamma)^{n-2} \\ + b^2\Phi(\chi)(1 - f(\chi))\sum_{n=1}^{\infty} A_n (b\gamma)^n = \frac{1}{2} f(\chi) J_0(b\gamma)$$

For $\chi = \chi_0$ the last equation becomes

$$A_1\Phi(\chi_0)\frac{1}{b\gamma} + 4A_2\Phi(\chi_0) + \sum_{n=1}^{\infty}[(n+2)^2\Phi(\chi_0)A_{n+2} \\ + (-a\Phi''(\chi_0) + (1 - f(\chi_0))\Phi(\chi_0)A_n]\gamma^n \\ = \frac{1}{2a} f(\chi_0)[1 - \frac{\gamma^2}{2^2} + \frac{\gamma^4}{2^2 4^2} - \frac{\gamma^6}{2^2 4^2 6^2} + ...]$$

and, therefore,

$$A_n = 0 \mathit{\ for\ odd\ } n,$$

$$A_2 = \frac{1}{2a}\frac{f(\xi_0)}{\varphi(\xi_0)}\frac{1}{2^2},$$

$$A_{2k+2} = [\frac{f(\xi_0)}{2a}\frac{(-1)^k}{2^2 4^2 ...(2k)^2} + (\frac{a^2}{b^2}\varphi''(\xi_0) - \\ (1 - f(\xi_0))\varphi(\xi_0))A_{2k}]\frac{1}{(2k+2)^2\varphi(\xi_0)},$$

$$k = 1, 2, 3...$$

Assume

$$\frac{a^2}{b^2}\Phi''(\chi_0) = (1 - f(\chi_0))\Phi(\chi_0), \Phi(\chi_0) = f(\chi_0) \qquad (17)$$

It follows that

$$A_{2k+2} = \frac{1}{2a}\frac{(-1)^k}{2^2 4^2 ...(2k)^2}, k = 1, 2, 3...$$

and

$$\omega(\chi, \gamma) = \frac{1}{2a}[J_0(b\gamma) + (1 - J_0(b\gamma))\varphi(\chi)] \qquad (18)$$

Substitute (18) into (16) and we obtain that the solution $\varphi(\chi)$ satisfies the following equation

$$-a(1 - J_0(b\gamma))\varphi''(\chi) + \\ (J_0(b\gamma) + J_2(b\gamma))(\chi - \chi_0)\varphi'(\chi) + \qquad (19) \\ (1 - f(\chi)(1 - J_0(b\gamma)))\varphi(\chi) = J_0(b\gamma) f(\chi)$$

and subject to the boundary conditions

$$\varphi(\chi_0) = f(\chi_0), \quad f(\pm\infty) = 0 \qquad (20)$$

## IV. Numerical Algorithm and Calculations

A solution $\omega(\chi_1, \tau_1)$ of the partial differential equation (15) at any particular point $(\chi_1, \tau_1)$ can be reduced to solving the boundary value problem (19), (20) with fixed value of $\gamma$ , where

$$\gamma = \sqrt{(\tau_1 - \tau_0)^2 - \frac{1}{a^2}(\chi_1 - \chi_0)^2} .$$

A family of curves $\gamma = const$ define hyperbolae imbedded into the characteristic triangle (Fig.4). The solution surface (15) can be represented as a family of curves over the hyperbolae in the 3D space $(\chi, \tau, \omega)$ . The surface representing the Riemann function for $\chi_0 = 0$ is shown in Fig. 5 and was drawn using MAPLE.

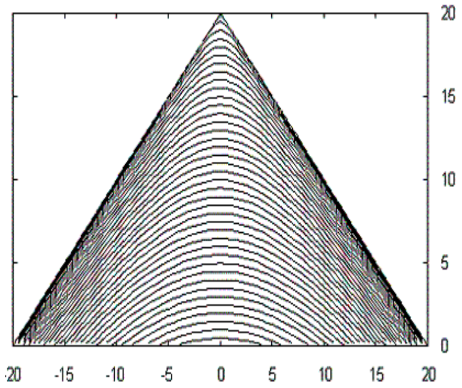

Fig. 4. The Characteristic triangle with the family of curves $\gamma = const$ .

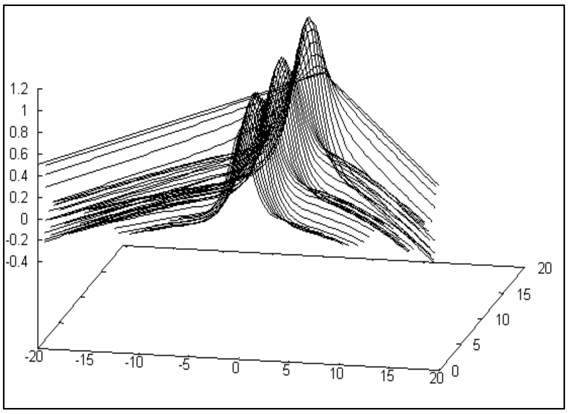

Fig. 5. The solution surface of (15) representing the Riemann function. Each curve is a solution of (19), (20) for particular fixed value of $\gamma$ .

The boundary value problem (19), (20) can be solved numerically using the relaxation method [9]. Since the solution of this BVP approaches zero when $\chi \to \pm\infty$ then for numerical calculations this problem can be solved for finite values of $\chi_{\lim}$ which are found manually from the condition $\lim_{\chi\to 0} f(\chi) \to 0$.

In the numerical calculations of the double integrals (13) and (14) one of the most difficult tasks is integration over the triangle $A$. First, the integral needs to be calculated for various values of $(\chi_0, \tau_0)$. The area of the rectangle A becomes larger when the value of $\tau_0$ increases. The second difficulty is that changing the value of the parameter $a$ leads to changing the rectangle $A$ shape. Therefore, it is very difficult to develop a universal algorithm for various values of $(\chi_0, \tau_0)$ and the parameter $a$ . The integration area $A$ (Fig. 3) can be mapped into a rectangle $R = \left\{ \frac{-1+V}{1+V} \le v \le 1, 0 \le u \le 1 \right\}$ (Fig. 6) with coordinates ($v$, $u$) by means of transformation

$$\chi = \chi_0 + a \cdot t_0 \left(1-u\right) v / \left(1-V\right),$$

$$\tau = t_0 u - V \chi_0 / a - V t_0 \left(1-u\right) v / \left(1-V\right),$$

where $t_0 = \tau_0 + V\chi_0 / a$ .

This transformation allows simplifying significantly numerical integration and speed up the algorithm of calculation of functions $u_{1,2}.(\chi, t)$. The area of integration can be covered by a rectangular mesh and then, the standard Simpson method can be used [9].

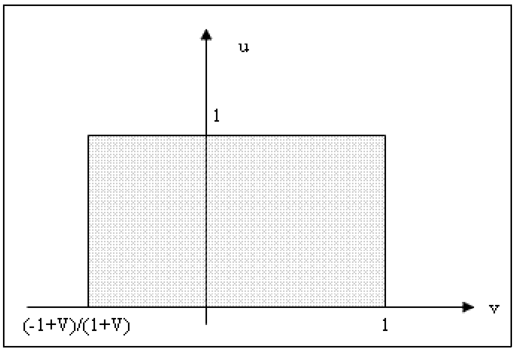

Fig. 6. The rectangular integration area R($v$, $u$).

The first integral (13) in the new variables ($v$, $u$) has the form

$$u_1\left(\chi_0, \tau_0\right) = \frac{t_0^2}{2}\left(1+V\right)\iint_R \{(1-u)\Phi(t_0 u)\times$$

$$\left[J_0\left(\alpha(v,u)\right) + \left\{1 - J_0\left(\alpha(v,u)\right)\right\}\varphi(v,u)\right]\}dudv \qquad (21)$$

$$\alpha(v,u) = t_0(1-u)\sqrt{(1+V)(1-v)(1+v+Vv-V})$$

where the double integral is calculated using the Simpson method and the value of $\varphi(v,u)$ at each point of the integral sum is a solution of the boundary value problem (19), (20).

The numerical algorithm was implemented in a program written in C++. For calculating values of the Bessel functions, double integrals and solving ordinary differential equations the code given in [9] was used.

As an example, the function $\Phi(t) = \sin(10t)$ was considered. Two graphs in a plane $(x, u_1)$ representing results of calculations of the integral (21) for $-1 \le x \le 1$ are shown in Fig. 7 and Fig. 8.

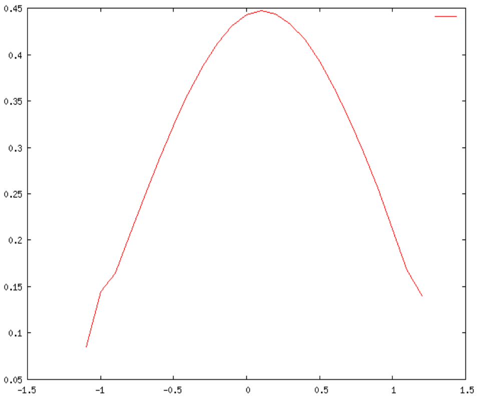

Fig. 7. $V = 0.95, t = \pi$

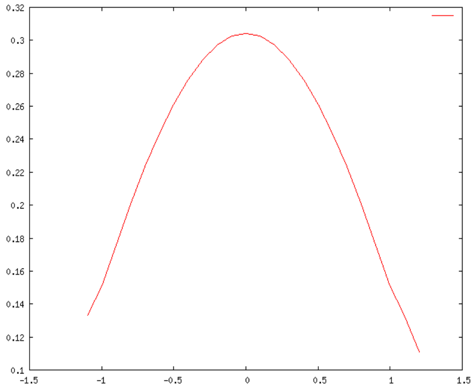

Fig. 8. $V = 0, t = 4088$

The values of $\varepsilon$ in (3) depend on a particular physical problem and are not discussed in this paper. They can be up to 0.3 in some cases.

***Abstract*—The authors consider the use of the parallel iterative methods for solving large sparse linear equation systems resulting from Markov chains—on a computer cluster. A combination of Jacobi and Gauss-Seidel iterative methods is examined in a parallel version. Some results of experiments for sparse systems with over $3 \times 10^7$ equations and about $2 \times 10^8$ nonzeros which we obtained from a Markovian model of a congestion control mechanism are reported.**

## I. Introduction and Motivation

DISCRETE-STATE models are widely employed for modeling and analysis of communication networks and computer systems. It is often convenient to model such a system as a continuous time Markov chain, provided probability distrbutions are assumed to be exponential (or combinations of exponential ones).

A CTMC (Coninuous-Time Markov Chain) may be represented by a set of states and a transition rate matrix $\mathbf{Q}$ containing state transition rates as coefficients, and can be analysed by using probabilistic model checking. Such an analysis proceeds by specifying desired performance properties as some temporal logic formulae, and by verifying these properties automatically, using the appropriate model checking algorithms. A core component of these algorithms is a computation of the steady-state probabilities of the CTMC. This is reducible to the classical problem of solving a (homogeneous) sparse system of linear equations, of the form $\mathbf{Ax} = \mathbf{b}$, of size equal to the number of states in the CTMC.

A limitation of the Markovian modeling approach is the fact that the CTMC models tend to grow extremely large due to the state space explosion problem. This is caused by the fact that a system is usually composed of a number of concurrent subsystems, and that the size of the state space of the overall system is generally exponential in the number of subsystems. A realistic system can give rise to a large state space, typically over $10^6$. As a consequence, much research is focused on the development of techniques, that is, methods and data structures, which minimise the computational (space and time) requirements for analysing large and complex systems.

One of such techniques is parallelization. Problems of parallel computations for such systems and finding its steady-state probabilities in parallel is brought up in [3], [8], [13], [15]. In [2], [4], [7], [17] a manner of distributed generation of the matrix $\mathbf{Q}$ in a network environment is desribed and in [6] a similar algorithm—on a computer cluster—is presented. Paper [5] describes solving sparse linear systems with the use of the GMRES algorithm [18] in a network environment. The parallel Jacobi method was discussed and a parallel method for the CTMC steady-state solution is presented in [15]. The Gauss-Seidel method is used for parallel solving of Markov chains in [14], [20].

In this paper a combination of two classical iterative methods for solving linear equation systems, namely Jacobi method and Gauss-Seidel method is presented. These methods were chosen because the presented algorithm is intended for computer clusters and Jacobi method is inherently parallel (Gauss-Seidel method has not got such a property and its parallelization requires a lot of communication), but Gauss-Seidel method usually converges much faster than Jacobi method [1]. Properties of such a combined method are experimantally examined in this paper. We try to study relative speedup and efficiency of the algorithm—as the traditional characteristics of parallel algorithms.

The rest of the paper is organized as follows. Section II presents the problem. In Section III classical iterative methods are reminded. Section IV shows used data distribution. Section V presents traditional block/parallel iterative methods and (in Section V-C) an approach employed by the authors. Section VI describes conducted experiments and Section VII contains some conclusions.

## II. CTMCs and the Steady-State Solution

While modeling with Markov chains, in a steady state (independent of time), we obtain a linear equation system like follows;

$$\mathbf{Q}^T\mathbf{x} = \mathbf{0}, \qquad \mathbf{x} \geq \mathbf{0}, \qquad \mathbf{x}^T\mathbf{e} = 1 \tag{1}$$

where $\mathbf{Q}$ is a transition rate matrix, $\mathbf{x}$ is an unknown vector of states probabilities and $\mathbf{e} = (1, 1, ...., 1)^T$. The matrix $\mathbf{Q}$

This work was partially supported within the project *Metody i modele dla kontroli zatłoczenia i oceny efektywności mechanizmów jakości usług w Internecie następnej generacji* (N517 025 31/2997). This work was also partially supported by Marie Curie-Sklodowska University in Lublin within the project *Równoległe algorytmy generacji i rozwiązywania mechanizmów kontroli przeciążenia w protokole TCP modelowanych przy użyciu łańcuchów Markowa*.

is a square one of size $n \times n$, usually a big one, of rank $n-1$, sparse, with dominant diagonal. It is also a singular matrix demanding adequate methods to solve the equation. Markovian models solving demands overcoming both numerical and algorithmic problems. Solving the equation system (1) generally requires applying iterative methods, projection methods or decomposition methods but occasionally (for the need of an accurate solution) direct methods are used as well. The rich material concerning the methods mentioned above can be found in [19].

## III. Iterative methods—Jacobi and Gauss-Seidel

In this section classical iterative methods are reminded. The general form of such a method step is

$$\mathbf{x}^{(k+1)} \leftarrow \mathbf{M}^{-1}\mathbf{N}\mathbf{x}^{(k)} \tag{2}$$

where

$$\mathbf{M} - \mathbf{N} = \mathbf{Q}^T. \tag{3}$$

### A. The Method of Jacobi

The method of Jacobi is a classical iterative method with the coefficient matrix $\mathbf{Q}^T$ split as following:

$$\mathbf{Q}^T = \mathbf{D} - (\mathbf{L} + \mathbf{U}) \tag{4}$$

which corresponds to assigning:

$$\mathbf{M} = \mathbf{D}, \qquad \mathbf{N} = \mathbf{L} + \mathbf{U} \tag{5}$$

in (3). The matrix $\mathbf{D}$ is a diagonal matrix, the matrix $\mathbf{L}$ is a strictly lower triangular matrix (with zeroes on its diagonal) and the matrix $\mathbf{U}$ is a strictly upper triangular matrix (with zeroes on its diagonal). So in this method the step (2) looks as following:

$$\mathbf{x}^{(k+1)} \leftarrow \mathbf{D}^{-1}(\mathbf{L} + \mathbf{U})\mathbf{x}^{(k)} \tag{6}$$

and in scalar form (for $i = 1, \ldots, n$):

$$x_i^{(k+1)} \leftarrow \frac{1}{d_{ii}} \left( \sum_{j=1}^{i-1} l_{ij} x_j^{(k)} + \sum_{j=i+1}^{n} u_{ij} x_j^{(k)} \right). \tag{7}$$

The method of Jacobi is very convinient to vectorize and to parallelize. It can also be seen in the Jacobi equation (7) that the new approximation of the solution vector ($\mathbf{x}^{(k+1)}$) is calculated by using only the old approximation of the vector ($\mathbf{x}^{(k)}$). This method, therefore, possess a high degree of natural parallelism. However, Jacobi methods has relatively slow convergence.

### B. The Method of Gauss-Seidel

In this method we have the same splitting of the matrix $\mathbf{Q}^T$ but with a different grouping of components:

$$\mathbf{Q}^T = (\mathbf{D} - \mathbf{L}) - \mathbf{U} \tag{8}$$

(the matrices $\mathbf{D}$, $\mathbf{L}$, $\mathbf{U}$ are defined as in the previous section). Here we have $\mathbf{M} = (\mathbf{D} - \mathbf{L})$ and $\mathbf{N} = \mathbf{U}$, so the step (2) is:

$$\mathbf{x}^{(k+1)} \leftarrow (\mathbf{D} - \mathbf{L})^{-1}\mathbf{U}\mathbf{x}^{(k)} \tag{9}$$

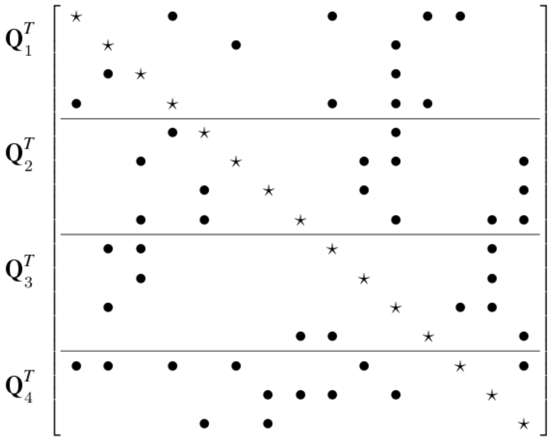

Fig. 1. An example of the matrix $\mathbf{Q}^T$ division

and in scalar form (for $i = 1, \ldots, n$):

$$x_i^{(k+1)} \leftarrow \frac{1}{d_{ii}} \left( \sum_{j=1}^{i-1} l_{ij} x_j^{(k+1)} + \sum_{j=i+1}^{n} u_{ij} x_j^{(k)} \right). \tag{10}$$

The method of Gauss-Seidel is not so convinient for vectorization or parallelization, but it converges faster—what can be explained by the fact that although both methods use the same scalar formulas (7) and (10), but in the method of Gauss-Seidel the newly computed approximation of a solution component is used as soon as it is available.

The Gauss-Seidel method typically converges faster than the Jacobi method by using the most recently available approximations of the elements of the iteration vector. The other advantage of the Gauuss-Seidel algorithm is that it can be implemented using only one iteration vector, which is important for large linear equation systems where storage of single iteration vector alone may require 10GB or more. However, a consequence of using the most recently available solution approximation is that the method is inherently sequential—it does not possess natural parallelism.

## IV. Data Distribution

In parallel programming a very crucial issue is a division of data among computational nodes (machines, processors etc.). In the algorithm described later (in Section V-C) the matrix $\mathbf{Q}^T$ is divided among cluster nodes as in Figure 1—that is the matrix is divided into $p$ rectangular submatrices $\mathbf{Q}_i^T$, each stored in the $i$th cluster node.

Each submatrix is a sparse matrix and takes part in the computations on its node (where it is stored).

## V. A Parallel Method of Jacobi/Gauss-Seidel

The description of the parallel Jacobi/Gauss-Seidel method will be started from the presentation of the well-known block iterative methods, namely block Jacobi method and block Gauss-Seidel method.

Block-based formulations of the iterative methods which perform matrix computations on block-by-block basis usually turn out to be more efficient and easier to parallelize. Generally iterative block methods demand more calculations per iteration, which is recompensed by a faster convergence rate (and sometimes better cache utilization).

It is possible in Markov chains to divide the transition rate matrix into blocks (or even generate it in blocks straight away [4], [7]) and develop iterative methods basing on that division.

In Markov chains problems it is often the case that the state space can be meaningfully partitioned into subsets and thus, it is possible to partition the transition rate matrix respectively and to base the solution method on blocks implied by such a partition.

The homogeneous equations system (1) is divided into $K^2$ square blocks of the same size in the following way:

$$\begin{bmatrix} \mathbf{Q}_{11} & \mathbf{Q}_{12} & \dots & \mathbf{Q}_{1K} \\ \mathbf{Q}_{21} & \mathbf{Q}_{22} & \dots & \mathbf{Q}_{2K} \\ \dots & \dots & \dots & \dots \\ \mathbf{Q}_{K1} & \mathbf{Q}_{K2} & \dots & \mathbf{Q}_{KK} \end{bmatrix} \begin{bmatrix} \mathbf{x}_1 \\ \mathbf{x}_2 \\ \vdots \\ \mathbf{x}_K \end{bmatrix} = \mathbf{0}. \tag{11}$$

We introduce block splitting:

$$\mathbf{Q}^T = \mathbf{D}_K - (\mathbf{L}_K + \mathbf{U}_K), \tag{12}$$

where $\mathbf{D}_K$ is a block-diagonal matrix, $\mathbf{L}_K$ is a strictly block lower triangular matrix, $\mathbf{U}_K$ is a strictly block upper triangular matrix with form:

$$\mathbf{D}_K = \begin{bmatrix} \mathbf{D}_{11} & 0 & \dots & 0 \\ 0 & \mathbf{D}_{22} & \dots & 0 \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & \mathbf{D}_{KK} \end{bmatrix}, \tag{13}$$

$$\mathbf{L}_K = \begin{bmatrix} 0 & 0 & \dots & 0 \\ \mathbf{L}_{21} & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots \\ \mathbf{L}_{K1} & \mathbf{L}_{K2} & \dots & 0 \end{bmatrix}, \tag{14}$$

$$\mathbf{U}_K = \begin{bmatrix} 0 & \mathbf{U}_{12} & \dots & \mathbf{U}_{1K} \\ 0 & 0 & \dots & \mathbf{U}_{2K} \\ \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & 0 \end{bmatrix}, \tag{15}$$

where $\mathbf{D}_{ii} = \mathbf{Q}_{ii}$, $\mathbf{L}_{ij} = -\mathbf{Q}_{ij}$, $\mathbf{U}_{ij} = -\mathbf{Q}_{ij}$.

### A. A Block Jacobi Algorithm

The iterative method of Jacobi was described in Section III-A. In this section, a block parallel Jacobi algorithm for the solution of the linear equation system (1) is presented.

Block Jacobi method is given by (for $i = 1, \dots, K$):

$$\mathbf{Q}_{ii}^T \mathbf{x}_i^{(k+1)} = -\sum_{j<>i} \mathbf{Q}_{ij}^T \mathbf{x}_j^{(k)} \tag{16}$$

where blocks are as in (11).

Having $K$ computational nodes (computers or processors), every equation of (16) can be solved independently by a computational node. The equtions (16) can be solved by an arbitrary method.

### B. A Block Gauss-Seidel Algorithm

Just like the scalar Gauss-Seidel algorithm (see Section III-B), the block Gauss-Seidel algorithm can be written:

$$(\mathbf{D}_K - \mathbf{L}_K)x^{(i+1)} = \mathbf{U}_K x^{(i)}. \tag{17}$$

Describing the equation mentioned above in a scalar-like form we get (for $j = 1, \dots, K$):

$$\mathbf{Q}_{jj}\mathbf{x}_j^{(i+1)} = -\left( \sum_{l=1}^{i-1} \mathbf{Q}_{jl}\mathbf{x}_l^{(i+1)} + \sum_{l=j+1}^{K} \mathbf{Q}_{jl}\mathbf{x}_l^{(i)} \right) \tag{18}$$

where $\mathbf{x}_j^{(i)}$ is the $j$th $(n/K)$-element subvector of the vector $\mathbf{x}^{(i)}$ (as in (11)).

As a result of above in every step we must solve $K$ equation systems of $n/K$ size each in the following form (for $j = 1, \dots, K$):

$$\mathbf{Q}_{jj}\mathbf{x}_i^{(i+1)} = \mathbf{z}_j^{(i+1)} \tag{19}$$

where

$$\mathbf{z}_j^{(i+1)} = -\left( \sum_{l=1}^{i-1} \mathbf{Q}_{jl}\mathbf{x}_l^{(i+1)} + \sum_{l=j+1}^{K} \mathbf{Q}_{jl}\mathbf{x}_l^{(i)} \right). \tag{20}$$

We can apply different direct and iterative methods to the solve equation (19). There is a small number of iterations demanded to obtain convergence for a small number of blocks (i.e. submatrices are big). The difficulty is that it is very hard to parallelize effectively—it is caused by the use of the newly computed values just after their computation.

### C. A Modified Block Jacobi Algorithm

In this section we present an algorithm, which takes advantage of the division of the matrix $\mathbf{Q}$ between computational nodes described in Section IV. The algorithm proposed here is a combination of Jacobi and Gauss-Seidel iterative methods.

To start from a usual Jacobi method, there is

$$\mathbf{Q}^T = \mathbf{D} - (\mathbf{L} + \mathbf{U}) \tag{21}$$

(see Section III-A).

Let

$$\mathbf{H} = \mathbf{D}^{-1}(\mathbf{L} + \mathbf{U}). \tag{22}$$

Thus, the (6) can be written

$$\mathbf{x}^{(k+1)} = \mathbf{H}\mathbf{x}^{(k)}. \tag{23}$$

In a block iterative method the linear system (23) is divided into some subsystems. In this section the matrix $\mathbf{H}$ is divided into $p$ blocks ($p$ is the number of computatinal nodes), each block $\mathbf{H}_i$ ($i = 1, \dots, p$) of the size of $n$ columns and $n/p$ rows (last one, $\mathbf{H}_p$ can be shorter—as in Figure 1—it does not influences general considerations). Such a division corresponds to the division of the matrix $\mathbf{Q}^T$ proposed in Section IV, because to obtain elements of the matrix $\mathbf{H}_i$ one needs only elements of the matrix $\mathbf{Q}_i^T$.

Similarly, the vector $\mathbf{x}$ (and some auxiliary vectors in the implementation) is divided into $p$ subvectors, each of the size $n/p$.

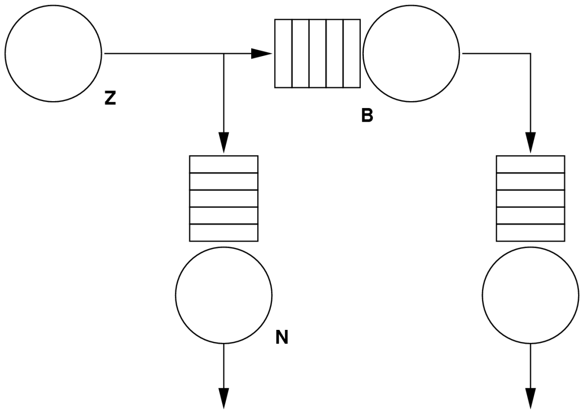

Fig. 2. A Markovian queuing model of the tail-drop mechanism

Now, the (23) can be written:

$$\begin{bmatrix} \mathbf{x}_1^{(k+1)} \\ \mathbf{x}_2^{(k+1)} \\ \vdots \\ \mathbf{x}_p^{(k+1)} \end{bmatrix} = \begin{bmatrix} \mathbf{H}_1 \\ \mathbf{H}_2 \\ \vdots \\ \mathbf{H}_p \end{bmatrix} \mathbf{x}^{(k)} \tag{24}$$

and, in another manner, for $i = 1, \ldots, p$:

$$\mathbf{x}_i^{(k+1)} = \mathbf{H}_i \mathbf{x}^{(k)}. \tag{25}$$

(25) is a formula for the block Jacobi method (Section III-A). All the equations in (25) are solved independently, so it is very suitable to parallelize for $p$ processors – each of them solves one equation and then they exchange the resulting vectors $\mathbf{x}_i^{(k+1)}$ to build its new version $\mathbf{x}^{(k+1)}$.

However, the Jacobi method is rather slowly convergent, so in the presented algorithm, every computational node can employ the formula of the Gauss-Seidel algorithm (10) instead of the Jacobi algorithm (7)—using the newly obtained elements of the vector $\mathbf{x}_i^{(k+1)}$ (although only those which are stored in the same computational nodes) and hoping for the better convergency.

In other words, the algorithm can be described as a block Jacobi iterative method with solving inner blocks with the Gauss-Seidel iterative method.

In borderline cases the presented algorithm reduces to the pure Jacobi algorithm (for $p = n$) and to the pure Gauss-Seidel algorithm (for $p = 1$).

### D. Implementation details

We propose an algorithm for homogeneous cluster environments. This algorithm is based on a message-passing paradigm and consists of one module for each of nodes. The algorithm presented below is just a skeleton, and the detailed implementation, such as data preparation, parameters passing, and so forth, might be different according to requirements of various applications.

The algorithm is composed of several steps. First, the starting information is acquired. Next, the matrix $\mathbf{Q}$ is generated in parts so that every node keeps only needed states (as in Figure 1) Next, in loop, in every node for its block we make a step of the Gauss-Seidel method.

The algorithm for every node (in pseudo-code) is described as follows:

```
Initialization(&MyNumber);

FindBeginAndEnd(MyNumber, &n0, &n1);
  /* computes starting index n0 and
     ending index n1 for the block of
     the node MyNumber */
QT=Generate(n0, n1);
  /* generates adequate block */
FillVector(X, 1.0/n);
IterNo=0;

do
{
  IterNo++;
  InnerGaussSeidel(QT, X);
    /* the node computes only its own
       part of the vector */
  GatherVector(X)
    /* every node needes the whole vector
       for further computations */
  Normalize(X);
} while(Remainder(QT, X)>EPSILON &&
        IterNo<MAXITER);

Finalizetion();
```

## VI. Experimental Results

### A. Properties of the Used Matrices

The matrices obtained for tests were transition rate matrices for a very simple model of a tail-drop mechanism (a very simple congestion control mechanism in a router's buffer). The queuing model for such a mechanism is shown in Figure 2. It is a passive mechanism, that is, it does not make any decision, as far as the moment of dropping packets is concerned—they are always dropped when there is no room for new packets. Moreover, in the tail-drop mechanism the packet that just arrived, is dropped. A Markovian queuing model for such a mechanism consists of: a source **Z** (which sends packets with variable rates), a service station **B** (which corresponds to a router's buffer) and two auxiliary service stations **A** and **N** (which correspond to confirmations and rejections, respectively, returning to the source **Z**).

The rate of the source **Z** is not constant but it increases (not above a given maximum) as confirmations leave the station **A** and it decreases (not below a given minimum) as rejections leave the station **N** (both events represent reaching the source by the information about the packet's fate). The states of such a model can be written as vectors of numbers. In our example it would be $(l, b, a, m)$, where $l$ is an integer between 1 and $l_{max}$ and it means the current relative intensity of the source **Z** and $b$, $a$ and $m$ are integers between 0 and $b_{max}$, $a_{max}$,

$m_{max}$ (respectively) and they mean the number of packets waiting or being processed currently in the stations **B**, **A**, **N** (respectively).

### *B. Computational Environment*

Experiments were carried out in a cluster environment (part of CLUSTERIX – a cluster of Linux machines consisting of more than 800 machines distributed all over Poland and connected with a fast optical network; one of the fastest European distributed supercomputers [21]) dedicated for computing.

The CLUSTERIX itself is built as a cluster of local clusters. So up to 10 machines were used—all belonging to a single local cluster— as we were interested in investigating behavior of the algorithm in such an environment. Each of the machines was equipped with two 64-bit processors Intel Itanium 2 1.4 GHz and 4 GB RAM, but we used only one processor in every machine, because we were interested in distributed results. The cluster nodes were used when they were idle—in order to assure credible performance times.

The algorithm was implemented with the use of the MPI (message passing interface) standard and MPICH library.

### C. Numerical Results

The properties of the models and the matrices used in tests are shown in Table I. All the matrices have about 5–6 elements in a row (very sparse matrices). There are also some characteristics of the performance—$T_p$, $S_p$ and $E_p$ presented there. The distributed run-time of 50 iterations of the algorithm is measured as the maximum run-time from the start and we denote it as $T_p$ (for $p$ machines). The speedup for $p$ processors is denoted by $S_p$ and is given by $S_p = T_1/T_p$. The efficiency for $p$ processors is denoted by $E_p$ and is defined as $E_p = S_p/p$.

We can see in Figures 3–6 and in Table I that the relative speedup and the efficiency grows with the growth of the size of matrices, so we can expect that for bigger matrices we can get better results.

## VII. Conclusion

The authors have developed a parallel and somewhat scalable algorithm that computes the vector $\mathbf{x}$ from the equation (1) for a very large $n$; the matrix $\mathbf{Q}$ is distributed among the computational nodes. To find $\mathbf{x}$, a parallel combination of Jacobi and Gauss-Seidel iterative methods was used. The numerical experiments on a parallel system have been carried out in order to assess the effectiveness of the distributed algorithm on a computer cluster. The numerical tests indicate that some efficiency is possible if the sufficient amount of work per processor is provided (for small sizes of the matrix the scalability is worse). The parallel implementation was benchmarked using a Markovian model of congestion control.

The results suggest an important area for future research—writing numerical algorithms (which find probability vectors) for huge matrices modeling Markov chains distributed in row-striped manner among many processor (as in our algorithm) and performance optimization—perhaps using preconditioned iterative methods [2], [9], [10], [11], [12], [17].

The proposed method is tested on matries connected with Markov chains, but we can use this method to different application to other problems with sparse matrices.

In the future we want to examine the combination of Jacobi and Gauss-Seidel methods theoretically and compare our approach with others.

***Abstract*—We present some problems related to the influence of molecular models on Molecular Dynamics simulation of water nanoflows. Out of large number of existing models of water we present some results of the MD simulation of water nanoflows for four molecular models: TIP4P, PPC TIP4P-2005, TIP5P.**

## I. Introduction

COMPUTER simulation methods have become a very powerful tool for solving many-body problems in statistical physics, physical chemistry and biophysics. Although theoretical description of complex systems in the framework of statistical physics is well developed and the experimental techniques for obtaining detailed microscopic information are quite sophisticated, it is often only possible to study specific aspects of those systems in detail via simulation. On the other hand, simulations need specific input parameters characterizing systems in question, which either come from theoretical considerations or are provided by experiment [1].

The deterministic method of Molecular Dynamics (MD) simulation [2], although theoretically valid for the whole range of densities, is employed mainly for liquids and solids. The long flight paths between collisions of gas molecules make the method of Molecular Dynamics prohibitively expensive, while other methods, like e.g. Direct Monte-Carlo Simulation, can give satisfactory results at much lower computational cost. In liquids the molecules are densely packed and remain in constant contact with the neighbours. Under such conditions Molecular Dynamics seems to be the most accurate and, at the same time, the most efficient simulation method.

Molecular Dynamics requires description of the molecules and the forces acting between them. Perhaps the most often, to describe the forces, the Lennard-Jones potential is used; it assumes that the  molecules are spherically symmetric, repelling one another at close and attracting at far distances.

The motivation for this research stems from real nanochannel flow problem. For flows of liquids in nanochannels the continuum description is no longer valid and the Molecular Dynamic Simulation seems to be the only appropriate approach to the problem. In the following some MD flow simulation results will be presented to illustrate usefulness of the method.

## II. Molecular models of water

The structure of the water molecule (Fig. 1) is relatively complex and can only be properly described in the framework of quantum mechanics. However, this kind of description is not applicable for Molecular Dynamics simulation, therefore a number of simplified models have been proposed. Unfortunately, each of them has only limited range of applications.

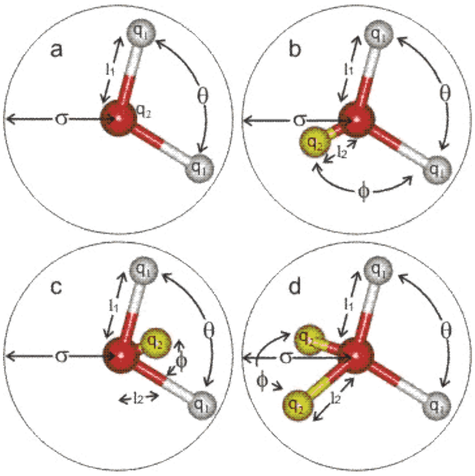

Fig.  1 Most frequently used geometrical model shapes of water molecule

In Table 1 and Fig. 2 we present four molecular models of water, selected for our Molecular Dynamics simulations of flow in nanochannels. Table 2 contains the values of some physical parameters of water, calculated with the use of those models, together with corresponding experimental data.  The molecular parameters of copper from [6] and [7] were used.

TABLE I.
PARAMETERS OF THE WATER MOLECULAR MODELS USED IN OUR SIMULATION [13]

| Model | Geometrical configuration (Fig. 2) | Lennard-Jones molecular diameter б , $1*10^{-10}$ m | Lennard-Jones potential well depth ε kJ/mol | $l_{1,}$ $1*10^{-10}$ m | $l_2$ $1*10^{-10}$ m | $q_1$ (e) | $q_2$ (e) | $\theta$ ° | $\Phi$ ° |

## III. MOLECULAR DYNAMICS

Molecular Dynamics simulation method treats the medium as an ensemble of molecules. Each molecule may consist of one or more atoms attached to each other in the way specific for given substance. It is assumed that:

- each atom is treated as a point mass,
- simple force rules describe the interactions between atoms; force acting on a molecule is a sum of forces acting on all constituent atoms,
- Newton's equations of motion are integrated to obtain coordinates and velocity of each molecule as a function of time (see Fig.2)
- thermodynamic statistics are extracted from positions and velocities of the molecules.

The orientation of the molecules can be represented in several ways, however the use of quaternions [4] seems to be the most advisable. The most important advantage of quaternions is the fact, that they lead to equations of motion free of singularities (which is not the case for e.g. Euler angles). This, in turn, leads to good numerical stability of the simulation.

Integration algorithms used in Molecular Dynamics simulation are based on finite difference methods, with discretized time and the time step equal to **Δt.** Knowing the positions and some of their time derivatives at time t (the exact details depend on the type of algorithm), the integration scheme gives the same quantities at a later time (**t** + **Δt**). With such procedure the evolution of the system can be followed for long times [3].

**Stages of simulation** :

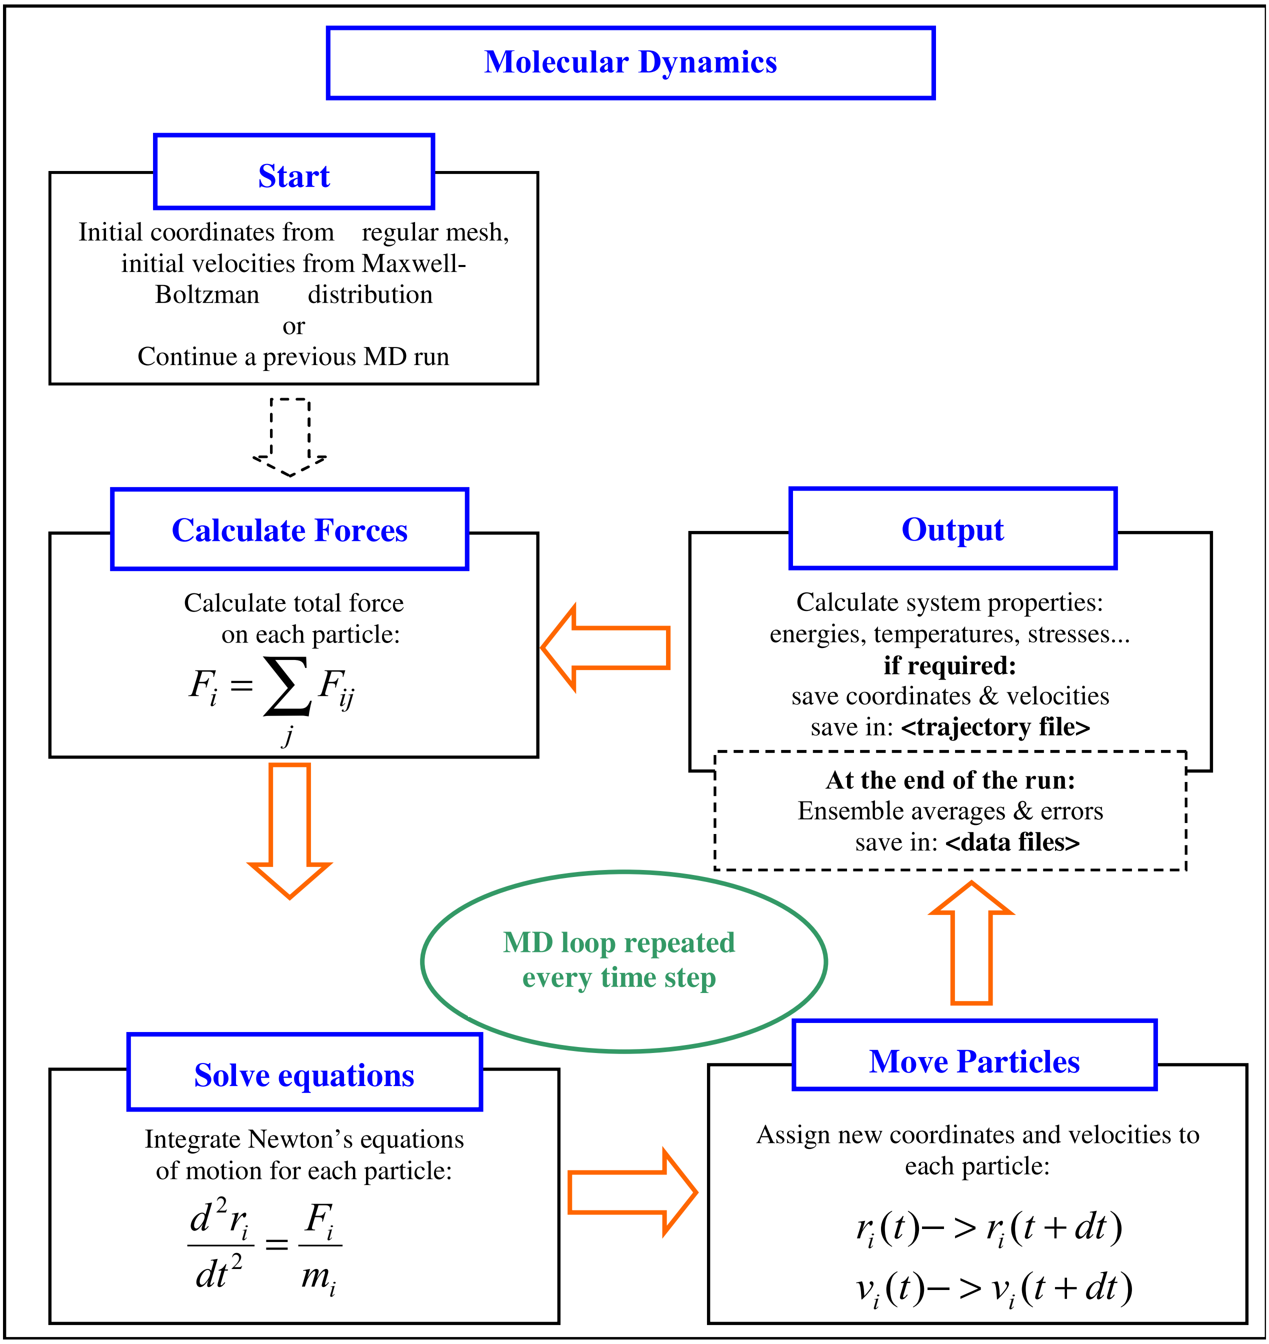
- Initiation: placing the molecules of water and the copper atoms in the knots of crystalline mesh. After that the velocities of the molecules are initialized. Their values are sampled at random from the Maxwell – Boltzmann distribution for the assumed temperature.
- Balancing: after initiation the positions of molecules are far from equilibrium. The whole ensemble is allowed to move freely for some time to attain equilibrium positions. This is always connected with decreasing the potential and increasing the kinetic energy of the molecules, i.e. increasing the temperature of the medium. This excess temperature must be removed by a suitable "thermostat".
- Actual simulation: after attaining equilibrium, the simulation starts. The required data (specified in advance) are accumulated in "dump-files" in preselected time intervals. Any property of interest, dynamic or static, may then be evaluated with the use of the data in the dump.

In molecular dynamics we follow the laws of classical mechanics,

$$F_i = m_i * a_i$$

for each atom i in system constituted by N atoms. Here $m_i$ is the atom mass, $a_i = d^2 r_i / dt^2$ its acceleration, and $F_i$ the force acting upon it, due to the interactions with other atoms [3].

The motion is governed by the Newton-Euler equations



Molecular Dynamics
Start
Initial coordinates from regular mesh, initial velocities from Maxwell-Boltzman distribution
or
Continue a previous MD run
Calculate Forces
Calculate total force on each particle:
$F_i = \sum_j F_{ij}$
Output
Calculate system properties: energies, temperatures, stresses...
**if required:**
save coordinates & velocities
save in: **<trajectory file>**
**At the end of the run:**
Ensemble averages & errors
save in: **<data files>**
MD loop repeated every time step
Solve equations
Integrate Newton's equations of motion for each particle:
$\frac{d^2 r_i}{dt^2} = \frac{F_i}{m_i}$
Move Particles
Assign new coordinates and velocities to each particle:
$r_i(t) -> r_i(t+dt)$
$v_i(t) -> v_i(t+dt)$

Fig. 2 Simplified algorithm of Molecular Dynamics

$$M_i \ddot{R}_i = F_i + F_x$$

where $M_i$ is total mass molecule *i*, $R_i$ is the centre of mass of molecule *i*, $F_i$ is the total force acting on molecule *I*, $F_x$ is a mass force necessary to set water in motion (see Section IV).

## IV. Molecular dynamics simulations of plane nanoflows

In the present chapter the results of the simulations of plane flows of water through narrow copper channels [9,10,11,12] are presented.

Simulations were carried out for four models of water, as described in Section 2. The assumed channel width was equal to approximately 5 diameters of the water molecule. Physical properties of the materials and, in particular, their electrostatic interactions were taken into account.

To set water in motion, a mass force $F_x$, directed along x – axis, in positive direction, was applied to every water molecule. Three values of $F_x$ were selected: 0.5, 2.5 and 5.0. Mass force is nondimensional. This force set the only molecules of water. Wall of channel is stable during flows of water.

The simulations were performed with the program MOLDY [4], suitably modified for our purposes. Moldy is a computer program for performing molecular dynamics simulations of condensed matter. Moldy is free software; which may redistribute it and/or modify it under the terms of the GNU.

As mentioned before, some methods of temperature control may sometimes be necessary during the simulation. At the initial stage of equilibration the excess heat comes from potential energy of nonequilibrium configuration of the molecules (first 10000 time step - Fig 3 and Fig 4). Later, when

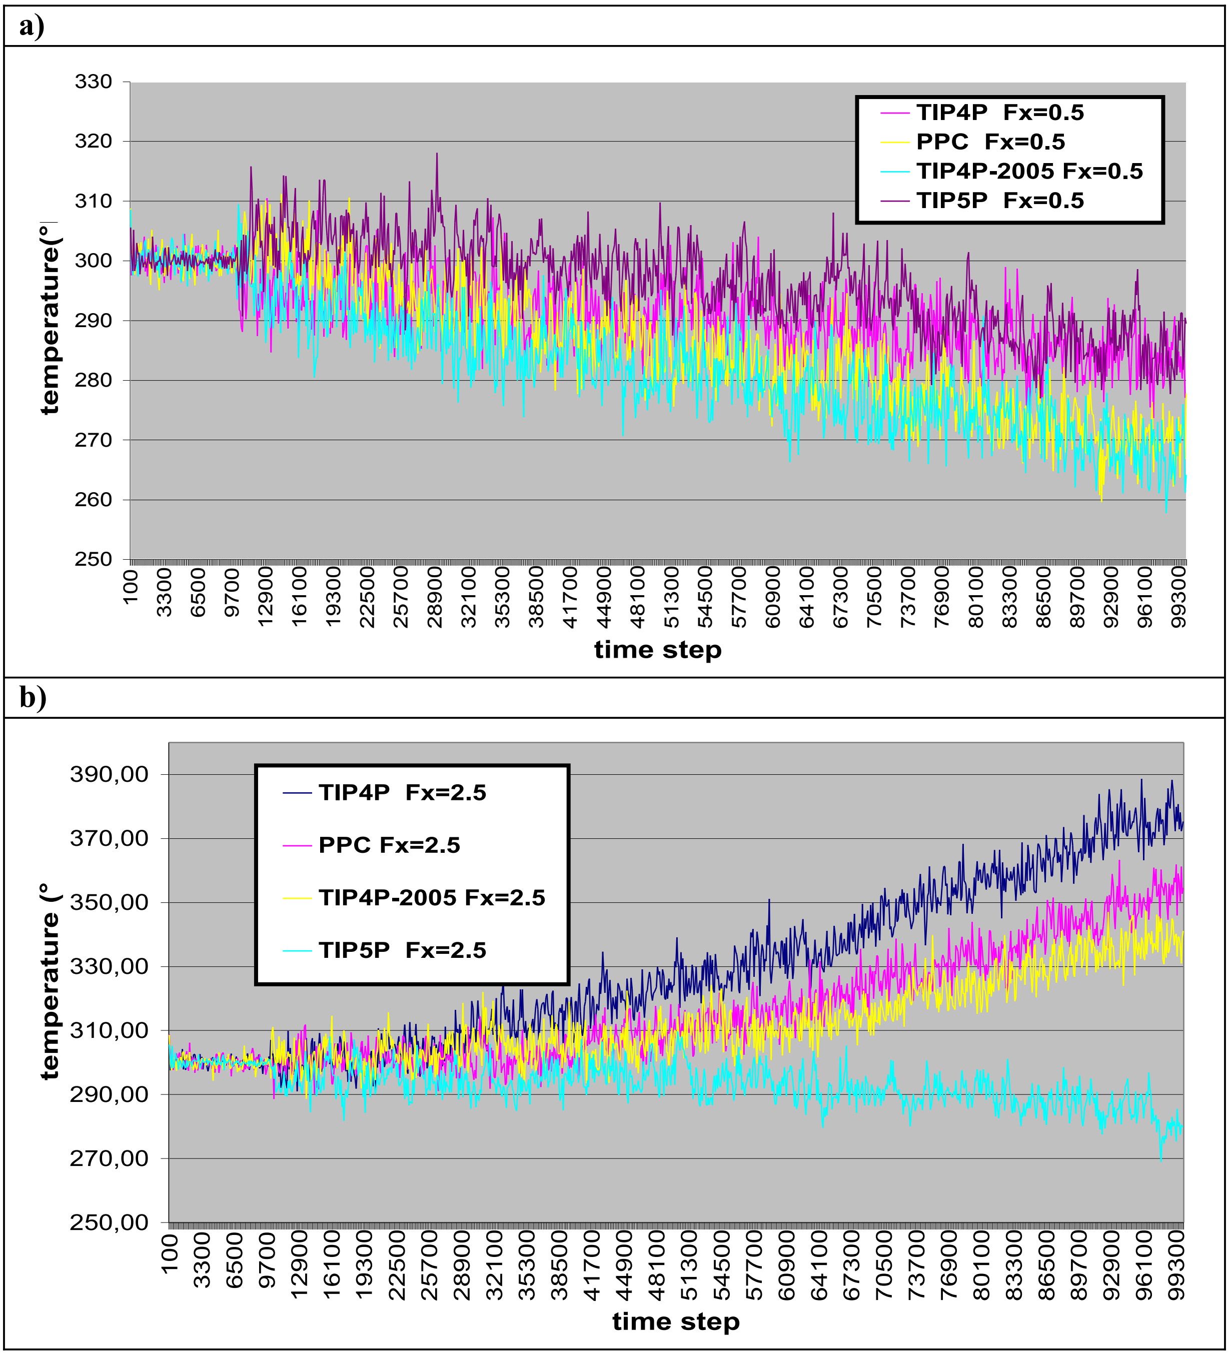


Fig. 3 Temperature of the system – Gaussian thermostat used for various models of water
a) mass force Fx = 0.5, b) mass force F x= 2.5.

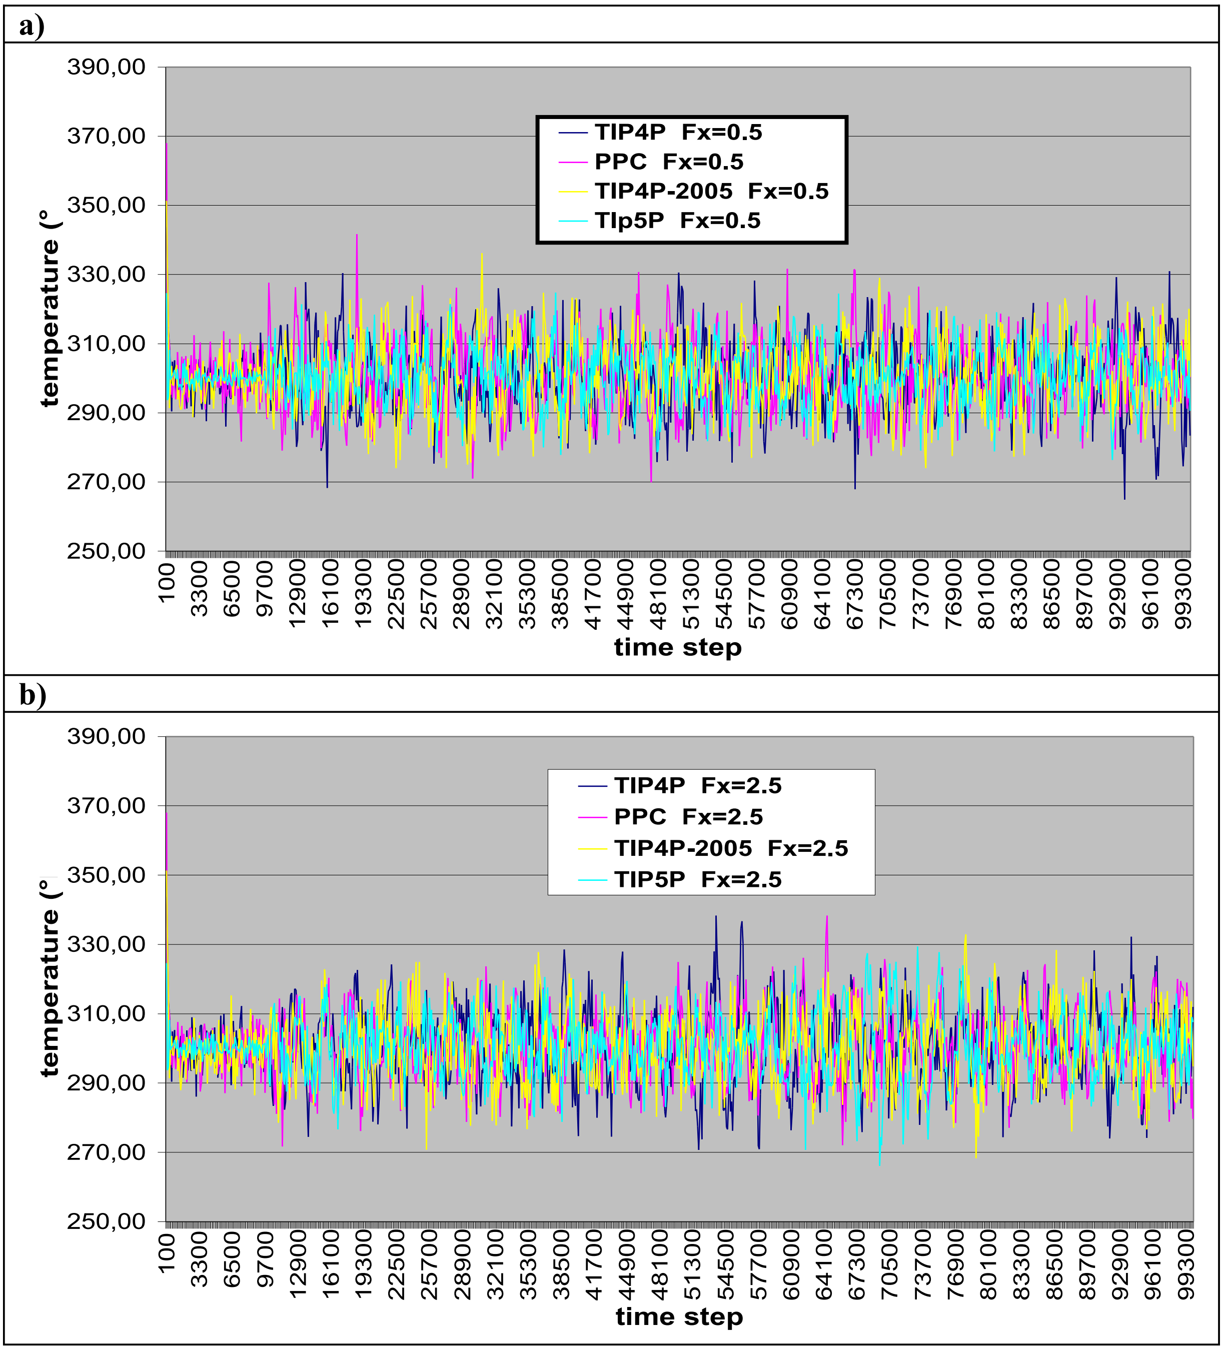

Fig. 4 Temperature of the system – Nosé-Hoover thermostat used for various models of water
a) mass force Fx = 0.5, b) mass force Fx = 2.5.

water flows under the influence of a mass force, heat is produced due to "friction" at the walls, which in molecular scale are always rough.

The program MOLDY offers three mechanisms of temperature control. In our simulations the technique of "velocity scaling" (multiplication of the molecular velocity components of all molecules by square root of the required temperature divided by the actual temperature of the medium) has been used during the equilibration period only, as it does not generate correct particle trajectories.

The Nosé-Hoover method couples the system to a heat bath using a fictional dynamical variable, while the Gaussian thermostat replaces the Newton-Euler equations by variants of which the kinetic energy is a conserved quantity [4]. The last two methods have been used to control temperature after equilibration of the system.

The calculations were carried out over 100 000 time steps **Δt**=0.005 picosecond long, after the system has reached the equilibrium. The positions and velocities of all molecules were recorded in dump files every 100 time steps, for further use.

Figures 3 – 7 present some selected results of our simulations. Figures 3 and 4 illustrate the efficiency of the two thermostats – Gaussian and Nosé-Hoover – for considered flows,

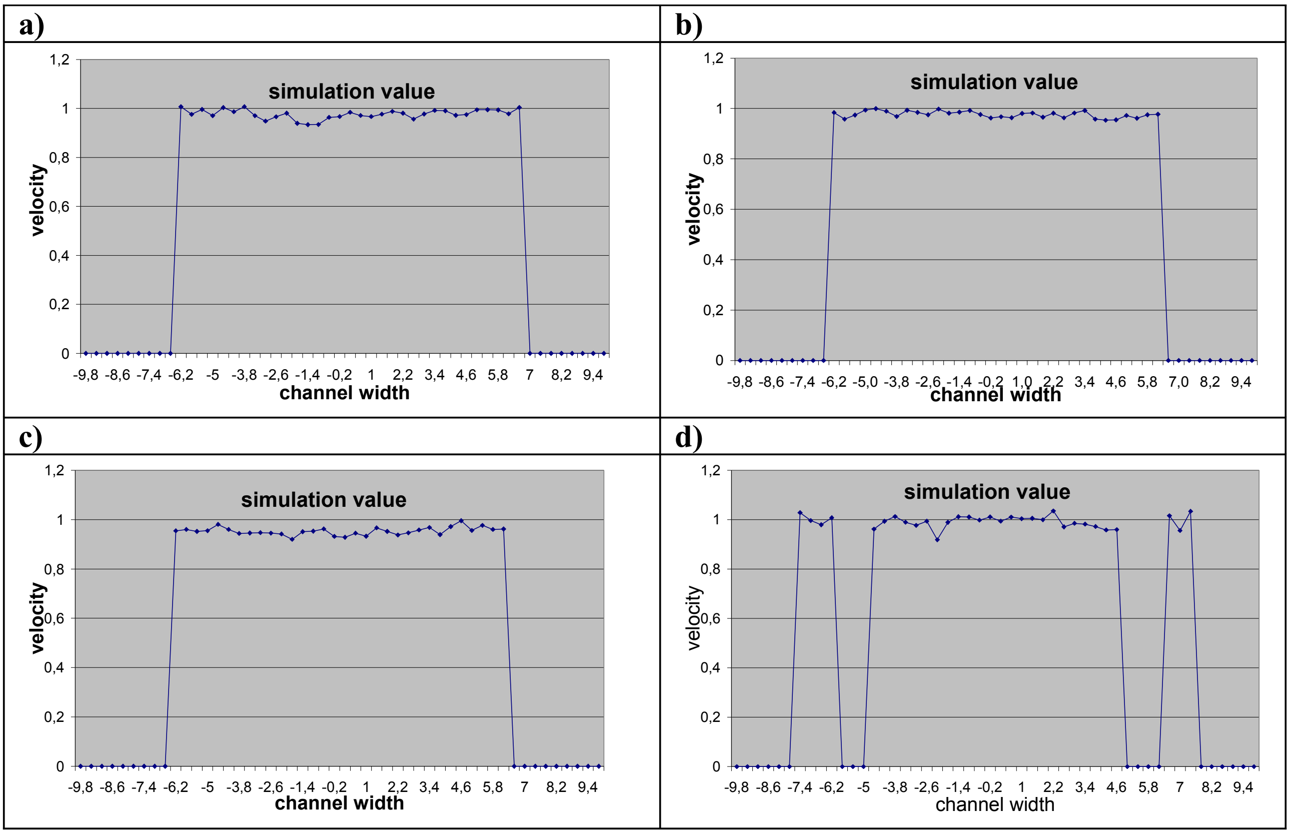

Fig. 5 Velocity distributions for flow of water in nanochannels, (Fx=0.5, Gaussian thermostat)
a) PPC, b) TIP4P, c)TIP4P-2005, d) TIP5P.

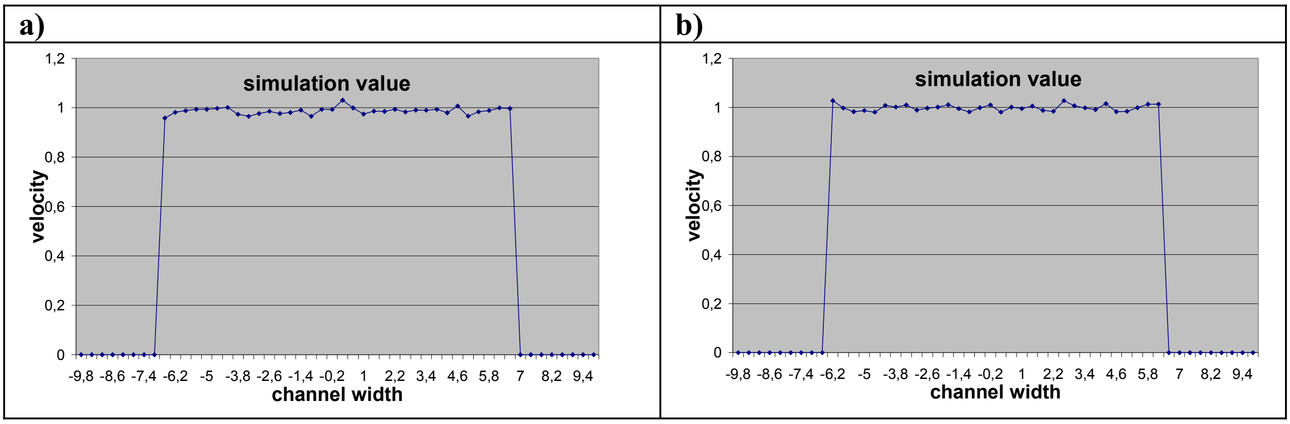

Fig. 6 Velocity distributions for flow of water in nanochannels, (Fx=0.5, Nosé-Hoover thermostat)
a) PPC, b) TIP4P.

at different mass forces acting on the molecules and different water models. On figure 3 we can see that for some the models of water the growth of force calling out the flow of water the growth of temperature effects.

Figures 5, 6 and 7 present velocity distributions in the channel cross-section perpendicular to the x – axis. Quickly increasing and declining graph it shows the wall of channel.

From the presented diagrams it is clear, that for the problems considered, i.e. flows in nanochannels, the Nosé-Hoover thermostat is much more efficient than the Gaussian one. The physical explanation of other peculiarities of the diagrams, particularly the behaviour of different models of water, requires further investigation. All our simulations be realized on our server on which programme MOLDY was compiled and started with different entrance described parameters overhead.

Email: sfialko@poczta.onet.pl

*Abstract*—**A block-based sparse direct finite element solver for commonly used multi-core and shared-memory multiprocessor computers has been developed. It is intended to solve linear equation sets with sparse symmetrical matrices which appear in problems of structural and solid mechanics. A step-by-step assembling procedure together with simultaneous elimination of fully assembled equations distinguishes this method from the well-known multifrontal solver, so this approach can be interpreted as a generalization of the conventional frontal solver for an arbitrary reordering. This solver is implemented in the commercial finite element software SCAD (www.scadsoft.com), and its usage by numerous users has confirmed its efficiency and reliability.**

## I. Introduction

THE solver is based on the idea of a step-by-step assembling of a given structure out of separate finite elements and substructures obtained at the previous assembling steps, and a simultaneous elimination of the fully assembled equations. It is an evolution of the frontal solver [1], and it differs from the classical multifrontal solver [2][3] which is a purely algebraic solver and gets the assembled global matrix in a compressed format as input data.

The key distinctive features of the presented method are:

- Each node is associated with a group of equations (usually, 6 equations per node for shell and space frame finite elements, and 3 equations per node for volumetric elements in unconstrained nodes). Thus, this approach produces the natural aggregation of equations, in this way improving the quality of reordering algorithms and speeding up the performance at the factorization stage. We refer to the elimination of a node of a finite element model at each elimination step. It means that a group of equations associated with the given node will be eliminated.
- An object-oriented approach is applied. A front is a C++ class object that encapsulates eliminated nodes at the current elimination step, a list of nodes and a list of equations for the current front, a pointer to the dense matrix which we denote as a frontal matrix, and so on.
- The whole elimination process is performed on a sequence of frontal matrices of the decreasing dimensionality.

Key points of the method are described in [4]. The paper [5] presents an improved version of the solver. The Cholesky block factorization algorithm was applied instead of a low-performance LU factorization from [4], and more efficient reordering algorithms comparing to [4] were implemented.

The current paper presents an extension of this solver onto the class of multi-core and multiprocessor shared-memory computers which are very popular today. The contemporary version of the solver is implemented in SCAD – one of the most popular finite element software applications for analysis and design of building structures in the Commonwealth of Independent States region.

## II. Analysis Stage

### A. Reordering and Symbolic Factorization

Modern reordering algorithms have a heuristic nature and do not provide an exact solution of the nonzero entries minimization problem. Moreover, we never know in advance what reordering strategy leads to the more optimal result for a given problem. Therefore several reordering methods have been developed. The most efficient methods for problems of structural mechanics usually are the minimum degree algorithm MMD , the nested dissection method ND , and the hybrid approach ND_MMD .

The fast symbolic factorization algorithm calculates the number of nonzero entries for each method of the ones listed above and then chooses the method that produces the least number of nonzero entries.

The use of a nodal adjacency graph instead of a graph of equations reduces the amount of data in a natural way and makes the reordering algorithms and the symbolic factorization procedure very fast: it takes only a few seconds even in very large problems (2,000,000 – 4,000,000 equations) to check 3 reordering methods and do the symbolic factorization.

### B. A Process Descriptor Data Structure

The reordering method establishes an order of the node elimination. The next step is to define the order of the finite element assembling.

The node is considered fully assembled if all finite elements, including this very node, have been already coupled. Adding any of the remaining finite elements does not make any change in the coefficients of equations associated with

This work was supported by the software company SCAD Soft (www.scadsoft.com)

this node. So, all equations belonging to the fully assembled node should be eliminated.

Let us consider a simple example, a square plate with the mesh 2x2 (Fig. 1). Before starting the elimination process, the whole structure is presented as exploded into separate finite elements.

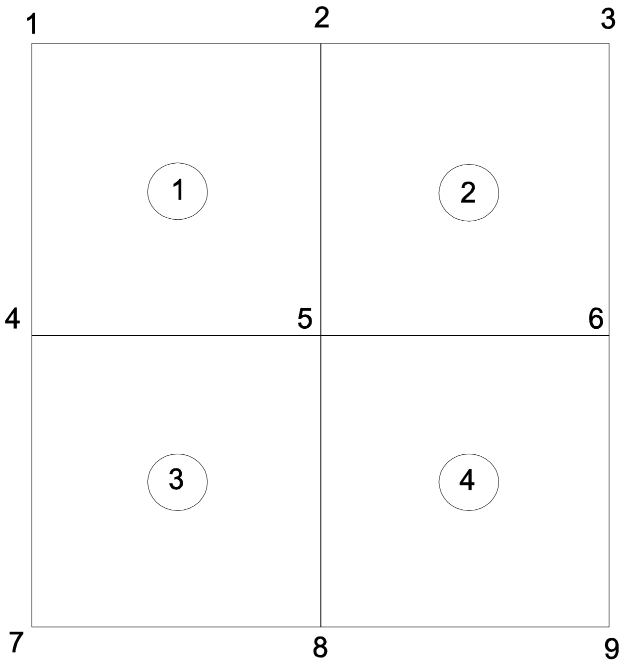

Fig. 1 Square plate 2x2

The sequence of nodal elimination produced by the reordering algorithm is: 1, 3, 7, 9, 2, 6, 8, 4, 5. Node 1 is the first node to be eliminated. This node belongs only to finite element 1. So, we take the finite element 1 and node 1 as fully assembled. The respective finite element matrix will be:

$$\begin{array}{cccc} 1 & 2 & 5 & 4 \\ \end{array}$$
$$\begin{pmatrix} s_{11} & & & \\ s_{21} & s_{22} & & \\ s_{31} & s_{23} & s_{33} & \\ s_{41} & s_{24} & s_{34} & s_{44} \end{pmatrix}, \qquad (1)$$

where $s_{\text{ij}}$ is a 6x6 matrix block because we suppose the design model to have six degrees of freedom per node. The global node numbers (global indexes) are shown at the top. The first block column contains the fully assembled equations. The partial factorization, covering only fully assembled equations, is then performed and the fully decomposed part of matrix is moved to a special buffer that contains the fully factorized global matrix. The remaining part of the matrix is an incomplete front; it will wait to be used at the following factorization steps. Local indexes are used during the partial factorization. Matrix (1) is a frontal matrix.

In the same way the nodes 3, 7, 9 are eliminated, and their respective incomplete fronts are created.

During the elimination of node 2 all finite elements have been already involved, and now we look through the lists of global indexes in the incomplete fronts. Node 2 is present in the global indexes of previous (incomplete) fronts 1, 2 (Table I), so we must assemble incomplete fronts 1, 2 to obtain a frontal matrix containing fully assembled equations for node 2.

This process is illustrated by Table I which shows a process descriptor data structure. The number of elimination steps is equal to the number of nodes of the design model.

We search for the node to be eliminated in the lists of nodes of each remaining finite element and in the lists of global indexes for each of the previous fronts. The fronts from the preceding elimination steps, which contain this eliminated node number, are the previous fronts. The previous fronts and their corresponding finite elements, pointed to by the last column of Table I, should be assembled to obtain the frontal matrix for the current front.

### C. Frontal Tree

The process descriptor data structure allows us to create a frontal tree. We take the last front from the bottom of Table I (it is Front 9) and put it at the top of the frontal tree (Fig. 2). Front 8 is the previous front for Front 9 – we put it under Front 9. For Front 8, Front 7 is its previous one – we put Front 7 under Front 8. And so on.

We reorder the fronts to reduce the storage memory required for incomplete fronts. The new front numbers are shown in italic under the original front numbers.

TABLE I.
A PROCESS DESCRIPTOR DATA STRUCTURE

| No. of front, elimination step | Node being eliminated | List of nodes in the frontal matrix | List of previous fronts | List of FEs fed to the assembling |
|---|---|---|---|---|
| 1 | 1 | 1,2,4,5 | — | 1 |
| 2 | 3 | 3,6,5,2 | — | 2 |
| 3 | 7 | 7,4,5,8 | — | 3 |
| 4 | 9 | 9,8,5,6 | — | 4 |
| 5 | 2 | 2,4,5,6 | 1,2 | — |
| 6 | 6 | 6,8,5,4 | 5,4 | — |
| 7 | 8 | 8,5,4 | 6,3 | — |
| 8 | 4 | 4,5 | 7 | — |
| 9 | 5 | 5 | 8 | — |

The frontal tree consists of (a) nodal fronts which have more than one previous front, (b) sequential fronts which have only one previous front, and (c) start fronts which do not have any previous front.

The core memory is allocated dynamically for objects of the nodal and start fronts. Each sequential front inherits the address of the frontal buffer from its previous front – this helps avoid the time-consuming memory allocation and copying of incomplete front. Moreover, if the sequence of sequential fronts does not have any assembled finite element, it is possible to consolidate such fronts to enlarge the block size of fully assembled equations and improve the performance. The consolidated frontal tree is presented in Fig. 3.

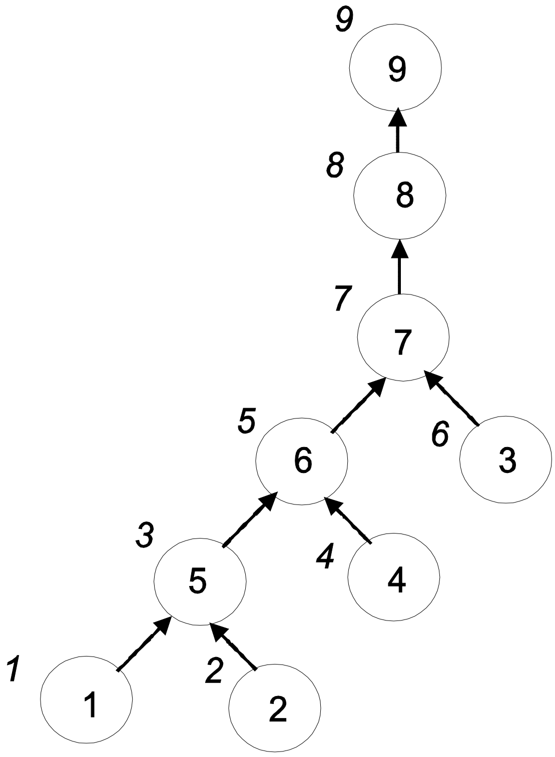

Fig. 2 A frontal tree

The buffer for storing the incomplete fronts (BuffFront), allocated in the core memory, is virtualized. When the size of the model exceeds the capacity of the random access memory (RAM), the buffer for the incomplete fronts is uploaded to hard disk. If all required previous fronts are in RAM during the assembling of the current nodal front, they are taken from BuffFront.

Otherwise, the previous fronts are taken from hard disk. The BuffFront is compressed from time to time to get rid of slow I/O operations during virtualization.

The presented method is a substructure-by-substructure approach, because each front presents a collection of coupled finite elements – a substructure, and the elimination process consists of a step-by-step assembling of these substructures and a simultaneous elimination of fully assembled equations.

## III. Factorization of Frontal Matrix

Generally, the structure of the frontal matrix can be very complex (Fig. 4). The matrix is symmetrical, and only the lower triangle part of it is stored in RAM. The fully assembled equations (grayed) are stored continuously but in arbitrary parts of the matrix (not necessarily at the top). This peculiarity restricts the direct application of the popular Lapack high-performance packages (Linpack, BLAS) and forces us to develop our own high-performance software for factorizations in frontal matrices.

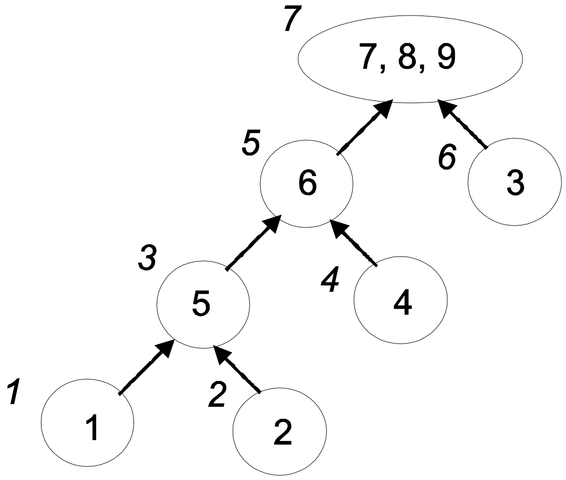

Fig. 3 Consolidated frontal tree

Thus, a Cholesky block method has been developed, which is a generalization of the frontal elimination approach [1], [4], where the fully assembled equations are stored in arbitrary parts of the matrix, onto the block version. It allows us to achieve the BLAS level 3 performance.

$$\begin{pmatrix} \mathbf{A} & \mathbf{W}_1^T & \mathbf{B}^T \\ \mathbf{W}_1 & \mathbf{F} & \mathbf{W}_2^T \\ \mathbf{B} & \mathbf{W}_2 & \mathbf{C} \end{pmatrix} =$$

$$= \begin{pmatrix} \tilde{A} & \tilde{W}_1 & \tilde{B}^T \\ 0 & L & 0 \\ \tilde{B} & \tilde{W}_2 & \tilde{C} \end{pmatrix} \cdot \begin{pmatrix} I & & \\ & S_L & \\ & & I \end{pmatrix} \cdot \begin{pmatrix} I & 0 & 0 \\ \tilde{W}_1^T & L^T & \tilde{W}_2^T \\ 0 & 0 & I \end{pmatrix} \qquad (2)$$

where $\mathbf{W}_1$, $\mathbf{F}$, $\mathbf{W}_2$ are blocks of fully assembled equations, **A, B, C** are blocks of partially assembled equations, which make up an incomplete front (Fig. 5) after the partial Cholesky factorization,

$$\begin{pmatrix} \tilde{\mathbf{A}} & 0 \\ \tilde{\mathbf{B}} & \tilde{\mathbf{C}} \end{pmatrix} \qquad (3)$$

The sign diagonal **I**, $\mathbf{S}_L$, **I** allows one to generalize the classic Cholesky factorization method onto a class of problems with indefinite matrices. The symbol "~" means that the corresponding matrix block is modified during the partial factorization.

The fully assembled blocks are moved to the buffer for the decomposed part of the matrix, and next the factorization of it is performed in the address space of this buffer.

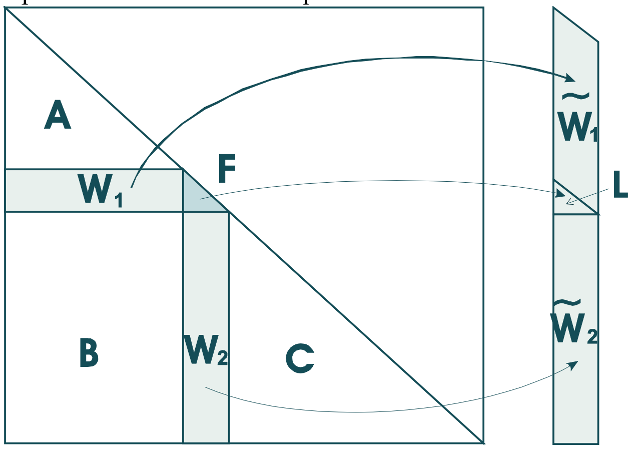

Fig. 4 The general structure of a frontal matrix. The fully assembled equations are moved to a buffer for the decomposed matrix

The incomplete front consists of sectors **A, B, C**. The symmetrical storage scheme is used. The coefficients of sector **A** remain in their positions, sector **B** moves up, and sector **C** moves up and to the left by the width of the grey strip. The final structure of the incomplete front is presented in Fig. 5.

The partial block factorization is performed in several steps:

- Factorize block **F**:

$$\mathbf{F} = \mathbf{L} \cdot \mathbf{S}_\mathrm{L} \cdot \mathbf{L}^\mathrm{T} \tag{4}$$

- Update blocks $\mathbf{W}_1$ , $\mathbf{W}_2$:

$$\begin{aligned} \mathbf{L} \cdot \mathbf{S}_L \cdot \widetilde{\mathbf{W}}_1^T &= \mathbf{W}_1 \rightarrow \widetilde{\mathbf{W}}_1^T \\ \mathbf{L} \cdot \mathbf{S}_L \cdot \widetilde{\mathbf{W}}_2^T &= \mathbf{W}_2^T \rightarrow \widetilde{\mathbf{W}}_2^T \end{aligned} \tag{5}$$

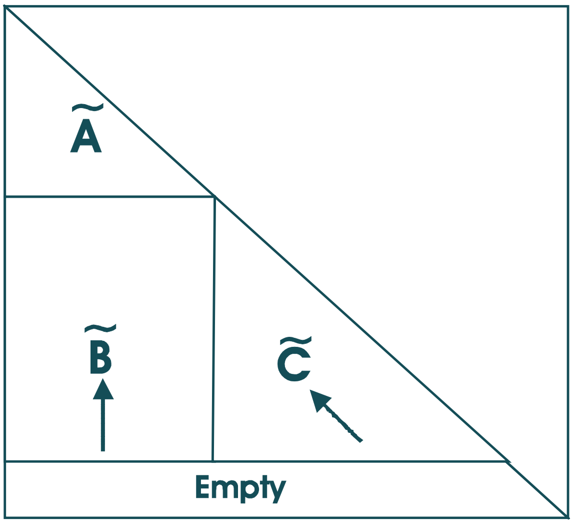

Fig. 5 The structure of the frontal matrix after the partial factorization. An empty strip appears at the bottom of matrix.

- Update sectors **A, B, C**:

$$\begin{aligned} \widetilde{\mathbf{A}} &= \mathbf{A} - \widetilde{\mathbf{W}}_1 \cdot \mathbf{S}_L \cdot \widetilde{\mathbf{W}}_1^T \\ \widetilde{\mathbf{B}} &= \mathbf{B} - \widetilde{\mathbf{W}}_2 \cdot \mathbf{S}_L \cdot \widetilde{\mathbf{W}}_1^T \\ \widetilde{\mathbf{C}} &= \mathbf{C} - \widetilde{\mathbf{W}}_2 \cdot \mathbf{S}_L \cdot \widetilde{\mathbf{W}}_2^T \end{aligned} \tag{6}$$

Expressions (4) – (6) are derived from (2) by means of the block matrix multiplication. Figs. 4, 5 help us to understand the structure of the frontal matrix. The main idea of the generalized Cholesky block factorization method is similar to the Gauss block elimination approach, reorganized to use the level 3 BLAS [10]. A particular case where a fully assembled part is at the top of the frontal matrix is presented in [5].

Matrix **F** has a small dimensionality, so there is no problem to store all matrix multipliers (4) in the processor cache and achieve a peak performance at this stage.

Stage (5) is a forward reduction performed on the package of right-hand sides – it is possible to achieve a good performance here, too.

The procedure that consumes most of the time is Stage (6). Each matrix multiplier $\mathbf{W}_1$, $\mathbf{W}_2$ is divided into smaller blocks, and the block matrix multiplication ensures the level 3 BLAS .

## IV. Parallel Implementation in Frontal Matrix

The bottleneck in the multi-core and multiprocessor shared-memory computing systems is an insufficient bandwidth of the system bus which leads to a weak speedup as the number of processors grows. A typical dependence for the speedup parameter, $S_p = T_1 / T_p$ , where $T_1$ is a computing time on one processor, $T_p$ is that on $p$ processors, for algorithms where the performance factor $q \le 2$ (matrix-vector multiplication, non-block matrix-matrix multiplication) is presented in Fig. 6. The performance factor is $q = f/m$ where $f$ is the number of arithmetic operations for a given algorithm and $m$ is the number of data transfers between RAM and the processor cache.

A totally different dependence takes place on the same computer for the block matrix-by-matrix multiplication; here $q \sim \sqrt{M}$ where $M$ is the cache size (fig. 7).

So, it is possible to achieve an efficient speedup for computers with an insufficient bandwidth of the system bus by increasing the number of processors for level 3 BLAS algorithms, where $q \sim \sqrt{M}$ , because these algorithms use significantly fewer RAM – cache – RAM transactions per single arithmetic operation than the algorithms where $q \le 2$ .

The results presented in Figs. 6 through 8 have been obtained by special tests prepared by the author.

Therefore the main attention during the development of the parallel code is paid to the Cholesky block factorization in the frontal matrix and the fork-joint parallelization technique, which is used mainly at the stage 6 during the block matrix-by-matrix multiplication.

The Microsoft Visual Studio 2008 environment (the C++ language for most of the code and the C language for “bottleneck” fragments of the code in order to achieve a peak efficiency by compiler optimizations) with the OpenMP support is used. All program code, including the factorization of frontal matrix, was developed by the author.

The local reordering of equations performed in the frontal matrix for the nodal and start fronts allows us to reduce the amount of time-consuming operations of moving sectors **B** , **C** block and thus increase the performance of method (Fig. 8).

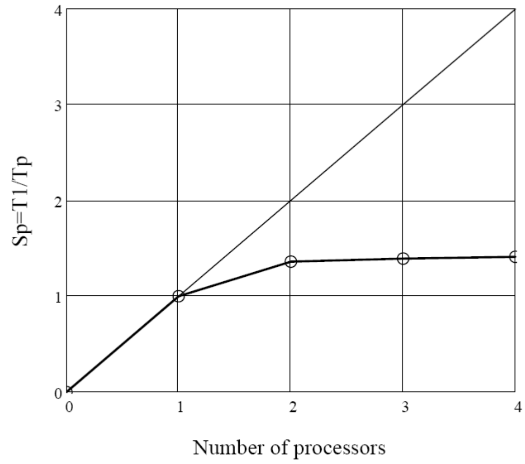

Fig. 6. $Sp = T_1 / T_p$ vs. number of processors $p$ for algorithms where the performance factor $q \leq 2$

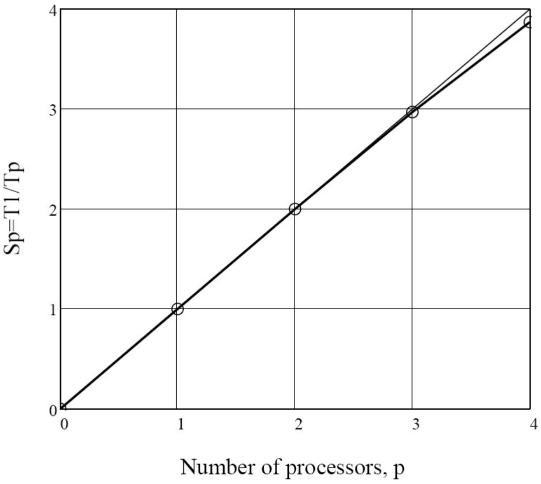

Fig. 7. $Sp = T_1 / T_p$ vs. number of processors $p$ for algorithms where the performance factor $q \sim M^{1/2}$

We reorder the frontal nodes according to the sequence of global reordering and then take the reverse order – each eliminated node occurs at the end of the node list. It ensures such a structure of the frontal matrix that the fully assembled equations are at the bottom and no moving of incomplete fronts is required (only sector A is shown in the figure, sectors B, C are omitted).

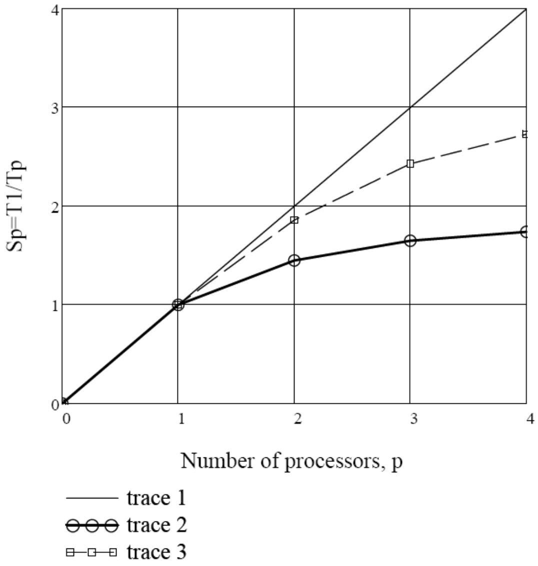

Fig. 8. $Sp = T_1 / T_p$ vs. number of processors $p$ for factorization of frontal matrices. Trace 1 – perfect speedup, trace 2 – local fronts not reordered, trace 3 – reordered fronts.

For instance, in the example of Fig. 1 the order of node processing for front 7 (tab. I) must be 5, 4, 8 rather than 8, 5, 4, because this numbering ensures that at each front elimination step the fully assembled equations stay at the bottom of the matrix and no moving of incomplete fronts is required.

Typical dependencies $S_p = T_1 / T_p$ vs. the number of processors $p$ for factorization of frontal matrices for presented method are shown in Fig. 8. The total time of factorization for all frontal matrices is under consideration. An essential improvement of performance occurs when the local reordering of equations in frontal matrices is performed (the dashed curve corresponds to local reordering and solid curve to no local reordering).

## V. Numerical Results

All results presented further below have been obtained on the computer Intel® Core™2 Quad CPU Q6600 @2.40 GHz, cache 4xL1: 32 KB (code), 4xL1: 32 KB (data), 2xL2:4096 KB, random-access memory DDR2 800 MHz 4 GB, operating system Windows XP Professional.

### *D. Test 1*

A cube with the mesh 40x40x40 consisting of brick volumetric finite elements is considered. Four corner nodes of the bottom face are restrained. This model comprises 68 921 nodes, 64 000 finite elements, 206 751 equations; the whole model is stored in RAM. The analysis stage, which includes reordering, symbolic factorization, creation of the process descriptor data structures, reordering and consolidation of the frontal tree, is performed as a serial computation. The computing time is 3 s. The solution stage, including forward – backward reductions, takes 4 s. The parallel computing stage covers only the factorization of frontal matrices and takes a predominant part of the whole time required by the numerical factorization stage (Table II).

The factorized matrix, as well as the buffer for incomplete fronts, is stored in RAM, and due to this fact the speedup parameter on four processors is about 3.0. It is a good result for multi-core and shared-memory office computers. For problems of structural mechanics solved by finite element software based on the Intel Math Kernel Library (PARDISO solver –[15]), the speedup parameter on four processors is about 2.9.

Table II.
Time of Numerical Factorization for Cube 40x40x40

| Number of processors | Numerical factorization – $T_p$, s | $S_p = T_1/T_p$ |
|---|---|---|
| 1 | 519 | 1.0 |
| 2 | 280 | 1.85 |
| 3 | 202 | 2.57 |
| 4 | 167 | 3.10 |

However, the PARDISO solver works only with the core memory, so its capabilities are restricted to problems of relatively small dimensions.

### *B. Test 2*

A square plate with two meshes 400x400 and 800x800 is considered. A quadrilateral flat shell finite element is used. The time of numerical factorization was compared with that for the sparse direct solver from ANSYS v 11.0. The first problem (mesh 400x400, Table III) contains 964 794 equations and the second one (mesh 800x800, Table IV) contains 3 849 594.

Table III.
Time of Numerical Factorization for Plate 400x400

| Number of processors | Numerical factorization for ANSYS v. 11.0, s | Numerical factorization for presented solver, s |
|---|---|---|
| 1 | 221 | 226 |
| 2 | 176 | 152 |
| 4 | 159 | 121 |

Table IV.
Time of Numerical Factorization for Plate 800x800

| Number of processors | Numerical factorization with ANSYS v. 11.0, s | Numerical factorization with the presented solver, s |
|---|---|---|
| 1 | failed | 2 091 |
| 2 | failed | 1 450 |
| 4 | failed | 1 080 |

For the first model (mesh 400x400), our solver stores the factorized matrix on hard disk, but the buffer for incomplete fronts is stored in the core memory. Due to virtualization of the factorized matrix, the scalability is worse comparing to the previous model – the speedup parameter on four processors is about 1.9. The performance demonstrated by both the sparse direct solver from ANSYS v. 11.0 and our solver is about the same.

For the second model (mesh 800x800), the solver from ANSYS v.11.0 failed due to insufficient RAM. Results for our solver are presented in Table IV. The factorized matrix is stored on hard disk, and virtualization is used for the buffer that contains incomplete fronts. The scalability is weak — the speedup parameter on four processors is about 1.9. The size of the factorized matrix is 9 723 MB.

### *C. Test 3*

The design model of a multistory building complex is presented in Fig. 9.

The number of equations is 1 534 674, the size of the factorized global matrix is 5 355 MB, the numerical factorization time on four processors is 860 sec. The disk memory is used for virtualization of the factorized matrix as well as for virtualization of the buffer where the incomplete fronts are stored.

Test A demonstrates that the scalability of the presented method for multi-core and multiprocessor office computers is similar to the scalability of the sparse direct solver based on Intel Math Kernel Library when the dimensionality of the model permits to use only the core memory. Test B proves that the performance of our solver is similar to the performance of the conventional multifrontal solver from the well-known ANSYS software. In addition, test B shows that the presented solver works very efficiently with the core memory. Test C illustrates that the presented method solves a really large finite element problem of structural mechanics very efficiently.

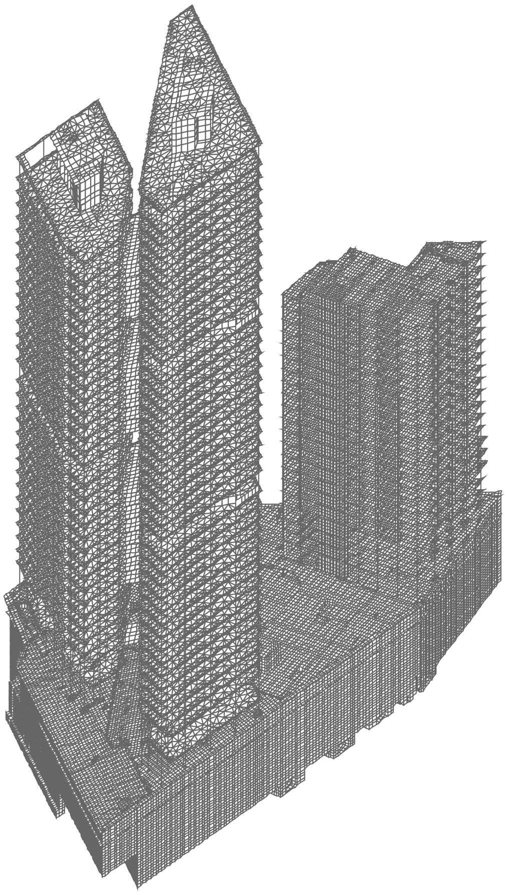

Fig. 9. Finite element model of a multistory complex “Moscow-city”, 255 779 nodes, 347 767 finite elements, 1 534 674 equations

## VI. Conclusion

A block-based sparse direct multifrontal solver for finite element problems of structural and solid mechanics has been developed. This method is oriented mainly at the usage on common shared-memory multiprocessor and multi-core computers.

The proposed solver has a clear mechanical interpretation as a substructure-by-substructure method. It uses the modern reordering algorithms which effectively reduce the fill-ins.

The Cholesky block algorithm with a generalization onto the class of indefinite matrices is applied here to the factorization of frontal matrix. The complicated structure of the frontal matrix restricts the direct application of the BLAS high-performance package and forces us to develop our own high-performance code based on a subdivision of the frontal matrix into blocks.

The OpenMP technique is applied to produce a fork-joint parallelization. The block subdivision and an appropriate numbering of equations in the frontal matrix, which reduces the amount of low-performance moving operations, allow us to improve the scalability of the method.

A comparison with the sparse direct solver from ANSYS v11.0 demonstrates that the performance of the proposed solver is close to the performance of ANSYS, but the proposed solver allows us to solve essentially larger problems on the same computers than the ANSYS solver is capable of processing.

The reliability and efficiency of the proposed solver has been confirmed by numerous users of the SCAD commercial software.

***Abstract*—The paper presents results of several experiments evaluating the performance of NVIDIA processors, implementing a new Tesla architecture, in matrix-vector multiplication. Three matrix forms, dense, banded and sparse, are considered together with three hardware platforms: NVIDIA Tesla C870 computing board, NVIDIA GeForce 8800 GTX graphics card and one of the newest Intel Xeon processors, E5462, with 1.6 GHz front side bus speed. The conclusions from experiments indicate what speed-ups can be expected when, instead of standard CPUs, accelerators in the form of presented GPUs are used for considered computational kernels.**

## I. Motivation

THE USE of graphics processing units (GPUs) in scientific computing is becoming an accepted alternative for calculations employing traditional CPUs [1]. The characteristics of GPUs, especially parallel execution capabilities and fast memory access, render them attractive in many application areas. One of the most important application domains is numerical linear algebra. The computational kernels from linear algebra are used in many scientific codes. Hence the widespread interest in porting and testing such kernels for GPUs [2].

The purpose of the present article is to assess the performance of the recent NVIDIA GPUs in performing one of linear algebra kernels, namely matrix-vector product. This kernel plays an important role in the implementation of iterative solvers for systems of linear equations. Moreover it is a typical memory-bound operation—its performance depends mainly on the speed of communication between a processor and memory chips, much less on the processing capabilities of the processor itself.

The organization of the paper is the following. In the next section performance characteristics of NVIDIA GPUs are described and compared to characteristics of typical contemporary CPUs. Section III presents the matrix formats considered in the paper and the corresponding matrix-vector multiplication algorithms. In Section IV the set-up of experiments as well as tests' results are described. Finally, conclusions are drawn in Section V.

## II. Performance characteristics of CPUs and GPUs

A typical contemporary processor is a two- or four-core unit equipped with a memory hierarchy comprised of several layers of cache and the main memory. From the point of view of performance for scientific codes two parameters are of premium importance: the processing speed and the speed of data transfer from the memory.

The processing speed depends on the number of cores, clock frequency and the number of instructions completed in every clock cycle. This last number varies greatly depending on the application. The theoretical maximum is usually two to four instructions per cycle. The practical performance can be closed to the maximum whenever "the memory wall" is not hit, i.e. the processor gets all necessary data on time. This is the case for BLAS Level 3 routines, like e.g. matrix-matrix product, on which the direct solution of systems of linear equations is usually based.

There is a different situation with memory bound algorithms. If the processor cannot get the necessary data on time the performance can be equal to a small percentage of the maximum.

Graphics processing units differs significantly from general purpose CPUs in both aspects affecting performance. Their processing speed is much greater due to the large number of specialised cores (though usually operating at lower frequencies that CPU cores). Also the throughput to the memory is greater for GPUs due to usually wider buses then that of CPUs. Hence both, processing speed limited and memory limited algorithms can benefit from off-loading to GPUs. One of serious drawbacks of contemporary GPUs is the use of single precision floating point numbers only. However, today all major producers of GPUs aiming at general purpose computing start offering double precision floating point capabilities in their products, so this limitation should shortly be overcome.

### A. An example CPU

Let us take, as an example CPU, one of the newest Intel Quad-core Xeon processors, E5462 with four cores, 2.8 GHz

**Algorithm 1** Simple matrix-vector product, $y := A \cdot x$, for dense matrices stored column-wise

```
for(i=0;i<n;i++){
   t:=x[i];
   for(j=0;j<n;j++){
      y[j]+=A[i*n+j]*t;
} }
```

clock speed and four double precision floating point instructions per clock cycle (maximum). The theoretical peak floating point performance is hence 44.8 GFlops. The processor is equipped with 12 MB cache memory and 1.6 GHz front side bus.

Let us consider a simple example of matrix-vector multiplication, a BLAS Level 2 operation that is memory bound. For a square matrix of size $n$ the number of floating point operations performed is $2 * n^2$. The number of memory accesses depends on the details of the algorithm. Let us consider a simple algorithm for column-wise stored matrix $A$ (Algorithm 1 on page 286). The minimal number of memory accesess (e.g. for small matrices fitting in cache together with vectors $x$ and $y$) is equal to $n^2 + 3 * n$ (one read for every element of $A$, $x$ and $y$ and one write for every element of $y$). The maximal number of memory accesses (e.g. for large matrices when at the end of the inner loop the first elements of $y$ are no longer in cache memory of any level) is $3n^2 + n$ (one read for every element of $A$, $n$ reads and $n$ writes for each element of $y$ and one read for every element of $x$). The number of memory accesses per one floating point operation varies, hence, between $\frac{1}{2} + \frac{3}{2*n}$ and $\frac{3}{2} + \frac{1}{2*n}$.

The theoretical peak throughput to the memory for the E5462 processor is 12.8 GB/s (1.6 GHz FSB speed combined with 8 bytes wide bus). This translates to 1.6 billions double precision numbers supplied to the processor per second. For the considered matrix-vector product algorithm this means (taking into account the number of memory accesses to the number of operations ratio and neglecting the terms with $n$ in the denominator) the constraint on the performance at the level between 3.2 Gflops and 1.067 Gflops. These constitutes only 7.14% and 2.38%, respectively, of the theoretical peak performance of the processor.

### B. An example GPU

Graphics processors have evolved in recent years from special purpose devices, with a sequence of fixed-function elements performing subsequent phases of the standard graphics pipeline, to processors that, although keeping many of special purpose solutions, can serve general purpose computations. NVIDIA, being the company that introduced the first GPU in 1999, has recently developed a special architecture that unifies the hardware for different stages of graphics processing and at the same time offers general purpose computing capabilities. The Tesla architecture is depicted in Fig. 1 (taken from [3], from which also the presented below facts about the Tesla architecture are taken).

From the general computing point of view the important elements of the architecture are the following:

- Host interface and Compute work distribution—the elements responsible for getting instructions and data from the host CPU and its main memory; they also manage the threads of execution by assigning groups of threads to processor clusters and performing contex switching
- TPC—texture/processor cluster, a basic building block of Tesla architecture GPUs (a single GPU can have from one to eight TPCs)
- SM—streaming multiprocessor, a part of TPC, consisting of eight streaming processor cores, two special function units (for performing interpolation and approximate evaluation of trigonometric functions, logarithms, etc.), a multithreaded instruction fetch and issue unit, two caches and a pool of shared memory
- Texture unit—each unit is shared by two SMs (each TPC contains two SMs and one texture unit), the unit plays its part in graphics calculations and is equipped with L1 cache memory accessible from SPs
- Level 2 Cache memory units—connected through fast network to TPCs

(ROP—raster operation processors usually do not take part in general purpose computations)

The most important characteristic of Tesla processing is that streaming multiprocessors manage the execution of programs using so called “warps”, groups of 32 threads. All threads in a warp execute the same instruction or remain idle (in such a way different threads can perform branching and other forms of independent work). Warps are scheduled by special units in SMs in such a way that, without any overhead, several warps execute concurrently by interleaving their instructions. So it is possible that, for example, with two warps the execution looks as follows: warp_1-instruction_1, warp_2-instruction_1, warp_1-instruction_2, warp_1-instruction_3, warp_2-instruction_2, etc. In such a way each SM can manage up to 24 warps, i.e. 764 threads. From the point of view of writing application codes it is, however, important to take into account the organization of the work, i.e. the use of 32 threads simultaneously. The code that does not break into 32 thread units can have much lower performance.

The processing capabilities of Tesla GPUs derive from many sources. Some of them, like texture and rasterization units, serve mainly the purposes of graphics processing. For general processing, especially scientific array operations, the main units are streaming processor cores (SP) and special function units (SFU). Each core can perform two floating point operations per cycle (by the multiply-add unit), each SFU is equipped with four multipliers, hence can perform 4 instructions per cycle. This gives 16 operations per cycle for 8 SPs and 8 operations per cycle for two SFUs in a single streaming multiprocessor. If an application can make both types of units work simultaneously (which is possible theoretically) it can achieve 24 operations per cycle per SM,

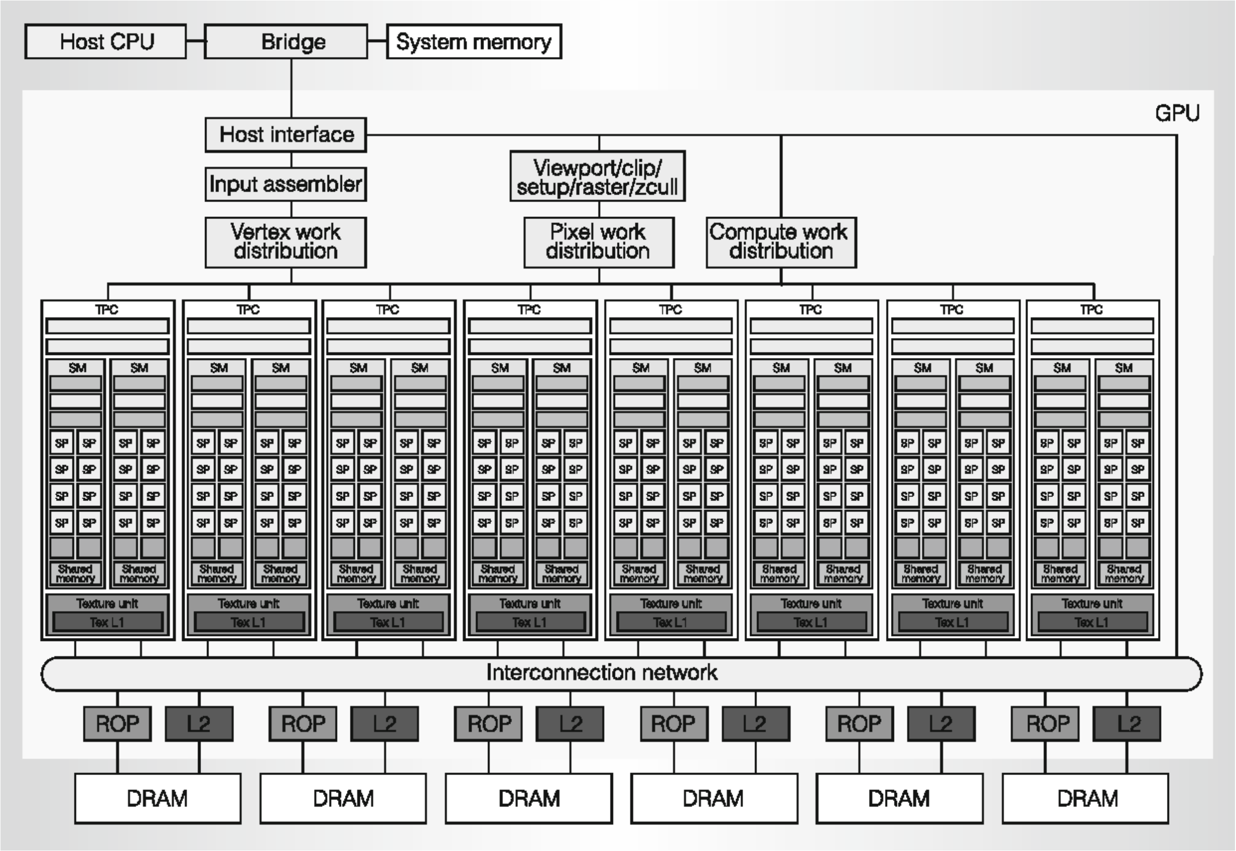

Fig. 1. Tesla architecture [3].

that for 1.5 GHz GPU with 16 SMs gives 576 Gflops. The performance possible to obtain in real applications is, however, much smaller.

One of reasons for smaller performance can be again limitations caused by too slow memory access. The memory system of Tesla architecture consists of even more layers than that of a CPU. Apart from the main memory of the host system, there is a DRAM card memory and two pools of cache memory - one within SMs, called shared memory, and the second within texture units. Both caches can be utilized by scientific codes. Important feature of the architecture is that the processor is not a vector unit, each thread issues its own memory requests. However, the performance is best when requests can be blocked by memory management unit to access contiguous memory areas.

The DRAM memory of a card consist of up to six modules, that comprise the whole physical memory space of a GPU. Each module is connected to the GPU by a link 64-bits wide. Combined with the DDR technology and clock frequency in the range of 1GHz this gives the memory throughput around 100 GB/s. This is four times faster than the theorethical memory throughput of the example Xeon CPU considered earlier. In our simple example of matrix-vector multiplication this translates to the speed between 37.5 and 50 Gflops, but now for single precision numbers only. Still this constitutes only less than 10% of the theorethical GPU performance.

### C. CUDA programming model

CUDA programming model is a model for programming Tesla GPUs using some extensions of standard C/C++. The extensions include two main domains: parallel work organisation through concurrent threads and memory accesses making use of the memory hierarchy of Tesla architecture.

Threads in the CUDA model are grouped into so called thread blocks. A programmer selects the block size. All threads in a block executes on one SM and can use its shared memory. Threads in one block can communicate with each other using the shared memory. Threads in different blocks cannot communicate. This constraint has also some positive consequenses since scheduling of different blocks is fast and flexible (independent of the number of SMs used for program execution).

Apart from shared memory variables, the programmer can explicitly address two other types of variables. Local variables reside in DRAM card's memory and are private for every thread. Global variables also reside in DRAM card's memory and are accessible to threads from different blocks, thus providing i.e. a way for global thread synchronisation. The DRAM memory is, however, much slower than the on-chip shared memory. For this reason threads within blocks can synchronise using a special instruction implemented using the shared memory.

Writing programs in CUDA consist in writing two types of routines. Standard routines are executed on CPU. From these routines kernel procedures are invoked, to be executed by the GPU. Kernels are written as procedures (declared with a keyword `__global__`) for one thread. Parallel execution is obtained by specifying in the invocation, using a special syntax, the number of thread blocks and the number of threads in each block. For our example of matrix-vector product the calling sequence in a program executed by CPU might look as follows:

```
dim3 threads( BLOCK_SIZE )
dim3 grid( n/BLOCK_SIZE );
mv_kernel<<< grid, threads >>>
  ( A_G, x_G, y_G, n );
```

where `threads` is a special variable of type `dim3` that has three components, each for one dimension of a thread block. Dimensions are used for identifying threads within blocks (in our example each thread is uniquely tagged by a triple `threads.x, threads.y, threads.z`, the first one within the range $(0, BLOCK\_SIZE - 1)$, the two latter equal to 0 by default, since the declaration of `threads` omitted them. Thread blocks form a grid of blocks—the dimensions of grids are specified similarly to dimensions of blocks and are used to identify blocks within grids (using triples `grid.x, grid.y, grid.z`). Thread and block identifiers are accessible within the kernel code through variables `threadIdx` and `blockIdx`.

The number of threads executing the `mv_kernel` is fixed and implied by dimensions of `threads` and `grid` arrays—in our example it was assumed that the number of threads is equal to $n$ and that $n$ is divisible by $BLOCK\_SIZE$ (if not simple adjustment has to be made).

For GPU threads to access variables in the GPU's DRAM memory (`A_G, x_G, y_G` in our example) they must be first allocated there and then their values transferred from the host memory, both operations done using special provided functions before kernel invocation.

A simple kernel function for implementing matrix-vector product on the Tesla architecture is given as Algorithm 2 on page 288.

## III. Matrix-vector multiplication algorithms

### A. Dense matrices

The CUDA algorithm presented in the previous section assumes that the thread that executes it performs all calculations for a single row of matrix `A_G` (this agrees with the assumption on the number of executing threads). As a consequence each thread can perform write operations perfectly in parallel with other threads but the performance can be poor due to not optimal memory accesses. The entries of matrix `A_G` (stored columnwise) transported to cache but not belonging to the row assigned to the thread are not used by it. To make the algorithm efficient the entries have to be used by other threads. That is the point where the proper arrangement of threads into thread blocks makes the difference.

**Algorithm 2** CUDA version of a simple matrix-vector product algorithm

```
__global__ void mv_kernel ( float* A_G,
  float* x_G, float* y_G, int n)
{
  int j;
  int i = blockIdx.x * BLOCK_SIZE
       + threadIdx.x;
  float t = 0.0f;
  for (j = 0; j < n; j ++ ) {
    t += A_G[i + j*n] * x_G[j];
  }
  y[i] = t;
}
```

Such an arrangement is done in the implementation of the standard SGEMV BLAS routine provided in the CUDA SDK [4], `cublasSgemv`. Blocks of threads are 1-dimensional with 128 threads per block and additionally fast shared memory is used for storing parts of vector $x$.

In [5] certain improvements to the original `cublasSgemv` algorithm have been proposed, consisting of using a texture memory unit to access elements of matrix $A\_G$ and grouping threads into 2-dimensional blocks of a fixed size 16x16.

### B. Banded matrices

For special types of matrices (banded, sparse, multi-diagonal, etc.) special algorithms can be used to exploit possible performance improvements. For all types of matrices the main indication is to perform operations only on non-zero elements. Despite the obvious intuitive advantage of such an approach the practical improvements may depend upon such details as the number of zeros in a matrix or influence of the memory access pattern on the performance.

In this and the next section two types of matrices frequently used in scientific computing are considered, banded matrices and sparse matrices stored in CRS (compressed row storage) format.

As an algorithm for banded matrices the implementation of SGBMV BLAS in CUDA SDK has been considered. The algorithm is very similar to the implementation of SGEMV in `cublasSgemv`. The main difference lies in accessing the elements of matrix `A_G`. As required by BLAS standards the matrix is stored columnwise, but with diagonals stored in rows. Hence, the matrix-vector product for the matrix `A_B` that stores entries of `A_G` in the required format and for a single thread that performs operations on a single row is shown, with some simplifications, as Algorithm 3 on page 289.

In the algorithm, `b` denotes bandwidth. `b` is the most important parameter determining the performance. For small values of bandwidth different threads still can use entries of `A_G` from cache but the values of `x_G` are different. The complex addressing of `A_G` may also pose problems for processing cores, since, unlike standard superscalar CPUs,

**Algorithm 3** Simple CUDA matrix-vector product algorithm for banded matrices

```
__global__ void
mvb_kernel ( float* A_G, float* x_G,
             float* y_G, int n, int b) {
  int j;
  int i = blockIdx.x * BLOCK_SIZE
        + threadIdx.x;
  int begin = max(0, i-b);
  int end = min(n, i+b+1)
  float t = 0.0f;
  for (j = begin; j < end; j++ ) {
    t += A_G[i+j*(2*b+1)-j+b] * x_G[j];
  }
  y[i] = t;
}
```

**Algorithm 4** Simple matrix-vector product algorithm for CRS storage format

```
void mv_crs( float* VA, int* JA, int* IA,
             int n, float* x, float* y ) {
  for(int i = 0; i < n; i++) {
    int size = IA[i+1] - IA[i];
    float sdot = 0.0f;
    for( int j = 0; j < size; j++ )
      sdot += VA[j]*x[JA[j]];
    y[i] = sdot
  }
}
```

they cannot perform integer and floating point operations in parallel.

### C. Sparse matrices

Sparse matrices are the most common form of matrices arising in approximations of partial differential equations describing different scientific and engineering problems. Hence, the importance of providing an efficient implementation of matrix-vector product, on which many iterative methods for systems of linear equations, like e.g. conjugate gradient or GMRES, can be based.

The CRS format [6] stores all non-zero entries of a matrix in a single one-dimensional vector, say VA, together with two other vectors: one, JA, with the same dimension as VA for storing column indices of the corresponding entries of the matrix and the other, say IA, with the dimension equal to the number of rows, for storing the indices of the first entries of subsequent rows in the array VA. A simple implementation of matrix-vector multiplication for CRS storage is shown as Algorithm 4 on page 289.

A CUDA implementation of Algorithm 4 has been proposed in [7]. The algorithm is shown as Algorithm 5 on page 289.

**Algorithm 5** Simple CUDA matrix-vector product algorithm for CRS storage format

```
__global__ void
mv_crs_kernel(float* VA, int* JA, int* IA,
              int n, float* x, float* y ) {
  __shared__ float cache[BLOCK_SIZE];
  int begin = blockIdx.x * BLOCK_SIZE;
  int end = block_begin + BLOCK_SIZE;
  int row = begin + threadIdx.x;
  int col;
  if(row < n) cache[threadIdx.x] = x[row];
  __syncthreads();
  if(row < n) {
    int r_b = IA[row];
    int r_e = IA[row+1];
    float sum = 0.0f;
    float xj;
    for(col = r_b; col<r_e; col++ ) {
      int j = JA[col];
      if( j >= begin && j < end )
        xj = cache[j-begin];
      else
        xj = x[j];
      sum += VA[col] * xj;
    }
    y[row] = sum;
} }
```

Again, one thread performs operations on a single row and elements of vector x are cached for better performance (the operation __syncthreads performs fast synchronization of threads belonging to a single block).

We propose a modification to Algorithm 5 consisting in using texture memory for elements of VA and JA. In Algorithm 5 the proper elements of both arrays are first put in texture memory (variable texture in the code) and than used by the corresponding threads. The update phase of the algorithm looks then as follows:

```
for(col = r_b; col<r_e; col++ ) {
  int j = texture.y;
  if( j>=block_begin && j<block_end )
    xj = cache[j-block_begin];
  else
    xj = x[j];
  sum += texture.x * xj;
}
y[row] = sum;
```

## IV. Experiments

### A. Hardware set-up

We tested the discussed algorithms on two platfroms. The first was Intel Xeon E5335, 2.0GHZ, with NVIDIA Tesla C870

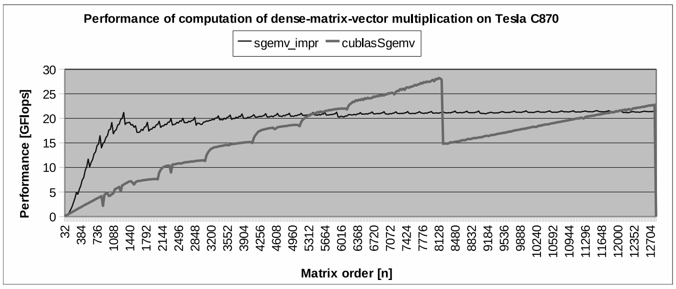

Fig. 2. Performance of matrix-vector multiplication algorithms for dense matrices on Tesla C870 (`cublasSgemv`, `sgemv_impr`)

as a CUDA device and ATI Radeon HD 2600 XT as a display device. The second was Intel Core 2 Duo E6750, 2.66 GHz, with ASUS EN8800GTX (with NVIDIA GeForce 8800GTX GPU as a CUDA and a display device). Both machines were running Fedora Core 8, 64-bit, with NVIDIA graphic driver version 177.13. The algorithms (CUDA and CUBLAS) presented previously, were implemented witch CUDA SDK version 2.0 beta. Note that, this version is the first that supports Fedora Core 8. For compilation we used gcc-compiler with standard optimization options (-*O*).

We tested the performance of matrix-vector product for three different matrix format representations: dense, sparse and banded, and measured the times for: allocating memory on graphic board, sending data from main memory to GPU memory, computing matrix-vector multiplication using card's DRAM and also getting results from GPU memory to main memory. All timing was performed by the functions provided by the CUDA environment.

### B. Performance

*1) Dense matrices:* We present first the results of two matrix-vector product algorithms for dense matrices residing already in GPU DRAM. The performance of `cublasSgemv` provided with CUDA SDK and the algorithm proposed in [5], denoted by `sgemv_impr`, is compared in Fig. 2 for matrices of dimension being a multiplicity of 32. Algorithm `sgemv_impr` presents more uniform performance and, moreover, does not exhibit a sudden break in performance for matrices of dimension not being the multiplicity of 32 (the effect reported in [5] which was also reproduced in our experiments). Nevertheless, the performance of any of the presented algorithms does not increase beyond 30 Gflops i.e. approx. 6% of the theoretical peak performance of the GPU (the theoretical limit derived from card's DRAM memory speed was between 37 and 50 Gflops).

For algorithm `sgemv_impr` we present also, in Figures 3–5, the timings for allocating data on a GPU and bandwidths for transporting data to and from GPU DRAM, both operations related to performing matrix-vector product on a GPU from a program running on a CPU (similar results were obtained for different types of matrices). The last figure, Fig. 6, shows the final performance of the matrix-vector operation performed on a GPU, taking into account the time necessary to transfer data to and from GPU.

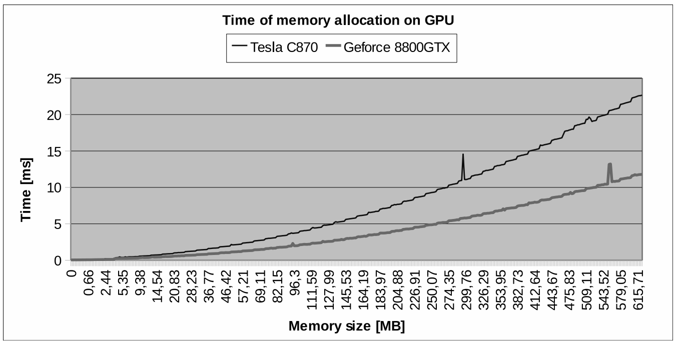

Fig. 3. Time of memory allocation on GPU for `sgemv_impr` algorithm and two CUDA platforms: Tesla C870 and GeForce8800GTX

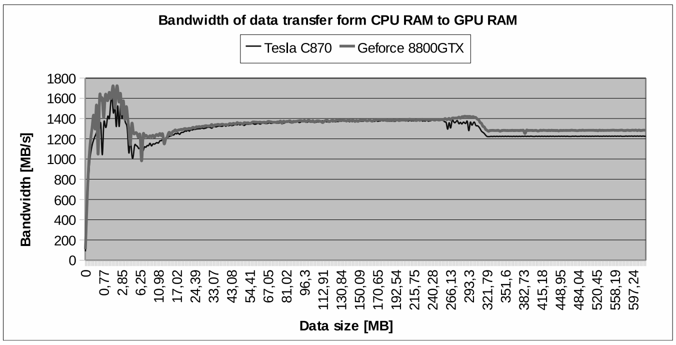

Fig. 4. Bandwidth of data transfer from CPU memory to GPU memory for `sgemv_impr` algorithm and two CUDA platforms: Tesla C870 and GeForce8800GTX

The timings and performance presented in Figures 3–6 show that the overall performance is determined almost exclusively by the time for transfering the entries of a matrix to GPU memory (for a matrix of size 10000 the transfer takes approx. 300 ms while all the other operations approx. 30 ms). The performance in Fig. 6 is slightly lower than that of a CPU (using the implementations from Intel MKL library we obtained 0.76 Gflops for Intel Xeon E5335 and 0.88 Gflops for Intel Xeon E5462). Hence, for scientific codes, especially iterative solvers employing matrix-vector product it is important how

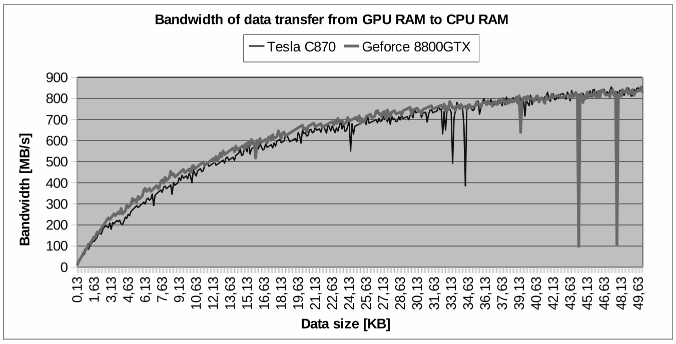

Fig. 5. Bandwidth of data transfer from GPU memory to CPU memory for `sgemv_impr` algorithm and two CUDA platforms: Tesla C870 and GeForce8800GTX

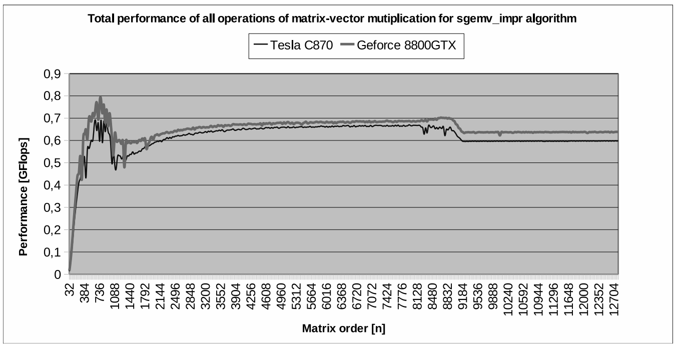

Fig. 6. Total performance of all operations of matrix-vector multiplication for `sgemv_impr` algorithm and two CUDA platforms: Tesla C870 and GeForce8800GTX

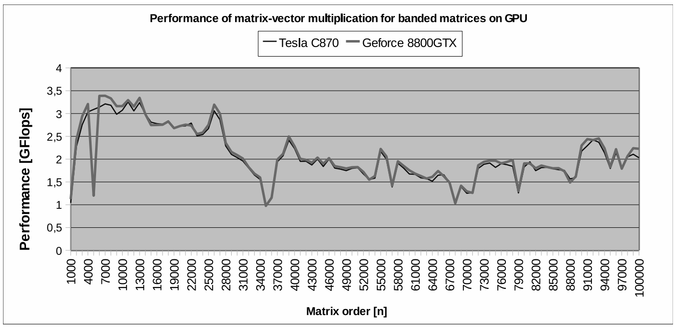

Fig. 7. Performance of matrix-vector multiplication for banded matrices, `cublasSgbmv` algorithm and bandwidth equal to 1.64% of matrix size (Tesla C870 and GeForce8800GTX)

many iterations will be performed on a given matrix, once it is transfered to the GPU memory.

*2) Banded matrices:* The results of experiments for banded matrices and the `cublasSgbmv` algorithm are presented in Fig. 7. The matrices had dimensions from 1000 to 100000 and the bandwidth was proportional to the matrix dimension (it was equal to 1.64% of matrix size to make the memory requirements for the largest matrices similar to memory requirements in dense matrix-vector product tests). A dramatic decrease in performance as compared to dense matrices can be observed. Moreover, the performance is far from uniform and strongly depends on the matrix size.

*3) Sparse matrices:* Two algorithms were tested in matrix-vector multiplication for sparse matrices stored in CRS format: the algorithm proposed in [7] ( Algorithm 5 on page 289) and its modification proposed in the current paper. The setting was similar to the setting for banded matrices, the dimensions of matrices changed from 1000 to 100000, but now the number of non-zero entries was equal to 1.64% of the matrix size. The results are presented in Fig. 8. Once again, a decrease in performance occured. The performance diminished with the increasing matrix size, as a result of more and more cache misses, since the non-zero entries of matrices occupied arbitrary positions in rows.

## V. Conclusion

Tesla architecture is still a new and evolving concept. For certain applications it can bring speed ups in the range of tens as compared to CPUs [3]. For the considered in the current paper problem of performing matrix-vector multiplication, the performance of cards with processors implementing the Tesla architecture vary significantly depending on the form of matrices as well as the overall context of calculations (e.g. whether the time necessary for transferring a matrix to GPU memory is taken into account or not). Recent experiences show that algorithms proposed for matrix-vector product, e.g. in CUDA SDK, still can be improved. One of slight modifications to published algorithms for sparse matrices in CRS format has been presented in the paper. For some matrix sizes it brings performance increase. We plan to investigate it further and report on the results in forthcoming papers.

## Acknowledgment

The authors would like to thank Mr Stanisław Rejowski and Mr Jacek Szwarga from the Action Company for providing the hardware on which the experiments were performed.

# Solving a Kind of BVP for Second-Order ODEs Using Novel Data Formats for Dense Matrices

Przemysław Stpiczyński
Department of Computer Science, Maria Curie–Skłodowska University
Pl. M. Curie-Skłodowskiej 1, 20-031 Lublin, Poland
Email: przem@hektor.umcs.lublin.pl

***Abstract*—The aim of this paper is to show that a kind of boundary value problem for second-order ordinary differential equations which reduces to the problem of solving tridiagonal systems of linear equations can be efficiently solved on modern multicore computer architectures. A new method for solving such tridiagonal systems of linear equations, based on recently developed algorithms for solving linear recurrence systems with constant coefficients, can be easily vectorized and parallelized. Further improvements can be achieved when novel data formats for dense matrices are used.**

## I. Introduction

LET consider the following boundary value problem which arises in many practical applications [10]:

$$-\frac{d^2u}{dx^2} = f(x) \quad \forall x \in [0,1] \tag{1}$$

where

$$u'(0) = 0, \quad u(1) = 0. \tag{2}$$

Numerical solution to the problem (1)–(2) reduces to the problem of solving tridiagonal systems of linear equations. Simple algorithms based on Gaussian elimination achieve poor performance, since they do not fully utilize the underlying hardware, i.e. memory hierarchies, vector extensions and multiple processors, what is essential in case of modern multicore computer architectures [1]. More sophisticated algorithms like *cyclic reduction*, *recursive doubling* [3] and *Wang's method* [15] lead to a substantial increase in the number of floating-point operations and do not utilize cache memory, what is crucial for achieving reasonable performance of parallel computers with a limited number of processors or modern multicore systems [4], [8], [14]. Following this observation, we have introduced a new fully vectorized version of the Wang's method devoted for solving linear recurrences with constant coefficients [12], [13] using two-dimensional arrays. In this paper we show how to apply this algorithm for solving tridiagonal systems of linear equations which arise after discretization of (1)–(2) and how to improve its performance using novel data formats for dense matrices [6].

## II. Simple solution

We want to find an approximation of the solution to the problem (1)–(2) in the following grid points

$$0 = x_1 < x_2 < \ldots < x_{n+1} = 1,$$

where $x_i = (i-1)h$, $h = 1/n$, $i = 1, \ldots, n+1$. Let $f_i = f(x_i)$ and $u_i = u(x_i)$. Using the following approximation

$$u''(x_i) \approx \frac{u_{i+1} - 2u_i + u_{i-1}}{h^2} \tag{3}$$

we get

$$-u_{i-1} + 2u_i - u_{i+1} = h^2 f_i \tag{4}$$

for $i = 2, \ldots, n$. When we apply the boundary condition $u_{n+1} = u(1) = 0$, we get a special case of (4)

$$-u_{n-1} + 2u_n = h^2 f_n. \tag{5}$$

To find an approximation of $u''(0)$ using the boundary condition $u'(0) = 0$, let us observe [5] that

$$u''(0) \approx \frac{u(0-h) - 2u_1 + u_2}{h^2} \tag{6}$$

and

$$u'(0) \approx \frac{u_2 - u(0-h)}{2h}. \tag{7}$$

From (7) and $u'(0) = 0$, we get $u(0-h) \approx u_2$, thus using (1) and (6) we have

$$u_1 - u_2 = \frac{1}{2} h^2 f_1. \tag{8}$$

Finally, using (8), (4) and (5) respectively, we get the following system of linear equations [10]:

$$A\mathbf{u} = \mathbf{d} \tag{9}$$

where

$$A = \begin{pmatrix} 1 & -1 & & & \\ -1 & 2 & -1 & & \\ & \ddots & \ddots & \ddots & \\ & & -1 & 2 & -1 \\ & & & -1 & 2 \end{pmatrix} \tag{10}$$

and

$$\mathbf{u} = (u_1, \ldots, u_n)^T, \quad \mathbf{d} = (d_1, \ldots, d_n)^T \tag{11}$$

with $d_1 = \frac{1}{2}h^2 f_1$ and $d_i = h^2 f_i$, $i = 2, \ldots, n$. The solution to the system (9) can be found using Gaussian elimination without pivoting. The matrix $A$ defined by (10) can be

978-83-60810-14-9/08/$25.00 © 2008 IEEE

factorized as $A = LR$, where $L$ and $R$ are bidiagonal Toeplitz matrices

$$L = \begin{pmatrix} 1 & & & & \\ -1 & 1 & & & \\ & \ddots & \ddots & & \\ & & -1 & 1 & \\ & & & -1 & 1 \end{pmatrix} \tag{12}$$

and

$$R = \begin{pmatrix} 1 & -1 & & & \\ & 1 & -1 & & \\ & & \ddots & \ddots & \\ & & & 1 & -1 \\ & & & & 1 \end{pmatrix}. \tag{13}$$

Thus we have to solve two systems of linear equations

$$L\,(y_1,\dots,y_n)^T = \mathbf{d} \tag{14}$$

and then

$$R\mathbf{u} = (y_1,\dots,y_n)^T. \tag{15}$$

The first stage (forward reduction) of the algorithm for solving (9), namely finding the solution to the system (14), can be done using

$$\begin{cases} y_1 = d_1 \\ y_i = d_i + y_{i-1} \quad \text{for } i = 2,\dots,n. \end{cases} \tag{16}$$

Then (second stage, back substitution) we find the solution to the system (15) using

$$\begin{cases} u_n = y_n \\ u_i = y_i + u_{i+1} \quad \text{for } i = n-1, n-2, \dots, 1. \end{cases} \tag{17}$$

Note that there is no need to allocate an array for the elements $y_i$, $i = 1,\dots,n$. Assuming that initially the array u contains the elements of the vector $\mathbf{d}$, namely u(i)$= d_i$, the algorithm based on (16) and (17) can be expressed as the following simple loops

```
do i=2,n
  u(i)=u(i)+u(i-1)
end do
do i=n-1,1,-1
  u(i)=u(i)+u(i+1)
end do
```

Unfortunately, this simple algorithm cannot be vectorized or parallelized, so it can utilize only a small fraction of the theoretical peak performance of modern multicore multiprocessors.

## III. "Divide and conquer" approach

It is clear that (16) and (17) are the special cases of the following more general problem of solving *linear recurrence systems with constant coefficients*

$$y_k = \begin{cases} 0 & \text{for } k \le 0 \\ d_k + \sum\limits_{j=1}^{m} a_j y_{k-j} & \text{for } 1 \le k \le n, \end{cases} \tag{18}$$

where simply $m = 1$, $a_1 = 1$ and in case of (17), the unknowns are calculated from $n$ down to 1. In [12] we introduced a new algorithm based on Level 2 and 3 BLAS routines [3], which is a generalization of our earlier fully vectorized algorithm [13]. It can be efficiently implemented on various shared-memory parallel computers [11]. In this section we present a very brief description of the algorithm applied for $m = 1$, $a_1 = 1$ and show how to improve its performance using novel data formats for dense matrices.

### A. Simple 2D-array algorithm

The main idea of the algorithm is to rewrite (18) as a block-bidiagonal system of linear equations [12], [13]. Without loss of generality, let us assume that there exist two positive integers $r$ and $s$ such that $rs \le n$ and $s > 1$. The method can be used for finding $y_1,\dots,y_{rs}$. To find $y_{rs+1},\dots,y_n$, we use (16) directly. Then for $j = 1,\dots,r$, we define vectors

$$\mathbf{d}_j = \left(d_{(j-1)s+1},\dots,d_{js}\right), \quad \mathbf{y}_j = \left(y_{(j-1)s+1},\dots,y_{js}\right) \in \mathbb{R}^s$$

and find all $\mathbf{y}_j$ using the following formula

$$\begin{cases} \mathbf{y}_1 = L_s^{-1}\mathbf{d}_1 \\ \mathbf{y}_j = L_s^{-1}\mathbf{d}_j + y_{(j-1)s}\mathbf{e} \quad \text{for } j = 2,\dots,r \end{cases} \tag{19}$$

where $\mathbf{e} = (1,\dots,1)^T$ and the matrix $L_s \in \mathbb{R}^{s\times s}$ is of the same form as $L$ given by (12). However, it is better to find the matrix

$$Y = (\mathbf{y}_1,\dots,\mathbf{y}_r) \in \mathbb{R}^{s\times r}$$

instead of individual vectors $\mathbf{y}_j$, $j = 1,\dots,r$. Indeed, for $k = 2,\dots,s$ we perform

$$Y_{k,1:r} \leftarrow Y_{k,1:r} + Y_{k-1,1:r}, \tag{20}$$

and this operation (simplified AXPY [3]) can be vectorized and parallelized. Then we use (19) to find the last entry of each vector $\mathbf{y}_j$, $j = 2,\dots,r$, and finally we use (19) to find $s-1$ first entries of these vectors (note that this operation can also be vectorized and parallelized). This approach has one disadvantage: the number of floating-point operations required by the algorithm is twice as many as for the simple algorithm based on (16) (see [12]). Analogously, we can find the solution to (15) using

$$\begin{cases} \mathbf{u}_n = R_s^{-1}\mathbf{y}_r \\ \mathbf{u}_j = R_s^{-1}\mathbf{y}_j + u_{js+1}\mathbf{e} \quad \text{for } j = r-1,\dots,1, \end{cases} \tag{21}$$

where

$$\mathbf{u}_j = \left(u_{(j-1)s+1},\dots,u_{js}\right) \in \mathbb{R}^s$$

and $R_s \in \mathbb{R}^{s\times s}$ is of the same form as $R$ given by (13). Note that there is no need to allocate an array for the matrix $Y$. We can allocate a two-dimensional array u as the storage for the matrix

$$U = \begin{pmatrix} u_{11} & \dots & u_{1r} \\ \vdots & & \vdots \\ u_{s1} & \dots & u_{sr} \end{pmatrix} \in \mathbb{R}^{s\times r}. \tag{22}$$

and assign u(i,j)=$d_{(i-1)s+j}$, $i = 1,\dots,s$, $j = 1,\dots,r$. The The leading dimension of the array (LDA for short) can be LDA $= s$, however the performance of the algorithm can be improved by the use of *leading dimension padding* [9], what

Fig. 2. Square blocked full column major order of a $7 \times 10$ matrix with $4 \times 4$ blocks.

means that we insert unused array elements between columns (Fortran) or rows (C/C++) of a multidimensional array by increasing the leading dimension of the array (Figure 1). Usually, it is sufficient to set $\mathtt{LDA} = M$, where $M \geq s$ and $M$ is *not* a multiple of a power of two.

The algorithm for solving (9) can be easily parallelized. Each processor can be responsible for computing a block of columns of the matrix $U$. The first stage (forward reduction) proceeds as follows. During the first (parallel) step, for $k = 2, \ldots, s$, each processor applies the operation (20) restricted to its own columns. Then the last entries of all vectors $\mathbf{y}_j$ are calculated sequantially. Finaly, each processor uses (19) to find $s-1$ first entries of its columns. Similarly we can parallelize the second stage of the algoritm (back substitution).

The value of the parameter $r$ should be at least $r = vp$, where $p$ is the number of processors and $v$ is the length of vector registers in a vector processor (if applicable). However, the best performance is achieved if $r = O(\sqrt{n})$ and $s = O(\sqrt{n})$ [12]. It should be noticed that sometimes the performance of the algorithm can be unsatisfactory. When the standard column major storage is used, successive elements of vectors $Z_{k,*}$ and $Z_{k-1,*}$ in (20) do not occupy contiguous memory locations, thus may not belong to the same *cache line* and *cache misses* may occur [9].

### B. Using novel data formats

Suppose that we have a $m \times n$ matrix $A$. The matrix can be partitioned as follows

$$A = \begin{pmatrix} A_{11} & \ldots & A_{1n_g} \\ \vdots & & \vdots \\ A_{m_g1} & \ldots & A_{m_gn_g} \end{pmatrix}. \qquad (23)$$

Each block $A_{ij}$ contains a submatrix of $A$ and it is stored as a square $n_b \times n_b$ block which occupies a contiguous block of memory (Figure 2). The value of the blocksize $n_b$ should be chosen to map nicely into L1 cache [6], [7]. Note that when $n_g n_b \neq n$ or $m_g n_b \neq m$, then $A_{1n_g}, \ldots, A_{m_gn_g}$ or $A_{m_g1}, \ldots, A_{m_gn_g}$ are not square blocks and some memory will be wasted ('`*`' in Figure 2). As mentioned in [6] the novel data format can be represented by using a four dimensional array where `A(i,j,k,l)` refers to the `(i,j)` element within the `(k,l)` block.

Let us observe that the algorithm introduced in the previous subsection can be implemented using a matrix representation based on the *square blocked full data format* presented above. The matrix $U$ can be partitioned as (23). Then the algorithm will operate on small $n_b$-vectors within $(n_b \times n_b)$-blocks and the number of cache misses will be substantially reduced.

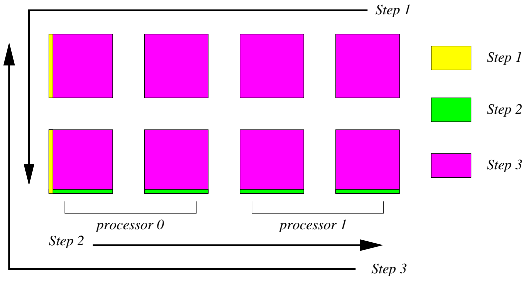

Fig. 3. The first stage using square blocked data format.

The first and the third step of the first stage can be done in parallel, while the second is sequential. To reduce the number of cache misses, blocks should be computed in the appropriate order. During the first step, columns of blocks should be computed from right to left and 'top-down' within each block column. Then during the second step we update elements in the lower row of blocks and finally (the third step) we update blocks from right to left and 'bottom-up' within each column of blocks (see Figure 3).

## IV. Results of experiments

Let us consider the algorithms described in the previous sections:

SEQ sequential algorithm based on (16) and (17),

DC divide and conquer algorithm based on (19) and (21) using two dimensional arrays,

ND divide and conquer algorithm based on (19) and (21) using the square blocked full data format.

The algorithms have been implemented in Fortran 95 with OpenMP directives [2] and all vector operations have been implemented using array section assignments. The experiments have been carried out on a dual processor Quad-Core Xeon (2.33 GHz, 12 MB L2 cache, 4 GB RAM running under Linux) workstation using the g95 Fortran Compiler.

We have measured the execution time (in seconds), the performance (in megaflops) of the algorithms for various values of $n$, $r$, $s$ and blocksizes $n_b$ and the speedup relative to Algorithm SEQ for optimal $n_b$, $r$, $s$ and various numbers of processors to find out how we can improve the performance of the simple scalar code (Algorithm SEQ) by the use of advanced computer hardware. Exemplary results are presented in Figures 4, 5 and Table I. The results of experiments can be summarized as follows.

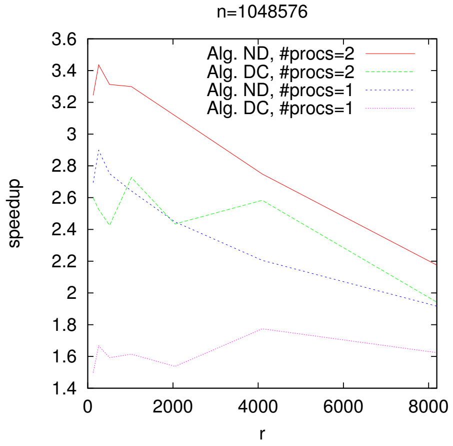

Fig. 4. Speedup of the algorithms DC and ND relative to Algorithm SEQ for various $r$.

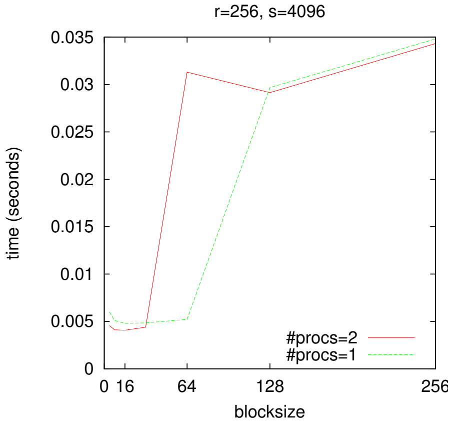

Fig. 5. Execution time of Algorithm ND for various blocksizes $n_b$.

TABLE I
EXECUTION TIME, SPEEDUP AND PERFORMANCE OF THE ALGORITHMS SEQ, DC, ND FOR $n = 1048576$

| | Time | | Speedup | | Mflops | |
|---|---|---|---|---|---|---|
| alg. | #p=1 | #p=2 | #p=1 | #p=2 | #p=1 | #p=2 |
| SEQ | 1.40E-2 | 1.40E-2 | – | – | 225 | 225 |
| DC | 7.96E-3 | 5.49E-3 | 1.75 | 2.55 | 659 | 954 |
| ND | 4.80E-3 | 4.06E-3 | 2.89 | 3.43 | 1093 | 1286 |

Both introduced algorithms (DC and ND) run faster than Algorithm SEQ. The performance of Algorithm ND depends on the blocksize $n_b$, so it should be chosen carefully. The optimal blocksize is $n_b = 16$ (Figure 5). When the blocksize $n_b$ is too large, the performance of the algorithm decreases dramatically because blocks do not fit into L1 cache and cache misses occur. For the optimal blocksize, the algorithm achieves reasonable speedup relative to Algorithm SEQ. Moreover, in case of the simple algorithm, fast vector instructions cannot be used without manual optimization of the simple scalar code. Although all optimization switches have been turned on, the compiler has produced rather slow output for the scalar code. The values of the parameters $r$ and $s$ should be chosen to minimize the number of flops required by the algorithms, however $r = s$ is rather a good choice in case of Algorithm DC and $r = \sqrt{n}/4$ in case of Algorithm ND. Finally, comparing the performance of the new algorithm which utilizes the novel data format with the performance of the divide and conquer algorithm which uses standard Fortran two-dimensional arrays with the column major storage order, we can observe that Algorithm ND is faster than Algorithm DC.

## V. CONCLUSION

We have shown that the performance of the simple algorithm for solving a kind of boundary value problem for second-order ordinary differential equations which reduces to the problem of solving tridiagonal systems of linear equations can be highly improved by the use of the divide and conquer vectorized algorithm which operates on the square blocked full data format for dense matrices. The algorithm can also be parallelized, thus it should be suitable for novel multicore architectures.

pl. Maria Curie Sklodowskiej 1, 20-031 Lublin, Poland
Email: vasyl@hektor.umcs.lublin.pl

***Abstract*—The paper is devoted to the special key management algorithm for the stream ciphers defined in [12] via finite automata corresponding to the family of directed algebraic graphs of high girth and two affine transformation. Security of the key based on the complexity of the discrete logarithm problem. It has additional heuristic security because of the "hidden base" and "hidden value" of the discrete logarithm function. We consider the heuristic evaluation of the complexity for different attack by the adversary on our private key cipher. The detailed description of the whole algorithm is given. Implemented software package has been used for the evaluation of mixing properties and speed of the private key encryption.**

## I. Introduction

WE WILL introduce the key management block for the stream ciphers defined in [12] via finite automata corresponding to the family of directed algebraic graphs of high girth. The time evaluation of software package implementing these algorithms compares well with the performance of fast but not very secure RC4, DES, algorithms based on simple graphs (symmetric anti reflexive binary relations) developed during last ten years [4].

In Section 3 we described modified algorithm in term of arithmetical dynamical systems. We add the key management block to our algorithm and consider the heuristic evaluation of active attacks by the adversary.

The explicit description of the dynamical system is given in last section in terms of corresponding finite automata. We give the explicit formula for invariants we use in algorithm.

Section 4 devoted to evaluation of speed of the encryption in case of special rings of kind $Z_2^s$, $s \geq 8$.

## II. Basic Cryptographical Terminology

Assume that an unencrypted message, *plaintext*, which can be image data, is a string of bytes. It is to be transformed into an encrypted string or *ciphertext*, by means of a cryptographic algorithm and a *key*: so that the recipient can read the message, encryption must be *invertible*.

Conventional wisdom holds that in order to defy easy decryption, a cryptographic algorithm should produce seeming chaos: that is, ciphertext should look and test random. In theory an eavesdropper should not be able to determine any significant information from an intercepted ciphertext. Broadly speaking, attacks to a cryptosystem fall into 2 categories: *passive attacks*, in which adversary monitors the communication channel and *active attacks*, in which the adversary may transmit messages to obtain information (e.g. ciphertext of chosen plaintext).

An assumption first codified by Kerckhoffs in the nineteen century is that the algorithm is known and the security of algorithm rests entirely on the security of the key.

Cryptographers have been improving their algorithms to resist the following two major types of attacks:

(i) *ciphertext only*—the adversary has access to the encrypted communications.

(ii) *known plaintext*—the adversary has some plaintextx and corresponding ciphertexts.

Nowadays the security of the plaintext rests on encryption algorithm (or private key algorithm), depended on chosen key (password), which has good resistance to attacks of type (i) and (ii), and algorithm for the key exchange (public keys) with good resistance to active attacks, when the adversary can generate each plaintext $p$ and get the corresponding plaintext $c$ (see [2], [3], [9] or [10]). The combination of appropriate private key and public key algorithms can lead to symmetric algorithm with good resistance even to active attacks. The example of such combination will be given in the next section of the paper.

## III. Arithmetical Dynamical Systems as Encryption Tools

Let $K$ be the commutative ring, $F(K) = K[t, x_1, x_2, \dots]$ is the ring of all polynomials in variables $t, x_1, x_2, \dots$. We use symbol $\mathrm{Reg}(K)$ for the totality of regular elements i.e not a zero divisors: $a \in \mathrm{Reg}(K)$ implies $a \times x \neq 0$ for each $x \neq 0$. Let $K^\infty = \{\mathrm{x} = (t, x_1, x_2, \dots)|x_i \in K, t \in K, \mathrm{supp}(\mathrm{x}), \infty\}$ and $K^n = \{(x_1, x_2, \dots, x_n)|x_i \in K\}$.

Let us consider two polynomial maps $P$ and $R$ of $K^\infty$ into $K^\infty$:

$$(t, x_1, x_2, \dots, ) \to (t, P_1(t, x_1, x_2, \dots), P_2(t, x_1, x_2, \dots), \dots)$$

and

$$(t, x_1, x_2, \dots, ) \to (t, R_1(t, x_1, x_2, \dots), \\ R_2(t, x_1, x_2, \dots), \dots),$$

where $P_i(t, x_1, x_2, \dots)$ and $R_i(t, x_1, x_2, \dots)$, $i = 1, 2, \dots$ are elements of $F(K)$.

We consider two families: $f_t^n$ and ${g_t}^n$ of $K^n$ onto $K^n$ sending $(x_1, x_2, \dots, x_n)$ to

$$(P_1'(t, x_1, x_2, \dots), P_2'(t, x_1, x_2, \dots), P_n'(t, x_1, x_2, \dots x_n))$$

and

$$(R'_1(t, x_1, x_2, \dots), R'_2(t, x_1, x_2, \dots), R'_n(t, x_1, x_2, \dots x_n)),$$

where $P'_i$ and $R'_i$, $i = 1, 2, \dots, n$ correspond to the specialisations $x_{n+1} = 0, x_{n+2} = 0, \dots$ of $P_i$ and $R_i$ associated with the pair ($P$, $R$). We identify $f_t$ and $g_t$, $t \in K$ with the corresponding maps $K^n \to K^n$

Let $\mathrm{r} = (r_1, r_2, \dots r_t) \in \mathrm{Reg}(K)^t$ be the tuple of length $l(\mathrm{r})) = t$. We introduce $F_{\mathrm{r}}$, as the composition of maps $f_{r_1}, g_{r_2}, \dots, f_{r_{2s-1}}, g_{r_{2s}}$ in case of $t = 2s$ and as composition of $f_{r_1}, g_{r_2}, \dots, f_{r_{2s-1}}, g_{r_{2s}}, f_{r_{2s+1}}$ for $t = 2s + 1$.

We say that the pair $P$ and $R$ form an arithmetical dynamical system depending on time $t$ if the following conditions hold

1) existence of $\mathrm{x} = (x_1, \dots, x_n) \in K^n$ such that $f_{t_1}(x_1, x_2, \dots, x_n) = f_{t_2}(x_1, x_2, \dots, x_n)$ for some $t_1$ and $t_2$ implies the equality $t_1 = t_2$.

2) maps $f_t$ and $g_t$, $t \in K$ are bijections and $f_{-t}$ and $g_{-t}$ are inverse maps for them.

3) There is a constant $c$, $c > o$ such that for each pair of tuples r, b of regular elements, conditions $l(\mathrm{r}) \leq cn$, $l(\mathrm{r}) \leq cn$ and $F_{\mathrm{r}}(\mathrm{x}) = F_{\mathrm{b}}(\mathrm{x})$ for some x implies $\mathrm{r} = \mathrm{b}$.

If $(P, R)$ form an arithmetical dynamical system, then the inverse of $F_{\mathrm{r}}$, $l(\mathrm{r}) = 2s + 1$ is $F_{\mathrm{b}}$, where

$$\mathrm{b} = (-r_{2s+1}, -r_{2s}, \dots, -r_1).$$

If $l(\mathrm{r}) = 2s$ then $F_{\mathrm{r}}^{-1}$ is the composition of $g_{-r_{2s}}$ and $F_{\mathrm{d}}$, where $\mathrm{d} = (-r_{2s-1}, -r_{2s-2}, \dots, -r_1)$.

We can treat $K^n$ as the plainspace, refer to the union U of $\mathrm{Reg}(K)^t$, $1 < t < cn$ as the key space and treat $\mathrm{x} \to F_{\mathrm{a}}(\mathrm{x})$ as the encryption map corresponding to the key a. The ciphertext $y = F_{\mathrm{a}}(\mathrm{x})$ can be decrypted by the map $F_{\mathrm{a}}^{-1}$ written above. So the algorithm is symmetrical. The property 3 implies that different keys of length $< cn$ produce distinct ciphertexts.

We introduce the following directed graph $\phi = \phi(n)$ corresponding to maps ${f_t}^n$ and ${g_t}^n$ over $K^n$. Firstly we consider two copies of $P$ (set of points) and $L$ (set of lines) of the free module $K^n$. We connect point $p \in P$ with the line $l \in L$ by directed arrow if and only if there is $t \in \mathrm{Reg}(K)$ such that $f_t(p) = l$. Let $t$ be the colour of such a directed arrow. Additionally we join $l \in L$ and $p \in P$ by directed arrow with the colour $t$ if there is $t \in \mathrm{Reg}(K)$ such that $g_t(l) = p$. We can consider $\phi$ as finite automaton for which all states are accepting states. We have to chose point $p$ (plaintext) as initial state. It is easy to see that $f_t$ and $g_t$ are the transition functions of our automaton. Let $t_1, \dots, t_s$ be the "program" i.e. sequence of colours from $\mathrm{Reg}(K)$. Then the computation is the directed pass $p$, $f_{t_1}(p) = p^1, g_{t_2}(p^1) = p^2, \dots$. If $s$ is even then the last vertex is $f_{t_s}(p^{s-1})$, in case of odd $s$ we get $g_{t_s}(p^{s-1}) = p^s$ as the result of the computation (encryption). The stop of the automata corresponds just to the absence of the next colour.

The inverse graph $\phi(n)^{-1}$ can be obtained by reversing of all arrows in $\phi$. We assume that colours of arrow in $\phi$ and its reverse in $\phi^{-1}$ are the same. So we can consider $\phi(n)^{-1}$ as an automaton as well. Then the decryption procedure starting from the ciphertext $p^s$ corresponds to the pass in $\phi^{-1}$ defined by sequence of colours $-t_s, -t_{s-1}, \dots, -t_1$.

Finally, we can consider well defined projective limit $\phi$ of automata $\phi^n$, $n \to \infty$ with the transition function $P_t(x_1, x_2, \dots) = P(t, x_1, x_2, \dots)$ and $R_t(x_1, x_2, \dots) = R(t, x_1, x_2, \dots)$. In case of finite $K$ we can use $\phi$ as a Turing machine working with the potentially infinite text in the alphabet $K$. Results of [41] allow to formulate the following statement.

THEOREM 1

*For each commutative ring $K$ there are a cubical polynomial maps $P$ and $R$ on $K^\infty$ forming arithmetical dynamical system with the constant $c \geq 1/2$ such that for each string* r *of elements from* $\mathrm{Reg}(K)$ *the polynomial map* $F_{\mathrm{r}}$ *is cubical.*

The example as above has been defined explicitly in [5] in graph theoretical terms. The maps $P$ and $R$ will stand further for that particular example. Corresponding to $(P, R)$ graphs $\phi(n)$ are strongly connected i.e. from the existence of directed pass from vertex $v$ to $w$ follows that $w$ and $v$ are connected by a directed pass. So connected components of $\phi(n)$ are well defined.

We combine the encryption process $F_{\mathrm{r}}$ corresponding to finite automaton $\phi(n)$ and string r of elements from $\mathrm{Reg}(K)$ with two invertible sparse affine transformation $\mathrm{Af}_1$ and $\mathrm{Af}_2$ and use the composition $\mathrm{Af}_1 \times F_{\mathrm{r}} \times \mathrm{Af}_2$ as encryption map. We refer to such a map as *deformation* of $F_{\mathrm{r}}$. In case of $\mathrm{Af}_1 = {\mathrm{Af}_2}^{-1}$ we use term *desynchronization*. In case of desynchronization the ciphertext is always distinct from the plaintext. We assume that $\mathrm{Af}_1$ and $\mathrm{Af}_2$ are parts of the key. Deformated or desynchronised encryption is much more secure, because it prevents adversary to use group automorphisms and special ordering of variables during his/her attacks.

In the case of deformation with fixed $\mathrm{Af}_1$ and $\mathrm{Af}_2$ and flexible r the property that the different passwords of kind r lead to different ciphertexts is preserved, but the situation, where the plaintext and corresponding ciphertext are the same can happen. Anyway the probability of such event is $1/|V|$, where $V = K^n$ is the plainspace.

### A. Watermarking Equivalence and Hidden Discrete Logarithm

THEOREM 2

*Let $\phi(n)$, $n \geq 6$ be the directed graph with the vertex set $K^{k+1}$ defined above for the pair $(P, R)$.*

*(i) There are the tuple $a = a(\mathrm{x})$, $\mathrm{x} \in K^{n+1}$ of quadratic polynomials $a_2, a_3, \dots, a_t$, $t = [(n+2)/4]$ in $K[x_0, x_1, \dots, x_n]$ such that for each directed pass $u = v_0 \to v_1 \to v_n = v$ we have $a(u) = a(v)$.*

*(ii) For any $t-1$ ring elements $x_i \in K)$, $2 \leq t \leq [(k+2)/4]$, there exists a vertex $v$ of $\phi(n)$ for which $a(v) = (x_2, \dots, x_t) = (x)$. So classes of equivalence relation $\tau = \{(u, v)|a(u) = a(v)\}$ are in one to one correspondents with the tuples in $K^t$.*

*(iii) The equivalence class $C$ for the equivalence relation $\tau$ on the set $K^{n+1} \cup K^{n+1}$ is isomorphic to the affine variety $K^t \cup K^t$ , $t = [4/3n]+1$ for $n = 0, 2, 3 \bmod 4$, $t = [4/3n]+2$ for $n = 1 \bmod 4$.*

We refer to $\tau$ as watermarking equivalence and call $C$ as above generalised connected component of the graph,

Let $|K| = d$ and $\eta$ numerating function i.e bijection between $K$ and $\{0, 1, \ldots, d-1\}$. For each tuple $\mathrm{t} = (t_0, t_1, \ldots t_s) \in K^{s+1}$ we consider its number $\eta(\mathrm{t}) = \eta(t_0) + \eta(t_1)d + \cdots + \eta(t_s)d^s$. Let $\mathrm{Reg}(K) = b \geq 2$, $\mu$ be the bijection between $\mathrm{Reg}(K)$ and $\{0, 1, \ldots, b-1\}$. We obtain $\mathrm{reg}(\mathrm{t})$ by taking the string of digits for $\eta(\mathrm{t})$ base $b$ and computing $\mu^{-1}$ for each digit. So $\mathrm{reg}(\mathrm{t})$ is a string of characters from the alphabet $\mathrm{Reg}(K)$.

THE ALGORITHM: Correspondents Alice and Bob are taking smallest prime number $p$ from interval $(b^{[(n+5)/2c]}, b^{[(n+5)/2]})$, where $c$ is some constant $> 3/2$ and some number $m$, $m < p$. Alice takes the plainspace $\mathrm{x}$ computes string $a(\mathrm{x})$ (see theorem ?), then $z = \eta(a(\mathrm{x}))$ and $u = z^m \bmod p$. She treats $u$ as integer and takes string $d(\mathrm{x}) = \mathrm{reg}(u)$ of characters from $\mathrm{Reg}(K)$. Her encryption is $\mathrm{Af}_1 \times F^n_{d(\mathrm{x}} \times \mathrm{Af}_2$. We think that numbers $m$, $c$ and fixed maps $\mathrm{Af}_i$, $i = 1, 2$ are parts of the key.

Let c be the ciphertext. Bob computes $z$ defined above az $z = \eta(a(\mathrm{c}))$, computes string $d(\mathrm{x})$ and use decryption map $(\mathrm{Af}_2)^{-1} \times {F^n_{d(\mathrm{x})}}^{-1} \times \mathrm{Af}_1$.

Let $C_n(\mathrm{x}) = C(\mathrm{x})$ be the encryption function corresponding to deformation of dynamical system. The adversary may try to find the factorization $C_n(\mathrm{x}) = ((\mathrm{Af}_1)) \times F^n_{d(\mathrm{x})} \times \mathrm{Af}_2$, where $Af_i, i = 1, 2$ are unknown and the function $d(\mathrm{x})$ is $\mathrm{reg}((\eta(a(\mathrm{x})^m))$, where $m$ is unknown also. During his active attack he can compute finite number of values $C(\mathrm{x}_i)$, $i \in J$ and use this information for finding the factorization. The following heuristic argument demonstrate that it can be difficult task.

Let as assume that affine transformation $\mathrm{Af}_i$, $i = 1, 2$ are known for adversary. Notice that finding them can be very difficult. Then the adversary can compute $\mathrm{d}_i = F^n_{d(\mathrm{x}_i)} = (\mathrm{Af}_1)^{-1} C(\mathrm{x}_i)(\mathrm{Af}_2)^{-1}$. The pass between vertices of the graph is unique. The Dijkstra algoritm is not suitable for finding the pass because the vertex space of the graph is the plainspace. But may be large group of automorphisms (see [14] and further referenes) will allow to find the pass. Then the adversary computes number $b_i = \eta(a(\mathrm{x})^m$ modulo known big prime. Still he is not able to find number $m$ because of the complexity of discrete logarithm problem. So he has to take for the set $\{\mathrm{x}_i | i \in J\}$ the totality of representatives from classes of watermarking equivalence (transversal). So $|J| > O(|K|^{[1/4]})$ because of theorem 2.

We use term *hidden discrete logarithm* for the name of modified algorithm because affine transformation do not allow the adversary to compute the class of watermarking equivalence containing the plaintext (base of the logarithm) and pass in the finite automaton corresponding to the value of the logarithm.

## IV. Explicit Construction, Algebraic Graphs of Arithmetical Dynamical System

Missing graph theoretical definitions the reader can find in [1] or [8]. E. Moore [7] used term *tactical configuration* of order $(s, t)$ for biregular bipartite simple graphs with bidegrees $s+1$ and $r+1$. It corresponds to incidence structure with the point set $P$, line set $L$ and symmetric incidence relation $I$. Its size can be computed as $|P|(s+1)$ or $|L|(t+1)$.

Let $F = \{(p, l) | p \in P, l \in L, pIl\}$ be the totality of flags for the tactical configuration with partition sets $P$ (point set) and $L$ (line set) and incidence relation $I$. We define the following irreflexive binary relation $\phi$ on the set $F$:

Let $(P, L, I)$ be the incidence structure corresponding to regular tactical configuration of order $t$.

Let $F_1 = \{(l, p) | l \in L, p \in P, lIp\}$ and $F_2 = \{[l, p] | l \in L, p \in P, lIp\}$ be two copies of the totality of flags for $(P, L, I)$. Brackets and parenthesis allow us to distinguish elements from $F_1$ and $F_2$. Let $DF(I)$ be the *double directed flag graph* on the disjoint union of $F_1$ with $F_2$ defined by the following rules

$(l_1, p_1) \to [l_2, p_2]$ if and only if $p_1 = p_2$ and $l_1 \neq l_2$,
$[l_2, p_2] \to (l_1, p_1)$ if and only if $l_1 = l_2$ and $p_1 \neq p_2$.

We will define below the family of graphs $D(k, K)$, where $k > 2$ is positive integer and $K$ is a commutative ring, such graphs have been considered in [5] for the case $K = F_q$.

let $P$ and $L$ be two copies of Cartesian power $K^N$, where $K$ is the commutative ring and $N$ is the set of positive integer numbers. Elements of $P$ will be called *points* and those of $L$ *lines*.

To distinguish points from lines we use parentheses and brackets: If $x \in V$, then $(x) \in P$ and $[x] \in L$. It will also be advantageous to adopt the notation for co-ordinates of points and lines introduced in [5] for the case of general commutative ring $K$:

$$(p) = (p_{0,1}, p_{1,1}, p_{1,2}, p_{2,1}, p_{2,2}, p'_{2,2}, \ldots, p_{i,i}, p'_{i,i}, p_{i,i+1}, p_{i+1,i}, \ldots)$$

$$[l] = [l_{1,0}, l_{1,1}, l_{1,2}, l_{2,1}, l_{2,2}, l'_{2,2}, \ldots, l_{i,i}, l'_{i,i}, l_{i,i+1}, l_{i+1,i}, \ldots]$$

The elements of $P$ and $L$ can be thought as infinite ordered tuples of elements from $K$, such that only finite number of components are different from zero.

We now define an incidence structure $(P, L, I)$ as follows. We say the point $(p)$ is incident with the line $[l]$, and we write $(p)I[l]$, if the following relations between their co-ordinates hold:

$$\begin{aligned} l_{i,i} - p_{i,i} &= l_{1,0} p_{i-1,i} \\ l'_{i,i} - p'_{i,i} &= l_{i,i-1} p_{0,1} \\ l_{i,i+1} - p_{i,i+1} &= l_{i,i} p_{0,1} \\ l_{i+1,i} - p_{i+1,i} &= l_{1,0} p'_{i,i} \end{aligned} \tag{1}$$

(This four relations are defined for $i \geq 1$, $p'_{1,1} = p_{1,1}$, $l'_{1,1} = l_{1,1}$). This incidence structure $(P, L, I)$ we denote as $D(K)$. We identify it with the bipartite *incidence graph* of $(P, L, I)$, which has the vertex set $P \cup L$ and edge set consisting of all pairs $\{(p), [l]\}$ for which $(p)I[l]$.

For each positive integer $k \geq 2$ we obtain an incidence structure $(P_k, L_k, I_k)$ as follows. First, $P_k$ and $L_k$ are obtained from $P$ and $L$, respectively, by simply projecting each vector onto its $k$ initial coordinates with respect to the above order. The incidence $I_k$ is then defined by imposing the first $k-1$ incidence equations and ignoring all others. The incidence graph corresponding to the structure $(P_k, L_k, I_k)$ is denoted by $D(k, K)$.

The incidence relation motivated by the linear interpretation of Lie geometries in terms their Lie algebras. $\alpha$ belongs to the root system

$$\mathrm{Root} = \{(1,0),(0,1),(1,1),(1,2),(2,1),(2,2),(2,2)'\ldots, \\ (i,i),(i,i)',(i,i+1),(i+1,i)\ldots\}.$$

The “root system”

$$\mathrm{Root} = \{(1,0),(0,1),(1,1),(1,2),(2,1),(2,2), \\ (2,2)'\ldots,(i,i),(i,i)',(i,i+1),(i+1,i)\ldots\}$$

contains all real and imaginary roots of the Kac-Moody Lie Algebra $\tilde{A}_1$ with the symmetric Cartan matrix. We just doubling imaginary roots $(i,i)$ by introducing $(i,i)'$.

To facilitate notation in future results, it will be convenient for us to define $p_{-1,0} = l_{0,-1} = p_{1,0} = l_{0,1} = 0$, $p_{0,0} = l_{0,0} = -1$, $p'_{0,0} = l'_{0,0} = -1$, and to assume that (1) are defined for $i \geq 0$.

Notice that for $i = 0$, the four conditions (1) are satisfied by every point and line, and, for $i = 1$, the first two equations coincide and give $l_{1,1} - p_{1,1} = l_{1,0}p_{0,1}$.

Let $DE(n,K)$ ($DE(K)$) be the double directed graph of the bipartite graph $D(n,K)$ ($D(K)$, respectively). Remember, that we have the arc $e$ of kind $(l^1, p^1) \rightarrow [l^2, p^2]$ if and only if $p^1 = p^2$ and $l^1 \neq l^2$. Let us assume that the colour $\rho(e)$ of arc $e$ is $l^1_{1,0} - l^2_{1,0}$. Recall, that we have the arc $e'$ of kind $[l^2, p^2] \rightarrow (l^1, p^1)$ if and only if $l^1 = l^2$ and $p^1 \neq p^2$. let us assume that the colour $\rho(e')$ of arc $e'$ is $p^1_{1,0} - p^2_{1,0}$.

It is easy to see that the vertex set of the new graph is isomorphic to $K^{n+1} \cup K^{n+1}$. If $K$ is finite, then the cardinality of the colour set is $(|K| - 1)$. Let $\mathrm{Reg}K$ be the totality of regular elements, i.e. not zero divisors. Let us delete all arrows with colour, which is a zero divisor. New graph $RDE(t,K)$ ($RD(K)$) with the induced colouring is the automaton in the alphabet $\mathrm{Reg}(K)$.

Let $P_t(x_{1,0}, x_{0,1}, x_{11}, \ldots)$ and $R_t(x_{1,0}, x_{0,1}, x_{11}, \ldots)$ are the transition function of infinite graph $RD(K)$ of taking the neighbour of vertex from the first and second copy of the flag set for $D(K)$. The connected components of graph $D(n,K)$ can be given in the following way.

Finally we define the tuple $\mathrm{a}$ of theorem 2.

Graph $\phi(n)$ is the double flag graph for $D(k,K)$. We assume that $k \geq 6$and $t = [(n+2)/4]$. Each flag $f$ from $F_1 \cup F_2$ contains the unique point $u$ $u = (u_{01}, u_{11}, \cdots, u_{tt}, u'_{tt}, u_{t,t+1}, u_{t+1,t}, \cdots)$ of $\mathrm{D}(n,K)$ . For every $r$, $2 \leq r \leq t$, let

$$a_r(f) = a_r(u) = \sum_{i=0,r} (u_{ii}u'_{r-i,r-i} - u_{i,i+1}u_{r-i,r-i-1}),$$

and $a = a(u) = (a_2, a_3, \cdots, a_t)$. So in fact each polynomial $a_i$ depends really from $n$ variables (see [6]).

## V. Time Evaluation

We have implemented computer application, which uses family of graphs $RDE(n,K)$ for *private key* cryptography. To achieve high speed property, commutative ring $K = Z_{2^k}$, $k \in \{8, 16, 32\}$, with operations $+, \times$ modulo $2^k$. Parameter $n$ stands for the length of plaintext (input data) and the length of ciphertext. We mark by $G1$ the algorithm with $k = 8$, by $G2$ the algorithm with $k = 16$, and by $G4$ the algorithm with $k = 32$. So $Gi, i \in 1,2,4$ denotes the number of bytes used in the alphabet (and the size of 1 character in the string).

The alphabet for password is the same $K$ as for the plaintext. For encryption we use the scheme presented in section (4). The colour of vertex is its first coordinate.

If $u$ is the vertex, $p(u)$ is the colour of this vertex, and $\alpha$ is the character of password, then next vertex in the encryption path $v$ have the colour $p(v) = p(u) + \alpha$. All the next coordinates of $v$ are computed from (3) set of equations.

All the test were run on computer with parameters:

- AMD Athlon 1.46 GHz processor
- 1 GB RAM memory
- Windows XP operating system.

The program was written in Java language. Well known algorithms RC4 and DES which were used for comparison have been taken from Java standard library for cryptography purposes—*javax.crypto*.

### A. Comparison our algorithm with RC4

RC4 is a well known and widely used stream cipher algorithm. Protocols SSL (to protect Internet traffic) and WEP (to secure wireless networks) uses it as an option. Nowadays RC4 is not secure enough and not recommended for use in new system. Anyway we chose it for comparison, because of its popularity and high speed.

RC4 is not dependent on password length in terms of complexity, and our algorithm is. Longer password makes us do more steps between vertices of graph. So for fair comparison we have used fixed password length equal suggested upper bound for RC4 (16 Bytes).

# Empirically Tuning LAPACK's Blocking Factor for Increased Performance

R. Clint Whaley
Department of Computer Science
University of Texas at San Antonio
San Antonio, TX 78249
Email: whaley@cs.utsa.edu

***Abstract*—LAPACK (Linear Algebra PACKage) is a statically cache-blocked library, where the blocking factor (NB) is determined by the service routine ILAENV. Users are encouraged to tune NB to maximize performance on their platform/BLAS (the BLAS are LAPACK's computational engine), but in practice very few users do so (both because it is hard, and because its importance is not widely understood). In this paper we (1) Discuss our empirical tuning framework for discovering good NB settings, (2) quantify the performance boost that tuning NB can achieve on several LAPACK routines across multiple architectures and BLAS implementations, (3) compare the best performance of LAPACK's statically blocked routines against state of the art recursively blocked routines, and vendor-optimized LAPACK implementations, to see how much performance loss is mandated by LAPACK's present static blocking strategy, and finally (4) use results to determine how best to block nonsquare matrices once good square blocking factors are discovered.**

## I. Introduction

LAPACK [1] (Linear Algebra PACKage) is one of the most widely-used computational libraries in the world. LAPACK is the successor to the highly successful LINPACK[2] and EISPACK[3] packages. The main difference between LAPACK and its ancestor packages is that it blocks for the cache, which allows it to run orders of magnitude faster on modern architectures. Since linear algebra is computationally intensive, it is important that these operations, which are inherently very optimizable, run as near to machine peak as possible. In order to allow for very high performance with a minimum of LAPACK-level tuning, LAPACK does the majority of its computation by calling a lower-level library, the BLAS (Basic Linear Algebra Subprograms). The BLAS are in turn split into three "levels" based on how much cache reuse they enjoy, and thus how computational efficient they are. In order of efficiency, they are: Level 3 BLAS[4], which involve matrix-matrix operations that can run near machine peak, Level 2 BLAS[5], [6] which involve matrix-vector operations and are considerably slower, and Level 1 BLAS[7], [8], which involve vector-vector operations, and usually run at the speed of memory.

In order to maximize performance, LAPACK is therefore formulated to call the Level 3 BLAS whenever possible. LAPACK's main strategy for accomplishing this can be understood by examining its factorizations routines, QR, LU, and Cholesky. For each of these factorizations, LAPACK possesses two implementations: the first is an unblocked implementation that calls the Level 1 and 2 BLAS exclusively, which results in low performance. These routines are called DGEQR2/DGETF2/DPOTF2, respectively for QR/LU/Cholesky (assuming double precision). To get better performance, LAPACK has statically blocked versions of these routines (DGEQRF/DGETRF/DPOTRF), which calls the unblocked code on a subsection of the matrix, and then updates the rest of the matrix using the Level 3 BLAS (especially matrix multiply, DGEMM). The idea is that the updating of the rest of the matrix will run near peak when using a well-tuned BLAS implementation, and that this cost will dominate the unblocked factorization cost enough to allow LAPACK to be extremely computational efficient on any cache-based architecture.

Because LAPACK is such a large and complex library, allowing almost all the system tuning to occur in a smaller kernel library like the BLAS is critical, since LAPACK is too large for hand-tuners to make the individual routines computationally efficient. Through careful design, almost all platform-specific tuning has been moved to the BLAS, leaving LAPACK to concentrate on algorithm development. However, LAPACK possesses one key parameter that must be tuned to the platform to achieve maximal performance, which is the blocking factor (NB) used in LAPACK's statically blocked routines. To understand this further, we quickly overview the algorithm of DGETRF, which operates on an $M \times N$ matrix $A$: DGETF2 is called to factor an $M \times$ NB column panel of $A$ into $L$ and $U$, then an NB $\times (N - NB)$ row panel is updated using the Level 3 BLAS routine DTRSM, and these two results are then used to update the entire $(M - NB) \times (N - NB)$ trailing submatrix using DGEMM. This process is repeated, with the $M$ and $N$ above shrinking by NB each time, until the entire matrix has been factored. This type of blocked operation is roughly what occurs in a great many of LAPACK routines, including QR and Cholesky, though the details of the exact partitionings and routines used in updates vary widely.

NB cannot be chosen arbitrarily if good performance is to be maintained. NB=1 results in unblocked operation, and so defeats the whole purpose of blocked algorithms. Increasing NB typically allows the Level 3 updates to become more efficient,

This work was supported in part by National Science Foundation CRI grant SNS-0551504

as these operations have $O(N^3)$ computations which dominate the $O(N^2)$ memory references as $N$ is increased. However, we cannot set $\mathtt{NB} = N$, since this would wind up calling the unblocked code for the whole algorithm (no Level-3 updates left to do). Choosing a good NB is therefore a balancing act: making it large typically improves Level 3 performance, but as it grows, the unblocked code's performance becomes an increasing percentage of computational time, resulting in reduced performance. Therefore, the best NB is essentially unknowable a priori: it depends on the LAPACK routine being tuned, on the architecture being used, the relative performance of the Level 1 and 2 BLAS vs. Level 3 for the particular BLAS library being used, etc. The designers of LAPACK were aware of this, and so they did not hardwire the NB into the algorithm. Rather, most blocked LAPACK routines query a service routine called ILAENV for what blocking factor should be used. The LAPACK documentation stresses that users should tune this blocking factor in ILAENV for their problems of interest during install. Unfortunately, almost no users do so in practice: most are unaware that they should, and the remainder find it too hard to do. Therefore, the majority of LAPACK installations use the default blocking factors, which we show can yield significantly lower performance.

We have developed a framework for auto-tuning NB for LAPACK in order to fix this problem. This framework is part of our empirical tuning package, ATLAS [9], [10], [11]. ATLAS (Automatically Tuned Linear Algebra Package) provides empirically-tuned BLAS, and a few improved LAPACK routines. This new LAPACK tuning mechanism is part of ATLAS's empirical tuning framework, but it can be used to tune LAPACK for any BLAS, as this paper will describe.

The remainder of this paper is organized in the following way: Section II provides a quick overview of the empirical NB-tuning framework and service routines we have developed; Section III then presents results from empirically tuning LAPACK's factorization routines. We show that this can make a large difference in performance for a variety of platforms and BLAS implementations, and that these results point to a simple algorithmic change that could improve performance still further. Finally, Section IV summarizes our findings, and discusses future work.

## II. ATLAS's Empirical Tuning Framework for LAPACK

In this section we briefly overview the tools we developed for this investigation, as other BLAS users and researchers may find them useful. There are two main routines of interest, both of which appear in ATLAS's ATLAS/bin directory (assuming ATLAS version 3.9.2 or later).

The main tool is an LAPACK timer that can empirically tune NB for a variety of LAPACK routines, ATLAS/bin/lanbtst.c. This general-purpose timer links in a specialized ILAENV that allows the timer to change the ILAENV return value as part of the timing process. It can time arbitrary problem sizes, using arbitrary blocking factors, and be built against any mixture of (system LAPACK, ATLAS LAPACK, netlib LAPACK) + (system BLAS, ATLAS BLAS, F77BLAS). We presently support timing the three LAPACK factorizations: GETRF (LU), POTRF (Cholesky) and GEQRF/GERQF/GEQLF/GELQF (QR); adding additional routines is straightforward. Therefore, this timer/tuner can be used in a variety of ways to investigate performance, but here we use it to tune the blocking factor as $N$ changes. When used in this way, it generates either C macros or FORTRAN77 functions that take in the problem size, and return the best NB found by the empirical tuning for a problem of comparable size. The user can control what sizes of problems to tune, what range of NBs to try, how many times to repeat each timing, how many FLOPS are necessary to get reliable timings, etc. This timer automatically flushes the caches for realistic out-of-cache performance results, as described in [12]

To build the various LAPACK/BLAS combinations, the user fills in ATLAS's Make.inc BLASlib (system BLAS), FLAPACKlib (Fortran77/netlib LAPACK), and SLAPACKlib (system LAPACK). For instance, to tune LAPACK for the GotoBLAS installed in /opt/lib, you would fill in:

```
BLASlib = /opt/lib/libgoto_opteronp-r1.26.a \
          $(CBLASlib) $(ATLASlib)
FLAPACKlib = /opt/lib/libreflapack.a
SLAPACKlib = /opt/lib/libgoto_opteronp-r1.26.a \
             $(FLAPACKlib)
```

The LAPACK tuner's base name is x<pre>lanbtst, where <pre> is replaced by the precision prefix (eg., xdlanbtst for double precision). To this base name add a suffix indicating what variation should be timed. The suffix looks like: 'F_[f,s]l_[f,s,a]b. The first [f,s] before the 'l' chooses what LAPACK to use: fortran or system. The second part of the suffix determines what BLAS are linked in (thus the 'b' at the end): 's' links in the system BLAS, 'f' links in the Fortran BLAS (defined in the macro FBLASlib), and 'a' links in the ATLAS BLAS. To build a timer for ATLAS LAPACK with ATLAS BLAS, the make target is simply: 'xdlanbtst'. Thus, to build a tuner for the FORTRAN77 reference LAPACK linked to the GotoBLAS (assuming the above BLASlib setting), we would issue make xdlanbtstF_fl_sb. Calling the LAPACK tuner with invalid arguments or --help prints usage information.

The other tool of interest can be built with 'make xstattime'. This program reads in output from various ATLAS timers, and provides the results in a spreadsheet-friendly format. When timings are repeated multiple times, it also provides some basic statistical information (eg., average, max, min, standard deviation, etc.). If xstattime is used to compare two different runs, it uses a Student's T-Test [13] to compare whether the two means, from distributions with possibly different variances, are statistically different or not (this last feature requires a high number of samples to be reliable). Again, --help will provide more detailed usage information.

## III. Results

### A. Experimental Methodology

Version information: `gcc/gfortran 4.2`, ATLAS3.9.2 (labeled **atl**), ACML4.1.0 (**acm**), and GotoBLAS v2.91 (**got**). All performance results are gathered with a timer that flushes the caches, as described in [12]; therefore the small-case performance here may be much lower than those typically published, but more indicative of most real-world performance. Since MFLOP results are easier to understand in terms of peak performance, we report MFLOP rates rather than time. This could be problematic, in that some LAPACK routines (eg. GEQRF) do extra FLOPS as `NB` grows. In order to avoid this kind of problem, we compute the FLOP count for all algorithms as if they used the unblocked code, regardless of the blocking factor actually used. Therefore, these MFLOP results may be converted to time by simply by dividing by the FLOP count of the algorithm and inverting. The FLOP counts for (Cholesky, LU, QR) are very roughly $(\frac{N^3}{3}, \frac{2N^3}{3}, \frac{4N^3}{3})$, assuming square matrices. The exact FLOP counts can be found in LAPACK's `dopla.f`[14] routine.

Our main results are for two machines: a 2.4Ghz Core2Duo (abbreviated as **c2d**) and 2.2Ghz AMD Athlon-64 X2 (**ath**), both of which were running Kubuntu 8.04 (2.6 Linux kernel). On the **c2d**, we provide results for ATLAS[11] and Goto[15] BLAS: we are unable to provide results for Intel's MKL[16], since their libraries are not freely available for academic use. On the AMD system, we provide results for ATLAS, GotoBLAS, and AMD's ACML[17]. For both these machines, we time 64-bit libraries (which tend to have better performance than 32-bit). Unless otherwise specified, all timings were taken with a cycle-accurate wall-time, all results are the best of eight runs, with small problems being repeated within the timing interval to avoid resolution problems, as described in [12]. We also present a small subset of results for a 900Mhz Itanium 2 system. The Itanium is not featured more prominently because we only have ATLAS results on this machine: MKL was not available, and the GotoBLAS seg faulted during installation when compiled with `gcc 4.2` (we know GotoBLAS install without error with `gcc 3.x` on this platform, but were unable to install `gcc 3.x` on the Itanium in time for this paper). As it is, the limited Itanium results are provided mainly to demonstrate that this technique is in no way x86-specific. The Itanium timings use Linux's `gettimeofday` as the system timer.

### B. Tuning Speedups and Performance Overview

Figure 1 shows the performance in MFLOP for the appropriate BLAS's `DGEMM`, and netlib LAPACK's factorizations, using various BLAS. For each problem size in each figure, the first three bars are timings on the **ath**, while the last two are on **c2d**. The first column (white with black horizontal bars) uses ACML BLAS on **ath**, the second column (solid blue/gray) uses ATLAS BLAS on **ath**, the third column (slanting cross-hatching) uses GOTO BLAS on **ath**, the fourth column (textured solid blue/gray) uses ATLAS BLAS on **c2d**, and the final column (square cross-hatching) uses GotoBLAS on **c2d**.

The DGEMM timings of Figure 1(a) should provide an estimate on the peak performance the respectively libraries can achieve on these platforms. The Core2Duo has twice the theoretical peak of the Athlon-64, and so we see that the **c2d** is considerably faster regardless of the library. On the **ath**, the libraries' DGEMM performance is roughly equal, with ATLAS trailing ACML and GotoBLAS slightly (roughly 3%) for large problems. On the Core2Duo, the GotoBLAS have a noticable advantage, particularly for small problems.

Figures 1(b-d) show the performance of `DGEQRF` (QR), `DGETRF` (LU), and `DPOTRF` (Cholesky), respectively. Each of these timings is for the netlib LAPACK's factorization routine using the default blocking factor returned by the stock `ILAENV` (`NB` = 32, 64, and 64, respectively). It is the performance of these routines that we show can be improved with an empirical tuning of `NB`. On the **ath**, all libraries have similar performance, with the GotoBLAS doing generally better for small problems. We will see that tuning for the blocking strongly improves small-case performance, particularly for `ATLAS` and `ACML`, which are weak for small problems when using the default `NB`.

We then used the ATLAS infrastructure to tune the blocking factor for each operation on each architecture. We don't have room for full results, but blocking factors for all `DGEQRF` and some `DPOTRF` settings are shown in Table I. We give full results for `DGEQRF`, because neither the ATLAS nor GotoBLAS libraries supply an optimized version of this routine (they *do* supply optimized `DGETRF` and `DPOTRF`, as we will see in Section III-D). Therefore, the LAPACK version we tune here is actually the best one available when using these libraries. The `DGETRF` results are very similar to those for QR, but `DPOTRF` is very different, so we show full `DPOTRF` results for the Athlon-64 architecture.

For QR, the general trend is that the larger the problem, the larger the best blocking factor, up until a maximum is reached. This maximum represents the point at which the DGEMM performance gain from further increasing `NB` is offset by the performance loss due to spending greater time in the unblocked code. If we can optimize the unblocked part of the algorithm (a promising approach for doing this is outlined in Section III-C), then we can almost certainly increase performance further by using larger blocking factors for large problems.

`DPOTRF` looks very different, in that `NB` has apparently stopped growing only for ACML. One advantage Cholesky has over LU is that it doesn't require pivoting, which makes the unblocked portion of the algorithm much cheaper. In LU or QR, vastly increasing `NB` will speed up DGEMM, but the corresponding slowdown in the unblocked code will make it a net loss. Since the unblocked cost is relatively trivial in Cholesky, the block factor is free to grow much larger before the unblocked costs become prohibitive. There is further pressure in Cholesky for larger blocking factors: Cholesky's performance is strongly affected not only by DGEMM, but

also DSYRK. DSYRK's performance, like DGEMM, grows strongly with problem size.

We note that the GotoBLAS DGEQRF's NB on the **c2d** is still growing at our last problem size, though it is nowhere near as large as the Cholesky block. There are probably at least two factors in play here. The first is that such an excellent DGEMM (Goto achieves as much as 94% of theoretical peak) can hide quite a bit of poor unblocked performance before being washed out. The second reason the GotoBLAS's blocking factor is still growing is linked to the fact that the GotoBLAS block for the Level 2 cache, which we discuss further below.

Figures 2(b-d) show the % improvement from empirically tuning NB for a range of problem sizes for each BLAS library; each of Figures 2(b-d) shows the % improvement over the MFLOP rates provided in Figures 1 (b-d), respectively. More specifically, the X-axis of Figure 2 is computed as: $100.0 \times \left(\frac{\texttt{NB-tuned factorization performance}}{\texttt{default-blocked factorization performance}}\right)$. Since LAPACK's default NB is chosen to optimize mid-range problems, it is unsurprising that the general trend is that tuning NB helps most for small and large problems, with less benefit generally in the middle areas. We notice that the tuning is particularly helpful in the small-case problems for ACML and ATLAS, which displayed relatively poor performance in this area when using the default blocking factors. For large problems, we see that the **goto** BLAS on the Core2Duo almost always show substantial speedups. This is probably due to the fact that the GotoBLAS block for the L2 cache [18], and thus utilizing a larger block factor as $N$ is increased allows the factorization's GEMM calls to perform nearer peak. In Figure 2 (b), we see that ATLAS on the Core2Duo shows substantial speedups across the entire range. This is mainly due to their being a mismatch between the default NB of 32, which is not large enough for ATLAS's DGEMM to reach its full potential. All in all, we observe substantial speedups for both small (as high as 30%) and large (as high as 20%) problems.

In order to demonstrate that there is nothing x86-specific in this tuning advantage, Figure 2 (a) shows the improvement from tuning LAPACK's factorizations using the ATLAS BLAS on a 900Mhz Itanium 2. We see a huge (as much as 75%!) improvement for small cases when NB is tuned; large problems are improved substantially (as much as 15%).

With these results, we see that the empirical tuning of LAPACK's factorization routines provides substantial speedups, and it seems this should hold for most of LAPACK's blocked routines. Therefore, we strongly believe that this is a simple, general technique that can be used to markedly increase the performance of an overwhelming majority of LAPACK routines.

### C. *Tuning NB for Non-Square Problems*

Many LAPACK routines operate on non-square matrices, and some operate almost exclusively on highly rectangular arrays. In particular, many service routines operate on matrices where one dimension is constrained to the blocking factor of a higher-level routine (for instance, N is always 64), but the other dimension is unconstrained (and so might be something like 1000). For this discussion, the constrained (small) matrix dimension will be referred to as the *minor dimension*, while the unconstrained dimension is the *major dimension*. Both LU (DGETRF) and QR (DGEQRF) can operate on nonsquare matrices, so we use these operations to probe nonsquare behavior.

One obvious idea is to attempt to use the blocking factors discovered in the square matrix tuning for non-square. Obviously, we can't use the major dimension to select the tuned NB, since blockings greater than the smallest dimension of the matrix don't make sense (assuming the square blockings used in LAPACK). Therefore, our first question is: how much performance is lost if we use our square-tuned NBs, where our decision is based on the minor dimension? Table II provides the answer to this question.

In Table II, we have surveyed all three libraries on the **ath** architecture, with varying operations. The first column gives the architecture, library, and LAPACK operation, the second column indicates which dimension (matrix is $M \times N$) is constrained, and to what value it is constrained to. The third column indicates the blocking suggested by our square-tuned NBs, where NB choice is based on the indicated minor dimension. Then, for this minor dimension, we tune the blocking factor for a variety of major dimension sizes. For each size, we report the best blocking factor found, and in parenthesis, the percentage of its performance that the square-tuned NB achieves.

While the details change with architecture, operation, and matrix dimensions, several important trends are immediately obvious. The first is that if the operation is called on these

TABLE II
SELECTED RESULTS FOR TUNING NB FOR NON-SQUARE PROBLEMS. FOR EACH PROBLEM SIZE, WE REPORT BOTH THE BEST NB, AND, IN PARENTHESIS, THE % OF ITS PERFORMANCE THAT WE GET USING THE SQUARE-TUNED NB WITH N = MIN(M,N).

| **arch/** | **minor** | **square** | **Major Dimension** | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| **lib/op** | **dim** | **NB** | 50 | 100 | 300 | 500 | 1000 | 2000 | 10000 |
| ath/acml/QR | M=32 | 12 | 1(74%) | 1(84%) | 8(100%) | 12(100%) | 12(100%) | 12(94%) | 16(93%) |
| ath/acml/QR | N=32 | 12 | 1(76%) | 1(90%) | 8(100%) | 8(97%) | 8(92%) | 8(92%) | 8(83%) |
| ath/acml/QR | N=64 | 12 | 1(82%) | 16(98%) | 8(x4%) | 8(99%) | 8(97%) | 8(100%) | 8(88%) |
| ath/goto/QR | M=32 | 4 | 1(79%) | 12(89%) | 16(81%) | 16(78%) | 24(64%) | 24(61%) | 24(65%) |
| ath/goto/QR | N=32 | 4 | 1(73%) | 1(78%) | 1(84%) | 16(85%) | 8(89%) | 8(92%) | 8(92%) |
| ath/atlas/LU | N=32 | 8 | 8(100%) | 8(100%) | 8(100%) | 12(99%) | 12(97%) | 12(95%) | 8(100%) |
| ath/atlas/LU | N=64 | 16 | 8(98%) | 16(100%) | 12(94%) | 12(92%) | 12(92%) | 12(94%) | 12(84%) |

highly nonsquare shapes, then it makes sense to tune for it explicitly, as the best rectangular NB may substantially outperform the square-tuned cases (this is particularly true for the GotoBLAS). Even for a given minor dimension, we see that the best NB often grows as the major dimension is increased; this observation alone is a strong indication that even very well-tuned square-case NBs will not provide optimal non-square results as the gap between minor and major dimensions grow. Another take-home lesson from this table is that the best tuning parameter for a column panel (eg, minor dimension is N) is not necessarily the same as that for an equal-sized row panel (minor dimension is M): row panels tend to need larger NBs, (this would provide more TLB reuse, which is not a problem for column panels).

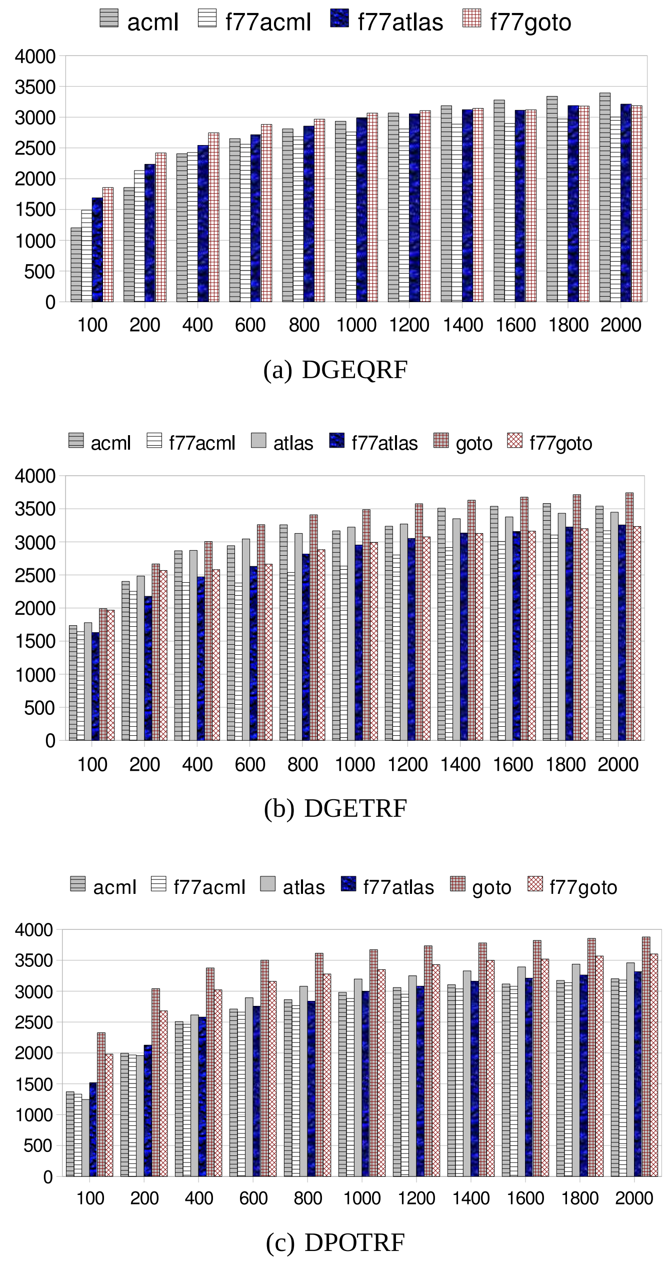
This table also points us to an obvious way to speed up LAPACK beyond merely tuning the blocking factor. Note that choosing NB=1 in these timings essentially means that the unblocked service routines (DGETF2 for DGETRF and DGEQR2 for DGEQRF), which call the Level 1 and 2 BLAS only, are used instead of the Level-3 BLAS-based blocked implementations. Blocked LAPACK routines typically call their unblocked equivalents with one dimension (usually $M$) set to the size of the original problem (in the first step; its size will decrease by NB during each iteration), while the second dimension is set to NB. DGETRF will factor an $M \times \mathtt{NB}$ portion of $A$ into L and U using the unblocked routine DGETF2 in its first step. Now, if we assume NB is 32 or 64, then Table II actually shows the performance we can expect from a NB-tuned DGETRF (DGEQRF) routine when used in place of DGETF2 (DGEQR2). Anytime the best NB $\neq 1$, then it would be faster to have the blocked routine call a second blocked routine, which uses the smaller blocking factor indicated in the appropriate column of the table. Unfortunately, we don't have room to indicate how much of a performance win this would be for all table entries, but we can bring out a few highlights: For $N = 1000, N = 64$, the tuned blocked implementation is (1.67,1.34,1.76) times faster than the unblocked implementation of (**ath**/ACML/QR, **ath**/Goto/QR, **ath**/ATLAS/LU), respectively. Note that this would allow LAPACK's statically blocked routines to block the "unblocked" code, just as the recursive formulation does, which is key, in that it allows the outer implementation to use larger blocking factors, and thus achieve a higher percentage of DGEMM peak (i.e., the speedup from this technique can go beyond that of merely speeding up the "unblocked" code, since faster "unblocked" code means that we can afford a large NB, which may substantially improve DGEMM performance).

### *D. Tuned Reference vs. Library-Provided LAPACK*

The surveyed optimized libraries (ACML/ATLAS/Goto) provide LAPACK routines in addition to the BLAS. The natural question is how well do the empirically tuned reference LAPACK routines compare with their optimized-library counterparts. The answer is surprisingly well, as we can see in Figure 3. In this figure, we compare the performance of various implementations of DGEQRF, DGETRF, and DPOTRF on the Athlon-64. The native implementations (i.e. LAPACK routines present in the optimized library) are annotated with only the library name (eg., "acml"), while the version that use the netlib FORTRAN77 reference implementations with an empirical tuning step have f77 prefixed to the library that provided the BLAS (eg., "f77acml" is the reference implementation of the LAPACK routine from netlib, with the blocking factor empirically tuned for the ACML BLAS).

Figure 3 (a) shows the performance of various implementations of DGEQRF on selected problem sizes on the Athlon-64 (the number of problem sizes shown has been reduced as an aid to legibility). As mentioned, neither GotoBLAS nor ATLAS provides a native QR, so for these libraries we show only the performance of the tuned netlib LAPACK. ACML provides a native QR, and so we see its performance as the first bar for each problem size. For small problems, it is the worst performing QR, with the best performance coming from the empirically tuned LAPACK using the GotoBLAS. For large problems, ACML's native implementation provides the best performance.

For LU factorization (Figure 3 (b)), all libraries provide a native routine, and the native routines beat their tuned netlib versions across the entire surveyed range. For small problems, there is little gap between the f77 and native implementations, but this gap gets noticeably larger for large problems, particularly for the GotoBLAS library. The same basic trend is seen for Cholesky (Figure 3 (c)), with the marked exception of the GotoBLAS-optimized DPOTRF. The GotoBLAS provides a noticeably superior Cholesky regardless of LAPACK used,



(a) DGEQRF

(b) DGETRF

(c) DPOTRF

Fig. 3. Tuned reference vs. library-provided (native) LAPACK on the Athlon-64. Native routines have same pattern as reference, but the background color is light gray rather than white (or blue/dark gray for ATLAS). From left to right: ACML-LA+ACML-BLAS, NETLIB-LA+ACML-BLAS, ATLAS-LA+ATLAS-BLAS, NETLIB-LA+ATLAS-BLAS, GOTO-LA+GOTO-BLAS, NETLIB-LA+GOTO-BLAS (there is no ATLAS- or GOTO-provided DGEQRF, and so these bars do not show up in figure (a)).

but its native implementation is commandingly better for small problems.

These results are fairly easy to understand for ATLAS: ATLAS uses recursive implementations (based on the work of [19], [20], [21]) of LU and Cholesky, and for large problems it is expected that the much larger DGEMM calls seen at the top of the recursion will naturally lead to the performance advantage we see for large problems. Recursion is essentially the only advantage ATLAS has over netlib LAPACK: we don't currently do any system tuning at this level. For Cholesky, the ATLAS `DPOTRF` actually loses to the empirically-tuned netlib LAPACK. This is probably due to recursive overhead: remember that in LU and QR, the recursion cuts only the $N$ dimension, while in Cholesky it cuts both dimensions, which leaves very few operations over which to amortize the cost of the recursive calls. It seems likely that if the unblocked code in LAPACK was replaced with blocked code, as discussed in Section III-C, that the netlib LAPACK could win for small problems on LU as well, again mostly due to overhead savings. It seems unlikely that even this improved version could compete for very large problems: the recursive advantage should grow with problem size, so eventually recursion will begin to win for large enough matrices. However, the gap is not too large for the problem sizes surveyed here, so with better unblocked code, it is possible the netlib LAPACK could be made to run competitively across this entire range.

It is difficult to know what the other libraries are doing to produce these performance curves. GotoBLAS does get better `DSYRK` (particularly small-case) performance than ATLAS, which in turn gets much better `DSYRK` performance than ACML, which probably helps explain `DPOTRF` results. GotoBLAS's small-case performance advantage is large enough that there are probably additional factors needed to explain this gap, however.

## IV. Summary and Future work

We have presented a survey of factorization performance on two important architecture families (with a few results from a third). Using our empirical tuning system, we have demonstrated that tuning `NB` can provide substantial performance improvements regardless of BLAS used or the architecture it runs on. This simple tuning can be extended to speed up an overwhelming majority of LAPACK routines, in addition to the factorizations discussed here. We note that many routines may be further improved by rewriting them as recursive algorithms, but this is not currently possible for several important LAPACK routines. Therefore, empirically-tuned `NB` LAPACK implementations of such routines would actually represent the best available implementations today. Even in the case where recursive formulations are possible, we have shown that statically-blocked LAPACK performance can be made competitive with these techniques. We have also investigated tuning for nonsquare matrices, which could improve the performance of many of LAPACK's service routines, and this investigation has pointed out a straightforward adaptation of LAPACK's present strategy that can yield further performance improvements without requiring LAPACK to be rewritten in languages supporting recursion.

### A. Future work

In this paper, we concentrated on the factorizations, since they are probably the most widely used routines in the library (they are called by many higher-level routines, in addition to being called directly), in addition to being well understood routines which possess optimized implementations we can compare against. The tuning framework can be easily extended to other operations, and we plan to do so (we are particularly interested in tuning additional routines used in finding eigenvalue/vectors). The framework already allows other data types/precisions to be tuned, and probing the effect of varying type and precision on optimal blocking is an experiment worth doing. This investigation concentrated on serial performance: an obvious extension of great interest would be to see how results vary when the same libraries are used, but threading is enabled. Finally, our investigations pointed to significant speedups if we block the present unblocked codes with the small blocking factors discovered in our rectangular tuning. This should be investigated for the factorizations, and see how the resulting performance stacks up against state-of-the-art recursive formulations. If successful here, we should see if this technique can be used on some of the LAPACK routines that do not currently possess recursive formulations.

# Computational Linguistics—Applications

ACCORDING to the European Commission, Human Language Technologies are one of the key research areas for the upcoming years. The Computer Linguistics—Applications Workshop is in part a response to the fast-paced progress in the area.

The workshop will focus on the applied aspect of Computer Linguistics, i.e. the practical outcome of modeling human language.

The aim of the Applied Computer Linguistics is to enable the user to communicate with the computer in his/her native language. This may be useful for retrieving information from databases or raw texts as well as controlling a robot (virtual or real). Computer Linguistics may help communicate people with each other by means of computerized translation. Computer Linguistics is applied to make the full use of the Internet: we need software that can handle texts if we want to find the information we need in the web.

Furthermore, because of its location within the framework of the IMCSIT conference, we hope to initiate dialog between researchers involved in Computer Linguistics and other areas of information technology to build bridges between disciplines and find a way of applying CL-based tools in other areas. In this spirit, we invite papers that present research on all aspects of Natural Language Processing such as (this list is not exhaustive):

- machine translation and translation aids
- proofing tools
- semantic ontologies in computer linguistics
- lexical resources
- POS-tagging
- corpus-based language modeling
- extraction of linguistic knowledge from text corpora
- ambiguity resolution
- parsing issues
- information retrieval
- text classification

In addition to theoretical papers, we invite all participants to present practical demonstrations of existing tools. We require the papers to include a section describing an existing tool (or a prototype), which demonstrates the theory.

We intend the workshop to be a demo session. In the first part of the workshop the authors will shortly (no longer than 5 minutes each) demonstrate their tools to the audience. For the second part we will arrange environment in which authors will be able to present their software and discuss it with other conference participants.

The best demonstrations will be elected to be shown to the audience of the conference at a plenary session.

***Abstract*—In this paper, we try to fathom the real impact of corpus quality on methods performances and their evaluations. The considered task is topic-based text segmentation, and two highly different unsupervised algorithms are compared: $C99$, a word-based system, augmented with $LSA$, and $Transeg$, a sentence-based system. Two main characteristics of corpora have been investigated: Data quality (clean vs raw corpora), corpora manipulation (natural vs artificial data sets). The corpus size has also been subject to variation, and experiments related in this paper have shown that corpora characteristics highly impact recall and precision values for both algorithms.**

## I. Introduction

THERE are several distinct tasks labeled as ‘text segmentation’, among which **topic-based text segmentation** is the particular process that tries to find the topical structure [8] of a text and thus provide a possible thematic decomposition of a given document [17]. It relies on the evidence that most texts do not talk about only one topic and the longer the documents, the more topics they include. There are several definitions of a topic in the relevant literature. Generally speaking, a topic is: *the subject matter of a conversation or discussion*. In linguistics, it is defined as: *the part of the proposition that is being talked about (predicated)*. In this paper we do not consider the formal definition of topic, but the more commonly admitted definition that a topic of a text is *what talking is about*. So, the goal of an automated text segmentation could be simplified into dividing a text in segments, each sentence of which ’talks about’ the same subject. Segments are supposed to be distinct, and coherent [14].

Text segmentation, whether topic-based or not, has been thoroughly evaluated in several campaigns (in several TREC (Text Retrieval Evaluation Conference) editions, as well as in its French equivalent DEFT (Défi Fouille de Textes), especially in the DEFT 2006 session devoted to text segmentation [1]). However, if protocols (concatenating texts like in [7]), methods [2], and measure metrics [16] have been evoked, the corpora features have not been at the center of the attention. Apart from some general characteristics such as corpus lengths (in words, sentences or MBytes), or origin (e.g. news [20], newspapers or magazine articles [9]), corpora seem to have escaped their own evaluation procedure.

As participants in several text retrieval evaluation campaigns, we have been accustomed to dealing with corpora that were provided by the challenge organizing committees, and thus, not tailored for our demonstration needs. We have noticed that, the same algorithm, run on different corpora, had its results highly impacted by two items:

- The ’cleanliness’ of the corpus: Does it contain typos, unreadable words, several punctuation marks, unanticipated abbreviations, ill-formed sentences? All these elements could prevent some algorithms, especially those relying on NLP techniques such as syntactic and semantic analysis, from obtaining the results they are supposed to produce.
- The ’naturality’ of the corpus: Is it an artificially generated set of words, obtained through concatenation of segments or texts of different origins, or is it a real document or collection of documents, written in a given style, addressing a given subject, and so forth? Artificial corpora could favor techniques sensitive to clean cuts in topics, whereas natural corpora would introduce a higher difficulty, since transitions are smoother, and so topic shifting more difficult to detect.

In this paper, we try to fathom the real impact of corpus quality on the performances of topic-based segmentation methods. We have set up an experiment using two unsupervised segmenting algorithms, Choi’s $c99$ [7], a renowned segmenting method, and $Transeg$ [10], [18]. We chose unsupervised methods because they are not attuned to corpus idiosyncrasies as supervised methods are: Corpus adjustment by learning would have prevented us from studying the impact of its quality. The second reason for this choice is that both algorithms highly differ methodologically: The first is lexical, based on words frequencies, and neglects syntactical or rhetorical information, the second is more sentence or segment oriented, based on syntactic parsing and sentence semantics calculus, and is not sensitive to frequencies. The difference is crucial. A pending question is always the robustness issue: Would a lexical based system be less sensitive to an ’raw’ corpus than a sentence based system? Would it be more sensitive to an artificial corpus of concatenated texts, where differences in topics are neat and precise? This would mark a differential approach to quality sensitivity, and we wanted to know whether this feeling was justified or not.

978-83-60810-14-9/08/$25.00 © 2008 IEEE

In section 2, we present both methods, their features and characteristics. In section 3, we describe our experiment and the working hypothesis that we have tried to evaluate. As it will be seen in results comments(section 4) and in conclusion (section 5), the impact of on precision/recall performances of both algorithms isn't to be ignored. But interesting differences are pointed out when matching both items (i.e. clean/dirty vs natural/artificial) distinct values. We hope this will help evaluation campaigns organizers shape up test corpora that will be as reliable and as discriminant as possible for the running methods they intend to evaluate.

## II. A brief overview of $c99$ and $Transeg$

In this section we present the two methods we compared during our experiments: the well known $c99$ algorithm [6] and $Transeg$ the method we are currently developing. Both are unsupervised and thus corpus free approaches.

### A. C99

Developed by Choi, $c99$ is a text segmentation algorithm strongly based on the lexical cohesion principle [15]. It is, at this time, one the best and most popular algorithms in the domain [2], which convinced us to choose it as a baseline for our experiments.

$C99$ uses a similarity matrix of the text sentences. First projected in a word vector space, sentences are then compared using the cosine similarity measure (by the way, the most used measure). Similarity values are used to build the similarity matrix. More recently, Choi improved $c99$ by using the Latent Semantic Analysis (LSA) achievements to reduce the size of the word vector space [7].

The author then builds a second matrix known as the *rank matrix*. The latter is computed by giving to each cell of the similarity matrix a rank equal to the number of cases around the examined one (in a layer) which have a lesser similarity score. This rank is normalized by the number of cases that were really inside the layer to avoid side effects.

$C99$ then finds topic boundaries by recursively seeking the optimum density of matrices along the rank matrix diagonal. The algorithm stops when the optimal boundaries returned are the end of the current matrix or, if the user gave this parameter to the algorithm, when the maximum number of text segments is reached. By definition, $c99$ always retrieves the first sentence of a text as a the beginning of a new topic (which is obviously true). Choi's original experiments in both cited papers use an 'artificial' corpus, created by concatenating multiple texts. So, retrieving text boundaries in a concatenation and segmenting topically a text have been considered as equivalent tasks by the authors.

All experiments in this paper have been conducted using the original latest version of the algorithm (it can be found at http://myweb.tiscali.co.uk/freddyyychoi/) to avoid any implementation bias. So testing $c99$ on natural, non concatenated texts provides information about its behavior in an environment different from the original protocol.

### B. Transeg

$Transeg$ is also based on a vectorial representation of the text and on a precise definition of what a *transition* between two text segments should be. It has been developed with a sentence parser, and until now, experiments and results have been obtained for the French language. A shifting to any other language is naturally possible, provided that a syntactic parsing occurs and the language words are dipped into a Roget-based representation. Since this system has not yet been as widely described as $c99$, we focus on its principles for the sake of information.

*1) Text Vector Representation:* The first step is to convert each text sentence into a semantic vector obtained using the French language parser SYGFRAN [3]. Vectors are mathematical representations of the Roget Thesaurus indexing each English word with a set of $1043$ concepts [19], but 'exported' to French, through the local Roget equivalent, the Larousse thesaurus [11] . Sentence vectors are recursively computed by linearly combining sentence constituents, in turn computed by linearly combining word vectors. The weights of each word vectors are computed according to a formula relying on a constituents and dependencies syntactic analysis (The formula is given in [4]). So, sentence vectors bear both the semantic and the syntactic information of the sentence, but are not sensitive to words frequencies.

*2) Transition zones and boundaries: How to detect topic shifts:* In well written structured texts, the transition between a topic and the next one is not abrupt. An author should conclude one topic before introducing another.This specific part of text between two segments is waht we call a **transition zone**. Ideally, the transition zone should be composed of two sentences:

- The last sentence of the previous segment.
- The first sentence of the beginning new segment.

$Transeg$ tries to identify these two sentences in order to track topic boundaries.

*a) Transition score and the beginning of a new segment:* The **transition score** of a sentence represents its likelihood of being *the first sentence of a segment*. Each sentence of the text is assumed to be the first of a $10$ sentences long segment. This 'potential segment' is then compared with another one composed by the $10$ preceding sentences. The $10$ sentences size was chosen by observing results on the training corpus of French political discourses in the DEFT06 competition, segmented by human experts. Competitors such as [10] noticed that the average size of a segment was around $10$ sentences $(10.16)$ with a $\sigma$ of $(3.26)$. So they decided to use this empirical value as the standard segment size. However, this value has no impact on boundaries detection. Any other might fit as well.

To compute the score of each sentence, $Transeg$ slides a $20$ sentences long window along the text, considering each half of the window as a potential segment. The latter is then represented by one vector, calculated as a weighted barycenter of its sentence vectors (which are designated as centroid in figure 1). Stylistic information was added by giving a better weight to first sentences, relying on the fact that introductions bear important information [13],[12]. Then a 'thematic' distance is calculated between the two barycenters, and is considered as the window *central sentence transition score* (figure 1). It is computed according to the augmented concordance distance formula defined in next paragraph.

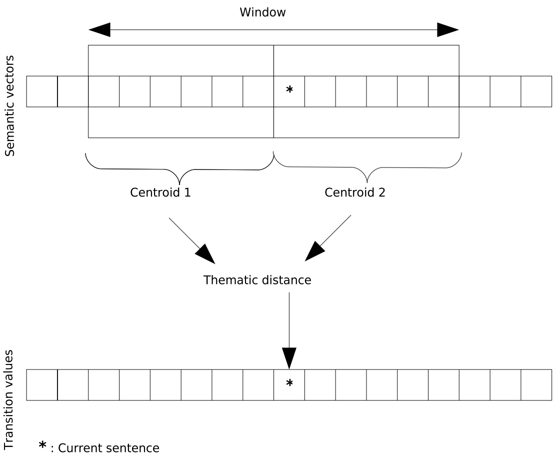

Fig. 1. The transition score of a sentence represent its likelihood of being the first sentence of a segment

*b) Concordance distance:* Semantic vectors resulting from parsing and semantic calculus have $873$ components and most of which having null values. Therefore, either cosine or plain angular distance are not able alone to finely detect a shift in direction. The goal of the concordance distance is to be more discriminant by considering vectors components ranks as well as their values. For the purpose of being more discriminating, we developed the concordance distance, which is itself based based on the concordance measure presented in [5].

Considering $\vec{A}$ and $\vec{B}$ two semantic vector representing respectively two sentences $A$ and $B$. Their values are sorted from the most activated to the least activated and only $\frac{1}{3}$ of the original vectors is kept. $\vec{A_{sr}}$ and $\vec{B_{sr}}$ are respectively the sorted and reduced versions of $\vec{A}$ and $\vec{B}$.

Obviously, if both vectors have no common components then their distance is set to 1. If $\vec{A_{sr}}$ and $\vec{B_{sr}}$ have common components, two differences are necessary to evaluate their 'distance':

— THE RANK DIFFERENCE: if $i$ is the rank of $C_t$ a component of $\vec{A_{sr}}$ and $\rho(i)$ the rank of the same component in $\vec{B_{sr}}$, the rank difference is calculated as:

$$E_{i,\rho(i)} = \frac{(i-\rho(i))^2}{Nb^2 + (1+\frac{i}{2})} \tag{1}$$

Where $Nb$ is the number of values kept in the sorted vector.

— THE INTENSITY DIFFERENCE: One has to compare the intensity of common strong components. If $a_i$ is the intensity of $i$ rank component from $\vec{A_{sr}}$ and $b_{\rho(i)}$ the intensity of the same component in $\vec{B_{sr}}$ (its rank is $\rho(i)$), then intensity difference is given by the formula:

$$I_{i,\rho(i)} = \frac{\left\| a_i - b_{\rho(i)} \right\|}{Nb^2 + (\frac{1+i}{2})} \tag{2}$$

These two differences allow us to compute an intermediate value $P$:

$$P(\vec{A_{sr}}, \vec{B_{sr}}) = \left(\frac{\sum_{i=0}^{Nb-1} \frac{1}{1+E_{i,\rho(i)} * I_{i,\rho(i)}}}{Nb}\right)^2 \tag{3}$$

As $P$ concentrates on components intensities and ranks, the overall components direction is introduced by mixing $P$ with the classical vector angular distance. If $\delta(\vec{A}, \vec{B})$ is the angular distance between $\vec{A}$ and $\vec{B}$, then:

$$\Delta(\vec{A_{sr}}, \vec{B_{sr}}) = \frac{P(\vec{A_{sr}}, \vec{B_{sr}}) * \delta(\vec{A}, \vec{B})}{\beta * P(\vec{A_{sr}}, \vec{B_{sr}}) + (1-\beta) * \delta(\vec{A}, \vec{B})} \tag{4}$$

Where $\beta$ is a coefficient used to give more weight (or less) to $P$. $\Delta(\vec{A_{sr}}, \vec{B_{sr}})$ is the *concordance value*, presented in [4]. It is easy to prove that neither $P$ nor $\Delta(\vec{A_{sr}}, \vec{B_{sr}})$ are symmetric. But $Transeg$ needs a symmetric value (a distance). To have one, we just have to compute an average between $\Delta(\vec{A_{sr}}, \vec{B_{sr}})$ and $\Delta(\vec{B_{sr}}, \vec{A_{sr}})$:

$$D(\vec{A}, \vec{B}) = \frac{\Delta(\vec{A_{sr}}, \vec{B_{sr}}) + \Delta(\vec{B_{sr}}, \vec{A_{sr}})}{2} \tag{5}$$

*c) Practical example of the concordance distance: :* If we considerate these two sentences:

- "Car overuse has a disastrous impact on the environment and more precisely on the global warming."
- "Our new car model only emit $127g$ of $CO_2$ per miles, be kind to the environment, buy a X car !"

Both sentences speak about environment and cars, but the first sentence is about ecology, the second sentence is an advertisement for a car. If we represent both sentences with semantic vectors:

- $\vec{Ph_1} = [0,0,0,0,0,1,0,0,0,0,2,0,0,0,0]$ for the first sentence.
- $\vec{Ph_2} = [0,0,0,0,0,2,0,0,0,0,1,0,0,0,0]$ for the second sentence.

Where the sixth value of vectors is the CAR concept and the eleventh the ECOLOGY concept[1]. If we compute a normalized angular distance[2] between the two vectors, we obtain a value of $0,41$. Which means that the to sentences are close enough to be part of the same topic (see next paragraph for the threshold value).

If we compute a concordance distance between the two sentences, the result is $0.56$ (rounded down). Such a value undoubtly differentiate the two sentences.

*d) Transition zones:* Once each sentence has a transition score, parts of the text where boundaries are likely to appear are identified. These zones are successive sentences with a score greater than a determined threshold $S$ (figure 2). Since the ideal transition zone is assumed to be a two sentences long text segment, isolated sentences are ignored. Distance helps

[1] The representation as been greatly simplified for the purpose of the demonstration

[2] The result would be between 0 and 1 instead of 0 and $\frac{\pi}{2}$

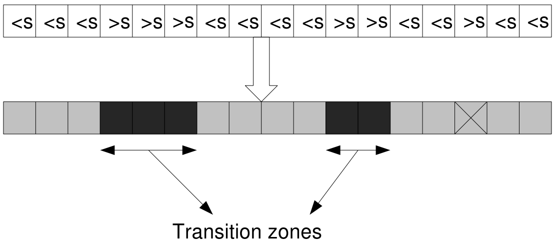

Fig. 2. Identifying transition zones

comparing sentences, but cutting a text into segments needs a maximal distance value acting as a threshold. The chosen one for $D$ (formula 5) is $0.45$, also empirically deduced, like the $10$ sentences segment size. In order to know whether it is corpus dependent or not, $Transeg$ designers browsed two other corpora segmented by human experts, and belonging to the fields of computer science and law (available for the same edition of the DEFT06 competition mentioned before). The threshold seemed to remain constant on these data. This is not a proof that it is completely corpus independent, and needs to be further investigated. However, at a first attempt, it resisted variation, and authors assumed it to be representative of a 'natural trend' of topical discrimination, among other criteria, of course.

The augmented concordance distances were computed between all identified text segments and as a result, the average distance of $0.45$ with a $\sigma$ of $0.08$ appeared to be clearly identified.

*e) Ending sentences and breaking score :* Identifying boundaries inside transition zones needs information about topic ending. The transition score of a sentence is defined as its likelihood of being the first sentence of a segment. The **breaking score** is a sentence likelihood of being *the last sentence of a segment.*

It is obvious that the last sentence of a topic should conclude the topic and more or less introduce the next topic. So the thematic distance of this sentence to its segment should be quite equal to the thematic distance of this sentence to the next segment. The breaking score $B_i$ of the $i$ sentence is:

$$B_i = 1 - |D_p - D_n| \tag{6}$$

Where $D_p$ is the thematic distance of the sentence to the previous segment and $D_n$ the thematic distance of the sentence to the next segment. The closer $D_p$ and $D_n$ are to each other, the closer to $1$ $B_i$ is.

The last step of $Transeg$ method consists in multiplying the transition score of each sentence of a transition zone with the breaking score of the previous sentence. The higher score has high probabilities of being the first sentence of a new segment.

## III. Experiment

The two methods presented in the previous section are obviously quite different, even though tackling the same task and belonging to unsupervised methods. $C99$ concentrates on lexical cohesion to find topic segments by regrouping them. $Transeg$, on the opposite, concentrates on supposed characteristics of topic boundaries to identify them.

To test the incidence of corpus quality and origin on both $c99$ and $Transeg$ results, we used four different corpora during this experiment, impersonating the four variations of our pair of items (clean/raw, natural/artificial).

### *A. Corpus descriptions*

— A 'clean and natural' corpus (Corpus CN). Consisting in $22$ French political discourses extracted from the DEFT'06 training corpus [1]. These discourses have been segmented by human experts into topic segments, and have been cleaned from the noise (typo errors, full capital sentences, etc.). To impersonate this situation, we did not concatenate them. Corpus size: $54,551$ words, $1,895$ sentences.

— A 'raw and natural' corpus (Corpus RN). Consisting in many French political discourses extracted from the same data pool than the previous corpus. Also segmented by human experts, these discourses display lots of noisy items (many typo errors and full capital sentences for example, which in French often introduces diacritics errors). Corpus size: $69,643$ words, $2,214$ sentences.

— A 'clean and artificial' corpus (Corpus CA). Consisting on $134$ concatenated short news from the French news paper "Le Monde". For this corpus each short news is considered as a topic segment. Corpus size: $50,691$ words, $1,574$ sentences.

— A 'raw and artificial' corpus (Corpus RA). Consisting on $131$ concatenated laws extracted from another training corpus from DEFT'06. Corpus size: $53,919$ words, $2,310$ sentences.

As all the cleaning on corpora CN and CA has been hand made, there can still be some noise but far less than before the cleaning. This also explain the relatively short amount of text the experiment was running on. The effort of producing clean data is very heavy. Moreover, other experiments in the domain have been presented with corpora not considerably bigger than ours [7], [20]. In order not to introduce a size bias, we restricted the R corpora (RN and RA) to roughly the same size as the CA and CN corpora (results presented in subsections 4.1 and 4.2). However, since producing raw corpora is very easy, we wanted to know whether size could have an effect on performance results, therefore, we doubled RA and DN corpora sizes, and Tables V (RN: $160,524$ words, $5,445$ sentences) and VI ( RA: $105,350$ words, $4,854$ sentences) have brought up interesting results about the impact of corpus lengths, commented in section 4.3.

### *B. Tolerant measures*

We ran both methods on each corpus and evaluated the results using the DEFT'06 **tolerant recall and precision** described in [1]. They consider as relevant, potential boundary sentences which are in a window around the boundary sentence identified by experts. This evaluation gives a better idea of algorithms efficiency on the task of finding inner texts topic boundaries and does not have a significant influence on the task of finding concatenated texts boundaries. The DEFT'06 organizing committee noticed that the use of either strict or tolerant measures had no effect on the ranking of the submissions they had to evaluate, but gave better scores to all methods.

Note that both methods consider first sentences of texts as a boundary, so every first sentence of the CN and RN corpus texts is counted as a boundary (which means both algorithms have at least one good boundary per text). The results on other corpora are not too affected by this specificity as they are all one big text with several sentences and topic segments.

Even if $c99$ isn't corpus or language sensitive, it has been slightly optimized to English language by using a stop list. As our experiment hab to be the fairest possible, we used $TreeTagger$ to stem the corpora and eliminate tool words from it (based on their categories).

## IV. Results

### A. Clean Vs Raw: The Impact of Corpus Data Quality

The individual results of each of the 22 texts of CN Corpus have been combined in Table I into an average precision and an average recall summarizing the 22 individual values (too long to expose here). Table I presents the best conditions output of both methods. It highlights the differences between the two methods. With its default boundaries detection $c99$ has a better precision, but proposes less solutions and so has a worse recall. On the opposite $Transeg$, by actively searching for boundaries, is more sensitive to variation between sentences. It suggests more solutions than $c99$ and so worsens its precision for a better recall. These 'ideal' conditions clearly demonstrate the strengths and weaknesses of both approaches and give hints about means to improve them. As shown in next paragraphs, results considerably worsen whenever corpus quality drops. As soon as we deteriorate the quality of the corpus (Table II) results drop. At first sight, the natural tendency of $c99$ toward precision seems to be conserved, whereas its recall is dramatically affected (with a $1.54\%$ value, one wonders whether it still has a meaning!). A deeper observation of results indicates that $c99$ brings only $3$ sentences back as a boundaries, including the first one, which is a boundary per se. So its relatively good precision is mostly due to the experiment conditions. $Transeg$ seems to be sturdier: Its precision is almost untouched, but its recall has badly deteriorated. A counterintuitive output: $Transeg$ does better than $c99$ in conditions where we thought that the latter would be the most robust. $Transeg$ is considered to be more sensitive to ill-formed sentences, unknown or misspelled words. It was supposed to be distanced by $c99$ on corrupt data. It seems that it is not the case.

TABLE I
Average precision and recall on the $22$ texts of the 'clean and natural' (CN) corpus

| | C99 | Transeg |
|---|---|---|
| Precision | **53.32**% | 45.49% |
| Recall | 23.12% | **38.76**% |

TABLE II
Precision and recall on the 'raw and natural' (DN) corpus

| | C99 | Transeg |
|---|---|---|
| Precision | 35.14% | **43**% |
| Recall | 1.54% | **9.85**% |

### B. Artificial Corpora: Do Corpus Manipulations impact Methods Results?

TABLE III
Precision and recall on the 'clean and artificial' (CA) corpus

| | C99 | Transeg |
|---|---|---|
| Precision | **30.77**% | 22.3% |
| Recall | 5.03% | **19.5**% |

When coming to an artificial but clean corpus (Table III), we retrieve the original balance between the two methods: A precision oriented output for $c99$ and a recall oriented one for $Transeg$. When compared to Table I, the results range is far worse, and becomes difficult to interpret. $C99$ bad recall (around $5\%$) is quite surprising. One would also have expected the opposite: Concatenating distinct texts would make the segmenting task much easier to a word-based algorithm! The 'worst' conditions case, impersonated by the DA Corpus, have not been matched with the worst results by both methods: Only $Transeg$ seems to be very sensitive to this loss in quality and naturality! When compared with the best case, $c99$ precision is less by $11$ points, whereas $Transeg$ precision looses $35$. On the other hand, recalls are strongly impacted by both data corruption and manipulation (a $2.14\%$ recall for $c99$ and a less than $10\%$ one for $Transeg$ are very bad scores). But the orientation seems to be maintained: $C99$ is still leading in precision, and $Transeg$ in recall. However, with such low values, interpretation is risky. One cannot but acknowledge the impact of data reliability on performances degradation.

TABLE IV
Precision and recall on the 'raw and artificial' (DA) corpus

| | C99 | Transeg |
|---|---|---|
| Precision | **42.86**% | 8.02% |
| Recall | 2.14% | **9.27**% |

### C. Complementary Experiment: The Impact of Size on the D Corpora

The impact of corpora length could be assumed to have two opposite effects.

- Either a biggest data would introduce more corruption cases, and thus worsens results (because of the D aspect)
- Or it would provide both algorithms with more opportunities to detect boundaries 'by chance' and thus augment their performances.

In order to see which of these two assumptions is more likely to be supported, we run the experiments on the doubled RN and RA corpora. Results are summarized in Tables V and VI. When comparing Tables II (simple RN corpus) and V (double RN corpus), we see that both methods 'orientation' is

TABLE V
PRECISION AND RECALL ON THE 'RAW AND NATURAL' (RN) BIGGER CORPUS

| | C99 | Transeg |
|---|---|---|
| Precision | 33.33% | **35.7%** |
| Recall | 0.12% | **20.28%** |

TABLE VI
PRECISION AND RECALL ON THE 'RAW AND ARTIFICIAL' (RA) BIGGER CORPUS

| | C99 | Transeg |
|---|---|---|
| Precision | **15.91%** | 8.54% |
| Recall | 5% | **19.29%** |

maintained: $Transeg$ does better, in both precision and recall, but if its precision has been reduced by $8$ points, its recall has improved by $11$!.It seems that 'chance' retrieved boundaries are rather significant. At the same time since precision drops, the number of corrupt data cases prevent good boundaries to be found. Let us notice that the Recall/Precision ratio is invariant with size. On the other hand, $c99$ recall continues to drop down to incredible values. One cannot risk an interpretation.

Table VI has to be compared to Table IV. The better values in Table VI could be interpreted with a 'canceling' effect provided by size. More data corrupted cases, but also more boundaries to be retrieved by chance. This drives us to conclude that providing a bigger set of data adds more noise to algorithms performances interpretation.

### D. Overall Results

In short, the rather unexpected results obtained in experiments could be summarized by the following statements.

- Data quality (i.e. clean vs dirty) has an impact on results of both methods: Best comparative results in recall and precision are achieved with the CN corpus. The dramatic fall in recall for $c99$ (Tables II, V, VI) is difficult to explain. But, surprisingly, a deterioration in quality seems to favor $Transeg$ over $c99$, provided that the corpora keep their 'natural' origin. This is highly counterintuitive.
- Corpus manipulations (i.e. natural vs artificial) has no impact on both methods orientation (a trend toward precision for $c99$ and one toward recall for $Transeg$), in Tables I, III, IV, VI. Values drop for both methods between the best case (Table I) and the worst case (Table IV), but $Transeg$ is more affected than $c99$.When comparing Table I and Table III, there is a loss of $20$ points in general. So artificial corpora seem to lower results. This is also opposite to our previous intuition, in which a general improvement of $c99$ results was expected.
- The comparison between Tables II and IV shows that it is $Transeg$ which is the most affected by data manipulation (artificially built corpora) when corrupt data is present. Since RA corpora are what most evaluation campaigns provide, then $Transeg$ presents a liability which has to be improved.
- The comparison between Tables II and III, the 'diagonal values' is most interesting. The 'artificiality' of the CA corpus has a discriminant effect on $Transeg$ precision (from $43$ in Table II down to $22$ in Table III), but an improvement on its recall (it is doubled). $C99$ looses the $5$ points in precision that it gains in recall. This confirms that $Transeg$ should not run on artificial corpora.
- Tables V and VI show the impact of corpora size. Recall and precision values improve with size for $Transeg$ but they drop down for $c99$. This means that $Transeg$ will resist better with bigger corpora, however, an artificial corpus is what handicaps it most.
- By choosing to show recall and precision values in call cases, and not an $FScore$ built on their ratio, we hope to have grasped the variations introduced by different corpus quality criteria.

## V. CONCLUSION

The impact of copora constitution on methods evaluation cannot be neglected. The previous experiments and their results tend to show it. What is interesting is that given two quite different but corpus independent methods, they cannot resist a deterioration in corpora. The latter can be introduced by either data corruption or data handling. If one is more apt to stand data corruption ($Transeg$) and the other data handling ($c99$) both give their best when quality is granted. For us this means that: (1) If evaluation campaigns organizers do not test their corpora quality, they already handicap unsupervised methods, which will never achieve spectacular results. Supervised methods will tune to corpus bias and overcome them. However they won't be able to do so well with unlearnt data. (2) If they manipulate their data, they will favor lexical based methods over those which are not. (3) If they don't clean it, they will favor sentence or segment based methods. (4) A big corpus is not necessarily more informative on algorithms capabilities than a smaller one. If data is not of a high quality then chance and noise are more likely to temper with results.

Of course, topic-based segmentation methods should be able to deal with any kind of text. But depending on what we want to evaluate the kind of the corpus could be very important. If the goal is to evaluate a method in a practical applicative context, then any corpus should be used as in real conditions anything could happen. On the opposite, if the goal is to to evaluate the validity of a theory or to the feasibility of a task, the choice of the corpus become important. If we do not want to add the complexity of the corpus properties to the complexity of the task, then we should carefully choose our corpora depending on exactly what we want to evaluate. Otherwise the soundness of our evaluations will be jeopardized.

email: bartosz.rapp@speechlabs.pl

July 14, 2008

***Abstract*—Usage of language models in automatic speech recognition systems usually give significant quality and certainty improvement of recognition outcomes. On the other hand, wrongly chosen or trained language models can result in serious degradation not only recognition quality but also overall performance of the system. Proper selection of language material, system parameters and representation of the model itself is important task during language models construction process.**

**This paper describes basic aspects of building, evaluating and applying language models for Polish language in automatic speech recognition systems, which are intended to be used by lawyer's chambers, judiciary and law enforcements.**

**Language modeling is a part of project which is still early stage of development and work is ongoing so only some basic concepts and ideas are presented in this paper.**

## I. Introduction

GENERALLY it is known that language models (LM) can be effective support for speech recognition process and rise the recognition quality even by tens of percents. This is why elements of language modeling are included in practically all modern automatic speech recognition systems (ASR). Often collected sound material contains many different kinds of noises and artifacts and the speakers utter words in incorrect or negligent way. Automatic analyses of such speech signal on acoustic models ([6]) level can be insufficient to obtain satisfying recognition correctness and certainty. Information supplied by language models can be invaluable help in this kind of situations. Language models used in ASR systems work in similar way to this in which human brain tries to recognize speech on the higher levels of functioning. In case when not all of the heard words are understandable, we are trying automatically replace these words with others—most probable ones. This replacement is done on our knowledge basis (formerly heard or read sentences etc.). We are simply choosing words in the process of statistical and semantical deduction that are the best fit. Hearing sentence "*Ala **na** kota*" we are very certain that the correct sentence should be "*Ala **ma** kota*". Our choice is driven by semantical knowledge and the fact that the second sentence we have heard so many times in our lifetime and probably this is what author of the message was trying to say. Additionally if we know the global context of whole conversation our deduction can be much more certain. Language models can also be used in similar way to correct mistakes which have been made on acoustic models level. Recognized by sound analysis, words not always will suit to the rest of sentence i.e. grammatically or semantically (although sentence is correct according to the rules of Polish language in fact it can have no real meaning and sense i.e. "*ryba jedzie na rowerze*"). As we can see language models are used to correct mistakes and errors which appear as the result of incorrect acoustic recognition or presence of artifacts in the speech signal.

Many language modeling techniques have been developed and proposed during last years. Some of them are based on "brute-force" statistical analysis (n-gram word LMs and n-gram class LMs ([1]), factored LMs etc.) and others are more formal with heavy theoretical and linguistic background (PCFG or HPSG ([2])). In this article only n-gram language models will be discussed more widely.

N-gram language model is a set of probabilities of the word sentences $P(w_i|w_1,...,w_{i-1})$. These probabilities can be estimated using following equation:

$$P(w_1,...,w_n) = \prod_{i=1}^{n} P(w_i|w_1,...,w_{i-1})$$

Unfortunately chance that out training set will contain the same word sequence $(w_1,...,w_n)$ more than couple of times is rather low. Good solution is therefore to treat the process of word generation as a Markov process (process without memory). According to Markov assumption we accept the fact that only $N$ previous words will have the influence on what word $w_n$) will be. This is what we call n-gram ([1], [3]) language model[1] Selection of the right n-gram length has tremendous impact on the usefulness of language model and depends mainly on what results are expected to be achieved. Higher values of $n$ give better knowledge about context (*discrimination*), lower $n$ values are much more probable to

[1] n-gram means here subsequence of n words from some word sequence. n-gram which has length of 1 are called *unigrams*, 2—*bigrams*, 3—*trigrams*, 4—*tetragrams*, etc.

appearer in the text (*reliability*). In real world application the most common $n$ values are $1 \leq n \leq 4$. It is important to mention that for a vocabulary containing $100\ 000$ words, 4-gram LM can have even $100\ 000^4$ parameters. In fact many of them will represent word sequences that are impossible to appear in real language and can be pruned. It is expected that real language model is usually far less complex than theoretical one. Unfortunately main disadvantage of n-gram language models if fact, it can only estimate probabilities of words from its vocabulary (which is given at the beginning) and adding new word to that vocabulary results in need of rebuilding whole model.

It is needed to remark here, that this project has a research status and the result, that is language models, is only a preliminary version. Main goal of this project (developed at Laboratory of Language and Speech Technology) is to design and implement technology demonstration ASR systems—intended to be used by lawyer's chambers, judiciary and police forces. Basic specifications assume real-time or near to real-time speech recognition of spontaneously dictated speech (i.e. reports, protocols, documents, statements etc.).

## II. Training material selection

Selection of the training texts and language material is one of the most important tasks in LM building process. It should be done with care and some additional factors in mind. First of all training texts need to be appropriate for the occupational category for witch ASR system is intended. Although the same language, there are some slight differences in vocabulary used by lawyers, physicians, politicians and police officers. Each of these groups use some specific therms and sentences typical for the occupation. Nowadays creation of universal language model that suits all kinds of speech is practically impossible. It is worth to mention here that LMs developed as a part of this project are designed with lawyer's chambers, judiciary and police in mind. In the training set following texts are included: many kinds of newspaper texts (for general speech), professional press notes, court protocols, whitens testimonies and statements, police reports and government acts and Parliament speeches. Currently our laboratory owns almost 4GB of different types of texts and linguistic materials. The database is still under development and in near future should reach size of nearly 60GB of data. It should be pointed that while gathering more language material chance to include in this set rarely used words increases. This is why texts which will be used to build language models should be chosen with care.

In case of Polish language which is similar i.e. to Russian ([4]) or Turkish ([5]) vocabulary size should be couple hundred thousands of words. This is only preliminary estimation and further research is needed to obtain the real effective vocabulary size needed for building high quality language model.

## III. Training texts preprocessing

Raw training texts will always contain some mistakes and artifacts like non existing words, misspellings etc. They contain also many unnormalized abbreviation i.e. *mgr inż.* instead of "*magister inżynier*" (*M.Sc.Eng.—Master in Science Engineer*) and numbers in mathematical (i.e. *100* instead of "*sto*") or roman notation. It is obvious that achieving high quality language models will require training materials prepared (preprocessed) in correct way. Having access to word dictionary it is possible to do some automated orthographic and spelling check (manual checking of millions of words is impossible). This is not really necessary step, but if there are possibilities to do this in automated way this kind of spell checking can be applied. It is worth to remark that having really large corpora single and rare misspellings are not harmful during language model construction. If much effort is needed to perform this step it should be skipped. Next normalization of abbreviation is needed. This is the hardest part of preprocessing because shortenings should be expanded to their correct form as should be in sentence according to grammatical and inflection rules and not only to base form i.e. "*Dzisiaj nie ma* ***prof.*** *Jarząbka*" should be "*Dzisiaj nie ma* ***profesora*** *Jarząbka*" and not "*Dzisiaj nie ma* ***profesor*** *Jarząbka*". Generally if we have access to really big corpora it is no need to bother about normalization. Even if one million sentences will be removed from set containing couple billion of sentences this would not be a problem. However some difficulties can be encountered when dealing with small corpora. In this project such relatively small corpora is used to model language specific for lawyers and police. Text material from that set contains large number of numeric values in mathematical notation, abbreviations and shortenings i.e. "KK" instead of "kodeks karny" (penal code) and special characters like i.e. $, §, £, €. In this case normalization is task which should be performed. Normalization is the most complicated part of text preprocessing. Classic approach used while determining the correct word form requires inflectional and semantical analysis of whole sentence. Construction of such automatic analyzer is not an easy task and is not a part of this project. Second proposed approach is to create a set of transformation rules. Using these rules it will be possible to process unnormalized texts and replace all instances of shortenings and numbers, numerals with their expanded and correct form. In this experiment two different approaches will be used to create transformation rule sets. First rules set will be developed manually by linguistic expert according to grammatical and lexical rules of Polish language. As an alternative method some attempts to discover knowledge from collected data will be made. All texts will be divided into two parts. First (test set) will only contain sentences with unnormalized numbers, numerals, shortenings and abbreviations. Second (training set) will consist of sentences containing normalized numbers and numerals together with words (expanded forms) known from abbreviation and shortenings dictionary. Then knowledge discovery algorithms will be used to process sentences from second subset of our corpora on raw and POS labeled sentences. Discovered rules will be applied to the test set. Results of normalization made with manually developed transformation rules set and those discovered from examples will be compared. It is hard to evaluate which approach will be better in practical application. At this moment no goodness index has been proposed to be used to decide which rule set gives better results. At last all words should be capitalized. This will make further text processing much easier and less ambiguous i.e. same words because of capitalized letters will not be classified as different ones: "***Pies** jest najlepszym przyjacielem człowieka*" and "*Moim najlepszym przyjacielem jest **pies** Azor*". Language material preprocessed in this way is ready to be used to train language models.

## IV. Language models

Having decent training material it is possible to proceed with language model construction. At this stage it is needed to recall that the generated language model is static structure and all vocabulary modifications, such as adding new text to training set, require rebuilding whole LM.

The most simple and common form of LM is a technique applying to evaluate probabilities of n-grams sequences for single words. Words, which have not been seen in training material are marked as abstract word *unk*. N-gram models for single words are rather rarely seen in practical applications, because of their requirements for memory and processing power, which result in higher LM's answer time latencies. This kind of resource demand can be unacceptable in real world and real-time application.

One among the methods designed to deal with limitations like such mentioned above is algorithm assigning words to some abstract classes on training texts statistical analysis basis (word exchange algorithm) or using some custom classification function i.e. assigning words to their real part of speech class (POS).

In this project at the early stage of work both mentioned methods are planned to be applied. Statistical derivation of abstract equivalent classes will be made using word exchange algorithm implemented in HTK toolkit. Grammatical POS classification will be made by tagging words according to Inflectional Vocabulary for Polish developed under management of Wiesław Lubaszewski ([8] and morphological analyzer *Morfeusz SIAT* designed by Zygmunt Saloni and Marcin Wolski ([9]). It is expected to achieve better results using inflectional vocabulary. With inflectional vocabulary words can be assigned to 60 POS categories. Furthermore detailed information about word form is also available so in practical applications number of tags can be significantly expanded. In case of *Morfeusz SIAT* there is less than 20 categories. Morphological analyzer contains on the other hand some additional information which are unavailable in inflectional vocabulary. As a part of this project results of POS tagging by these to tools will be compared. Unfortunately *Morfeusz SIAT* and inflectional vocabulary have nowadays some limitations mainly because of small word list. Problem arises in case of proper names, which are commonly seen in training texts and language material.

## V. Probabilities estimation

Because of limited size of language material used to train the language model, some previously unseen and unknown words, will sometimes appear at LM input. Language model is therefore only some approximation of real language. Fact that some of the mentioned word have not been included in the training material does not mean that these words are incorrect on should be considered as non-existent. Occurrences of such words cannot be estimated as a 0 probability. During language model training process some probability mass is needed to be "reserved" for the event of seeing such unknown words. One of the available techniques designed to deal with this problem is discount coefficient factor. There are several algorithms used to calculate discount coefficients form which most popular are: Good-Turing algorithm and absolute discounting used i.e. in HTK toolkit.

## VI. Enhancements techniques

Often some enhancement techniques are used to improve language model quality and decrease its complexity. Most commonly used ones are: the first technique prunes language model and cuts off rare words, the other one is a method of smoothing probabilities. According to this algorithm (probability smoothing) probabilities of some rare n-word sequences are replaced by probabilities of their corresponding shorter contexts (n-1-word sequences). This technique used in parallel with discounting coefficient factor reduces complexity of language model.

## VII. Language model quality estimation

Nowadays most often used metric to evaluate the language model goodness or quality is *perplexity*. This measure has its roots in information theory. In language modeling *perplexity* expresses average number of word choices for current context. Lower *perplexity* value, the better language model was build (it makes lower error). To calculate *perplexity* test text and a language model itself is needed. Unfortunately *perplexity* seems not to be the best measure for evaluating language model quality. This is very simple and basic measure witch additionally highly depends on LM application domain and can be only applied to probabilistic models. Because of its weaknesses it is recommended to support it with other quality indicators such as i.e. Out-Of-Vocabulary (OOV) rate. Some more general measures should be used. Different approaches to language model evaluation which extend *perplexity* or constitute other independent quality factors has been discussed in [11].

## VIII. Summary

In this article basic aspects and concepts of language modeling for applications in real world ASR systems have been discussed. Most of the experiments are conducted using HTK toolkit which is reliable, efficient and proven framework for designing and building automatic speech recognition systems. It is expected to achieve better results during further research of algorithms, techniques and methods (such as using some semantic and context knowledge in language model engine, using fuzzy logic and perhaps some derivations of formal languages elements). It is important to realize that nowadays this is still a research project.

Language model intended to be used in real-time ASR systems need to be applicable, that is, there must be some balance between efficiency and performance. It is needed to notice that this balance is really hard to determine and to achieve. According to our preliminary expectations, language model included in ASR system should increase its recognition accuracy even by 20%. Although we realize that designing good language model for languages like Polish, Turkish, Russian or Finish is quite challenging task.

# SemCAPTCHA—user-friendly alternative for OCR-based CAPTCHA systems

Paweł Łupkowski, Mariusz Urbański
Chair of Logic and Cognitive Science
Institute of Psychology
Adam Mickiewicz University
Szamarzewskiego 89
60-568 Poznań, Poland
Email: {Pawel.Lupkowski, Mariusz.Urbanski}@amu.edu.pl

***Abstract*—In this paper we present a new CAPTCHA system (*Completely Automated Turing Test To Tell Computers and Humans Apart*). This proposal, SemCAPTCHA, is motivated by an increasing number of broken OCR-based CAPTCHA systems and it is based not only on text recognition but also on text understanding.**

**We describe SemCAPTCHA from both user's perspective and system's perspective and compare it to some currently popular CAPTCHAs. We also briefly describe an experiment carried out to test our CAPTCHA on human users.**

## I. Introduction

IN MANY domains there is an increasing demand for simple and efficient way to differentiate real human users from malicious programs (bots). Just a few examples of such domains are: services offering free e-mail accounts, community portals, online polls etc.

One of the most popular ways to tell human users and bot users apart are so called CAPTCHA systems (this acronym stands for *Completely Automated Turing Test To Tell Computers and Humans Apart*).

Design of an effective CAPTCHA system is a difficult task, since two distant needs must be satisfied: it has to be really hard for a machine and at the same moment it has to be simple and friendly for a human. User friendliness is important as CAPTCHAS cannot engage to much of a user cognitive resources and cannot consume to much of her time. Registering a free e-mail account is a good example here. There are many alternative providers of such accounts on the market, so if you want a potential user to solve CAPTCHA on your site, it has to be as unproblematic for her as possible (and you want her to solve it in order to prove that she is a human, not a bot who will send tons of spam from your servers). If a potential user gets irritated, she will go away and pick another provider. To make things more difficult, there's also a third factor: a CAPTCHA has to be open, that is, the algorithms used by a system must be public. The idea is that CAPTCHA efectiveness should be based on hardness of an underlying AI problem and not on a secret cryptographic mechanism or other copyrighted mystery. Finally, test instances of a CAPTCHA should be generated automatically.

Internet users encounter CAPTCHAS very often. Most of them are visual CAPTCHAS where the task consists in recognition of a word or string of symbols (letters, numbers) from a distorted picture. To solve such CAPTCHA a user has to write down words or symbols from the picture. Such systems work e.g. on Yahoo, Gmail, Wirtualna Polska, Gazeta.pl and many other sites. Exemplary CAPTCHAS are presented in table V.

Currently it is an important issue that AI problem underlying such CAPTCHAS is challenged by constantly developing Optical Character Recognition (OCR) systems with increasing success rate. Mori and Malik [8] describe an attack on a visual CAPTCHA EZ-Gimpy used by Yahoo!, which enjoyed a success rate of 92%. In more difficult case of Gimpy they passed the test 33% of the time. As the authors claim: "with our 33% accuracy, this CAPTCHA would be ineffective in applications such as screening out "bots" since a computer could flood the application with thousands of requests." [8, p. 7]. After all, year 2008 seems to be a really bad year for visual CAPTCHAs: Yahoo! CAPTCHA was hacked again (http://osnews.pl, 21.01.2008), as well as Gmail one (http://osnews.pl, 27.02.2008) and MS Windows Live Hotmail (http://arstechnica.com, 15.04.2008). Many visual CAPTCHAS are broken 'out of the box' by PWNtcha system (see http://libcaca.zoy.org/wiki/PWNtcha—examples of 12 broken CAPTCHAS where success rate is from 49% to 100%).

As a consequence, there is a great need for more secure alternative CAPTCHAS, which are based not only on OCR problem. There are some proposals, like question-based CAPTCHA [7], ARTiFACIAL [12], PIX [1], sound oriented CAPTCHAS [3] etc. In our opinion the current situation offers a great motivation to look for an inspiration for CAPTCHA systems not only in simple sensory processing but in higher levels of human data processing.

## II. SemCAPTCHA system

Our proposal is to base a CAPTCHA system on a combination of an OCR problem and some linguistic task, and to apply the effect of positive semantic priming to strengthen human odds against computers. Everything what is needed to break a simple visual CAPTCHA is an good OCR program. Breaking our system—SemCAPTCHA, where "Sem" stands for

This research was partially supported by AMU Faculty of Social Sciences grant No. WSO/133/2006.

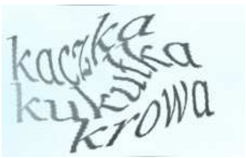

Fig. 1. Sample instance of SemCAPTCHA test

“semantic”—is not that straightforward for a machine and still for a human user it remains quite simple. The process of solving SemCAPTCHA task consists of three steps, based on different cognitive activities (which must be completed within a certain amount of time): reading a text—understanding it—applying user’s knowledge about the world.

### *A. SemCAPTCHA—a user’s perspective*

A SemCAPTCHA test instance consists of a distorted picture, on which three words are presented. All of them are the names of animals. One animal differs from the rest (e.g. it is a mammal among reptiles). The task is to recognize its name and point it by a mouse click. It has to be stressed that the words do not differ substantially as for their graphical properties (like, e.g. length). The difference is of semantic character: one word differs from the other two in its meaning.

An example of such test instance is given in figure 1: a user is presented with the words “kaczka” (a duck), “kukułka” (a cuckoo), “krowa” (a cow; SemCAPTCHA is designed in Polish). The proper answer is “krowa” and the semantic difference is based on taxonomy: ducks and cuckoos are birds while cows are mammals.

To solve this task a user first has to recognize the words from a distorted picture, then identify their meaning and finally find an underlying pattern and the word which does not fit it. The choice of words makes it easy even for not very fluent language users.

In order to make SemCAPTCHA even easier for humans we decided to employ the positive semantic priming effect. Each test instance is preceded by a prime (exposition time is ca. 70 ms). The prime is a word semantically connected with the task solution; in case of the above example it might be a word “mleko” (milk). It is known from cognitive psychology that this setting enables human to recognize a target word much faster than a stand alone target word. Consequently, human user will solve SemCAPTCHA test instances easier and faster (cf. next section, [5] and [6]).

### *B. SemCAPTCHA—a system’s perspective*

SemCAPTCHA is not implemented yet, but the procedures needed for the system are already developed.

SemCAPTCHA works on a word base consisting of 500 animals’ names. Names are grouped in categories, e.g. mammals, birds, reptiles. Each word has its own semantic field (stored as semantic network). Semantic field contains words semantically connected with a given animal name. Each connection of words is marked by a label containing information about relation type and relation strength, expressed by a numerical value 1–100 (as sources for semantic fields generation we used IPI PAN—corpus of Polish developed by the Polish Academy of Sciences—and Google). Such architecture enables efficient and automatic generation of test instances.

To generate a test instance system chooses randomly two categories from the word base. Then it picks (also randomly) one word ($w_1$) from the first category and two words from the second one ($w_2$, $w_3$). Then the system picks a prime for $w_1$, using semantic network stored for $w_1$. The system randomly chooses possible relation strength with $w_1$ (e.g. 50–70) and a word that obeys this restriction. Then a distorted picture is generated using $w_1$, $w_2$, $w_3$ and it is preceded by a prime and a mask.

After a test is generated and displayed SemCAPTCHA starts measuring the time. A solution time (an interval between exposition of a picture and a mouse click) is compared with a standard solution time for SemCAPTCHA. On this basis SemCAPTCHA estimates the probability that a user is a human and decides if a test has been passed or not.

Our experiment shows, that for humans solution time varies from 1,2 to 5,5 seconds (cf. next section, [5] and [6]; more thorough research could help verify these limits). This is one of the most characteristic properties of SemCAPTCHA: it not only generates and scores test instances but it also constantly checks solution time, and its verdict depends not only on correctness of a solution but also on time needed for it. In this point SemCAPTCHA differs substantially from widely used OCR-based CAPTCHA systems.

## III. SemCAPTCHA Experiment

To verify the idea of using linguistic competence and positive semantic priming in SemCAPTCHA system we have carried out an experiment (details on the instruments used and methods of statistical analysis can be found in [5] and are available from the authors).

Our research questions for these issues were:

1) Is the effect of positive semantic priming statistically significant for solution time of SemCAPTCHA test instances?
2) Is the effect of positive semantic priming statistically significant for solution accuracy of SemCAPTCHA test instances?

The experiment consisted of one training task and 10 test instances. A single instance consisted of a picture with 3 Polish words (names of animals). One word was different from the other two in that it was a name of an animal of a different class. For each picture we used one of standard CAPTCHA’s method of distortion. We prepared two sets of tasks, $A$ and $B$, consisting of the same test instances. In an experimental set $A$ each test instance was preceded by a prime, semantically connected with the word which formed the correct solution of a task. A prime was followed by a mask. In a control set $B$ there was no prime. Detailed characteristics of test instances are given in table I.

The sample consisted of 64 students at the Adam Mickiewicz University (19 males, 43 females, 2 no data), who

TABLE I
TASKS CHARACTERISTICS

| Task | Prime (ms) | Mask (ms) | Text dist. | Bg. dist. |
|---|---|---|---|---|
| T1 | 70 | 50 | G-blur | HSV |
| T2 | 60 | 50 | G-blur | RGB |
| T3 | 80 | 50 | G-blur | fog |

|  | $B$ | 33 | 3,5239 | 22 | 5,28 |
| T8 | $A$ | 31 | 1,7810 | 28 | 3,67 |
|  | $B$ | 33 | 3,2051 | 31 | 5,25 |
| T9 | $A$ | 31 | 1,4193 | 30 | 2,67 |
|  | $B$ | 33 | 2,6340 | 32 | 2,97 |
| T10 | $A$ | 31 | 1,5180 | 23 | 3,07 |
|  | $B$ | 33 | 2,6648 | 27 | 3,47 |

volunteered to participate in the experiment. They all belonged to the largest group of Internet users, i.e. people aged between 21 and 25. Participants were randomly distributed over groups $A$ (experimental group) and $B$ (control group).

The subjects were asked to choose on each picture from three names of animals the name of an animal which differs from other two and point it by a mouse click. Solution time was measured as an interval between exposition of a picture and a click. Time and correctness of a solution were written down automatically by a server. After completion of all ten test instances the subjects were asked to fill a short questionnaire concerning subjective difficulty of each task (a complete set of pictures was presented on the monitor at this stage) and their willingness to solve such tasks while surfing the Internet.

The results enable to formulate a positive answer to our first question and a negative answer to the second one (cf. table II). First and foremost, we observed the effect of positive semantic priming in solving test instances of SemCAPTCHA: there was statistically significant difference in time of solving test instances between the experimental group ($A$) and the control group ($B$). Participants from group $A$ solved test instances faster than participants from group $B$ and thus it is possible to differentiate betwen experimental and control group on the basis of the average time of solving test instances. This effect was present in case of eight out of ten test instances (T3 – T10). Lack of positive semantic priming effect in case of the first and second instance can be explained by the need for some practice in solving such tasks.

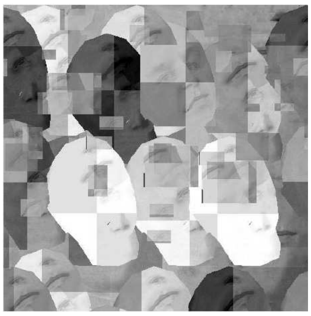

Fig. 2. Example of ARTiFACIAL test [12]

On the other hand, improvement in time of solving test instances does not affect in a statistically significant way the accuracy of solutions. Participants from the experimental group solved test instances just faster, not more accurate than participants from the control group.

## IV. SemCAPTCHA AND OTHER PROPOSALS

As we noticed above, user friendliness is one of the crucial issues for an effective CAPTCHA systems: for humans they should be as easy as possible. Thus it is interesting to compare our system with other CAPTCHAs on the basis of declared subjective difficulty of test instances and declared willingness to use them in practice. For comparison we have chosen CAPTCHAs for which such data were available.

We mentioned already that in our experiment we asked participants to declare subjective difficulty of test instances (on the scale 1–10, where 1 means the simplest). For each test instance subjective difficulty declared by participants from experimental group was slightly lower than the one declared by participants from the control group (however, only in one instance this difference was statistically significant). We observed high correlation between average declared difficulty and average solution time ($r^2 = 0.71$ for group $A$). As a consequence, time of solution seems to be a good estimator of task complexity. This observation gives some base for comparing SemCAPTCHA with other CAPTCHA systems on the objective basis of their solution times.

One of the alternatives for OCR-based CAPTCHA is ARTiFACIAL. It is based on ability to recognize faces. Motivation for this system is similar to ours—make use of higher levels of human data processing. ARTiFACIAL test consists of one picture containing background (with randomly choosen facial features) and a face (exemplary tets instance is presented in figure 2). The task is to find and point six points on such picture (left and right corner of: left eye, right eye and mouth). As could be expected, ARTIFiCIAL is really

TABLE III
AVERAGE TIME (IN SEC.) OF ARTiFACIAL TEST SOLUTION

| task | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| time | 22 | 15 | 16 | 13 | 12 | 11 | 12 | 12 | 11 | 12 |

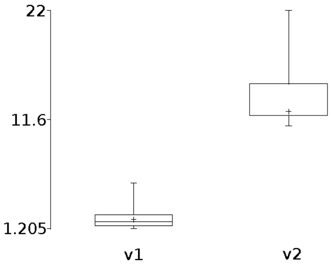

Fig. 3. Average time of solution for SemCAPTCHA (v1) and ARTiFACIAL (v2)

hard for machines, but is it simple enough for human users? ARTiFACIAL authors carried out an experiment on this issue. It consisted of 10 ARTiFACIAL test instances. The sample consisted of 34 subjects (accountants, administrative staff, architects, executives, receptionists, researchers, software developers, support engineers, and patent attorneys). Average solution times are presented in table III (cf. [12, p. 500]).

The mechanics of ARTiFACIAL and SemCAPTCHA are quite similar and it can be claimed that ARTiFACIAL's underlying problem is not more difficult than SemCAPTCHA's one. Thus, if we use the solution time as an estimator of task complexity for human users we may say that ARTiFACIAL is a really complex CAPTCHA system. Average solution time for all tasks is 14 seconds. SemCAPTCHA seems to be much easier, since the average solution time is 2.3 seconds (cf. figure 3).

On the basis of declared willingness to use them in practice we can compare SemCAPTCHA to a simple visual CAPTCHA system—BaffleText. In [4, p. 7] there are given results of a short questionnaire which was ment to investigate BaffleText users feelings about this system. It has been filled by 18 out of 33 subjects (Palo Alto Research Center employees):

1) 16,7 % reported they would be willing to solve a BaffleText every time they sent email;
2) 38,9 % reported they would be willing, if it reduced spam tenfold;
3) 94,4 % reported they would be willing, if it meant those sites had more trustworthy recommendations data;
4) 100 % reported they would be willing to solve one every time they registered for an e-mail account.

In our experiment we asked subjects to answer the same questions (61 out of 64 did this):

1) 15,6 % reported they would be willing to solve a SemCAPTCHA every time they sent email;
2) 43,8 % reported they would be willing, if it reduced spam tenfold;
3) 65,6 % reported they would be willing, if it meant those sites had more trustworthy recommendations data;

TABLE IV
OCR TESTS FOR SEMCAPTCHA

| GOCR | | Asprise OCR | | ABBYY FR | |
|---|---|---|---|---|---|
| words | letters | words | letters | words | letters |
| 0 % | 4,11 % | 0 % | 6,16 % | 13,33 % | 13,01 % |

TABLE V
EXEMPLARY TASKS OF CAPTCHAS USED BY YAHOO!, WP.PL AND GAZETA.PL

| | | |
|---|---|---|
| Yahoo! | wp.pl | gazeta.pl |

4) 34,4 % reported they would be willing to solve one every time they registered for an e-mail account.

We think that this results are very promising for SemCAPTCHA. One possible explanation of low results for third and fourth question is that our subjects were students. They might be not so keen in web security issues as PARC employees.

We have also performed some OCR tests, to see how hard are SemCAPTCHA tests for OCR programs. SemCAPTCHA uses slightly distorted pictures, so we intended to compare them with OCR-based CAPTCHAs currently used on popular portals. We tested our experimental test instances against three OCR programs: GOCR, Asprise OCR and ABBYY Fine Reader 9.0 PE. Results (percentage of correctly recognized words and symbols) are presented in table 4.

For comparison we also performed OCR tests (against the same three programs) for other popular visual CAPTCHAs: the ones used by Yahoo!, wp.pl and gazeta.pl (10 instances for each). These CAPTCHAs do not use regular words, but only strings of symbols (letters and numbers). Exemplary tasks are presented in table V.

For CAPTCHA used by Yahoo! (considered as hard) GOCR recognised 2.82% signs; Asprise OCR 1.41% and ABBYY FR 19.72%. As for wp.pl results were following: GOCR 52.94%, Asprise OCR 16.67%, ABBYY FR 5%. And for gazeta.pl: GOCR 45%, Asprise OCR 0%, ABBYY FR 47.06%. All results are presented in figure 4.

All tested CAPTCHAs are based on an OCR problem. SemCAPTCHA results are comparable with the others (and it

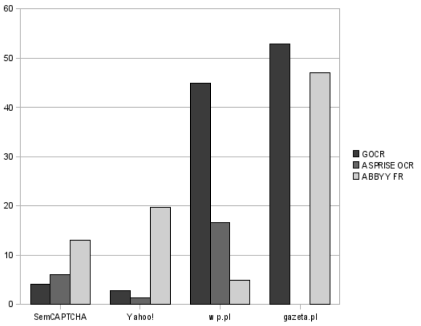

Fig. 4. OCR tests results (in % of recognised symbols)

should be stressed that recognising words in SemCAPTCHA task is only a first step towards solution; cf. section II). Thus we may conclude, that OCR-hardness of SemCAPTCHA is set high enough, i.e. it is at least as hard for machines as CAPTCHAs currently used and still quite easy for human users.

## V. Conclusions

SemCAPTCHA, based on a combination of an OCR problem, some linguistic task and positive semantic priming, seems to be a promising system for telling humans and computers apart. On the one hand, engagement of higher level human data processing makes it harder for machines than currently used visual CAPTCHAs. On the other hand, it is not as complex for human users as other alternatives to current systems. SemCAPTCHA has a simple and open algorithm, is easy for humans and can be designed for any language.

***Abstract*—We present a word sense disambiguation approach with application in machine translation from Arabic to English. The approach consists of two main steps: First, a natural language processing method that deals with the rich morphology of Arabic language and second, the translation including word sense disambiguation. The main innovative features of this approach are the adaptation of the Naïve Bayesian approach with new features to consider the Arabic language properties and the exploitation of a large parallel corpus to find the correct sense based on its cohesion with words in the training corpus. We expect that the resulting system will overcome the problem of the absence of the vowel signs, which is the main reason for the translation ambiguity between Arabic and other languages.**

## I. Introduction

INITIALLY, online documents were used predominately by English speakers. Nowadays more than half (50.4%)[1] of web users speak a native language other than English. Therefore, it has become more important that documents of different languages and cultures are retrieved by web search engines in response to the user's request. Cross Language Information Retrieval CLIR allows the user to submit the query in one language and retrieve the results in different languages, providing an important capability that can help to meet that challenge. Cross-Language In-formation Retrieval (CLIR) approaches are typically divided into two main categories: approaches that exploit explicit representations of translation knowledge such as bilingual dictionaries or machine translation (MT) and approaches that extract useful translation knowledge from comparable or parallel corpora.

In the last few years, Arabic has become the major focus of many machine translation projects. Many rich resources are now available for Arabic. For example a GigaWord Arabic corpora, Arabic/English Parallel corpus, which contains several thousands sentence pairs of bilingual text for Arabic and English. The existence of these resources was a crucial factor in building effective translation tools. Bilingual dictionaries (Arabic with other languages) have been used in several Arabic CLIR experiments. However, bilingual dictionaries sometimes provide multiple translations for the same word, which need to be disambiguated. This is due to the fact, that the dictionary may have poor coverage; and it is difficult to select the correct sense of the translated word among all the translations provided by the dictionary.

This paper proposes a method to disambiguate the user translated query in order to determine the correct word translations of the given query terms by exploiting a large bilingual corpus and statistical co-occurrence. The Arabic language properties that hinder the correct match are taken into account by bridging the inflectional morphology gap for Arabic. We use one of the well-known Arabic morphological Analyzers [1] that includes the araMorph package, which we use to translate the user query from Arabic to the English language in order to obtain the sense inventory for each of the ambiguous user query terms.

### *A. Arabic language*

Arabic is a Semitic language, consisting of 28 letters, and its basic feature is that most of its words are built up from, and can be analyzed down to common roots. The exceptions to this rule are common nouns and particles. Arabic is a highly inflectional language with 85% of words derived from tri-lateral roots. Nouns and verbs are derived from a closed set of around 10,000 roots [4]. Arabic has three genders, feminine, masculine, and neuter; and three numbers, singular, dual (represents 2 things), and plural. The specific characteristics of Arabic morphology make Arabic language particularly difficult for developing natural language processing methods for information retrieval. One of the main problems in retrieving Arabic language text is the variation in word forms, for example the Arabic word "kateb" (author) is built up from the root "ktb" (write). Prefixes and suffixes can be added to the words that have been built up from roots to add number or gender, for example adding the Arabic suffix ”ان “ (an) to the word "kateb" (author) will lead to the word "kateban" (authors) which represent dual masculine. What makes Arabic complicated to process is that Arabic nouns and verbs are heavily prefixed. The definite article ”ال “ (al) is always attached to nouns, and many conjunctions and prepositions are also attached as prefixes to nouns and verbs, hindering the retrieval of morphological variants of words [5]. Arabic is different from English and other Indo-European languages with respect to a number of important aspects. Words are written from right to left. It is mainly a consonantal language in its written forms, i.e. it excludes vowels. Its two main parts of speech are the verb and the noun in that word

[1] http://www.worldlingo.com/en/resources/ languag_statistics.html

978-83-60810-14-9/08/$25.00 © 2008 IEEE

order and these consist, for the main part, of trilateral roots (three consonants forming the basis of noun forms that are derived from them). It is a morphologically complex language in that it provides flexibility in word formation: as briefly mentioned above, complex rules govern the creation of morphological variations, making it possible to form hundreds of words from one root [6].

Arabic poses a real translation challenge for many reasons; Arabic sentences are usually long and punctuation has no or little affect on interpretation of the text. Contextual analysis is important in Arabic in order to understand the exact meaning of some words. Characters are sometimes stretched for justified text (word will be spread over a bigger space than other words), which hinders the exact match for the same word. In Arabic, synonyms are very common, for example, “year” has three synonyms in Arabic سنة ، حول ، عام and all are widely used in everyday communication. Despite the previous issues and the complexity of Arabic morphology, which impedes the matching of the Arabic word, another real issue for the Arabic language is the absence of diacritization (sometimes called vocalization or voweling). Diacritization can be defined as a symbol over and underscored letters, which are used to indicate the proper pronunciations as well as for disambiguation purposes. The absence of diacritization in Arabic texts poses a real challenge for Arabic natural language processing as well as for translation, leading to high ambiguity. Though the use of diacritization is extremely important for readability and understanding, diacritization are very rarely used in real life situations. They don’t appear in most printed media in Arabic regions nor on Arabic Internet web sites. They are visible in religious texts such as the Quran, which is fully diacritized in order to prevent misinterpretation. Furthermore, the diacritization are present in children’s books in school for learning purposes. For native speakers, the absence of diacritization is not an issue. They can easily understand the exact meaning of the word from the context, but for inexperienced learners as well as in computer usage, the absence of the diacritization is a real issue. When the texts are unvocalized, it is possible that several words have the same form but different meaning.

### *B. Tim Buckwalter Arabic morphological analyzer (BAMA)*

(BAMA) is the most well known tool for analyzing Arabic texts. It consists of a main database of word forms that interact with other concatenation databases. An Arabic word is considered a concatenation of three regions: a prefix region, a stem region and a suffix region. The prefix and suffix regions can be null. Prefix and suffix lexicon entries cover all possible concatenations of Arabic prefixes and suffixes, respectively. Every word form is entered separately. It takes the stem as the base form and also provides information on the root. (BAMA) morphology reconstructs vowel marks and provides an English glossary. It returns all possible compositions of stems and affixes for a word. (BAMA) groups together stems with a similar meaning and associates it with a lemma ID. The (BAMA) contains 38,600 lemmas. For our work, we use the araMorph package. araMorph is a sophisticated java based Buckwalter analyzer. This package is described in detail in section 1.2.

## II. Word Sense Disambiguation

The meaning of a word may vary significantly according to the context in which it occurs. As a result, it is possible that some words can have multiple meanings. This problem is even more complicated when those words are translated from one language into others. Therefore there is a need to disambiguate the ambiguous words that occur during the translations. The word translation disambiguation, in general, is the process of determining the right sense of an ambiguous word given the context in which the ambiguous word occurs (word sense disambiguation; WSD). We can define the WSD problem, as the association of an occurrence of an ambiguous word with one of it is proper sense. As described in the first section, the absence of the diacritization in most of the Arabic printed media or on the Internet web sites lead to high ambiguity. This makes the probability that the single word can have multiple meaning a lot higher. For example, the Arabic word “يعد“ can have these meanings in English (Promise, Prepare, count, return, bring back) or the Arabic word “علم“ can have these possible meanings (flag, science, he knew, it was known, he taught, he was taught). The task of disambiguation therefore involves two processes: Firstly, identifying all senses for every word relevant, secondly assign the appropriate sense each time this word occurs. For the first step, this can be done using a list of senses for each of the ambiguous words existing in everyday dictionaries. The second step can be done by the analysis of the context in which the ambiguous word occurs, or by the use of an external knowledge source, such as lexical resources as well as a hand-devised source, which provides data useful to assigning the appropriate sense for the ambiguous word. In the WSD task, it is very important to consider the source of the disambiguation information, the way of constructing the rules using this information and the criteria of selecting the proper sense for the ambiguous word, using these rules. WSD is considered an important research problem and is assumed to be helpful for many applications such as machine translation (MT) and information retrieval. Approaches for WSD can be classified into three categorizations: supervised learning, unsupervised learning, and combinations of them.

### *A. Word Sense Disambiguation Approaches*

Several methods for word sense disambiguation using a supervised learning technique have been proposed. For example, Naïve Bayesian [7], Decision List [8], Nearest Neighbor [9], Transformation Based Learning [10], Winnow [11], Boosting [12], and Naïve Bayesian Ensemble [13]. Using bilingual corpora to disambiguate words is leveraged by [14]. For all of these approaches, the one using Naïve Bayesian Ensemble is reported as the best performance for word sense disambiguation tasks with respect to the data set used [13]. The idea behind the previous approaches is that it is nearly always possible to determine the sense of the ambiguous word by considering its context, and thus all methods attempt to build a classifier, using features that represent the context of the ambiguous word. In addition to supervised approaches for word sense disambiguation, unsupervised approaches and combinations of them have been also proposed for the same purpose. For example, [15] proposed an Automatic word sense discrimination which divides the occurrences of a word into a number of classes by determining for any two occurrences whether they belong to the same sense or not, which is then used for the full word sense disambiguation task. Examples of unsupervised approaches were proposed in [16][17][18][19][20][21]. [22] an unsupervised learning method using the Expectation-Maximization (EM) algorithm for text classification problems, which then was improved in [23] in order to apply it to the WSD problem. In [24] the combination of both supervised and unsupervised lexical knowledge methods for word sense disambiguation have been studied. In [25] and [26] rule-learning and neural networks have been used respectively.

Corpora based methods for word sense disambiguation has also been studied. Corpora based methods provide an alternative solution for overcoming the lexical acquisition bottleneck, by gathering information directly from textual data. Due to the expense of manual acquisition of lexical and disambiguation information, where all necessary information for disambiguation have to be manually provided, supervised approaches suffer from major limitations in their reliance on pre-defined knowledge sources, which affects their inability to handle large vocabulary in a wide variety of contexts. In the last few years, the natural data in electronic form has been increased, which helps the WSD researches to extend the coverage of the existing system or train a new system. For example, in [27] and [28] the usage of parallel, aligned Hansard Corpus of Canadian Parliamentary debates for WSD has been performed, in [29] the authors use monolingual corpora of Hebrew and German for WSD. All of the previous studies were based on the assumption that the mapping between words and word senses is widely different from one language to another. Unlike machine translation and dictionaries, parallel corpora provide very high quality translation equivalents that have been produced by experienced translators, who associate the proper sense of a word based on the context that the ambiguous word is used in.

In the next section, we describe the proposed algorithm based on Naïve Bayesian classification, explaining the way of solving or at least relaxing the Arabic morphological issues. Afterward, we explain the features used to represent the context in which ambiguous words occur, followed by experimental results, which show the results of disambiguating some ambiguous words using a parallel corpus. This paper closes with a conclusion and future work.

## III. Proposed Approach

Our approach is based on exploiting parallel texts in order to find the correct sense for the translated user query term. The minimum query length that the proposed approach accepts is two. Given the user query, the system begins by translating the query terms using the araMorph package. In case the system suggests more than one translation (senses inventory) for each of the query terms, the system then starts the disambiguation process to select the correct sense for the translated query terms. The disambiguation process starts by exploiting the parallel corpus, in which the Arabic version of the translation sentences matches fragments in the user query. A matched fragment must contain at least one word in the user query beside the ambiguous one. The words could be represented in surface form or in one of its variant forms. Therefore, and to increase the matching score quality, special similarity score measures will be applied in order to detect all word form variants in the translation sentences in the training corpus.

### *A. Bridging the Inflectional morphology gap*

The rich inflectional morphology languages face a challenge for machine translation systems. As it is not possible to include all word form variants in the dictionaries, inflected forms of words for those languages contain information that is not relevant for translation. The inflectional morphology differences between high inflectional language and poor inflectional language, presents a number of issues for the translation system as well as to disambiguation algorithms. This inflection gap causes a matching challenge when translating between rich inflectional morphology and relatively poor inflectional morphology language. It is possible to have the word in one form in the source language, while having the same word in few forms in the target language. This causes several issues for word translation disambiguation, where more unknown words forms will exist in the training data and will not be recognized as a relevant to the user query terms.  As a result, it is possible to have lower matching scores for those words, even though there is a high occurrence of them in the training data.

The aim of this initial step is to alleviate the Arabic language morphology issues, which has to be done before accessing the Arabic language by the disambiguation algorithm. In order to deal with Arabic morphology issues, we used araMorph package [1] , which is based on an n-gram model. The two main benefits of using the n-gram approach are that it is language independent and that it takes the misspelled and transliteration words that we face in the training data into account. The approach differs from the existing Arabic approaches done in this manner, in terms of the enhancement of the pure n-gram model. Based on the conflation approach, in this step, all word form variants of the user query and in the training data will be detected based on similarity scores measured between the user query term and the words existing in the lexicon.

To describe the problem more clearly, we consider for simplicity the Arabic word "دين" as described in section II. The absence of the diacritization from the Arabic printed media or the Internet web sites causes high ambiguity. The Arabic word "دين" has two translations in English (Religion or debt). We calculate the occurrences of this word in the training corpus for both senses. As it is shown in Table I the word "دين " was found in basic form for the sense (Religion) 49 times and for the sense (Debt) only 10 times.

As Table II shows, when we consider the inflectional form for the word "دين " we see that the occurrence of the inflectional form for the word "دين " with the sense (Religion) is 1192 and with the sense (Debt) is 231.

Table III shows sentence examples from the training corpus where the ambiguous word "دين "appears in basic or inflectional form with both senses. Detecting all word forms variants of the user query terms in the corpus is very essential when computing the score of the synonym sets, as it is shown in the Table II. More than 1386 sentences will be visible to the approach to disambiguate the ambiguous word "دين". For more details about the word form variant detection and their impact on the retrieval performance, we refer the reader to our previous work [2][3].

TABLE I.
THE OCCURRENCE OF THE AMBIGUOUS WORD "دين" IN THE BASIC FORM FOR BOTH SENSES

| The ambiguous word | senses | Occurrence in training data |
|---|---|---|
| | | Basic form |
| دين | Religion | 49 |
| دين | Debt | 10 |
| Total | | 59 |

TABLE II.
THE OCCURRENCE OF THE INFLECTIONAL FORM FOR THE AMBIGUOUS WORD "دين" FOR BOTH SENSES

| The ambiguous word | senses | Occurrence in training data |
|---|---|---|
| | | Inflectional form |
| الدين | The Religion | 75 |
| والدين | And the Religion | 22 |
| الأديان | The Religions | 45 |
| والأديان | The Religions | 7 |
| الدينية | The Religious | 63 |
| والدينية | And the Religious | 28 |
| Total | | 240 |
| الدين | The debt | 860 |
| والدين | And the debt | 22 |
| الديون | The debts. | 255 |
| والديون | And the debts. | 9 |
| Total | | 1146 |

In the following, our approach based on the Naïve Bayesian algorithm, where we learn words and their relationships from a parallel corpus, taking into account that the morphological inflection that differs across the source and target languages, is described.

### *B. Approach based on Naïve Bayesian Classifiers (NB)*

The Naïve Bayesian Algorithm was first used for general classification problems. For WSD problems it had been used for the first time in [28]. The approach is based on the assumption that all features representing the problem are conditionally independent giving the value of classification variables. For a word sense disambiguation tasks, giving a word $W$, candidate classification variables $S = (s_1, s_2, ..., s_n)$, which represent the senses of the ambiguous word, and the feature $F = (f_1, f_1, ..., f_1)$ which describe the context in which an ambiguous word occurs, the Naïve Bayesian finds the proper sense $s_i$ for the ambiguous word $W$ by selecting the sense that maximizes the conditional probability of occurring given the context. In other words, NB constructs rules that achieve high discrimination between occurrences of different word-senses by a probabilistic estimation. The Naive Bayesian estimation for the proper sense can be defined as follows:

$$P(s_i \mid f_1, f_2, ...., f_n) = p(s_i) \prod_{j=0}^{m} p(f_j|s_i) \qquad (1)$$

TABLE III.
SENTENCES EXAMPLES FOR THE AMBIGUOUS WORD "دين" FOR BOTH SENSES IN BASIC AND INFLECTIONAL FORM

| sense | Form | Arabic sentence | English translation |
|---|---|---|---|
| Religion | Basic | لأن الإسلام الذي هو *دين* حوار وانفتاح على الناس | because Islam, which is a ***religion*** of dialogue and openness to people |
| Debt | Basic | نضيف إلى ذلك أن الولايات المتحدة الأمريكية أكبر دولة مدينة في العالم، فلديها 400 مليار دولار عجزاً في ميزانيتها، يتم تمويلها عن طريق الاقتراض من المؤسسات الدولية والبنوك أو عن طريق تحويل هذا العجز إلى *دين* في الموازنة | In addition, the USA is the biggest debtorcountry in the world as it has a budget deficit of $400 billion which is financed through borrowing from international institutions and banks or through converting such a deficit into a budget ***debt***. |
| Religion | Infl. | ودعوا الوزير إلى التراجع عن قرار افتتاح المدرسة واستبدالها بمركز ثقافي ينشر تعاليم *الدين* والثقافة العربية | They called on the Minister to backtrack from that decision and to replace that school with a cultural centre promoting tenets of the ***religion*** and Arabic culture. |
| Debt | Infl. | وأكد الوزير أن الدين الخارجي على مصر هو في مستويات آمنة استناداً إلى ترتيبات جدولة *الدين* في نادي باريس | The minister emphasized that the foreign debt on Egypt was at safe levels due to the arrangements ***of debt*** scheduling in Paris Club. |

The sense $s_i$ of a polysemous word $w_{amb}$ in the source language is defined by a synonym set (one or more of its translations) in the target language. The features for WSD, that are useful for identifying the correct sense of the ambiguous words, can be terms such as words or collocations of words. Features are extracted from the parallel corpus in the context of the ambiguous word. The conditional probabilities of the features $F = (f_1, f_2, ..., f_m)$ with observation of sense $s_i$, $P(f_j|s_i)$ and the probability of sense $s_i$, $P(s_i)$ are computed using maximum-likelihood estimates with $P(f_j|s_i) = C(f_j, s_i) / C(s_i)$ and $P(s_i) = C(s_i)/N$. $C(f_j, s_i)$ denotes the number of times feature $f_j$ and sense $s_i$ have been seen together in the training set. $C(s_i)$ denotes the number of occurrences of $s_i$ in the training set and $N$ is the total number of occurrences of the ambiguous word $w_{amb}$ in the training dataset.

### *C. Features Selection*

The selection of an effective representation of the context (features) plays an essential role in WSD. The proposed approach is based on building different classifiers from different subset of features and combinations of them. Those features are obtained from the user query terms (not counting the ambiguous terms), topic context and word inflectional form in the topic context and combinations of them.

In our algorithm, query terms are represented as sets of features on which the learning algorithm is trained. Topic context is represented by a bag of surrounding words in a large context of the ambiguous word:

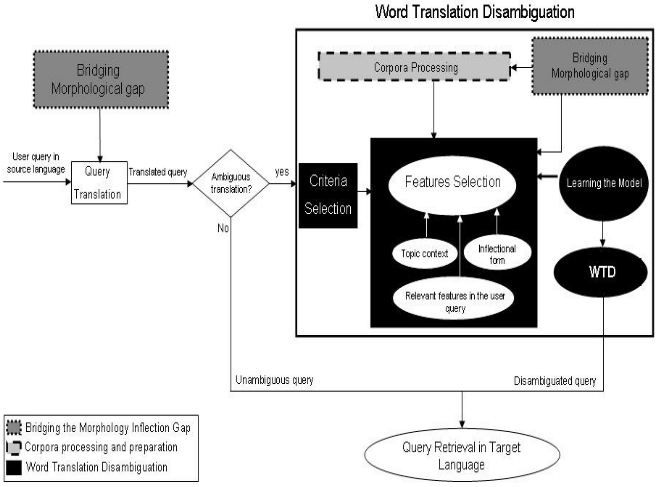
$$F = \{w_{w_{amb-k}}, \ldots, w_{w_{amb-2}}, w_{w_{amb-1}}, w_{amb}, w_{w_{amb+1}}, w_{w_{amb+2}}, \ldots$$
$$, w_{w_{amb+k}}, q_1, q_2, \ldots, q_n\}$$

where $k$ is the context size, $w_{amb}$ is the ambiguous word and *amb* its position. The ambiguous word and the words in the the context can be replaced by their inflectional forms. These forms and their context can be used as additional features. Thus, we obtain *F'* which contains in addition to the ambiguous word $w_{amb}$ and its context the inflectional forms $w_{\inf_i}$ of the given sense and their context, as it is shown in table II. Detecting all word form variants of the user query terms in the corpus will make 1386 sentences visible to the approach to disambiguate the ambiguous word "دين". In addition, we count for each context word the number of occurrences of this word and all its inflectional forms, i.e.

$$F' = F \mathop{\square}_{i=0}^{l} \{w_{w_{\inf_i -k}}, \ldots, w_{w_{\inf_i -2}}, w_{w_{\inf_i -1}}, w_{\inf_i}, w_{w_{\inf_i +1}}, \ldots, w_{w_{\inf_i +k}}\} .$$

### D. General Overview of the System

As Figure 1 shows, the system starts to process the user query. The input is a natural language query $Q$. The query is then parsed into several words $q_1, q_2, q_3, .., q_n$. Each word is then further processed independent of the other words. Since the dictionary does not consist of all word forms of the translated word, only the root form, for each $q_m$ in our query, we find its morphological root using the araMorph tool[2].



Word Translation Disambiguation

Fig. 1 General overview of the system

After finding the morphological root of each term in the query, the query term will be translated. In case the query term has more than one translation, the model will provide a list of translations (sense inventory) for each of the ambiguous query terms. Based on the obtained sense inventory for the ambiguous query term, the disambiguation process can be initiated. The algorithm starts by computing the scores of the individual synonym sets. This is done by exploiting the parallel corpora in which the Arabic version of the translated sentences matches words or fragments of the user query, while matched words of the query must map to at least two words that are nearby in the corpus sentence. These words could be represented in surface form or in one of its inflectional forms. Therefore, and to increase the matching score quality, special similarity score measures will be applied in order to detect all word form variants in the translation sentences in the training corpora. Since the Arabic version of the translation sentences in the bilingual corpora matches fragments in the user query, the score of the individual synonym sets can be computed based on the features that represent the context of the ambiguous word. As additional features the words in the topic context can be replaced by their inflectional form. Once we have determined the features, the score of each of the sense sets can be computed. The sense which matches the highest number of features will be considered as the correct sense of the ambiguous query term and then it will be the best sense that describes the meaning of the ambiguous query term in the context.

### E. Illustrative examples

To consider how the algorithm perform the disambiguation steps, consider the following simple query:

رسم جمركي للسلع
(A customs tax of commodities)

Step 1: The natural language query $Q$ is parsed into several words $q_1, q_2, q_3, .., q_n$.

Step 2: For each $q_m$ in the query, we find its morphological root.

Step 3: Translation of the query terms and creation of the sense inventory array in case of any for each of the query term is done. Table IV shows the sense inventory for each of the ambiguous query terms.

Step 4: The disambiguation process is initiated. The algorithm starts by computing the scores of the individual synonym sets:

- Number of times feature $f_j$ and sense $s_i$ have been seen together in the training set is computed.
- Number of occurrences of $s_i$ in the training set is computed.
- The total number $N$ of occurrences of the ambiguous word $w_{amb}$ in the training dataset is computed.
- The disambiguation score is computed and the sense which matches the highest number of features will be considered as the correct sense of the ambiguous query term.

Table V shows the disambiguation scores of the individual synonym sets for each ambiguous query terms with other query terms. As Table V shows there are 135 possible translations set for the original query in source language.

| 70 | appoint AND (control OR goods) | 0 | | | |

### *F. Training data*

The proposed algorithm was developed using Arabic/English parallel corpus[3]. This corpus contains Arabic news stories and their English translations. It was collected via Ummah Press Service from January 2001 to September 2004. It totals 8,439 story pairs (Documents), 68,685 sentence pairs, 93,120 segments pairs, 2 Million Arabic words and 2.5 Million English words. The corpus is aligned at sentence level.

## IV. Evaluation

We evaluated our approach through an experiment using the Arabic/English parallel corpus aligned at sentence level. We selected 30 Arabic sentences from the corpus as queries to test the approach. These sentences have various lengths starting from two words up to five words, as future work the maximum query length will be extended. These queries had to contain at least one ambiguous word, which has multiple English translations. In order to enrich the evaluation set, these ambiguous words had to have higher frequencies compared with other words in the training data, ensuring that these words will appear in different contexts in the training data. Furthermore, ambiguous words with high frequency sense were preferred. The sense (multiple translations) of the ambiguous words was obtained from the dictionary. The number of senses per test word ranged from two to nine, and the average was four. For each test word, training data were required by the algorithm to select the proper sense. The algorithm was applied to more than 93,123 parallel sentences. The results of the algorithm were compared with the manually selected sense.

For our evaluation, we built different classifiers from different subsets of features and combinations of them. The first classifier based on features that were obtained from the user query terms and topic context, which was represented by a bag of words in the context of the ambiguous word. The second classifier was based on the topic context and its inflectional form.

In order to evaluate the performance of the different classifiers, we used two measurements: applicability and precision [29]. The applicability is the proportion of the ambiguous words that the algorithm could disambiguate. The precision is the proportion of the corrected disambiguated senses for the ambiguous word. The performance of our approach is summarized in Table IV. The sense, which is proposed by the algorithm was compared to the manually selected sense.

As it is expected the approach is better in the case of long query terms which provide more reach features and worse in short query, especially the one consisting of two words. We consider that the reason for the poor performance is that, when the query consists of few words it is possible that the features which are extracted from the query terms can appear in the context of different senses. For example, consider the query "الدين الإسلامي" (The Islamic religion). When the algorithm goes through the corpus, the ambiguous word "الدين" (The Religion or The debt) will be found in two different context whether in Religion or Debt context. The query term "الإسلامي" (Islamic) can be found in both contexts of the ambiguous word as (Islamic religion) or as a name of bank (Islamic Bank), which is the context of the second sense (Debt). One possible solution for this issue is query expansion. This can be done by exploiting the corpus and suggesting possible term expansion to the user. The user then confirms this term expansion, which will help to disambiguate the ambiguous query term when translating to the target language.

Another reason for the poor performance is that due to the morphological inflectional gap between languages such as Arabic the same word can be found in different forms. In order to increase the performance of the disambiguation process all of these forms need to be detected.

Table VI shows the overall performance of the algorithm based on building two classifiers from different subsets of features and combinations of them. Those features are user query terms, topic context and word inflectional form in topic context and combinations of them. As is shown in Table IV, the performance of the algorithm is poor when using the basic word form. The reason for that, the Arabic word can be represented not just in its basic form, but in many inflectional forms and so we will have more training sentences that will be visible to the algorithm to disambiguate the ambiguous query terms.

Table vi.
the overall performance using Applicability and precision

| classifiers | Applicability | Precision |
|---|---|---|
| Query term + Topic context | 52 % | 68 % |
| Query term+ feature Inflectional form | 82 % | 93 % |

***Abstract*—This paper discusses a framework for development of bilingual and multilingual comprehension assistants and presents a prototype implementation of an English-Bulgarian comprehension assistant. The framework is based on the application of advanced graphical user interface techniques, WordNet and compatible lexical databases as well as a series of NLP preprocessing tasks, including POS-tagging, lemmatisation, multiword expressions recognition and word sense disambiguation. The aim of this framework is to speed up the process of dictionary look-up, to offer enhanced look-up functionalities and to perform a context-sensitive narrowing-down of the set of translation alternatives proposed to the user.**

## I. Introduction

AT PRESENT, even regular Internet users often access on-line resources in English which require lexical knowledge beyond their current level.

While Machine Translation has been expected to make this problem history, the state-of-the-art is still far from achieving this dream. Full-text machine translation is yet unreliable, and typical users are assisted in translation and language learning with only a variety of word-translation ‘electronic dictionaries’, operating either on-line on the Internet, or as off-line computer software. Generally, such dictionaries offer very simple look-up options and are based on the following functionalities:

1. The u ser types or copy-pastes a word in the input box, or clicks on a word from an alphabetical list of words.

2.The dictionary displays an entry if it contains one whose head word exactly matches the word which is entered. In most cases, the entry is from a scanned version of a paper dictionary. It is not difficult to see that the way a user consults an electronic dictionary is not very different from the way s/he queries paper dictionaries. As with paper dictionaries, the user is presented a list of possible meanings for every word under consideration. In many cases this could cause confusion or misunderstanding. Recent years have seen the development of new lexicographic/language learners’ tools referred to as *comprehension assistants* which seek to enhance the look-up functionality and in particular to narrow down the list of alternative translations through applying basic NLP techniques.

## II. Previous Work

### A. Xerox

The first comprehension assistant reported, *Locolex* (Feldweg and Breidt 1996), was developed by Xerox for French-English and English-German comprehension assistance. Locolex inspired applications developed later including Smarty, which is being discussed in this paper. Locolex, unlike conventional electronic dictionaries, offers the functionality for the user to click on words occurring in any machine-readable text, as opposed to copy-and-pasting separate words. Once the user clicks on a specific word, Locolex performs POS tagging which attempts to identify the correct part-of-speech tag, thus decreasing the number of possible translations. Multiword expressions recognition, based on regular expressions, is also applied, which could help identify the correct translation in particular cases. Locolex also keeps record of user sessions, allowing quick recall of previously checked words.

A recent version of Locolex incorporates word sense disambiguation which contributes to the narrowing down of the set of possible meanings even further.

### *B. Morphologic*

The comprehension assistants developed by Morphologic introduce several additional features.

In particular, one of their products, *MobiMouse* , correctly identifies multiword expressions even if the selected word is not the head of the expression and also offers comprehension assistance in any application running in the operating system environment. The user can click anywhere; the comprehension assistant is running in the background and flashes a translation in the corner of the screen.

### *C. SmartDict*

SmartDict (Kolev, 2005) is an English-Bulgarian dictionary which is somewhere between comprehension assistants and advanced conventional dictionaries. It performs a number of NLP preprocessings, including tokenisation, sentence-splitting, normalisation and multiword expression recognition, but it does not perform reduction of the possible translations by POS-tagging or word-sense disambiguation.

## III. Smarty – framework for bilingual and multilingual comprehension assistants

Inspired by Locolex, we developed Smarty - a framework for comprehension assistants for English-Bulgarian. While Smarty and Locolex share certain similarities, our comprehension assistant has the following distinctive features.

### *A. New Features*

While Smarty and Locolex share certain similarities, our comprehension assistant has the following distinctive features.

*1) Hybrid System*

Smarty represents a hybrid system. The interface is more comprehensive and elaborate than the interface of Locolex or MobiMouse in that it allows users to virtually work with two dictionaries – both an enhanced conventional dictionary and a comprehension assistant (see Fig. 1). In enhanced conventional dictionary mode users can browse freely all dictionary entries and familiarise themselves with the meanings of a specific word. This mode offers additional options such as suffix search, rhyme search, synonymy search etc. which are not present in conventional dictionaries.

*2) New Lexicographical Resource*

WordNet (Miller, 1995) is the lexicographical resource for this comprehension assistant. WordNet adds glosses which can be browsed by the user. Additionally, it makes it possible for word sense disambiguation to be performed.

*3) Extendability*

The alignment between the lexical database of WordNet and corresponding lexical databases for other languages allows bilingual word sense disambiguation to be performed. The incorporation of the existing databases of EuroWordNet (Vossen, 1998) and BalkaNet (Oflazer et. al, 2001), make it perfectly possible for comprehension assistants covering more languages to be developed using the same framework and the same core system. Smarty could be easily extended to be English to Greek, Turkish, Czech, Romanian, Serbian, Italian, Spanish, German, French, Dutch and Estonian comprehension assistants, if their already made lexical databases are available.

### *B. Graphical User Interface*

The aspects of the graphical user interface in the framework, which are different from the framework of conventional dictionaries, are:

*1) Free Text Input*

There is a free text input box, where the full text is pasted or typed. Users can point to the words in their context, instead of copy-pasting (Fig. 2).

*2) Tooltip*

Suggested translated meanings can appear in a tooltip, near the mouse pointer. This is less distracting for users than the translation appearing in a side window.

3) Additional Information

Additional information which assists comprehension is available - glosses, examples of usage etc. and can also be presented to the user in tooltip or in side windows, on demand.

Translation in tooltip proves to be much more convenient for users than translation in separate windows in the same applications or in the worse case - in another application.

POS-tagging allows Smarty to fit the most relevant translations in a tooltip, which could be scanned in few seconds by the user, without touching a scroller and without moving his or her sight away from the context. This also allows immediate continuation of the reading without distraction.

When using a conventional bilingual dictionary, if the queried word has ambiguous part-of-speech and a long entry with sections for each one, the user faces two problems: s/he is forced to figure out the correct part of speech alone; and if the user knows the part-of-speech s/he is forced to scroll and scan with the bare eye where the section for the correct part-of-speech begins. Also, the appearance of the translation in window of another application causes two other time penalties: first, the user is distracted from the reading flow and has to spend time switching attention from the text to the dictionary and back; and second, after the query is done, the user has to find the exact place in the text window where he or she has stopped reading.

### *C. Linguistic Databases*

The framework makes use of at least three linguistics databases: a conventional dictionary database and at least two lexical databases used to provide glosses and word sense disambiguation.

*1) Conventional Dictionary Database*

The conventional dictionary database allows the system to work in conventional dictionary mode. It could be a scan of a paper dictionary, which in this case is to be parsed and transformed in suitable format for processing. This database is used to build indices for *predictive typing* (known also as *autocompletion* ), suffix-search, rhyme search etc.

An English-Bulgarian dictionary database (a scan of a paper dictionary with about 51000 entries) was used in Smarty because it was freely available and suited for the purpose of this prototype.

Some of the entries include examples of usage, multiword expressions and phrasal verbs, which are parsed and used as resources for multiword expression recognition.

*2) WordNet*

WordNet is a large lexical database, consisting of synonym sets of words – "synsets" –s tructured by part-of-speech and numerous types of semantic relations. The richness of its structural information makes it a highly acceptable resource for various NLP tasks (Mitkov, 2003). In the proposed framework, it provides glosses, which are used as semantic database for word sense disambiguation (WSD).

Semantic relations included in WordNet – hyperonymy, meronymy, synonymy etc. – could be used in future versions to improve the precision of the WSD.

*3) EuroWordNet, BalkaNet etc.*

EuroWordNet is a multilingual set of semantic databases for European languages, which are aligned to WordNet and to each other. It consists of databases for Dutch, Italian, Spanish, French, German, Czech and Estonian.

BalkaNet is a similar set, including Bulgarian, Greek, Romanian, Serbian and Turkish lexical databases.

The links between the lexical databases enable direct translation of specific senses. It also allows multilingual translation within a single framework.

In the implementation discussed in this paper, a small version of Bulgarian BalkaNet is used, consisting of about 15000 synsets. However, the system could easily be extended with other databases from the BalkaNet or EuroWordNet frameworks, thus making it possible for "Smarty" to operate as an English-Greek, English-Romanian, English-Serbian etc. comprehension assistant.

## D. Natural Language Processing Stages

### 1) POS-tagging

Selecting a word in context, instead of copy-pasting or typing in a text box allows POS-tagging to be performed. For languages which exhibit typical ambiguity of lexical categories such as English, this could narrow the set of returned dictionary entries by two or three times.

The POS-tagger in Smarty prototype is SharpNLP – an LGPL .NET library, which was chosen because the system is coded in C#.

### 2) Lemmatisation and Normalisation

This stage saves the user the trimming of words copied from texts and thus speeds up the look-up. Lemmatisation and normalisation are also used in the multiword expression recognition and word-sense disambiguation stages to allow capturing variations.

### 3) Multiword expressions recognition

At this stage the context of the selected word is checked for matches with multiword expressions in the conventional dictionary database. The words from the context are lemmatised and then fuzzy-matched to patterns from a multiword expressions database. Different techniques are applied to compute the degree of match: bag of words, POS-matching, regular expressions. The fuzzy matching algorithm applied imply high recall, still delivering only one or few most relevant multiword expressions, which fit in a tooltip or a small text box.

Automatic multiword expressions recognition capabilities of Smarty allow faster look-up of multiword expressions, compared to the operation of conventional dictionaries, which usually lack such functionalities or capture only exact matches. A sorted list of multiword expressions and phrasal verbs, presented in Smarty, also helps users quickly find wanted translations of multiword expressions.

Using conventional dictionaries, finding out that there is a multiword expression in certain contexts may require the user to scroll and scan the whole dictionary entry by sight. It must be pointed out, that in cases of words with short entries Smarty does not have a significant advantage because a visual scan of possible expressions could also be done in few seconds. However, the advantage of multiword expressions recognition is significant when quering entries of common words like "run", "take", "go", "have" etc., which have many tenths of examples of usage.

### 4) Word-Sense Disambiguation

The ultimate goal of comprehension assistants is to find the most appropriate translation in a given context. Word sense disambiguation contributes to the further narrowing down of the list of possible senses. Figure 3 illustrates how the selected word initially featuring 80 potential meanings has the number of its possible translations reduced to 21 after POS tagging and even further reduced to 1 single possible meaning after correct word sense disambiguation.

In this implementation Smarty uses glosses from WordNet to perform simple WSD in English, related to the method of Lesk (Lesk, 1986) . The framework benefits from the alignment between the lexical databases of WordNet and BalkaNet, which allows word-sense disambiguated sense in English to be mapped directly to precise sense in Bulgarian or other language from BalkaNet or EuroWordNet.

The method for WSD in the prototype of Smarty applies the following algorithm:

1. A word in a text is pointed and then its context is tokenized, normalised and POS-tagged. It is then cleaned from stop-words which are considered to be confusing for the process of WSD.
2. WordNet synonym sets corresponding to the queried word are found in the database and their glosses are extracted.
3. Each gloss is tokenised, part-of-speech tagged, lemmatised/normalised and cleaned from stop-words.
4. The normalised context and the gloss are matched and word-matches are counted.
5. Until there are more glosses, go back to step 3. Otherwise:
6. The gloss with highest number of matches is suggested as the most probable sense. If there are not any matches, the most frequent sense referring to WordNet is suggested. If there are more than one senses with the same number of matches, the most frequent sense is suggested also, again referring to the order of senses in WordNet.
7. The index of the synonym set of the suggested sense is matched to the indices of BalkaNet.
8. If BalkaNet contains the disambiguated sense, then disambiguated translation in Bulgarian is displayed with confidence. Otherwise, other available senses are displayed with a sign of uncertainty.

This algorithm has low precision, due to its simplicity. Disambiguation in English is correct in two cases. The first case is when the context of the queried word includes specific discriminative words from the gloss of the correct sense. The second case is when discriminative words are not present in the context, but the most frequent sense is used, because the most frequent sense is suggested in case of uncertainty.

Precision in WSD to Bulgarian is lower than the precision in English, due to the limited size of the lexical database used–15000 synsets [Windows U1] versus 115000. Also, in most cases BalkaNet includes only one or few most frequent senses for a given word.

Examples of correctly disambiguated senses follow. The words from the glosses which are used to discriminate the sense are underlined.

*- What <u>instrument</u> do you play, Paul?*

*- I play the **bass.***

**Suggested sense*:*** bass – n. the member with the lowest range of a family of musical instruments.

– You are fired! – said the boss.

**Suggested sense:** fire – v. terminate the employment of; "The boss fired his secretary today"; "The company terminated 25% of its workers".

## IV. User Evaluation

Some aspects of Smarty's performance and features were evaluated in real environment by users and compared with two other electronic dictionaries - *SA Dictionary* and *Babylon*.

*SA Dictionary* is a popular English-Bulgarian conventional dictionary, based on the standard simple framework. *Babylon* is an advanced multilingual conventional dictionary framework with graphical user interface having certain similarities to the interface of comprehension assistants – the system captures words clicked anywhere on the screen. Babylon can recognise[Windows U1] phrasal verbs and multiword expressions, but only if they are in the exact form as they appear in the dictionary database. Also, the dictionary lacks NLP functionality for reducing the number of possible translations of single words.

Babylon offers machine translation, however it employs third-party on-line services (probably Systran) and this specific functionalities are not relevant for this evaluation.

### *A. Query time for single words translation*

Smarty framework provides three main quick results in tooltips:

1. The most relevant part-of-speech portion of the entry from a conventional dictionary.

2. A suggested multiword expression which matches the context of the pointed word.

3. Suggested word-sense disambiguated sense in Bulgarian.

A bubble with either a translation from these types appears virtually immediately on the test PC with 1.8 GHz Athlon CPU. The query time is between 0.2 sec to 1.2 sec. This is where the worst cases are met when querying words with the longest list of multiword expressions, due to the time needed to match them to the context.

SA Dictionary also provides virtually immediate results for single-word queries, while Babylon is delayed by a few seconds due to access to Internet resources. However, both lack the capability to reduce the entries to the most relevant sections. This often slows down the time for actual translation as the user is forced to scan long entries with the bare eye.

A small test was conducted in order to assess the time saved with Smarty (if any) in a real environment. Several chapters from Dan Brown's *The Da Vinci Code* were selected, in order to represent a common text with similar style and language complexity. Two native-Bulgarian speakers with different English proficiency read three chapters with Smarty, SA Dictionary and Babylon. Users queried unknown or ambiguous words, and searched their meanings in the entry displayed in dictionary's window (SA Dictionary and Babylon) or in the tooltip, provided by Smarty. The number of queries, the total time needed for the look-up in seconds and the average time per query were computed.

Table I .
User 1 - Undergraduate student

| Chapter | Dictionary | Words | Queries | Time | **Average** |
|---|---|---|---|---|---|
| 2 | SA | 909 | 31 | 153 | **4.94 s/q** |
| 45 | Babylon | 1149 | 23 | 173 | **7.52 s/q** |
| 100 | Smarty | 1183 | 24 | 80 | **3.33 s/q** |

Table II .
User 2 – PhD student

| Chapter | Dictionary | Words | Queries | Time | **Average** |
|---|---|---|---|---|---|
| 2 | SA | 909 | 29 | 74 | **2.55 s/q** |
| 45 | Babylon | 1149 | 28 | 100 | **3.57 s/q** |
| 100 | Smarty | 1183 | 37 | 97 | **2.62 s/q** |

The tables show that the PhD student is much faster than the undergraduate student with all three dictionaries. The results also suggest, that in the experiments carried out by the PhD student,Smarty and SA Dictionary are practically equal in performance, while the undergraduate student translates significantly faster with Smarty. Generally both observations could be explained by the higher English proficiency of the PhD student. The equal speed of operation using Smarty and a conventional] dictionary in one of the tests could be explained by the genre of the texts and by the high English proficiency of the PhD student. Her queries consist of rare words, which are not ambiguous , thus the entries in the conventional dictionary could also be scanned in a moment.

We conjecture that Smarty would perform much faster than conventional dictionaries if tested by language learners with much lower English proficiency. Language learners are expected to query more frequent words, which exhibit higher lexical and part-of-speech ambiguity. This is where Smarty's NLP preprocessing can offer significant advantage over the simple operation of conventional dictionaries, and where Smarty would be most useful.

## Acknowledgment

We would like to express our gratitude to Constantin Orasan, Irina Temnikova and Kiril Kolev for their suggestions and taking part in the evaluation experiments.

# SuperMatrix: a General Tool for Lexical Semantic Knowledge Acquisition

Bartosz Broda, Maciej Piasecki
Institute of Applied Informatics, Wrocław University of Technology, Poland
Email: {bartosz.broda, maciej.piasecki}@pwr.wroc.pl

***Abstract*—The paper presents the SuperMatrix system, which was designed as a general tool supporting automatic acquisition of lexical semantic relations from corpora. The construction of the system is discussed, but also examples of different applications showing the potential of SuperMatrix are given. The core of the system is construction of co-incidence matrices from corpora written in any natural language as the system works on UTF-8 encoding and possesses modular construction. SuperMatrix follows the general scheme of distributional methods. Many different matrix transformations and similarity computation methods were implemented in the system. As a result the majority of existing Measures of Semantic Relatedness were re-implemented in the system. The system supports also evaluation of the extracted measures by the tests originating from the idea of the WordNet Based Synonymy Test. In the case of Polish, SuperMatrix includes the implementation of the language of lexico-syntactic constraints delivering means for a kind of shallow syntactic processing. SuperMatrix processes also multiword expressions as lexical units being described and elements of the description. Processing can be distributed as a number of matrix operations were implemented. The system serves huge matrices.**

## I. Introduction

IF A *WORDNET*[1] for some language does not exists, then . . . it should be created as quickly as possible. This point of view is probably shared by the majority of researchers working in the area of Natural Language Processing. The stand of developers and companies is much less clear, but even them would love to have an occasion to criticise an existing wordnet for not solving all the large scale problems. There are two weakest points of the wordnet in general: its construction is very laborious process, in which skilled lexicographers must be involved, and it takes a lot of time to construct a new wordnet, even if we start with translating a wordnet built for another language (i.e. mostly the English wordnet). Both problems are strictly correlated. While starting a project on the construction of the Polish Wordnet [2], called plWordNet (or *Słowosieć* in Polish), we decided to build it from scratch, in order to construct it as a faithful description of the Polish lexical semantic relations. So we increased the amount of work to be done, but in the same time we did not increase the amount of money assigned to the project (anyway, as it was quite moderate, so it was not a big difference). However, from the very beginning we planned to support the work of lexicographers by different types of language tools automatically constructed on the basis of large corpora:

- delivering some means of intelligent semantic browsing across *lexical units*[2] (henceforth LU),
- or even suggesting to the lexicographer some lexical semantic relations between LUs or groups of LUs (e.g. wordnet synsets).

Browsing on the basis of LU meaning relations requires some way of measuring *semantic relatedness* between pairs of LUs. Following Edmonds and Hirst [3] we prefer the term semantic relatedness instead of the widely used term of *semantic similarity*, because the former better expresses the nature of a numerical measure one extracts from corpora. A Measure of Semantic Relatedness (henceforth MSR) is a function which for a given pair of LUs returns some real number expressing how semantically close the elements of the given pair are, regardless of the exact nature or cause of this relation:

$$MSR : L \times L \to R \tag{1}$$

where $L$ is the set of lexical units and $R$ is the set of real numbers.

As our objective is to build a set of language tools supporting wordnet construction, we will limit the rest of our considerations only to the automatic extraction of instances of lexical semantic relations from corpora. There are two main paradigms of automatic extraction of instances of lexical semantic relations, e.g. [4]:

- *pattern-based*,
- and *clustering-based*, called also distributional paradigm, as it originates directly from the *Distributional Hypothesis* formulated by Harris [5].

According to the pattern based approaches there are some lexico-syntactic patterns, which combine two LUs and mark the two LU as an instance of some lexical semantic relation, e.g. hypernymy, see e.g. a seminal work of Hearst [6]. So only one occurrence of a precise pattern can signal the given association of LUs.

The clustering-based approaches assume that the similarity of distributions of some LUs across different lexico-syntactic or even semantic contexts is evidence for their close semantic relation. The stronger the similarity is the closer the LUs are

[1] By wordnet we mean here an electronic thesaurus of a structure following the main lines of the Princeton WordNet thesaurus [1].

[2] A lexical unit is a one word or multiword lexeme named in the lexicon by its morphological base form and representing a whole set of one word or multiword forms possessing the same meaning and differing in the values of morphological categories.

in their meaning. The name of the paradigm emphasises that we are looking for similar distributions of LUs and, in some way, we cluster them into groups of highly semantically related LUs.

There are plenty of methods proposed for the automatic extraction of Measures of Semantic Relatedness. All start with processing a corpus and constructing a coincidence matrix describing co-occurrences of LUs (rows) and lexico-syntactic contexts (columns). They differ in three aspects: definitions of contexts, transformations of the raw frequencies and calculation of the final measure value. At the beginning of our project project it was completely unclear which known MSRs perform better, and which of them would work for Polish. Polish is not only a language using alphabet extended in comparison to the ASCII code[3], is a language typologically different than English, but also is a language with fewer language tools and resources than English. The third problem was the worst, as the difference between English and Polish in this area is huge. Thus we decided to construct a system capable of utilising existing Polish language tools, Polish corpora and reimplementing, investigating and evaluating as many MSRs as possible.

The goal of the paper is to present the constructed system called *SuperMatrix* and discuss its various successful applications. As we would like to make SuperMatrix free for research uses, we hope that the latter can guide potential users to the areas of its applications. The first experiments done with the help of SuperMatrix were presented in [7], and the general scheme of processing was discussed in [8]. Here we are going to present the first thorough description of SuperMatrix.

## II. Blueprint for the Construction of MRSs

There is a plethora of approaches to extraction of similarity between LUs, e.g. [9]–[12]. Basically, they all follow similar pattern for construction. This general blueprint as implemented in SuperMatrix is shown on Figure 1. Following the idea of *distributional similarity* and Distributional Hypothesis [5], first, co-occurrence data is collected from text corpora for selected words.

There are three main approaches to represent a context. One can count words occurring together with the given LU inside a passage of text, e.g. inside a paragraph or document. This approach has been used in the technique called *Latent Semantic Analysis (LSA)* [13]. Another popular method for context representation is counting words co-occurring inside a text window, this approach is called a *Word Space* [14]. In *Hyperspace Analogue to Language (HAL)* [15] smaller weights are assigned to words if they occur further from the centre of the context — the centre is occupied by the LU being described.

Very good results were observed after enriching description of a context with syntactic information, e.g. [8], [9], [12]. This method counts only co-occurrences between an LU in the context centre and selected lexico-syntactic relations in which the LU is involved.

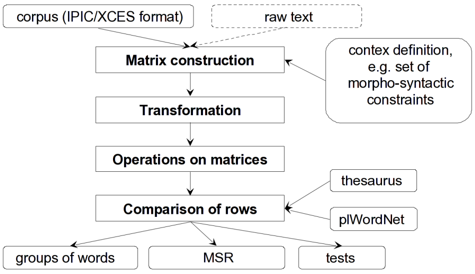

Fig. 1. General blueprint for creation of measures of semantic relatedness.

Usually LUs are represented as feature vectors in a high dimensional space. Each feature corresponds to a single context, in which an LU occurs in corpus. It is convenient for further processing to think about the collection of feature vectors in terms of a matrix $M$ (see figure 2), consisting of $i$ rows (words) described by $j$ features (context). The value of $M[n_i, c_j]$ tells how many times the word $n_i$ occurred in the context $c_j$.

In the next step co-occurrence matrices are used to calculate similarity between words. There are many methods for doing this. One can measure the Euclidean distance between word vectors, calculate cosine between vectors to measure how close they are one to another, etc. [16].

Experiments showed that raw frequency counts of co-occurrences are not very useful from the perspective of lexical semantic knowledge acquisition. First, after the analysis of the collected data it can become apparent that not all the features used are descriptive enough to differentiate between LU meanings. That is why an additional step of *filtering* features is often preformed [8], [12]. Second, there is a need to emphasise an inner structure (or a latent structure) of the data before comparing word vectors. There are two main approaches to this problem: based on *transformation* and *weighting*.

One of the well known example of transformation is *Singular Value Decomposition* [17]. It is a method for reducing matrix dimensionality, and was applied in LSA to achieve a form of generalisation from the raw frequency counts.

When comparing nouns one can quickly arrive to the conclusion, that almost every noun can be modified by "*liczny*" (*numerous*, *countless*), but "*bezołowiowy*" (*unleaded*) will be a feature of a few very specific LUs. This is where the weighting is helpful. The basic idea of weighting is to assign greater weights to features that are more descriptive than the others.

The above steps are required to create an MSR. But rarely the construction of MSR is the main aim of one's work. Usually it is only a means for achieving some other goal. For example one can cluster LUs in order to semi-automatically extend lexicons [18] or use similarity for the correction of medical handwritten documents [19].

Last, but not least, there remains a question about comparing different MSRs. There are three main approaches to evaluation of MSRs [20], [21]: mathematical analysis of

[3] In 2005, when we started, many similar systems did not process the extended ASCII code, not mentioning UTF-8.

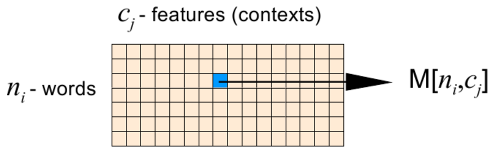

Fig. 2. Schematic view of co-occurrence matrix.

their formal properties, application specific evaluation and comparison with human judgement. For example, Landauer and Dumais used the third approach for the evaluation of LSA. They used a synonymy part of the *Test of English as a Foreign Language (TOEFL)* to test the ability to automatically differentiate between synonymous and non-synonymous LUs. Because TOEFL is limited in the number of questions it includes and is available only for English, a *WordNet Based Synonymy Test (WBST)* was proposed to generate “a large set of questions identical in format to those in the TOEFL” [22]. An analysis of WBST-based approach to evaluation of MSRs is presented in [21].

An instance of the WBST test is built thus: first, a pair of LUs: $\langle q, s\rangle$, is chosen from a wordnet (*WordNet* 2.0 in [22]), where $q$ is a question word, and $s$ is a randomly chosen synonym of $q$; next, three other words that are not in synsets of $q$ and $s$ are randomly drawn from the wordnet — they are a detractor set $D$. The task for MSR is to point which word from the set $A = D \cup \{s\}$ is a synonym to $q$. For example for the word *administracja (administration)* $A$ consists of: *poddasze* (attic), *repatriacja* (repatriation), **zarząd** (board, management) and *zwolennik* (follower, zealot).

## III. SuperMatrix

SuperMatrix is a collective name for a set of libraries for programmers and end-user tools for creation, storing and manipulation of co-occurrence matrices describing distributional patterns of LUs.

Overall, the implementation and design has been dictated by requirements placed upon SuperMatrix. Above all the system should be *extensible* and *flexible*. This property is necessary for experimenting with different methods of MSR extraction. *Efficient* processing is also crucial, as statistical methods tends to yield better results with the increasing amount of data [23]. Thus, the software has been written in C++, with additions of Python bindings and helper scripts.

Because we are working in heterogeneous environment we wanted the system to be as much *portable* as possible. This could also lead to lessen effort in embedding parts of the system in end-user applications. After conducting a few experiments we realized that ability to quickly test new algorithms would be very convenient, so we added *fast prototyping* to the requirement list.

SuperMatrix consists of several modules, namely:

- Matrices – a library for storing matrices.
- Comparator – a library enabling computation of similarity between rows of matrices (i.e. between LUs) using different MSRs.
- Set of tools, including (but not limited to) tools for creation of matrices: LUs by features, tools for evaluating of MSRs, tools for joining different matrices and analysis of the matrix content, e.g. manually browsing selected rows and columns from any matrix, including transformed and weighted matrices.
- Clustering – package consisting of several clustering algorithms. SuperMatrix can interact with CLUTO [24] and perform Clustering by Committee(CBC) [18], RObust Clustering using linKs (ROCK) [25] and Growing Hierarchical Self-Organising Maps (GHSOM) [26]. We reimplemented ROCK and GHSOM with little modification, CBC was reimplemented as well as significantly extended [27].
- Set of helper scripts and SWIG[4] wrappers for main classes of the Matrices and Comparator libraries.

For portability reasons we wanted to avoid external dependencies as much as possible. Only required components are open-source and cross-platform. CMake[5] is used for our build system. SuperMatrix is also heavily dependant on availability of Boost libraries[6], Other used software packages are not so crucial for SuperMatrix, e.g. SWIG is needed only for generating Python wrappers, CLUTO for clustering. For the construction of matrices from Polish corpora we also use parts of TaKIPI [28] engine – an open-source mopho-syntactic tagger for Polish[7]. We have tested SuperMatrix under different flavours of Linux as well as Microsoft Windows.

This system has been under active development for almost two and a half years now. At the time of writing it consists of almost 24 thousands lines of C++ code and almost 3.5 thousands of lines of code written in Python.

### A. Matrices

Most fundamental question for software toolkit performing heavy computation on matrices is: how to represent a matrix object in computer memory? There are many options for doing this, i.e. one can store it in a dense or sparse format, for a sparse format there exists many possible representations. Not wanting to be bound to only one implementation we have defined set of operations that a matrix has to be able to perform and tested several different approaches.

A dense format was used for small matrices. *Compressed Column Storage* (CCS) [17] is not very convenient for a matrix whose content is being changed constantly. During first experiments [7] we created implementation for storing matrix in database. We tested three possible representations (storing columns, rows or non-zero cells of a matrix), but performance overhead was too large for practical usage. So we have removed support for the storage in database.

It appeared that the most powerful (in terms of flexibility and efficiency) representation is the one using `map` collection of the standard C++ library. Thanks to guaranteed

$O(log(n))$ complexity we have achieved both flexible and efficient implementation of a matrix. We have encapsulated functionality of a word feature vector using this representation in `CompressedVector` class. Matrices using this representation were called `CCSMatrix` (for storing matrix columnwise) and `CRSMatrix` (for storing in row fashion).

To improve performance we cache some information together with vectors of features. Most importantly we keep entropy of a vector and sum of vector cells. A `SuperMatrix` class is a composition of such cached data (`Feature` class) and `CRSMatrix` (`CCSMatrix`).

Classes in the namespace `Matrices:IO` are capable of saving matrices in a few popular format. Native SuperMatrix format is based on sparse format used by CLUTO [24]. This makes interaction with CLUTO easier. Matrix can also be exported to CCS or CRS format, which enable interaction with such tools like Infomap NLP [29], SenseClustres [11] or SVDPACK [17].

In the current representation we have been able to perform efficient computation[8] using matrices for 13 thousands words described by more then 270 thousands of features created on the basis of a corpus consisting of more then 550 million words[9].

### B. Comparator

Comparator library is used for calculating similarity values between rows of a matrix. It is extensible library used for constructing and testing different approaches to computation of MSRs.

A typical framework for processing is presented on Figure 3. After creation of a matrix some global filtering of columns is performed. It follows intuition that some features are not good discriminators for a matrix row. SuperMatrix can do filtering using three methods:

- Using a stoplist. This step is performed by most of the algorithms, even if it is not implicitly mentioned. Stoplist consists of functional words (like conjunction or prepositions) and words that are not good meaning bearers. Usually this step is performed before creation of a matrix, but we allow to do it afterwords.
- Filtering using the *minimal global term frequency* of a word. Most statistically based methods do not cope well with events of extremely low frequencies, so those events are usually treated as outliers and are removed from dataset.
- Filtering using entropy of a column as a measure of noise it introduces. We used Shannon's entropy:

$$Entropy_w = -\sum_i p_{w,i} \cdot \log p_{w,i}, \qquad (2)$$

  where $p_{w,i}$ is probability of occurrence of the $i$'th feature with the word $w$. Entropy is maximised for events of maximal uncertainty — here for features that do not differentiate good between rows of a matrix.

We observed that, some features are globally good discriminators, but for certain LUs they are caused by some accidental frequencies (e.g. an error of morpho-syntactic disambiguation, sentence boundary detection or a simple spelling mistake). That is why we have isolated yet another step in the process, namely *local feature selection*. It is implicitly present in co-occurrence retrieval models [12] (CRM). The feature sequences selected from the rows for both LUs may have to be padded (usually with zeroes), if the similarity measure requires equal-size vectors.

Z-Score (variant of t-score) can be used as a measure of association between an LU and a feature. If the observed frequency of occurrence of some feature with some LU is significantly greater then expected, then this feature is a good discriminator for this LU.

In the following step we performed weighting of feature vectors of LUs. This stage aim for emphasising important data in matrix. Several weighting schemes were implemented in SuperMatrix:

- Term frequency – inversed document frequency is a popular method for decreasing weights of the very frequent words used in Information Retrieval (IR) for assigning lower scores to words occurring in all documents:

$$tf.idf_{w,d} = tf_{t,d} \cdot \log \frac{N}{df_t}, \qquad (3)$$

  where $tf_{t,d}$ is a number of occurrences of the word $t$ in the document $d$, $df_t$ is the number of documents containing the word $t$, $N$ is number of documents. This weighting scheme has been used mainly for processing of document by words matrices.
- In LSA [13] before reduction of the dimension, a matrix has been weighted in two-step process. First the cells of a matrix were scaled logarithmically: for each $i$, $j$: $M[w_i, c_j] = \ln(M[w_i, c_j] + 1)$ and divided by entropy of a row of a matrix. We use *logent* as a name for this weighting scheme.
- Z-Score (or t-score) can be used not only for local selection of features, but also as a weighting function, e.g. [8], [33].

[8] On a contemporary PC, i.e. 1,5 GHz processor with 1 GB of RAM.

[9] 254 millions words from IPI Pan Corpus [30], 100 millions from Rzeczpospolita [31] (Polish newspaper), and 100 from the Polish edition of Wikipedia [32]

- Another popular family of weighting schemes is based on *Mutual Information* (MI). In [9] some formal introduction for MI in the context of extraction of MSRs is presented. In *The Sketches Engine* [34] this measure was used for the generation of a distributional thesauri. In [18] a variant of this measure called *Pointwise Mutual Information* was used (extended with a *discounting factor*).
- Some measures of similarity operate in probability space. There are few methods for transition from frequencies to probabilities. We used for this purpose *Maximum Likelihood Estimation*.
- To reimplement best faring MSRs from [12] we added weighting schemes based on $CRM_{MI}$ and $CRM_{dt}$.
- During experiments with different MSRs we noticed [8] that feature values in the matrix depend too directly on frequencies. However no corpus is perfectly balanced, and any weighting function alone does not solve the problem. We need some generalisation from the raw frequencies. Applying SVD to very sparse matrices does not help [7]. We assumed that similarity of two types of objects depends more on which significant features characterise them than on the exact numerical values of those features' "strength". So, we developed *Rank Weight Function*(RWF) – a weighting scheme that builds relative ranking of importance of features from raw frequencies[10]. Experiments showed that for Polish the MSR based on RWF produces better results [35], in the WBST test. SuperMatrix supports methods enabling transition into the rank space.

After weighting of a matrix one can perform similarity computation. We implemented several similarity functions, e.g. the commonly used, geometry inspired *cosine function*, $SIM_{IRAD}$ – function using divergence of the two probability distributions, $SIM_{CRM}$ for the reimplementation of the co-occurrence retrieval models (CRM), Lin's measure based on information theory, etc. Surprisingly, cosine performed very well in comparison to other functions.

On the figure 3 one step is not shown: transformation of a matrix. Transformations are usually computationally intensive, so most of the time they are performed independently of typical process shown described earlier. We use a few methods of transformation in current version of SuperMatrix, namely:

- Singular value decomposition using SVDPACKC [17].
- Transformation of a LUs by features matrix into the similarity matrix. This transformation is useful for example during exporting data into CLUTO for clustering.
- Relative Frequency Focus — a transformation required for reimplementation of the approach presented in [36].

As a final note on Comparison module we want to emphasise that the framework presented on Figure 3 is not fixed in SuperMatrix. Our framework seems to encompass many, if not all, methods of MSR construction. For instance, to reimplement CRM, one needs the identity function for global selection, some weight function analysed in CRM for transformation, local selection by the condition $\mathbf{M}[w_i, c_j] > 0$ (applied after transformation) and the CRM F-score as the similarity measure.

### *C. Tools*

This section selectively describes tools available in SuperMatrix package for usage with little to no coding at all.

*1) Architect:* Collective name for applications used to create different kinds of co-occurrence matrices. Using tools in this category we can create:

- a documents by words matrix (for document clustering or Information Retrieval),
- a window matrix, i.e. a matrix in which context describes co-occurrence of words in text window of fixed sized (e.g. 5 words to the left and 5 words to the right from the target word),
- a HAL-like matrix — a matrix created in a similar manner to window matrix, but higher scores are assigned to words occurring closer in the text window,
- a sentence matrix — a window matrix with non-fixed size of a text window, in which only co-occurrences in the same sentence are counted,
- a matrix describing LUs by co-occurrence of those LUs in syntactic relations.

Because there is no robust parser available for Polish, for the creation of a matrix describing co-occurrences of LUs in syntactic relation we used a simplified approach based on defining morpho-syntactic constraints. Those constraints are expressed in JOSKIPI — a specialised language developed for TaKIPI [28] — a Polish morpho-syntactic tagger.

It is worth noting that Architect can create matrix for LUs as well as for multiword expressions (MWE). We require only a limited description of syntactic dependencies between constituents of MWEs. In SuperMatrix a module for the automatic extraction of those dependencies is available (for the description of this method see [37])

As the amount of textual data is increasing, processing of a raw text (or annotated text in XML format) is becoming performance bottleneck. To speed up the process of matrix construction SuperMatrix can read binary format generated by Poliqarp [38].

*2) WBST Tester:* A tool performing evaluation of MSRs by the application of the *WordNet Based Synonymy Tests (WBST)*. With addition of a few Python scripts we can generate WBST, test MSRs and perform test on statistical difference of the results produced by different MSRs.

*3) Summator:* A tool for joining different matrices. We observed that combining several matrices created with usage of different morpho-syntactic constraints resulted in better MSRs [21].

*4) VectorExtractor:* A tool for supporting manual analysis of a matrix content. i.e. manual browsing of parts (rows and columns) of huge matrices.

*5) Relations:* SuperMatrix includes also a set of tools for preparing training data used during training classifiers processing pairs of LU and assigning them to different types

[10] For detailed description of RWF see [8], [35].

of wordnet relations, see [39]. Features extracted on the basis of raw matrices or transformed matrices are next stored in the ARFF format which is supported by many Machine Learning systems e.g. Weka system [40] used in [39]

*6) Simbuilder:* In many applications it is easier first to transform the matrix describing LUs by row vectors of features into the square matrix of LU similarity, e.g. the generation of the list of the most similar LUs to the given one applied in the initial phase of CBC [18], or calculation of weights in the RFF MSR [36].

This last task has complexity of $O(n^2)$, where $n$ is dependent on the number of LUs in the matrix. For large matrices the expected time of transformation to the domain of similarity is barely acceptable. For solving this problem, one can apply several approaches, e.g. based on some heuristics that are introduced to increase the speed of performed computations, e.g. [33], [34]. Mostly, precision become a little decreased, but the time of processing is reduced a lot.

From the point of view of the extraction of MSR for the needs of the construction of a lexical semantic network, precision is most important, so its decrease cannot be accepted. Fortunately, the calculation of the LU similarity matrix can be easily distributed. We constructed a tool that can divide the whole task into several computers or processing nodes in a cluster of computers. Communication between processes is based on the Message Passing Interface.

## IV. Usage examples

The primary application of SuperMatrix is construction of tools for semi-automatic extraction of instances of lexical semantic relations used next in extending plWordNet [41]. Mostly the system is used for the construction of different MSRs [7], [8], [21], [35], but also was applied to clustering text documents [42].

SuperMatrix was applied to the construction of MSRs for: Polish nouns [7], [8], [21], verbs and adjectives [35]. The system was also used in the development of the Rank Weight Function [8], which was next implemented in it. SuperMatrix was used for preparing training data for the construction of classifiers of types of lexical semantic relations [39], e.g. hypernymy, meronymy etc.

An interesting application was the support for the construction of a corpus on the basis of documents from the web. SuperMatrix was applied to construct a tool discovering duplicates of documents in a semi-automatic way. For the documents downloaded from the web[11] a matrix: documents by words was built. Next the matrix was transformed to the similarity matrix. On the basis of the similarity matrix pairs of documents whose similarity was above some defined threshold were stored in a file sorted in the descending order of their similarity. The high similarity of documents was a precise signal of duplication, so it was enough to manually check some of the top documents in order to remove duplicates.

Finally, SuperMatrix was utilised in the project whose goal was to develop an OCR of handwritten medical documents. A language model based on the distributional semantic similarity of words was built on the basis of SuperMatrix [19]. The model was next used for the correction of recognition done on the graphical level. A sequence of token positions was delivered to the system. Each token position was assigned a list of potential recognitions for this position. The semantic language model built on the basis of the domain corpus was used in the algorithm called SemWnd, which tried to find a sequence of potential recognitions maximising the semantic consistency of the sequence.

## V. Existing systems

There exists a few software solutions that can satisfy some of design requirements stated in Section I. Reimplementation of LSA for Polish [43] was performed using the combination of *MC Toolkit* [44] and SVDPACKC [17]. We have stumbled upon few problems with that combination. Most important, MC Toolkit supported only ASCII encoding and could only create a words by documents matrix. Also SVD approach is computationally expensive, we were able to reduce dimensions of a matrix describing only four thousands nouns appearing in about 180 thousands short documents [7]. *Infomap NLP* package [29] supports similar functionality to MC Toolkit with SVD, but it was especially created for the extraction of word meanings from free text corpora. One noticeable improvement over MC Toolkit is ability to operate in Word Space. It suffered from similar limitations because of using combination of MC Toolkit with SVDPACKC. Additionally we had problems with building and installing this system.

Recently, Infomap NLP package has been abandoned in favour of a new system called *Semantic Vectors* (SV) [10]. Main differences with Infomap NLP are: usage of random projection instead of SVD for dimensionality reduction and the implementation, which was written completely in Java, using Apache Lucene as a document-indexing engine. Although Semantic Vectors looks interesting it currently dose not support many MRSs. Also, it does not support other methods for the description of context than co-occurrences in document or text window. First public release of SV happened in October, 2007, when SuperMatrix had most of its functionality already implemented.

Natural Language Toolkit (NLTK) [45] is a popular software for performing fundamental natural language processing task. It does not fully support statistical lexical semantic knowledge acquisition and does not support any Polish corpora.

SenseClusters (SC) [11] is the most relevant and similar package to SuperMatrix. It is a collection of Perl modules and programs for clustering of similar words (and contexts) based on distributional similarity. It supports couple of MSRs, creation of Word Space matrices and interacts very well with SVDPACKC for dimensionality reduction and CLUTO for clustering. Unfortunately it does not support Unicode, and cannot use morpho-syntactic constraints or a similar mechanism for the definition of features during matrix construction.

[11] First the downloaded documents were filtered according to the presence of too many words not recognised during the morphological analysis

Sketch Engine (SE) [34] provides support for distributional thesauri out of text corpora. At the time of design phase of SuperMatrix SE did not provide full support for multiword expressions. For computation it used a modification of Lin's measure and currently it uses modification of the Dice coefficient for performance reasons. Being a commercial, closed-source application, we are not aware of possibilities of experimenting with self-made MSRs inside it. Keeping data on an external server would be inconvenient for our needs too.

## VI. Conclusions

We have presented SuperMatrix — a general tool for the acquisition of lexical semantic knowledge from text corpora. At the end of the project we would like to release the version 1.0 for public usage under a free research licence. Commercial licenses are already available.

Possible application areas for SuperMatrix include already mentioned extraction of MSRs from corpora and semantic correction of handwritten text. This system can be also used to perform unsupervised word sense disambiguation, named entity disambiguation, sentiment analysis, document indexing, clustering and retrieval and search engine construction. One can even use SuperMatrix for the extraction of lexical semantic relation in a way following the pattern-based paradigm, e.g. lexico-syntactic patterns expressed in JOSKIPI are used as features describing matrix columns.

We suspect that our system can be also used outside the domain of natural language processing, i.e. everywhere were an object can be represented as a feature vector (especially in high dimensional space).

We plan to use and extend SuperMatrix in upcoming research projects. Because of the highly parallel nature of processing we will extend tools in a way enabling flexible computation in distributed environment via Message Passing Interface (MPI).

We also want to create tools for the creation of matrices for other languages. As a primary goal we will focus on English, with possible addition of other languages. Also we will extend Comparator module with additional weighting schemes and similarity functions.

***Abstract*—The article discusses methods of improving the ways of applying Balanced Random Forests (BRFs), a machine learning classification algorithm, used to extract definitions from written texts. These methods include different approaches to selecting attributes, optimising the classifier prediction threshold for the task of definition extraction and initial filtering by a very simple grammar.**

## I. Introduction

THE paper deals with extracting definitions from relatively unstructured instructive texts (textbooks, learning materials in eLearning, etc.) in a morphologically rich, relatively free word order, determinerless language (Polish). The same methods could easily be used for other similar languages without or with only minor changes, though. The work reported here is a continuation of work carried out within the recently finished *Language Technology for eLearning* project (LT4eL; http://www.lt4el.eu/).

The aim of the paper is to show how the results of previous attempts, presented in [1], can be improved by choosing the optimal threshold of classifier's prediction, with respect to the task of definition extraction, as well as to show that these improved results are close to optimal, in the sense that preliminary filtering by a simple grammar does not improve them significantly, as it was the case in experiments described in [2]. Attempts to use a different set of attributes will also be mentioned.

We used the same corpus of instructive texts as in [1] and [2]. It was automatically annotated morphosyntactically and then manually annotated for definitions, and contains over 30000 tokens, almost 11000 sentences and 558 definitions. These were divided by annotators into 6 types, depending on the most recognisable marker of being a definition:

- copula verb (e.g. cat **is a** domestic animal…)
- other verbs (e.g. we **define** a cat as a domestic animal…)
- punctuation (e.g. cat**:** a domestic animal…)
- layout (e.g. defined phrase in bold, large font, the definition in smaller font in the next line)
- pronoun
- other

We performed the experiments on two corpora: the whole set (described above) and its copula-type subset (the same sentences, but only 173 definitions). The experiments for other languages, conducted by other members of the LT4eL project, have shown that copula definitions have the highest probability of being successfully extracted by means of machine learning methods.

Note that the number of definitions in both sets is not exactly equal to the number of what we later call *definitional sentences*. Manually annotated definitions may begin or end in the middle of a sentence, and span multiple sentences. However, the ML methods operate on sentence level: a definitional sentence in this context is a sentence that has a nonempty intersection with at least one definition. For instance, in the whole set there are 546 definitional sentences.

The rest of the paper is organized as follows. In Section II we describe the classification method used for definition extraction. In Section III we discuss the possibilities of choosing representative attributes of words for the task of definition extraction. In Section IV we present differences in the achieved results, with respect to chosen methodology of interpreting classifier's outcome. In Section V we present the influence of manually constructed grammars on the accuracy of our definition extraction approach. Finally, we present the previous work done in the field in Section VI and conclude in Section VII.

## II. BRF algorithm

Random Forest (RF; [3]) is a homogeneous ensemble of unpruned decision trees (e.g., CART, C4.5; [4]), where—at each node of the tree—a subset of all attributes is randomly selected and the best attribute on which to further grow the tree is taken from that random set. Additionally, Random Forest is an example of the bagging (bootstrap aggregating) method, i.e., each tree is trained on a set bootstrapped from the original training set. Decisions are reached by simple voting.

Balanced Random Forest (BRF; [5]) is a modification of RF, where for each tree two bootstrapped sets of the same size, equal to the size of the minority class, are constructed: one for the minority class, the other for the majority class. Jointly, these two sets constitute the training set.

Similarly as in [1], for the task of extracting definitions from a set of documents by sentence classification, we use the following version of the BRF algorithm:

978-83-60810-14-9/08/$25.00 © 2008 IEEE

- split the training corpus into $n_d$ definitions and $n_{nd}$ non-definitions; the input data is heavily imbalanced, so $n_d \ll n_{nd}$;
- construct $k$ trees, each in the following way:
  - draw a bootstrap sample of size $n_d$ of definitions, and a bootstrap sample of the same size $n_d$ of non-definitions,
  - learn the tree (without pruning) using the CART algorithm, on the basis of the sum of the two bootstrap samples as the training corpus, but:
  - at each node, first select at random $m$ features (variables) from the set of all $M$ features ($m \ll M$; selection without replacement), and only then select the best feature (out of these $m$ features) for this node; this random selection of $m$ features is repeated for each node;
- the final classifier is the ensemble of the $k$ trees and decisions are reached by simple voting.

We have chosen the value of $m$ to be equal to $\sqrt{M}$ in all the experiments, although other sufficiently small values of $m$ could be used, as discussed in [3].

Up to $k = 800$ random trees were generated in each experiment. We always quote the results for the best-performing number of iterations in a given configuration (corpus, attributes, optimisation and filtering). The best-performing number varied between 300 and 700 for different configurations.

## III. Choosing the attributes

In [1], a set of 10 permutations of $n$-gram types was used for document representation as machine learning attributes (Table I). The set was carefully chosen by a half-statistical, half-heuristic method (having in mind the $\chi^2$ statistic value with respect to the class attribute and statistical independence of the attributes). In these experiments 100 most common $n$-grams of each of the 10 types were used for document representation, resulting in a dataset of ca. 900 binary attributes (fewer than 100 values for *ctag* unigrams exist) and 10830 instances. Data instances correspond to document sentences, while the values of binary attributes indicate whether a particular $n$-gram appears in the sentence.

TABLE I
The previously used set of $n$-gram types.

| no. | $n$-gram | | | no. | $n$-gram | | |
|---|---|---|---|---|---|---|---|
| 1 | *base* | | | 6 | *base* | *base* | |
| 2 | *ctag* | *ctag* | *case* | 7 | *ctag* | *ctag* | |
| 3 | *ctag* | *base* | | 8 | *ctag* | *case* | |
| 4 | *base* | *case* | | 9 | *base* | *base* | *base* |
| 5 | *base* | *ctag* | | 10 | *ctag* | | |

In our current experiments we have tried a slightly different method. For each of the possible 39 permutations of 1-grams, 2-grams and 3-grams of available features: *base* (base word form), *case* (grammatical case) and *ctag* (part of speech of the word), we generate up to 100 most frequent $n$-grams. As not for all permutations 100 different $n$-grams exist, the final set has around 3750 attributes.

In each iteration of 10-fold cross-validation we proceed as follows:

- in the training set (90% of the corpus):
  1) order the attributes according to the value of the $\chi^2$ statistic with respect to the class attribute,
  2) select the top 900 attributes (those fitting the example class best),
  3) train the Balanced Forest classifier on the set;
- in the test set (10% of the corpus):
  4) reject all attributes not on the top 900 list,
  5) apply the classifier.

The number of attributes was not chosen arbitrarily. Previous experiments (cf. Table 4 in [1]) have shown that increasing the number of $n$-grams of each of the selected types over 100 does not improve the classification results. That is the reason why in that method (with 10 $n$-gram types, and not all types had 100 $n$-grams) about 900 attributes were used. For comparability, in the new method we used a similar number of attributes – chosen differently though.

The experiments were performed on the whole set of definitions (as in [1]), and also on a version of the corpus in which only the copula definitions were marked. We have used the two known versions of the F measures to assess the results:

$$F_\alpha = \frac{(1+\alpha)\cdot(\text{precision}\cdot\text{recall})}{\alpha\cdot\text{precision}+\text{recall}}$$

$$F_\beta = \frac{(1+\beta^2)\cdot(\text{precision}\cdot\text{recall})}{\beta^2\cdot\text{precision}+\text{recall}}$$

The new method gave promising results for the copula definitions:

TABLE II
Comparison of attribute selection methods, copula definitions

| attributes | precision | recall | $F_{\alpha=1}$ | $F_{\alpha=2}$ | $F_{\beta=2}$ | $F_{\alpha=5}$ |
|---|---|---|---|---|---|---|
| preselected | 16.50 | **84.40** | 27.60 | 35.59 | 46.30 | 50.06 |
| $\chi^2$ | **17.60** | 81.70 | **28.96** | **36.90** | **47.27** | **50.84** |

Unfortunately it turned out to be disappointing when applied to all definitions:

TABLE III
Comparison of attribute selection methods, all definitions

| attributes | precision | recall | $F_{\alpha=1}$ | $F_{\alpha=2}$ | $F_{\beta=2}$ | $F_{\alpha=5}$ |
|---|---|---|---|---|---|---|
| preselected | **21.37** | **69.04** | **32.64** | **39.60** | **47.74** | **50.33** |
| $\chi^2$ | 20.60 | 65.20 | 31.31 | 37.87 | 45.50 | 47.91 |

This leads to a conclusion that the more general method of choosing $n$-gram types for the task of definition extraction may still perform better than direct selection of specific $n$-grams in each classification iteration. The advantage of performing a purely statistical attribute selection lies in eliminating any preconceived notions about the role of certain word $n$-gram types in discriminating definitional sentences from non-definitional. On the other hand, a preselected set of $n$-gram types may be used without any further data analysis for document representation in other, similar problems, maybe even different languages.

## IV. Optimising the Threshold

The task of extracting definitions from an annotated corpus of documents was defined by the LT4eL project mentioned above, which focused on facilitating the construction and retrieval of learning objects (instructive material) in eLearning with the help of language technology. The results of automatic definition extraction were to be presented to the author or the maintainer of a learning object as candidates for the glossary of this learning object.

The intended use determines the appropriate approach. It is obviously easier to reject wrong definition candidates than to go back to the text and search for missed good definitions manually, so in this application recall was more important than precision. In [1] this assumption was exploited at the evaluation level only. $F_{\alpha=2}$ and $F_{\beta=2}$ were taken into account when comparing the approaches and datasets, to acknowledge the preference for recall. The classifier's prediction threshold of being a definition was set arbitrarily to 0.5 there. As Balanced Forest algorithm takes care of weighting the imbalanced number of examples of both classes (definitions and non-definitions), this approach does not favour any class, so the ratio of correctly classified examples to all examples was maximised.

However, it is worth noting that this is not exactly what we need here. Favouring recall over precision, we would like to focus more on the correctly classified positive examples, at the inevitable cost of misclassifying some of the negative ones. On the other hand, exactly how many times the recall is more important than precision in this case is an empirical issue. Answering this question would require user case evaluation experiments and as such is out of the scope of this article.

We have focused on maximising the $F_2$ measure, in two known approaches to its calculation, supposing recall is twice as important as precision.[1] Note that this *intended bias* towards recall has nothing to do with the imbalance of the classes in the training data (definitions vs. non-definitions). Thus, instead of maximising the ratio of correctly classified examples, we maximise the values of both $F_2$ measures by selecting the classification threshold appropriately. This means we may favour one of the classes over another, if this leads to an increase of the value of the chosen measure.

For the results, cf. Table IV and Table V. There is a clear improvement in terms of the chosen measures that can be explained by the accompanying four figures. The peaks of the graphs, especially those representing F-measures on the copula definition subcorpora, are located quite far to the right from 0.5 (that is, the default value used when there is no optimisation). However, we have to be well aware of the needs: fine-tuning the threshold value to one measure might also make the results with regard to other measures worse. On the other hand, both measures tend to peak close to each other (and not always close to 0.5). That may suggest that in case of an unknown corpus it is better to optimise with regard to a similar measure than not to optimise at all—as the graph for this corpus might peak far away from 0.5. The question what is a similar measure and what is not remains open though, and we will not attempt to address it in this paper.

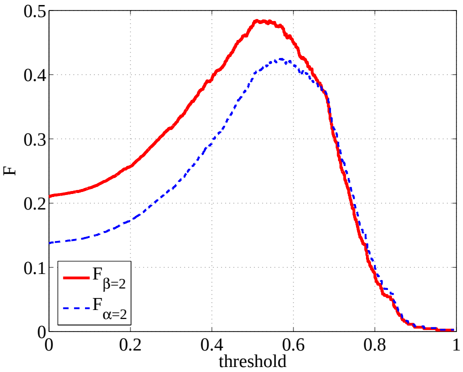

Fig. 1. F-measures values with respect to the chosen threshold on the dataset with all definitions and preselected set of attributes

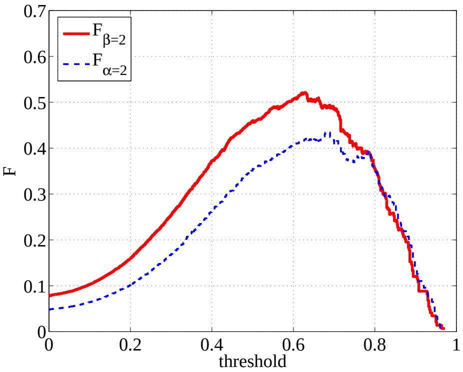

Fig. 2. F-measures values with respect to the chosen threshold on the dataset with copula definitions only and preselected set of attributes

## V. Applying a Manually Created Grammar

As described in [2], applying a very simple partial grammar before the classifiers such as Naïve Bayes, decision trees ID3 and C4.5, AdaBoostM1 with Decision Stump, Support Vector Machines and lazy classifier IB1 significantly improves the results. In that approach all sentences rejected by the grammar are unconditionally marked as non-definitions, and only those accepted by the grammar may be marked as definitions in the Machine Learning stage.

[1] There are different views in literature on how this should be done. For instance, [6] uses $F_\beta$, which is in fact the same formula as $F_\alpha$, but giving quadratic importance to the parameter instead of linear: $F_{\alpha=4} = F_{\beta=2}$. Something that could be interpreted as third version is used for instance in [7], but at a closer look it turns out to be effectively equivalent to $F_\alpha$ – used also in [2] and some medical papers – but encoding the intended result differently: $F_{0.5}$ is used to denote a measure giving equal weights to precision and recall (as $F_{\alpha=1}$), and $F_{0.75}$ is said to value recall three times more than precision (as $F_{\alpha=3}$).

TABLE IV
GAIN IN F-MEASURES FROM OPTIMISING THE THRESHOLD, ALL DEFINITIONS

| | preselected attributes | | | | $\chi^2$ attributes | | | |
|---|---|---|---|---|---|---|---|---|
| threshold | precision | recall | $F_{\alpha=2}$ | $F_{\beta=2}$ | precision | recall | $F_{\alpha=2}$ | $F_{\beta=2}$ |
| no optimisation | 21.37 | 69.04 | 39.60 | 47.74 | 20.60 | 65.20 | 37.87 | 45.50 |
| optimised for $F_{\alpha=2}$ | 27.80 | 57.69 | **42.47** | 47.48 | 26.38 | 55.13 | **40.44** | 45.26 |
| optimised for $F_{\beta=2}$ | 22.30 | 68.50 | 40.52 | **48.43** | 23.48 | 60.99 | 39.80 | **46.22** |

TABLE V
GAIN IN F-MEASURES FROM OPTIMISING THE THRESHOLD, COPULA DEFINITIONS ONLY

| | preselected attributes | | | | $\chi^2$ attributes | | | |
|---|---|---|---|---|---|---|---|---|
| threshold | precision | recall | $F_{\alpha=2}$ | $F_{\beta=2}$ | precision | recall | $F_{\alpha=2}$ | $F_{\beta=2}$ |
| no optimisation | 16.50 | 84.40 | 35.59 | 46.30 | 17.60 | 81.70 | 36.90 | 47.27 |
| optimised for $F_{\alpha=2}$ | 25.42 | 67.78 | **43.58** | 50.84 | 31.78 | 60.56 | **46.52** | 51.27 |
| optimised for $F_{\beta=2}$ | 22.68 | 77.22 | 42.86 | **52.14** | 28.26 | 65.00 | 45.35 | **51.59** |

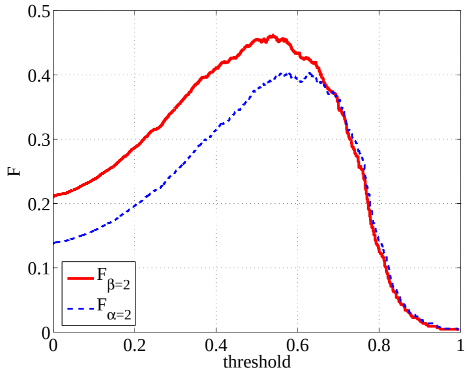

Fig. 3. F-measures values with respect to the chosen threshold on the dataset with all definitions and $\chi^2$ attribute selection

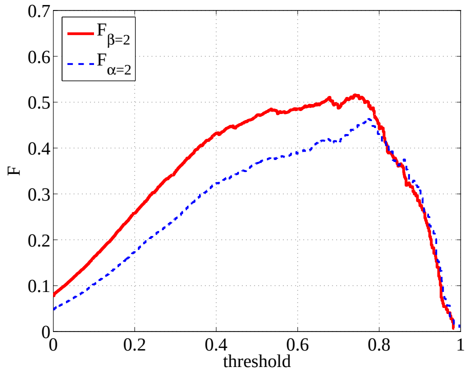

Fig. 4. F-measures values with respect to the chosen threshold on the dataset with copula definitions only and $\chi^2$ attribute selection

Even such a primitive grammar (that could also be described as a set of pattern-matching rules) rejected a significant part of potential false positives, i.e. those sentences that would be mistakenly marked as definitions by the classifiers. Thus, a significant relative increase of precision (for different classifiers from 36% up to 72%) was observed, accompanied only by a minor decrease of recall (between 3.4% and 7.5%). In terms of $F_{\alpha=2}$ measure, the increase was between 21% and 40%.

TABLE VI
THE RESULTS OF THE SIMPLE PARTIAL GRAMMAR BY ITSELF

| corpus | precision | recall | $F_{\alpha=2}$ | $F_{\beta=2}$ |
|---|---|---|---|---|
| whole | 9.10 | 89.60 | 22.69 | 32.36 |
| copula | 3.30 | 99.40 | 9.28 | 14.57 |

In case of the Balanced Random Forest classifier the gain turned out to be much smaller, up to 3.4%—cf. Table VII. Note that we look at the relative gain, not the absolute values of precision, recall and F-measures, because those numbers are not directly comparable: in [2] the experiments were not performed as a ten-fold cross-validation, but on a separate training and test subcorpora.

TABLE VII
GAIN OF APPLYING A SIMPLE GRAMMAR BEFORE THE CLASSIFIERS, ALL DEFINITIONS

| pre-filtering | $F_{\alpha=2}$ standard | $F_{\alpha=2}$ optimised | $F_{\beta=2}$ standard | $F_{\beta=2}$ optimised |
|---|---|---|---|---|
| no | 39.60 | 42.47 | 47.74 | 48.43 |
| yes | **40.95** | **43.09** | **48.62** | **49.30** |
| relative gain | 3.4% | 1.5% | 1.8% | 1.8% |

Balanced Random Forest classifier, especially with threshold optimisation, is inherently good enough not to require the initial pre-filtering by the grammar. We conclude that there is not that many potential false positives to be removed. This is clear when we look at the results for copula definitions in Table VIII.

TABLE VIII
GAIN OF APPLYING A SIMPLE GRAMMAR BEFORE THE CLASSIFIERS, COPULA DEFINITIONS

| pre-filtering | $F_{\alpha=2}$ standard | $F_{\alpha=2}$ optimised | $F_{\beta=2}$ standard | $F_{\beta=2}$ optimised |
|---|---|---|---|---|
| no | 35.59 | 43.58 | 46.30 | 52.14 |
| yes | **36.35** | **43.67** | **47.07** | **52.29** |
| relative gain | 2.1% | 0.2% | 1.7% | 0.3% |

## VI. PREVIOUS WORK

There is a substantial previous work on definition extraction, as this is a subtask of many applications, including terminology extraction [8], the automatic creation of glossaries [9], [10], question answering [11], [12], learning lexical semantic relations [13], [14] and the automatic construction of ontologies [15]. Despite the current dominance of the ML paradigm in NLP, tools for definition extraction are invariably language-specific and involve shallow or deep processing, with most work done for English and other Germanic languages, as well as French.

For Polish, first attempts at constructing definition extraction systems are described—in the context of other Slavic languages—in [16], and improved results are presented in [17]. [2] describes improvements achieved by using a simple manually created grammar.

The first NLP applications of the plain Random Forests are apparently those reported in [18] and in [19], where they are used in the classical language modelling task (predicting a sequence of words) for speech recognition and give better results than the usual $n$-gram based approaches.

The use of Balanced Random Forests for definition extraction in textual datasets was proposed in [1].

## VII. Conclusion

For definition extraction, the Balanced Random Forest classification method may be further improved by optimising the threshold above which we classify a given sentence as a definition. With this improvement, the algorithm does not gain much more from initial filtering of the data by a very simple, high-recall hand-crafted grammar, as it was in case of other ML classifiers we experimented with; however, the gain, being small, is always positive, so it may be worth trying, when the best possible result is desired, even at the cost of complicating the algorithm and lengthening the execution time. The same applies to using a more advanced set of attributes that are selected for each training set separately instead of using a preselected single set.

***Abstract*—The aim of the paper is to present an application supporting language analysis within the framework of the phonetic grammar. The notion of the phonetic grammar has been concisely introduced and the basic potential of the application and the algorithms employed in it are briefly discussed. The application is to enable a uniform description and a comparative analysis of many languages. At the first stage the languages taken into consideration are Polish, Chinese and Hindi.**

## I. The phonetic grammar

### A. Introduction

PHONETICS is a field of linguistics which is concerned with the articulatory, acoustic, auditory and distributive properties of phones. Phonetics of a given language is also sometimes understood as a set of phones relevant to a given language (e.g. the phonetics of Polish language). The phone is a set of all hic et nunc pronounced homophonous speech sounds. The speech sounds are of temporal character and their number is actually infinite. To reduce the number of elements belonging to hic and nunc pronounced speech sounds we classify them into sets of phones e.g. the set of all homophonous temporal realizations of the speech sounds p1, p2, p3, p4, .... is considered to be the phone [p]. All phones are described in terms of the articulatory features. E.g. the relevant features of [p] are: voiceless, oral, hard, plosive, labial etc. Assigning an exhaustive feature set to a given phone is equal with the definition of the phone.

Phonetic grammar is understood as a set of relations between articulatory features and articulatory dimensions (sets of homogenous articulatory features). The concept is based on the theory introduced in the works of Jerzy Bańczerowski ([1], [2]).

The aims of the present project are as follows:

- elaboratation of a uniform (for each language) set of articulatory features,
- elaboratation of a mathematical model of the relations between languages,
- preparation of computer tools for the processing of the collected data, i.e. to elaborate a model of the linguistic data collecting,
- implementation of algorithms of the data processing,
- preparation of algorithms of comparative analysis of languages using the mathematical model,
- comparative analysis of the phonetic grammars of Polish, Chinese and Hindi.

To enable the comparative analyses of languages we introduce a uniform description of the phones of a given language as a set of articulatory features belonging to one of the following articulatory dimensions:

- the mechanism of the air flow origin,
- the direction of the air flow,
- the state of glottis,
- the way of air flow
- the place of articulation,
- the articulator,
- the degree of supraglottal aperture,
- the vertical position of the tongue—the horizontal position of the tongue,
- the degree of labialization,
- the degree of delabialization,
- the duration of articulation
- the degree of supra- and subglottal tension,
- the frequency of articulatory approximation.

### B. Phones as objects in $n$-dimensional space

The original method introduced the notion of the articulatory distance between phones (see [2]). The distance is interpreted as a number of differential features (features by which given phones differ from others). It is thus reducible to the well known Hamming distance.

Our team has proposed to introduce numerical interpretation of the articulatory dimensions. Let $G$ be a set of all phones within which the subsets $G_l$ of the phones belonging to a given language can be specified (where $l$ is an index of a given language) and let $W = \{W_1, W_2, \ldots, W_n\}$ be a set of articulatory dimensions, where $n$ is a number of articulatory dimensions. Thus each phone $g$ from the set $G$ is specified by the vector in $n$-dimensional metric space $\mathbb{R}^n$. Each articulatory feature is uniquely specified by one numerical value from the interval $[0, k]$, where $k$ is a maximal number of features in a dimension. Ascribing a proper numerical value to the feature mirrors the natural order of the features in a given dimension.

The research project is supported by Ministry of Science and Higher Education grant N N104 327434.

Thus each phone $g = (c_1, c_2, \ldots, c_n)$ where $c_i$ belongs to the set of features of a given dimension $W_i$.

The notion of the phone as a point in $n$-dimensional space enables application of well known measures of distances. For example for the pair of phones $a, b \in G$ we can specify the following measures of distances:

- The Minkowski distance for $m \geq 1$:
$$Dist_M(a,b) = \left( \sum_{i=1}^{n} |a_i - b_i|^m \right)^{1/m}$$
- The Manhattan distance:
$$Dist_H(a,b) = \sum_{i=1}^{n} |a_i - b_i|$$
being a particular instance of the Minkowski distance for $m = 1$,
- The Euclidean distance:
$$Dist_E(a,b) = \sqrt{\sum_{i=1}^{n} (a_i - b_i)^2}$$
being a particular instance of the Minkowski distance $m = 2$.

The distances defined in this manner will enable us to build similarity measures between phones and between phonetic systems of given languages. We assume that sound more distant from each other in the sense of the appropriate metrics are less similar to each other. And this seems to be in accordance with the intuition.

## II. Computer application

### A. The tool for collecting phone inventories

The first essential element in the system has been to build a database and a relevant interface enabling data insertion using the standardized International Phonetic Alphabet (IPA).

Fig. 2. Inventory of phones

The application enables:

- defining dimensions and features occurring in them,
- ascribing proper numerical values to the dimensions,
- defining the number of languages,
- introducing a repertoire of phones of a given language and the description of the phones in terms of the relevant set of articulatory features.

### B. Basic analyses

The application is to generate the data concerning detailed levels of analysis in the phonetic grammar of each of the analyzed languages:

- the phone articulemization[1],
- the combining of the articulatory features,
- the articulatory opposition and similarity of phones,
- differential and identifying articulatory dimensions,
- the articulatory distance and proximity.

The computer application will automatically generate:

- the articulatory distance of any two phones in a given language,
- the articulatory similarity of any two phones in a given language,
- the articulatory features of a given phone,
- the articulatory category of a given articulatory feature,
- the dimensions in which given phones differ,
- the dimensions in which given phones are identical,
- the set of phones which have a specified articulatory distance,
- the set of phones which have specified articulatory features,
- the combination of a given set of articulatory features,
- the average articulatory distance between phones,
- the most numerous articulatory category specified by a given number of features,

[1] The operation of articulemization consists in ascribing the articulatory characteristics to a given phone.

- the least numerous articulatory category specified by a given number of features,
- the set of relevant features discerning at least one pair of sounds,
- the number of pairs of phones being discerned by particular features,
- the number of pairs of phones being discerned by particular sets of features,
- the most frequently combined articulatory features in a given articulatory distance.

### C. *Applied data-mining algorithms*

The analyses presented in the last section are the basis of language analysis. They apply rudimentary statistical and combinatorics methods. In the present section we are going to explore methods from the data-mining domain which will allow to discover automatically new interdependencies between phones. It will in turn enable to show certain relations between languages which have been so far unnoticed. All algorithms applied here use measures of distances as measure of similarity between phones. These algorithms can be used for phones from one ore more languages.

*1)* **K-means algorithm** *([9],[12]):* The first of the algorithms requires an input of expected number of phone clusters. It allows to divide the phone inventory into particular number of disjunctive classes. For example put $k := 2$ results in the division of the set of phones into vowels and consonants.

The algorithm is composed of the following steps:

1. Place K points into the space represented by the phones that are being clustered. These points represent initial group centroids.
2. Assign each phone to the group that has the closest centroid.
3. When all objects have been assigned, recalculate the positions of the $K$ centroids.
4. Repeat Steps 2 and 3 until the centroids no longer move. This produces a separation of the objects into groups from which the metric to be minimized can be calculated.

*2)* **The connected subgraphs algorithm** *([5],[7]):* This algorithm does not require an input of the number of clusters. It finds them itself on the basis of regularities in the data.

The algorithm operates on the basis of the matrix of distance $D$. It is a symmetric matrix $n \times n$ in which on the intersection of the columns and verses one receives the distance between the proper pair of phones and on the diagonal zero.

The algorithm operates in the following steps:

1. The distance matrix $D$ is calculated using the fixed distance.
2. Below the fixed threshold $\alpha$ all values in the matrix $D$ are zeroed. Finding the threshold is the basic element of the algorithm. In the simplest case it can be fixed as an average distance in the phone inventory reduced by the standard deviation of the average distance. The choice of the proper threshold mirrors our understanding how big the distance between phones must be to consider them too distant to be the members of the same group.

Fig. 3. The distances matrix for the Euclidean metric

3. Such a matrix is treated as a directed weighted graph in which non-zero values will mark weighted edges between the phones—the vertices. (also called threshold graph)
4. The algorithm Depth-first search (DFS) is applied. The algorithm results in finding connected subgraphs.
The subgraphs are wanted clusters.

*3)* **Agglomerative hierarchical clustering and dendrograms** *(see [10],[11]):* An agglomerative hierarchical clustering procedure produces a series of partitions of the data, $P_k, P_{k-1}, \ldots, P_1$. The first $P_k$ consists of $k$ single phone clusters, the last $P_1$, consists of a single group containing all $k$ phones.

At each particular stage the method joins together the two clusters which are closest together (most similar). At the first stage, this amounts to joining together the two objects that are closest together, since at the initial stage each cluster has one phone.

There are some different methods that use different ways of defining distance (or similarity) between clusters.

Fig. 5. The example of the dendrogram

1. **Single linkage clustering**: It is one of the simplest agglomerative hierarchical clustering methods. It is also known as the nearest neighbor technique. The defining feature of the method is that distance between groups is defined as the distance between the closest pair of objects, where only pairs consisting of one object from each group are considered.
2. **Complete linkage clustering**: It is also called farthest neighbor, clustering method is the opposite of single linkage. Distance between groups is now defined as the distance between the most distant pair of objects, one from each group.
3. **Average linkage clustering**: Here the distance between two clusters is defined as the average of distances between all pairs of objects, where each pair is made up of one object from each group.
4. **Average group linkage**: With this method, groups once formed are represented by their mean values for each variable, that is, their mean vector, and inter-group distance is now defined in terms of distance between two such mean vectors.

The result of the operation of the algorithm is presented in the dendrogram. It is a special type of the dendric structure which assures an easy way of presenting the results of the hierarchical grouping.

Cutting the dendrogram at the selected level we can receive a proper division into a particular number of the groups of phones.

## III. Summary

The paper has presented the first stage of the realization of the more complex project which is meant to apply computer methods for the purpose of linguistic analyses.

At the next stages, besides the interpretation of the results we are going to apply the methods of fuzzy sets (mainly the notion of the linguistic variable) for the description of the repertoires of phones. The methodology of the linguistic summarization as a tool of the data analysis also seems to be very promising.

The results can be further used in different linguistic disciplines (also applied linguistics), especially in teaching foreign languages, speech analysis and in basic research on natural languages (in theory of linguistics and literary phonostylistics, comparative linguistics, typology).

***Abstract*— Definition process of the active suffix chains of Azerbaijani (The Azerbaijani language) has been explained in this paper. Morphologically Azerbaijani word-forms consist of the stem and simple or compound suffixes (suffix chains). Because Azerbaijani is an agglutinative language the simple suffixes in this language can form the great number of suffix chains and consequently, it is possible to generate practically "endless" number of word-forms from the same stem. While developing machine translation system from Azerbaijani into non-Turkic languages for the translation of any word-form it is necessary to translate its suffix chain in whole. It is not possible to get the correct translation of a word-form by translating each simple suffix of its suffix chain separately and then by putting these translations together. For these reasons, it is necessary to define the subset of suffix chains frequently used in the texts instead of the set of every possible suffix chains.**

## I. Introduction

LANGUAGES of Turkic group (modern Turkish, Azerbaijani, Kazakh, Uzbek, Turkmen, Tatar, Kirghiz and others) are the morphologically rich languages and these languages are characterized by highly productive morphological processes that may produce a very large number of word forms for a given stem. Modeling each word-form as a separate lexical unit leads to a number of problems for the development of formal linguistic technologies as machine translation, speech recognition, text to speech etc. systems.

R esearch into the development of the machine translation (MT) systems for the languages of Turkic group is being carried out in two directions:

1. Development of the MT systems among languages of Turkic group;
2. Development of the MT systems from Turkic languages into languages not belonging to this group and vice versa;

While developing MT systems fro m the languages of Turkic group some problems related to the agglutinative nature of these languages arise. In Turkic languages, every word-form morphologically consists of the stem and the simple or compound suffixes (hereinafter we will call compound suffixes the suffix chains) and as mentioned above, it is possible to generate practically "endless" number of word-forms from the same stem.

Vocabul ary differences are prevalent for the languages of Turkic group. Since the morphological (for example: similar rules of the word formation, existence of the simple suffixes with the similar function) and syntactic structures (for example: the similar formation ways of the noun and verb phrases, the same word order) are very close, it is easier to develop machine translation systems of the first type than those of the second type.

Because the grammatical structures of these languages are very close, it is possible to develop an MT system by creating the Turkic-multilingual dictionary (Table A) of stems and the database of the equivalency (Table B) of simple suffixes [1]-[3].

For example, we presented the translation of the sentence "My little son goes to school" in six Turkic languages.

*Mən-im kiçik oğl-um məktəb-ə ged-ir* (Azerb.),
*Ben-im küçük oğl-um okul-a gid-iyor* (Turkish),
*Men-inq kiçik ўгл - uм maktab-qa bora-di* (Uzbek),
*Men-in bəlekey bala-m mektep-ke bara jat-ır* (Kazakh),
*Men-in kiçine uul-um mektep-ke bar-dı* (Kyrgyz),
*Min-em keçkene ul-um məktəp-qə bar-a* (Tatar).

But for the development of the MT system from Turkic languages into (for example) English (analytical language) or Russian (inflectional language) we have essentially different situation.

In these cases we should translate suffix chains in whole (without separating into simple suffixes) (Section 2) and this fact causes some problems. By adding various suffixes to the stem of the same verb, it is possible to create 17947 word-forms in Tatar [4], 11390 in Turkish and 13592 in Uzbek [5]. In the Kazakh language, the number of suffixes that create various word-forms from noun stems is about 500, while most verbs can be used up to 1000 various forms [6]. In Azerbaijani, the number of word-forms formed from the same stem is more than 8000 [7].

For these two reasons (the great number of suffix chains and the necessity to translate suffix chains in whole), it is necessary to define the subset of suffix chains used in texts i nstead of the set of every possible suffix chains.

Despite the great number of suffix chains we should also take into account that the frequency with which all these suffixes and their chains are used is not the same.

If this fact is considered while creating an MT system, then the diff iculties related to the great number of suffix

978-83-60810-14-9/08/$25.00 © 2008 IEEE

chains can be avoided. That's to say not all suffix chains, but the suffix chains used in written texts can be determined and included in the database of suffix chains.

Table A.
Turkic multilingual dictionary

| Azerb. | Turkish | Uzbek | Kazakh | Kyrgyz | Tatar |
|---|---|---|---|---|---|
| mən | ben | men | men | men | min |
| kiçik | küçük | kiçik | bəlekey | kiçine | keçkene |
| oğl | oğl | ўғл | bala | uul | ul |
| məktəb | okul | maktab | mektep | mektep | məktəp |
| ged | gid | bor | bar | bar | bar |

Table B.
Database of equivalency of simple suffixes

| | | | | | |
|---|---|---|---|---|---|
| im | im | ing | in | in | em |
| um | um | im | m | um | um |
| ə | a | qa | ke | ke | qe |
| ir | iyor | di | ır | dı | a |

Suffix chains regularly found in texts, we call *active* suffix chains and our purpose in this paper is to define the subset of active suffix chains of the Azerbaijani.

Hereinafter Azerbaijani is taken as a source and English as a target language and as a translation process, we will mean from Azerbaijani into the language not belonging to the Turkic group.

## II. Suffix Chains and Their Translations

In this section we will show the necessity of taking suffix chains in whole in the translation process.

As mentioned above, compound suffixes that consist of several simple suffixes are called *suffix chains* [8]. We will call the number of simple suffixes that comprise a suffix chain the *length* of this chain. Will also be referred simple suffixes as a suffix chain (whose length is one).

In the grammar of the modern Azerbaijani language, suffixes are divided into two groups—lexical and grammatical suffixes [8]. Lexical and grammatical suffixes form various word-forms from the same word stem by joining word stems both separately and in a certain sequence (for example, it is possible to form the word-forms *ev-də, ev-dəki-lər-in, ev-də-dir-lər, ev-dəki-lər-dən-siniz-mi* and etc. from the stem *ev* , Table 1 *)*.

While a word-form is translated into another language, it is necessary to take into account the meaning of each simple suffix that is included in the suffix chain.

At this moment, there is a question: is it possible to get the correct translation of a word-form by translating each simple suffix of its suffix chain separately and then by putting these translations together? It is very important question from the point of view of the development of the MT system from Azerbaijani, but as we will see below , the answer to this question is negative (Section 2).

Let's have a look at the examples shown below (suffixe chains and their translations are underlined in the same way) (Table 2). While the suffix - *də* is translated as *at* and the suffix - *dir* is translated as *he/she/it is* in the first example, in the second example, the suffix - *dir* cannot be translated separately. In this example, the suffix chain - *dir-lər* should be translated as *they are* . In the third example, the suffix chain —*dir-lər* is translated as *they are* and as the plural suffix—*s* which is added to the end of the word. In the fourth example, the rule of translating this chain changes again and the suffix chain - *dir-lər-mi* is translated as *are they* with the plural suffix - *s* added to the end of the word-form. The number of these examples can be increased.

Table 1.
Database of the active word-forms (fragment)

| Word-form | Word-form |
|---|---|
| *1.* ev | *14.* ev-indən |
| *2.* ev-dir | *15.* ev-inizə |
| *3.* ev-də | *16.* ev-inin |
| *4.* ev-dən | *17.* ev-inə |
| *5.* ev-i | *18.* ev-lə |
| *6.* ev-idir | *19.* ev-lər |
| *7.* ev-imdə | *20.* ev-lərdə |
| *8.* ev-imin | *21.* ev-lərdən |
| *9.* ev-imə | *22.* ev-ləri |
| *10.* ev-in | *23.* ev-lərin |
| *11.* ev-ində | *24.* ev-lərində |
| *12.* ev-lərinə | *25.* ev-lərindən |
| *13.* ev-indədir | … |

It is necessary to note, that these examples are right not only for English but also for other languages of non-Turkic group (Table C).

Table 2.
Examples to the translation of suffix chains into English

| Word-form | Stem of the word-form | Suffix chain | Translation of word-form |
|---|---|---|---|
| 1. *evdədir* | *ev*<br>home | *də* - *dir* | he is at home |
| 2. *evdədirlər* | *ev*<br>home | *də* - *dir-lər* | they are at home |
| 3. *tələbədirlər* | *tələbə*<br>student | *dir-lər* | they are student s |
| 4. *tələbədirlərmi* | *tələbə*<br>student | *dir-lər-mi* | a re they stu-dent s |

Table C.
Examples to the translation of suffix chains into Russian

| Azerbaijani su ffix | Russian equivalent |
|---|---|
| *-ir, - ır, -ur, -ür*<br>( *ged-ir* - he goes ) | *– ет , - ёт , - ит*<br>( *ид-ет* ) |
| *-lər, -lar*<br>( *kitab-lar* – books ) | *– и , - ы , - а , - я*<br>( *книг-и* ) |
| *-ir-lər*<br>( *ged-ir-lər* – they go ) | *-ут, -ют, -ат, -ят*<br>( *ид-ут* ) |

As it can be see n from the examples, the compositional translation of each suffix included in the suffix chain can lead to erroneous results. In order to get the right translation, the suffix chain should be translated as a whole, taking into account the meaning of each simple suffix which this chain is composed of.

So, for the development of an MT system, first we would define the set of not all, but only active suffix chains and to develop the translation rules of these chains.

## III. Active suffix Chains of Azerbaijani

In the previous section we have show n that in the translation process suffix chains must be taken in whole for correct translation of their meanings. In this section we will define the set of active suffix chains of the Azerbaijani. Creation of the suffix chains databases is also necessary for the morphological parsing. One of the main purposes of the formal morphological analysis in the Azerbaijani language is to separate the stem of the word-form from its suffix chain, because like all agglutinative languages, grammatical relations among word-forms in the Azerbaijani sentence are determined by the suffix chains and the correct determination of the suffix chain has a serious influence on the correct conduct of the further analysis process.

We should especially point out here that when we say suffixes and suffix chains, we only mean grammatical suffixes and suffix chains formed from them (Number of simple grammatical suffixes of Azerbaijani is about 100 [8]). We are not examining simple lexical suffixes or lexical suffixes in suffix chains, because words formed by lexical suffixes are kept as a separate lexical unit in the dictionary of MT system (this applies both to prefixes – *na, bi, ba, la, a, anti* and to other lexical suffixes - *lı, -li, -lu, -lü, -çı, -çi, -çu -çü, -lıq, -lik, -luq, -lük* etc.).

For example, although the words *balıq* (fish), *balıq-çı* (fisherman) and *balıq-çı-lıq* (fishery) come from the same stem, all three words are kept in dictionary as a separate lexical unit. Because, formally there are not general rules to generate the translation of the word-forms *balıq-çi* (fisherman), *araba-çı* (wagoner) etc. from the translation of the words *balıq* , *araba* (wagon) etc.

Before developing the MT system for the Azerbaijani language, the text corpus on various subjects with more than 300,000 word-forms was created (Later, volume of the text corpus has been increased to more than 12 million word-forms). Number of word-forms found in this corpus was about 39000 (after some processing). These word-forms were put in the database and stems of these word-forms were separated from their suffix chains manually as it presented in the Table 1.

During this process suffix chains were encountered 111,406 times, but the number of various suffix chains was 1,415 (with all variants of the suffix chains with the same meaning). These suffix chains form the basis of the "Database of suffix chains" of the Azerbaijani-English MT system. After grouping these chains (the ones that have the same function, but have different spelling, for example, *acaq, acağ, əcək, əcəy, yacaq, yacağ, yəcək, yəcəy),* the number of suffix chains reached 627.

The length of suffix chains was also calculated during the computer analysis. The arrangement of suffix chains by their length is given in the Table 3 (as we said above, when we talk about the length of suffix chains, we mean the number of simple grammatical suffixes that form this chain). As we can see from these results, very long suffix chains are rare and such chains almost are not used in writing. This can be clearly seen from Table 3. There are no suffix chains longer than five simple suffixes in the texts that were analyzed. The following table shows the frequency with which suffix chains are used by their length.

One of the possible reasons why suffix chains longer than five simple suffixes are not encountered could be that we did not take into account the lexical suffixes. On the other hand, the fact that long suffix chains are not used shows that although the use of such suffix chains is principally possible, no author uses them in writing or if it is necessary, the idea to be expressed by means of a long suffix chain is expressed by a shorter suffix chain (or words) that have the same meaning. For example: the sentence " *Siz bizim dəvət et-di-k-lər-imiz-dən-siniz-mi* " (Are you one of the people who we invited?) is replaced with an equivalent sentence " *Biz Sizi dəvət et-miş-ik-mi* " (Have we invited you?) or another similar equivalent sentence, for example, with the sentence " *Siz dəvət edil-mi-siniz-mi* " (Have you been invited?) A chain that has seven simple suffixes is replaced with a chain that has three simple suffixes.

As it can be seen from Table 3, a chain of five simple suffixes was encountered five times (0.004% of all cases), a chain of four simple suffixes was encountered 223 times (0.200%), a chain of three simple suffixes was encountered 6,895 times (6.189%), a chain of two simple suffixes was encountered 41,331 times (37.099%) and a chain of one suffix was encountered 62,952 times (56.507%).

The distribution of suffix chains that have the same functions without taking into account repetition was as follows (Table 3).

The number of various chains of five simple suffixes was four, the number of chains of four simple suffixes was 66, the number of chains of three simple suffixes was 248, and the number of chains of two simple suffixes was 257 while the number of chains of one simple suffix was 53.

TABLE 3.
FREQUENCY OF SUFFIX CHAINS

| **Length of chain** | **Frequency** | **Percentage of repeat** | **Unrepeated chains** |
|---:|---:|---:|---:|
| 5 | 5 | 0.004% | 4 |
| 4 | 223 | 0.200% | 66 |
| 3 | 6,895 | 6.189% | 248 |
| 2 | 41,330 | 37.099% | 256 |
| 1 | 62,952 | 56.507% | 53 |
| Total | 111,405 | 100.000% | 627 |

Based on these figures, we can say that most of all the suffix chains used in the Azerbaijani language are consisted of one, two or three simple suffixes.

These suffix chains com pound 99.795% of all most frequent suffix chains. Relative long suffix chains (the ones that have four, five simple suffixes and longer) compound only 0.205% of all chains.

The results that we obtained were analyzed again within the text corpus of 12 million word-forms. Although the volume of the text corpus is increased 40 times, the number of suffixes is increased 1.31 times, while the use of longer suffix chains did not change (that's to say an additional 196 suffix chains were determined and the number of encountered suffixes was 823). After getting this result it is possible to say confidently that active suffix chains of the Azerbaijani language do not exceed 1000.

The fact that the analyzed text corpus has a sufficiently great volume allows us to say that the expansion of the volume of the text corpus will not cause a considerable change in relative frequency indicators.

Besides, the types of active suffix chains on the definition of their capability to join the stems belonging to the different parts of speech are also determined. Because, besides well known ambiguity problems (lexical, syntactical etc.), there are grammatical ambiguity (ambiguity of suffixes) in agglutinative languages else and this information is used in the disambiguation process. 534 chains (≈64.88%) of all chains can join only verb stems (verb chain), 254 chains (≈30.86%) can join non-verb stems (non-verb chain) and 35 chains (≈4.25%) can join both types of stems (dual chain). For the dual chains their frequency of the using as verb or non-verb chains is also defined and this statistics is also used in lexical and grammatical disambiguation process.

So, we have defined the composition of the main information included in the database of the active suffix chains.

The fragmen t of this database is shown in the Table 4.

In the 3rd column of the table 4 are indicated the types of suffix chains. The letter "*V*" written in the third column shows that this suffix chain is a verb chain, while the letter "*N*" - non-verb chain. If none of these letters is written there, the suffix chain is a dual chain.

| … | | | |
| *mış* | *miş, muş, müş* | | |
| *mışdır* | *mişdir, muşdur, müşdür* | *mış-dır* | *V* |
| … | | | |

In addition, we would like to note that the database of the active suffix chains of the Dilmanc MT system has a more complex structure, but only necessary information used for morphological analysis in examples is presented here.

I n the next section we consider the use of the database of the active suffix chains in the morphological analysis process of the Azerbaijani word-forms.

## IV. THE USE OF THE ACTIVE SUFFIX CHAINS DATABASE IN MORPHOLOGICAL ANALYSIS PROCESS

The formation of the grammatical relations among word-forms in a sentence can appreciably differ for different languages. In analytical languages (for example: in English) the grammatical relations among word-forms in a sentence, in most cases, are defined by word order and/or prepositions. In analytical languages, separate words don't have grammatical information and such information can only be acquired in the existence of strict word order. But in agglutinative languages (for example, all the languages of the Turkic group are agglutinative), grammatical relations among word-forms in a sentence are formed by the rich set of suffix chains. For the definition of the grammatical relation among the word-forms at first it is necessary to separate stem and suffix chain of the word-form for the definition of the participation of the word-form in the syntactic structures of the sentence. For this reason morphological analysis algorithms are different for analytical and agglutinative languages.

In agglutinative languages, formal (by computer) morphological analysis can be carried out by creating *a Dictionary of stems* and *a Database of suffix chains*. The dictionary of the Azerbaijani word stems is also developed in frame of the project and in the Table 5 is indicated the simplified version of this dictionary (The dictionary of the Azerbaijani-English MT system has a more complex structure and most of information for the normal functioning of the translation algorithm is not presented here).

Not paying attention to the ambiguity problems, we will schematically describe the work of the morphological analyzer of Azerbaijani.

The morphological analysis algorithm of word-forms in Turkic languages is shown in [7]. This algorithm can be described shortly as follows:

1. The whole word-form is sought in the dictionary of stems (Table 5).
2. If the word-form is not found in the dictionary, its last letter is discarded and the remainder of the word-form – the truncated part is sought in the dictionary again. This process continues until the word-form or its truncated part is found in the dictionary of stems. Discarded part of the word-form is sought in the database of suffix chains (Table 4).
3. If discarded part of the word-form is a suffix chain and this chain can join the stem of this word-form (for example, if the stem is a verb, then the type of the suffix chain should be *V* – a verb chain), then this process stops, otherwise go to the second step;
4. After the stem and suffix chain of the word-form are defined, the word-form is provided with the information included in the databases of stems and suffix chains for its stem and suffix chain.

Example 1. Let's consider the formal morphological analysis process of the word-form *məktəbdədir* (he/she/it is in the school). Starting from the whole word-form all its reminders are sequentially sought in the dictionary of stems (Table 5). Only in the 6th step the stem *məktəb* of the word-form is found in the dictionary. Discarded part - *dədir* is also found in the database of suffix chains. So, process is stopped and we can right

*məktəbdədir* ⇔ *məktəb-dədir.*

The word-form and its remainders (according to above mentioned algorithm) with the discarding parts are shown below:

| | | |
|---|---|---|
| *1.* | *məktəbdədir* | |
| *2.* | *məktəbdədi* | *r,* |
| *3.* | *məktəbdəd* | *ir,* |
| *4.* | *məktəbdə* | *dir,* |
| *5.* | *məktəbd* | *ədir,* |
| *6.* | *məktəb* | *dədir*▲ |

The following examples show how to use the types of suffix chains in the formal morphological analysis process.

Example 2. Let's carry out a formal morphological analysis of the word-form *qorxuram* (I am afraid). According to the morphological analysis algorithm, in the 4th step – the word-form *qorxu* is sought and found in the Table 5. But discarded part of the word-form – *ram* is not suffix chain (Table 4). Therefore the process continues and in the 5th step – the word-form *qorx* (verb stem) is sought and found in the Table 5, discarded part – *uram* of this word-form is sought in the Table 4 and the process stops because such a suffix chain is found and it is verb chain.

Steps of this process are presented below:

1. *qorxuram*
2. *qorxura* *m,*
3. *qorxur* *am,*
4. *qorxu* *ram,*
5. *qorx* *uram.*

Thus, after this process we get

*qorxuram ⇔ qorx-uram* ▲

Example 3. For the word-form *yazır* (*yaz-ır,* he/she/it writes)

1. *yaz ır*
2. *yazı* *r,*
3. *yaz* *ır.*

in the 2nd step process does not stop, because *r* is not suffix chain (though *yazı* is found in the Table 5). In the next step two variants of the stem *yaz* (verb and noun) are found in the Table 5. Because discarded part – *ır* is a verb chain (Table 4) we chose the verb variant of the stem *yaz* ▲

Note that information included in the databases of stems and active suffix chains does not lead to the full solution of the lexical and grammatical ambiguity problem and it is necessary to return to the solution of the ambiguity problem in the next stages of the formal grammatical analysis (syntactic, semantic etc.).

Table 5.

Dictionary of Dilmanc MT system (Fragment)

| Stem | Part of speech | English translation |

## V. Dilmanc MT system

Despite some research works most of languages of Turkic group are still less investigated languages, except modern Turkish [9]-[13].

Researches on the development of Speech and NLP technologies for the Azerbaijani language are being led since 2003 [14]-[16]. Because Azerbaijani is one of less-investigated languages, the most of the necessary works (development of the MT dictionaries, creation of the formal grammar for Azerbaijani, algorithms for the automation of the translation process from/into Azerbaijani, synthesizer and analyzer algorithms of the Azerbaijani sentences, definition of the threephone set for the ASR system etc.) for the development of these technologies are carried out for the first time. The research work presented in this paper is one of such important steps on the creation of the applied linguistic technologies for Azerbaijani (All researches are carried out within the joint projects "Development of the MT system for Azerbaijani", "Development of the Speech Recognition system for Azerbaijani" of the Ministry of ICT of Azerbaijan and UNDP-Azerbaijan).

Dilmanc MT system is a hybrid MT system developed on the basis of RBMT (Rule Based MT) and SBMT ( Statistic Based MT) approaches.

Dilmanc MT system can translate for the present on three directions – Azerbaijani-English, English-Azerbaijani and Turkish-Azerbaijani (www.dilmanc.az). For the definition of the factors influencing the translation quality, first the set of test sentences consisting of 1000 sentences is formed. On the results of the test it is possible to say that the system gives good enough - intelligible translations in the most cases (http://www.science.az/cyber/pci2008/1.htm/1-26.doc).

Dilmanc MT system has the following characteristics on each direction (all these items have been developed for the first time):

*Azerbaijani-English direction.*

1. MT dictionary of Azerbaijani word stems (≈120000 lexical units including word phrases and terms);
2. Database of the active suffix chains (≈1000 active chains);
3. Database of the formalized rules for the decision of the lexical and syntactical ambiguity in Azerbaijani (≈1500 rules);
4. Database of translations of the active suffix chains of Azerbaijani (≈2300 rules);
5. Database of the formal signs of the parts of the sentence in Azerbaijani (≈2000 signs);
6. Formalized rules of the "traditional" grammar of Azerbaijani for the definition of the noun and verb phrases;
7. Formal morphological analysis algorithms of Azerbaijani word-forms;
8. Formal syntactic analysis algorithms of the Azerbaijani sentences;
9. Algorithms for the synthesis of the English sentences.

*English-Azerbaijani direction.*

1. English-Azerbaijani MT dictionary (≈115000 lexical units including word phrases and terms);
2. Database of the formalized rules for the decision of the lexical and syntactical ambiguity (≈1400 rules);
3. Database of the formalized rules for the synthesis of Azerbaijani suffix chains (≈300 rules);
4. Database of the rules for delimitation of the homogeneous parts in the English sentence (≈90 rules);
5. Database of the rules for delimitation of clauses in the English sentence (≈40 rules);
6. Algorithms for the formal syntactic analysis of the English sentences.
7. Algorithms for the synthesis of the Azerbaijani sentences.

*Turkish-Azerbaijani direction.*

1. Turkish-Azerbaijani MT dictionary (≈20000 lexical units);
2. Database of the equivalency of Turkish and Azerbaijani suffix chains (≈1000 chains).

It is necessary to note that this list is only a small part of all algorithmic and non-algorithmic means developed in the frame of the Dilmanc MT system.

In addition the formed set of active suffix chains may be used while developing other linguistic technologies as speech and other NLP systems.

Although the analyses are carried out for the Azerbai jani language, there is no doubt that this approach is also applicable for other Turkic languages.

*Abstract*—**Recognizing similarities between words is a basic element of computational linguistics and artificial intelligence applications. This paper presents a new approach for measuring semantic similarity between words via concepts. Our proposed measure is a hybrid system based on using a new Information content metric and edge counting-based tuning function. In proposed system, hierarchical structure is used to present information content instead of text corpus and our result will be improved by edge counting-based tuning function. The result of the system is evaluated against human similarity ratings demonstration and shows significant improvement in compare with traditional similarity measures.**

## I. Introduction

SEMANTIC similarity is an important topic in natural language processing (NLP) and Information Retrieval (IR). It has also been subject to studies in Cognitive Science and Artificial Intelligence. Application areas of semantic similarity include word sense disambiguation (WSD) [19], information extraction and retrieval [2,22,24], detection and correction of word spelling errors (malapropisms)[3], text segmentation [10], image retrieval [21], multimodal document retrieval [20], and automatic hypertext linking [5], automatic indexing, text annotation and summarization [13].

To quantify the concept of similarity between words, some ideas have been put forth by researchers, most of which rely heavily on the knowledge available in lexical knowledge bases like WordNet.

There are mainly two approaches to compute semantic similarity. The first approach is making use of a large corpus or word definitions and gathering statistical data from these sources to estimate a score of semantic similarity, which we call text-based approach. The second approach makes use of the relations and the hierarchy of a thesaurus, such as WordNet, which we call structure-based approach.

In text-based approach, word relationships are often derived from their co-occurrence distribution in a corpus [7,6]. Gloss overlap, introduced by Lesk [12] and extended gloss overlap, introduced by Banerjee and Pedersen, are another instances of this approach. The latter is a measure that determines the relatedness of concepts proportional to the extent of overlap of their WordNet glosses [1]. Besides gloss vector measure of semantic relatedness, introduced by Pedersen and Patwardhan, is based on second order co–occurrence vectors in combination with the structure and content of WordNet, a semantic network of concepts [16].

In structure-based approach, first studies date back to Quilian's semantic memory model [17], where the number of hops between nodes of concepts in the hierarchical network specifies the similarity or difference of concepts. Wu and Palmer's semantic similarity measure was based on the path length between concepts located in a taxonomy [23]. Also, the similarity measure of Leacock and Chodorow is based on the shortest path length between two concepts in is-a hierarchy [11].

In combining two approaches, Resnik introduced a new factor of relatedness called information content (IC) [18]. The Similarity measures of Resnik, Jiang and Conrath [9] and Lin [14] all rely on the IC values assigned to the concepts in an is-a hierarchy, but their usage of IC has little differences. Using a different approach Hirst G. and St-Onge assign relatedness scores to words rather than word senses. They set different weights for different kinds of links in a semantic network, and uses those weights for edge counting [8].

In this paper, we first introduce a new method for computing IC of concepts in a hierarchical structure. We will show that this method only uses hierarchical structure and not corpus to determine IC. Furthermore, information content obtained from this method implicitly includes depth and branch factor of the concept from root to target concept. Then we use formula that is similar to Lin formula for measuring similarity. Then we analyze our result and comparing it with benchmark result and introduce an edge counting-based function for improving and overcome their problems. For adjusting our function's parameters we use genetic algorithm. Finally our combined similarity measure is evaluated against a benchmark set of human similarity ratings, and demonstrates that the proposed measure significantly outperformed traditional similarity measures.

In section 2 we describe WordNet, which was used in developing our method. Section 3 describes the extraction of our new information content metric from a lexical knowledge base. Section 4 presents the choice and organization of a benchmark data set for evaluating the similarity method, how to define a tuning function, experimental results and dis cussion about it. Finally, paper concludes in Section 5 that,

[*] Authors thanks Iran Telecommunication Research Center (ITRC) for their support during this research work

[1] http://ceit.aut.ac.ir/islab/

based on the benchmark data set, our measure outperforms existing measures.

## II. WordNet

WordNet is the product of a research project at Princeton University which has attempted to model the lexical knowledge of a native speaker of English [4]. In WordNet each unique meaning of a word is represented by a synonym set or *synset*. Each synset has a gloss that defines the concept of the word. For example the words *car*, *auto*, *automobile*, and *motorcar* is a synset that represents the concept define by gloss: *four wheel Motor vehicle, usually propelled by an internal combustion Engine*. Many glosses have *examples* of usages associated with them, such as *"he needs a car to get to work."*

In addition to providing these groups of synonyms to represent a concept, WordNet connects concepts via a variety of semantic relations. These semantic relations for nouns include:

- Hyponym/Hypernym (IS-A/ HAS A)
- Meronym/Holonym (Part-of / Has-Part)
- Meronym/Holonym (Member-of / Has-Member),
- Meronym/Holonym (Substance-of / Has-Substance)

Figure 1 shows a fragment of WordNet taxonomy.

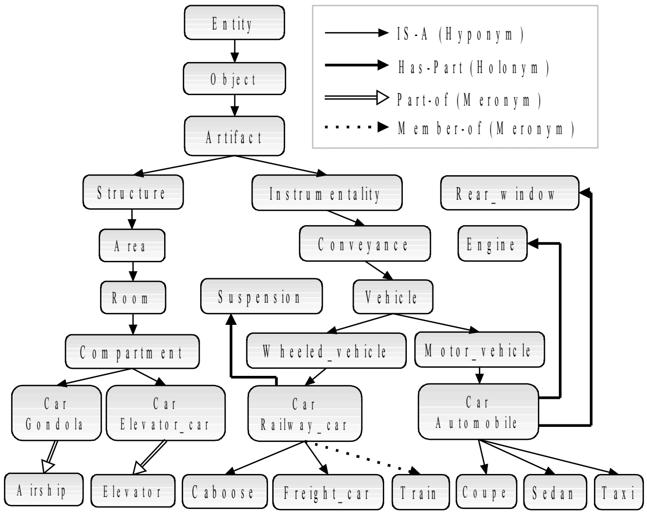

Fig. 1 fragment of WordNet taxonomy

## III. The new Information Content Metric

### A. Previous information content based approaches

Many researchers consider statistical figures to compute IC value. They assign a probability to a concept in taxonomy based on the occurrence of target concept in a given corpus. The IC value is then calculated by negative log likelihood formula as follow:

$$IC(c)=-\log(p(c)) \qquad (1)$$

Where c is a concept and p is the probability of encountering c in a given corpus. Philip Resnik [18] used this formula to compute semantic similarity between concepts. Basic idea behind the negative likelihood formula is that the more probable a concept appears, the less information it conveys, in other words, infrequent words are more informative then frequent ones.

Resnik showed that semantic similarity depends on the amount of information that two concepts have in common, this shared information is given by the Most Specific Common Abstraction (MSCA) that subsumes both concepts. Therefore we must first discover the MSCA and then shared information is equal to the IC value of the MSCA. If MSCA does not exist then the two concepts are maximally dissimilar. Formally, Resnik semantic similarity is defined as:

$$sim_{res}(c_1,c_2)=\max_{c\in S(c_1,c_2)} ic_{res}(c) \qquad (2)$$

where *S(c₁,c₂)* is the set of concepts that subsume $c_1$ and $c_2$. Another information theoretic similarity metric that used the same notion of IC was that of Lin [23], expressed by:

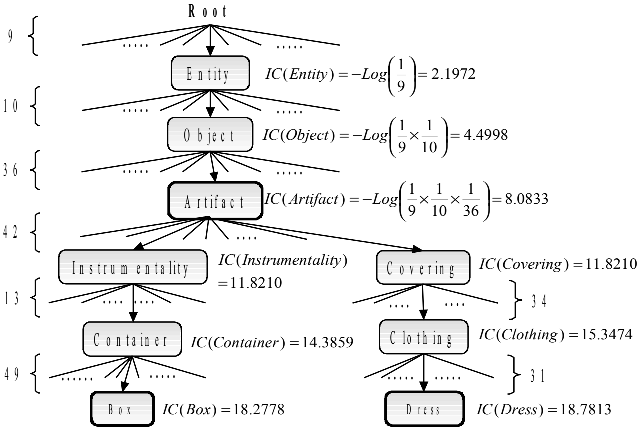
$$sim_{lin}(c_1,c_2)=\frac{2\times sim_{res}(c_1,c_2)}{(ic_{res}(c_1)+ic_{res}(c_2))} \qquad (3)$$

Jiang and Conrath [9] also proposed a new measure of semantic distance that its corresponding semantic similarity can be obtained from the reverse of it. Common version of their distance metric is:

$$\begin{aligned} dist_{jcn}(c_1,c_2)=&(ic_{res}(c_1)+ic_{res}(c_2)) \\ &-2\times sim_{res}(c_1,c_2) \end{aligned} \qquad (4)$$

### B. Our new information content metric

Our method of obtaining IC values is based on the assumption that the taxonomic structure of WordNet is organized in a meaningful and principled way, where concepts in higher depths and having more sibling concepts in the taxonomy structure are more informative and their IC values are bigger. Our method includes implicitly these two parameters that figure 2 represent this method for computing IC value for a fragment of concepts in WordNet.



Root
9
Entity
$IC(Entity)=-Log\left(\frac{1}{9}\right)=2.1972$
10
Object
$IC(Object)=-Log\left(\frac{1}{9}\times\frac{1}{10}\right)=4.4998$
36
Artifact
$IC(Artifact)=-Log\left(\frac{1}{9}\times\frac{1}{10}\times\frac{1}{36}\right)=8.0833$
42
Instrumentality
$IC(Instrumentality)=11.8210$
Covering
$IC(Covering)=11.8210$
13
34
Container
$IC(Container)=14.3859$
Clothing
$IC(Clothing)=15.3474$
49
31
Box
$IC(Box)=18.2778$
Dress
$IC(Dress)=18.7813$

Fig. 2 example of computing our IC metric for some concepts

For better understanding of this method we show in equation 5 how IC value of *Box* is computed according to figure 2:

$$IC(Box) = -Log\left(\frac{1}{9}\times\frac{1}{10}\times\frac{1}{36}\times\frac{1}{42}\times\frac{1}{13}\times\frac{1}{49}\right) = 18.2778 \qquad (5)$$

## IV. Implementaion

### A. Semantic similarity measure

To evaluate the effect of our Information Content Metric on semantic similarity, we first select an existing semantic similarity measure. For this purpose we use Lin semantic similarity measure. This approach makes the implementation easier with less complexity. Lin's formula is shown in equation 3.

### B. Benchmark data

In accordance with previous research, we evaluated the results by correlating our similarity scores with that of human judgments provided by Miller and Charles [15]. In their study, 38 undergraduate subjects were given 30 pairs of nouns and were asked to rate similarity of meaning for each pair on a scale from 0 (no similarity) to 4 (perfect synonymy). The average rating for each pair represents a good estimate of how similar the two words are. This benchmark data is used by many researchers in semantic similarity subject [1,16].

### C. Edge counting-based tuning function

For beginning our analysis, we first compute semantic similarity between pairs of words with Lin similarity and our similarity approach. As said before, our semantic similarity formula is the same as Lin formula. The difference between them is the method of computing IC value . Then, we draw our obtained result and Lin result and human judgments scores in a diagram. These results are showed in figure 3. As shown in figure 3, in some pairs of words our method is more accurate and in some pairs Lin similarity measure is better. We then decide to improve our accuracy in pairs that our method is less accurate. Therefore, the Next step is how we determine these pairs of words automatically. In others words we must define a new feature for pairs of words that discriminate pairs of words that our similarity method about them is less accurate toward Lin method.

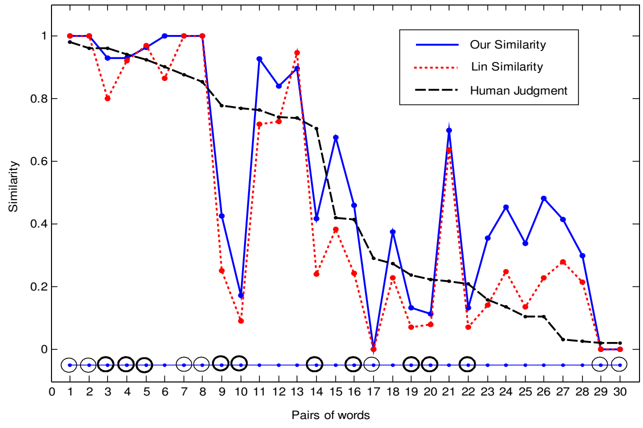


Fig 3 Compare our method with Lin and Human judgments

In figure 3 we show two types of circles: bold line circle and normal line circle. Bold line circles represent pairs of words that accuracy of our method is better than Lin and normal line circle shows that Lin and our method are the same. For other pairs, Lin method is more accurate. As said before in this step we extract a feature that determines inaccurate pairs. Table 1 shows our result, Human judgments, path of two words (concept) and depth of Lowest Common Subsumer (LCS) for two words. In this table if does not exist LCS for a pair, values of LCS depth and Path are -1.

Table 1
Result of our method, human judgment and three features

| Pairs of words | HJ | Ours | LCS depth | Path | $(LCS_{depth}+1)$ /(path+1) |
|---|---|---|---|---|---|
| car -automobile | 0.98 | 1 | 8 | 0 | 9 |
| gem – jewel | 0.96 | 1 | 6 | 0 | 7 |
| Journey - voyage | 0.96 | 0.93 | 5 | 1 | 3 |
| boy – lad | 0.94 | 0.93 | 4 | 1 | 2.5 |
| coast – shore | 0.92 | 0.96 | 4 | 1 | 2.5 |
| asylum -madhouse | 0.90 | 1 | 7 | 1 | 4 |
| magician – wizard | 0.87 | 1 | 4 | 0 | 5 |
| midday - noon | 0.85 | 1 | 7 | 0 | 8 |
| furnace - stove | 0.77 | 0.42 | 2 | 10 | 0.27 |
| food – fruit | 0.77 | 0.17 | 0 | 7 | 0.12 |
| bird - cock | 0.76 | 0.92 | 7 | 1 | 10 |
| bird - crane | 0.74 | 0.84 | 7 | 3 | 2 |
| tool - implement | 0.73 | 0.89 | 4 | 1 | 2.5 |
| brother -monk | 0.70 | 0.41 | 2 | 5 | 0.5 |
| crane - implement | 0.42 | 0.67 | 3 | 4 | 0.8 |
| lad - brother | 0.41 | 0.46 | 2 | 4 | 0.6 |
| journey - car | 0.29 | 0 | -1 | -1 | 10 |
| monk - oracle | 0.27 | 0.37 | 2 | 7 | 0.37 |
| cemetery - woodland | 0.23 | 0.13 | 0 | 9 | 0.1 |
| food - rooster | 0.22 | 0.11 | 0 | 13 | 0.07 |
| coast - hill | 0.21 | 0.69 | 3 | 4 | 0.8 |
| forest - graveyard | 0.21 | 0.13 | 0 | 9 | 0.1 |
| shore - woodland | 0.15 | 0.35 | 1 | 5 | 0.33 |
| monk - slave | 0.13 | 0.45 | 2 | 4 | 0.6 |
| coast - forest | 0.10 | 0.34 | 1 | 6 | 0.28 |
| lad - wizard | 0.10 | 0.48 | 2 | 4 | 0.6 |
| chord - smile | 0.03 | 0.41 | 3 | 10 | 0.36 |
| glass - magician | 0.02 | 0.29 | 1 | 7 | 0.25 |
| noon - string | 0.02 | 0 | -1 | -1 | 10 |
| rooster - voyage | 0.02 | 0 | -1 | -1 | 10 |

Our result shows the pairs of words that their LCS depth is little or path length of two concepts is large, our result is less accurate. These two conditions are combined with new feature that can be seen in the sixth column in table 1. Therefore if the new feature is low, pairs of words which our result is related to, is less accurate and hence is detectable. In figure 4 we show that, in new feature space a specific bund contains most inaccurate pairs of words.

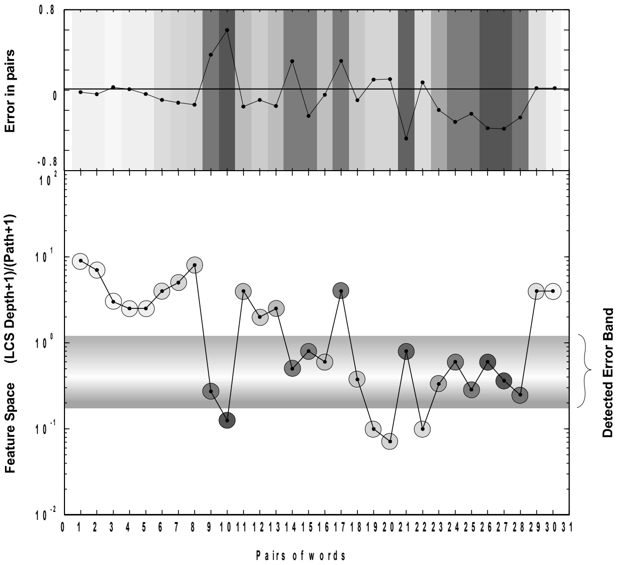

Fig 4 detecting error bund in new feature space

One considerable point is that, when new feature is too low, our similarity result is lower than human judgment and when not too low, our similarity result is higher than human judgment. This point persuades us to define a tuning function which modifies our result. Thus we define a function that its general shape is showed in figure 4. In equation 6 we show mathematical formula of this function.

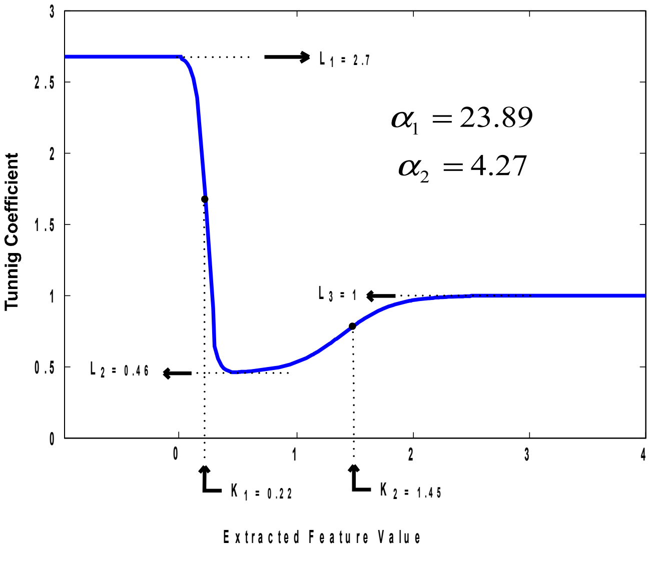

Fig 5 General shape of our tuning function

To determine the best value for parameters of this function we use genetic algorithm. Because of lack in data, for tuning parameters, we use Leave-one-out cross validation and then values of each parameters is average of the obtained values in 30 experiments. In Leave-one-out cross validation, for a dataset with N examples, perform N experiments. For each experiment use N-1 examples for training and the remaining example for testing. Figure 5 present the best value obtained by GA algorithm for $l_1$, $l_2$, $l_3$, $k_1$, $k_2$, $\alpha_1$ and $\alpha_2$. In table 2 we compare our final result with other methods. In all other similarity measures that use IC value, IC value is computed like Resnik's manner which was discussed in section III. For all of these experiments, Miller's benchmark data (30 pairs of words) is used. In order to make fair comparisons, we decided to use an independent software package that would compute similarity values using previously established strategies while allowing the use of WordNet 2.0. One freely available package is that of Siddharth Patwardhan and Ted Pederson [25]. This result shows that our similarity measure is comparable with other similarity measures.

$$f(x)=\begin{cases} x\le k_1-\frac{5}{\alpha_1} & l_1 \\ x>k_1-\frac{5}{\alpha_1} \quad and \quad x<k_1+\frac{5}{\alpha_1} & \frac{l_1-l_2}{1+\exp^{-\alpha_1(-x+k_1)}}+l_2 \\ x\ge k_1+\frac{5}{\alpha_1} \quad and \quad x\le k_2-\frac{5}{\alpha_2} & l_2 \\ x>k_2-\frac{5}{\alpha_2} \quad and \quad x<k_2+\frac{5}{\alpha_2} & \frac{l_3-l_2}{1+\exp^{-\alpha_2(x-k_2)}}+l_2 \\ x\ge k_1+\frac{5}{\alpha_2} & l_3 \end{cases} \tag{6}$$

TABLE 2

| **Our Similarity Measure** | **0.87** |

## V. CONCLUSION AND FUTURE WORK

In this paper, we have introduced a new word sense similarity measure with a proper tuning function. For computing information content, we used hierarchical structure alone, instead of text corpus. Experimental evaluation against a benchmark set of human similarity ratings demonstrated that the proposed measure significantly outperformed traditional similarity measures. In future work, we intend to that use this similarity measure in real world applications such as word sense disambiguation. Also, our tuning function can be used with other previous similarity measures.

***Abstract*—Semantic web ontologies are being increasingly used in modern text analytics applications and Ontology-Based Information Extraction(OBIE) as a means to provide a semantic backbone either for modelling the internal conceptual data structures of the Text Analytics(TA) engine or to model the Knowledge base to drive the analysis of unstructured information in raw text and subsequent Knowledge acquisition and population. Creating and targeting Language Resources(LR)s from a TA to an Ontology can be time consuming and costly. In [1] the authors describe a user-friendly method for Ontology engineers to augment an ontologies with a lexical layer which provides a flexible framework to identify term mentions of ontology concepts in raw text. In this paper we explore multilinguality in these lexical layers using the same framework. We discuss a number of potential issues for the "linguistic light" Lexical Extensions for Ontologies (LEON) approach when looking at languages more morphologically rich and which have more complex linguistic constraints than English. We show how the LEON approach can cope with these phenomena once the morphological normaliser used in the lexical analysis process is able to generalise sufficiently well for the language concerned.**

## I. Introduction

SEMANTIC web ontologies are being increasingly used in modern text analytics applications and Ontology-Based Information Extraction(OBIE) as a means to provide a semantic backbone either for modelling the internal conceptual data structures of the Text Analytics(TA) engine or to model the Knowledge base to drive the analysis of unstructured information in raw text and subsequent Knowledge acquisition and population. Creating and targeting Language Resources(LR)s from a TA to an Ontology can be time consuming and costly. A Language Engineer working with a TA system must typically manually align existing internal linguistic resources with a new Ontology or create new LR's to support a domain shift. If the creation of LRs for an TA system is integrated into the Ontology engineering process via user fiendly Ontology lexicalisation for non-linguists. A lexical layer, which describes the various lexical realisations of Ontological term facilitates such a process. The "linguistic light" approach described in [1] outlines such a lightweight lexical layer which can be easily implemented into an existing ontology. The lexical layer (LEON)—(Lexical Extensions for Ontologies) can be subsequently traversed and compiled into internal LRs of the TA engine. Additionally, Organisations working in multilingual enviroments creates a demand for multilingual Ontologies [2] [1] The authors also claim that their approach can be retargetted to a new domain or language by simply providing the appropriate lexical information. The cross language portability of this approach and associated issues will be presented in this paper. Portability across languages is an important characteristic for an approach to lexical layers because of the cost and effort involved in redeveloping an ontology for a new language. One of the main principles behind the semantic web is the ability to easily exchange and utilise semantic information so by having a unified approach to identifying occurrences of Ontological terms in text across a number of languages we can maintain this inter-operability by using the same ontology.

This rest of this paper is structured as follows: Section II discusses related work, Section III gives an overview of LEON type lexical layers, Section IV describes how LEON can provide a multilingual lexical layer and highlights some potentially problematic features of languages besides English, Section VI explains how the LEON approach copes with these phenomena and discusses the implications of false positives, finally, Section VII conludes.

## II. Related Work

The inclusion of a linguistic or lexical layer into an Ontology or Ontology lexicalization is by no means a new phenomenon. For example, Linginfo, was developed as part of the SmartWeb[3] project[3]. The work conceptualized the idea of a linguistic layer for a Semantic Web Ontology or more specifically a "multilingual/multimedia lexicon model for Ontologies" [3]. Linguistic representation in LingInfo can consist of: a Language identifier, POS (Part of Speech) tag, morphological data, and syntactic compositional data as well a contextual data in the form of grammar rules of N-grams. Furthermore, content and knowledge are organized into four layers, where the Ontology layer is located at the central layer and linguistic features and their subsequent associations to the central layer are located in the outer middle layers with the outer layer containing textual content. The LingInfo model is applied to the SmartWeb Integrated Ontology

[1] Although against good Ontology Engineering practice, a substantial amount of Ontologies on the Web are in English which forces the need for localising knowledge. One can observe this easily by accessing such tools as OntoSelect[2]

[3] http://smartweb.dfki.de/

978-83-60810-14-9/08/$25.00 © 2008 IEEE

SWInto, whereby the linguistic feature layer is compiled into Language Resources (gazetteers) within the SProuT IE engine based on a mapping between the SWIntO and SProuTs TDL Type Description Languages. This mapping is applied to both SWIntO concepts and properties. The work of [3] is influenced strongly by LMF Lexical Markup Framework,[4], which is part of the ISO TC37/SC4[4] working group on the management of Language Resources. LMF has its origins in Language Engineering standardization initiatives such as EAGLES[5] and ISLE[6] . LingInfo also caters for multilingual Ontology lexicalisation, but we argue that the LingInfo model is too complex for use but non-linguistic engineers where LEON attempts to shield the Knowledge Engineer from complex linguistic formalisms.

Ontology lexicalisation is closely related to work within Lingusitic Ontologies. Linguistic Ontologies are used to describe semantic constructs rather than to model a specific domain and they are typically characterised by being bound to the semantics of grammatical or linguistic units i.e. GUM and SENSUS [5]. Ontologies such as Wordnet [6] and EuroWordnet [7] however are concerned with word meaning. Certain linguistic Ontologies are language independent such as EuroWordnet while the majority are not. EuroWordnet is a multilingual database containing wordnets for several Eurpean languages [8]. Each language specific word net is similarly structured to the English WorldNet and are linked via an Interlingua index. Consequently, one can access the translation of similar words in a target language for a given word within the source language. Linguistic Ontologies are primarily descriptive though they are frequently exploited by NLP systems either directly or to bootstrap the creation of new Language Resources. LEON on the other hand is designed explicitly to support the text analytics (or IE) task by replacing the manual retargeting of multilingual LRs within an IE system to an Ontology either (semi-)automatically.

Ontology Localization is also a closely related field to that of Ontology lexicalization. ”Ontology Localization consists of dapting an Otology to a concrete language and cultural community”[2]. In [2] the authors describe LabelTranslator, an Ontology localization tool which automatically translates ontological term labels (rdfs:labels of classes, instances and properties) in a source language to their target language equivalent. The system caters for English, German and Spanish. LabelTranslator attempts to best the most approximate translation by accessing translation services such as Babelfish and FreeTranslation, in addition to various Language Resources such as EuroWordnet [7], Wikitionary and GoogleTranslate. A ranking method based on the Normalized Google Distance(NGD) [9] is also applied to propose the most approximate target translation label from collection of suggested translations by taking into account the similarity of the source language label’s lexical and semantic context. The LEON approach is tailored towards an IE task which is very different from that of localisation, since as already shown in [1], rdfs:labels is a form of Ontology lexicalistion are too simplistic to capture the lingusitic idiosyncracies of certain surface forms as is the case with Multi Word Expressions.

Finally, we note other OBIE systems such as GATE[7] which can be deployed as a mulitilingual OBIE platform [10], however LRs in GATE must be manually aligned to the Ontology, while the LEON approach attempt to subsume part of the Dictionary creation process within the Ontology Engineering process.

## III. LEON

A lexical layer which describes the lexical realisations corresponding to concepts encoded in an ontology provides an interface between the ontology and text processing applications which seek to exploit the semantics encoded in the ontology.

The number and type of lexical expressions which correspond to a particular semantic entity varies from concept to concept, however, often they occur in a form which is different from the citation form because of inflectional or grammatical needs imposed by the language. These lexical realisations are often complex and appear as multiple word units, which in turn are not always fixed expressions and can vary depending on the context.

It would appear that an adequate approach to provide such a lexical layer requires some level of linguistic knowledge to be encoded alongside the semantics. This approach however becomes somewhat untenable in practice as there are many different linguistic theories to choose from which can lead to incompatibilities between ontologies, not all linguistic theories can be implemented effectively, and the knowledge engineers who work with modern ontologies usually have little or no linguistic background.

To address these issues surrounding lexical layers [1] propose a “linguistic light” approach to lexical layers for ontologies called LEON. The LEON approach proposes that the lexical layer for an ontology consists of a tuple of the form

$$\langle CitationForm, Constraints\rangle$$

for each semantic entity with a lexical realisation encoded in the ontology. The first element of the tuple, the citation form, is the basic form of the lexical realisation. The second element of the tuple is a set of constraints which specifies if and how the citation form can vary. This facilitates linguistic phenomena such as inflection and derivation as well as allowing the modelling of multi-word units which vary in both their surface form and word order using this simple approach. This approach does not focus on the linguistic description of vocabulary associated with a concept but on the linguistic features of a given concept in order to identify class instances in text. This allows for when one concept might have

[4] http://www.tc37sc4.org

[5] http://www.ilc.cnr.it/EAGLES96/browse.html

[6] http://www.mpi.nl/ISLE/

[7] General Architecture for Text Engineering

several different lexical realisations with different linguistic descriptions for example:

- New York, Big Apple, NY
- Rosetta Stone, Stone of Rosetta
- International Business Machines, IBM, Big Blue

In addition, it is deliberately less complex in order to cater for users, in particular knowledge engineers, who lack a linguistic background, but may wish to develop an ontology with linguistic features included. We note that the interlingua here is an the ontology. Therefore the design and conceptualisation used in the ontology could be a limiting factor where there are semantic divergences between languages or domain terminology.

## IV. Linguistic Light Multilingualism

The "linguistic light" paradigm for lexical layers is flexible and can be applied multi-lingually with little effort. This is because the extensions are not tied to any particular language or formalism.

### A. Extending LEON's lexical layer

In order to expand the LEON lexical layer description to cope with another language we must provide an appropriate citation form and set of constraints for the lexical realisation(s) of that concept in the new language. This second tuple can then be merged with the existing data giving rise to a tuple consisting of a set of citation forms and a set of constraint sets corresponding to each citation form.

$$\left\langle \left\{ \begin{array}{c} CitationForm_{EN} \\ CitationForm_{FR} \\ CitationForm_{DE} \\ CitationForm_{...} \end{array} \right\}, \left\{ \begin{array}{c} \{cnstr1_{EN}, cnstr2_{EN}, ...\} \\ \{cnstr1_{FR}, cnstr2_{FR}, ...\} \\ \{cnstr1_{DE}, cnstr2_{DE}, ...\} \\ \{cnstr1_{...}\ , cnstr2_{...}\ , ...\} \end{array} \right\} \right\rangle$$

The multilingual lexical layer can then be used to easily retartget the ontology to a given language or locale by using the appropriate citation forms and constraint sets.

### B. Signature Detection

Effective use of the linguistic light LEON lexical layer in text analytics and ontology-based information extraction applications relies on unstructured text being processed and the "signature" of a term mention being detected. The lexical analyser used to process the text needs to have some means of normalising variant forms to a common stem or lemma in order to be able to put forward potential signature tokens.

To ensure high recall, normalisation of constituents is important, especially for languages with more a complex morphology than English. In this paper we pay more attention to the normaliser as a component of a linguistic light solution. Given proper normalisation, we believe that the LLA/LLS approach will provide very high recall in a multilingual environment.

## V. "Linguistic Light" Normalisation

### A. Character Normalisation

This type of normalization accounts for typographic variances like using capitalisation and diacritics in Latin and Cyrillic based scripts ("*Böblingen*" vs. "*Boeblingen*"), the use of different scripts in Japanese texts, auxiliary usage of vowels in Arabic or Hebrew; regular spelling variations (British "*colour*" vs. American "*color*"). Some types of character normalisation might be efficiently performed by algorithmic methods.

### B. Morphological Normalisation

Morphology is the subfield of linguistics that studies the internal structure of words. In linguistics, two types of morphological normalization are traditionally referred to, namely lemmatization and stemming. Lemmatization accounts for inflectional variants of the same word where part of speech is preserved. For example different cases, genders, numbers (like singular form of noun *database* and its plural form *databases*).

Stemming frequently involves a more "aggressive" normalization, which accounts for both inflectional and derivational morphology, where related words are mapped onto the same index, even if they have different parts of speech. For example, one can map the words *computerization*, *computerize*, *computer*, *computing*, *compute* onto the same index. An index term can be a non-word like *comput* (a minimal and hopefully unambiguous denotation of all related terms). Stemming therefore has the effect of "conflating" the index more aggressively than lemmatization, by mapping a wider set of word forms to a single index term, thereby resulting in higher recall i.e. in any query term finding more documents during search.

### C. Synonym Normalisation

At least for some domains, if not for language in general, it might be reasonable to consider some words as exact synonyms and map them into the same index (for example, liver/hepatic, renal/kidney). Dictionaries of linguistic synonyms are not frequently used in indexing because linguistic synonyms are typically not exact synonyms (for example, using the chain of synonyms in MS-Word: average ≈ mean ≈ nasty ≈ shameful one can wrongly equate average with shameful). The quality of IR and IE (depending on the task) is characterized by two intrinsic metrics: recall (the ratio of the number of relevant documents returned to the total number of relevant documents in the collection of documents indexed) and precision (the ratio of the number of relevant documents retrieved to the total number of documents retrieved). Search engines typically trade off precision for recall. In the absence of accurate relevancy ranking algorithms the user is left to sort through extensive lists of documents for the correct information. So the challenge is to achieve high precision without significantly reducing recall.

Word normalization is essential for the quality of IR systems. Research to date indicates that some character normalization is indispensable to improve recall. Morphological normalization in general improves recall, but may degrade precision. Although stemmers are widely used by the majority of IR systems, their role for IR is frequently disputed; however, it is generally accepted that morphological normalization is indispensable for highly inflected languages (like Finnish) when the same word might have dozens of forms. It is also needed for languages with frugal morphology (like English) in the scenarios where most of the analysed documents are short. For example, if the document about databases is rather long, one might expect that the term database will be encountered in both grammatical forms: data-base and databases, and one can afford not to map both forms into the same index because the document will be retrieved as relevant to the query containing the search item database anyway. However, if the document is short, it might happen that the document will contain only mentions of plural form, in which case the document will be missed. For some time Google did not use stemming in order "to provide the most accurate results to its users". However, Google subsequently introduced stemming technology into its system "Thus, when appropriate, it will search not only for your search terms, but also for words that are similar to some or all of those terms. If you search for "pet lemur dietary needs", Google will also search for "pet lemur diet needs", and other related variations of your terms[8]."

### D. Reversed Finite State Normalisation

Following [11], which is based on the work of [12], a normaliser can be built from the lexicon by combining common suffixes in a finite state automaton. A finite state automaton (FSA) is a computational model made up of states and transitions. Given an input sequence (e.g. a word as a sequence of letters), the FSA moves through a series of states according to transitions that given a current state match the current input symbol (letter). In Figure 1 there are a number of possible input sequences that reach the final state e.g. smart, start etc. The final state can be associated with information about the sequence that leads to it, such as an algorithm that produces a normal form.

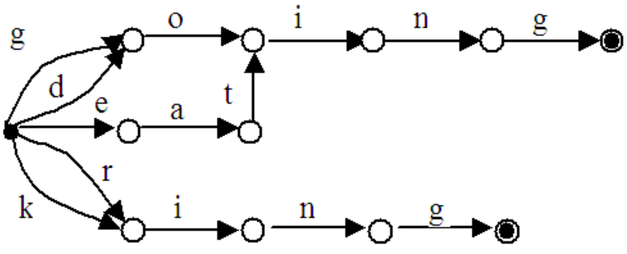

Fig. 1. Finite State Automaton

A reversed finite state normaliser is a finite state automaton which traverses the input string in reverse character order. A reversed FSA can be compiled from a full form word list, electronic dictionary or similar resource for the language or domain concerned. The resulting FSA will be such that morphological suffixes are conflated into common paths of transitions leaving word stems following branching states.

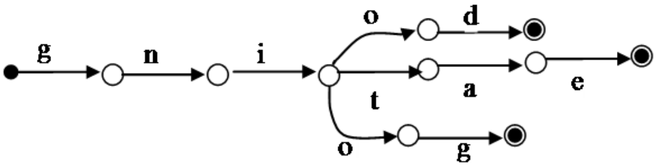

Fig. 2. Reversed Finite State Automaton

Notice that by exploiting common endings in this way the size and complexity of the FSA is reduced. This computational approach to building a normaliser does not necessarily produce proper root form lemmas for the input, instead a reduced stem is produced. These stems can often be non-word tokens but they will correspond to the orthographical root of one or more full form of the actual word it represents. These stems can then be used by a "Linguistic Light Scanner" (described in [1]) to increase recall in the identification of term mentions in text. The LEON constraints for a given citation form then determine which (if any) variants are permissible for a valid recognition.

By combining LEON and reverse FSA normalisation these two linguistically light, but computationally efficient models for lexical analysis no precision is lost because the stemming process reduces full forms to concise stems while the LEON constraints then allow or disallow inflected (or otherwise orthographically different) forms. This makes the process of adding a new language to a lexical layer relatively simple and quick to implement without any significant linguistic knowledge about the language, all that is necessary is a word list. For these reasons we suggest this type of approach to normalisation and signature detection. This approach can also deal with character normalisation where adding all variations into a full form lexicon would become unwieldy

## VI. Multilingual Issues

When dealing with identifying term mentions in multiple languages the compatibility of the lexical description with features of the various languages is an important consideration. In the previous work ([1]) the only language considered is English, which is relatively frugal with respect to morphology, casing, and agreement when compared with other languages. Other languages also have different constraints on sentential word order which can be important to detection. We will look at some examples of how these aspects of language can be problematic and how they are handled in the linguistic light paradigm.

*1) Agreement:* Many languages require that, for example, adjectives and nouns agree with respect to number, gender, case etc. So, for instance, a singular noun can only have a singular adjective used to describe it. These constraints are important regarding the grammaticality and correctness of the language. This type of constraint is not enforced in the LEON

[8] Taken from http://www.google.com/help/basics.html

model. However, as the following example shows, it is often beneficial not to enforce such linguistic constraintsas to do so would affect recall where there has been a human error, or a deliberate mistake owing to creative licence.

Take the French term “Intelligence Artificielle,” in this example, the gender and number agreement of the two tokens is obligatory. If it occurs with a disagreement, then it is likely a human typing mistake like “intelligence artificiel.” In this case, the disagreement is a typing error, as there is a disagreement between the noun (“intelligence”: singular feminine) and the adjective (“artificiel”: singular masculine). This can occur in texts, and it will be detected if the exact string match is turned off (to allow infleced variants of the citation form). However it would be missed if the agreement constraint were to be strictly enforced. This also allows the detection of instances in other contexts. For example, “vie et intelligence artificielles”, where “artificielles” disagrees in gender and number because here it refers to two entities which are “vie” and “intelligence.”

Likewise in Russian gender agreement is a present and important feature for grammatical correctness, however if we take the term “sistemnuj administrator” (system administrator) where both terms are in the masculine, and change one to feminine like

systemnaja administrator
Adj Masc Noun Masc

This ungrammatical noun phrase yields a single hit in a search on Google’s index.[9] The text in which the example was found is using the gender disagreement as a subtle device to highlight that the person in question is woman and draw attention to this fact.

*2) Word Order:* Some languages have a less rigid restriction on sentential word order than others, German for example has quite strict rules regarding word order, Russian on the other hand is less so. This needs to be considered with regards detecting MWU lexical realisations in text analysis. A language with a freer word order means there are more possible ways of constructing a sentence which refers to a given concept. Therefore, in theory, the search space is larger and correspondingly so is the likelihood of detecting false positives.

Consider the French MWU “Maladies Sexuellement Transmissibles” (sexually transmitted diseases). If we encounter the same words in varying order and forms like “maladie mortelle sexuellement transmissible,” and “Maladie transmise sexuellement” the underlying concept which is being referred to remains the same. So a language with a freer word order is not necessarily a problem for MWU lexical realisations.

## VII. CONCLUSIONS

We have examined a number of linguistic considerations for ontology lexicalisation across multiple languages. We have also discussed the LEON “linguistic light” approach to adding a lexical layer and shown how it is robust enough to handle various linguistic nuances without having to explicitly encode linguistic information. The caveat, however, is that in order to detect the linguist “signatures” of term mentions in text the LEON approach needs some suitable normalisation of the input text.

Following in the linguistic light vein we have shown how a simple, robust normaliser can be induced from a wordlist in the form of a reverse finite state automaton. Once the lexical layer for an ontology has been implemented, the appropriate wordlist already exists in the form of the citation form lexical realisations encoded in the lexicon, so a reverse FSA normaliser can be rapidly produced for the appropriate vocabulary. By combining these two linguistic light approaches to analysing natural language in text an ontology can be rapidly retargeted to a new language or domain with little or no linguistic information or expertise other than an appropriate vocabulary.

***Abstract*—There are well over a thousand phrasal verbs in English. For non-native speakers they are notoriously difficult to remember and use in the right context. We tried to construct a ranking of phrasal verbs according to their estimated occurrence frequency, based on quantitative information available from the public indexable Web. Technically, we used major Web search engines to acquire phrase-occurrence statistics, measured consistency between the rankings implied by their results and confirmed that a rough set of 'classes' of phrasal verbs can be distinguished.**

**While this technique relies on inaccurate and possibly biased estimation functions, we show that the overall distribution of ranks seems to be consistent among all the queried search engines operated by different vendors.**

## I. Introduction

A *PHRASAL verb* is, according to Oxford Advanced Learner's Dictionary [1]:

> [. . . ] a simple verb combined with an adverb or a preposition, or sometimes both, to make a new verb with a meaning that is different from that of the simple verb, e.g., *go in for*, *win over*, *blow up*.

There are a number of phrasal verbs in both spoken and written English ([2] lists over 6000 entries). As the definition states, the meaning of a phrasal verb cannot be easily guessed from individual components—many non-native speakers of English must therefore memorize phrasal verbs in order to be able to understand and use them in the right context. Our motivation for this work was a direct consequence of this observation.

SuperMemo[1] is a company specializing in helping people learn fast, use memory efficiently and aid in self-improvement processes. SuperMemo's line of products include, among others, dictionaries and language courses. While working on a list of English phrasal verbs, we stated the following problem:

- Which phrasal verbs should be memorized first?

There are two other related questions:

- Are there any phrasal verbs that are hardly ever present in a 'live' corpora of written language?
- Are there groups of 'frequent' and 'infrequent' phrasal verbs and is it possible to distinguish these groups?

There is certainly no definite answer to these questions; phrasal verbs and their meaning will vary by region and dialect of English, for example. Our research intuition was telling us though, that by relying on a really large corpora of existing texts rather than book resources or dictionaries, we could come out with a fairly good estimate on which phrasal verbs are common and which are infrequent. In other words, we wanted to measure possibly 'real' average occurrence frequency of each phrasal verb, then sort them in the order of this estimated frequency and distinguish several groups that could provide the basis for the construction of a training course.

## II. Related work and discussion

There exist a number of dictionaries [2], [3], books and papers concerning phrasal verbs and verb-particle associations at the linguistic layer. There are also on-line resources listing phrasal verbs and providing their meanings. However, we failed to find any resource that would attempt to *quantitatively* measure the frequency of use of phrasal verbs. The paper by Timothy Baldwin and Aline Villavicencio came closest to our expectations [4]. In this work, authors process raw text of the Wall Street Journal corpus using a number of different methods to identify verb-particle occurrences. The best technique reached the f-score of 0.865. The experiment in [4] was performed on an established corpus of press resources. While using a corpus like this (or a balanced language corpus in general) has many advantages, we wanted to stick to the Web because it reflects many different language users, use cases and is a great deal larger than any other corpus available. Although there are various opinions about the coverage of the Web, its information quality and bias (see [5] or [6] for an interesting discussion), we believe that in our case these aspects can be neglected and search engines provide suitable source of knowledge to answer the questions given in the introduction. Obviously, any research based on uncontrolled, proprietary information sources such as search engines should be approached with care. We tried to do our best to cross-validate the results against multiple vendors to make them more confident.

## III. Proposed methodology

Every search engine returns an estimation of the number of documents 'matching' a given query (note that this is the number of *documents*, not individual instances of the query). Figure 1 illustrates a query results page with the rough number

Fig. 2. A wildcard query may result in a false match (see the marked phrase).

of documents matching the exact phrase ‘ask out’. While the returned number is merely an estimate and may be inaccurate (we discuss this in Section V), we assumed that the estimation is correct at least to the order of magnitude, thus properly dividing frequent and relatively infrequent phrasal verbs.

## IV. Phrasal Verbs Considered

We used a hand-crafted set of phrasal verbs (PV) collected from several on-line resources and books. We made an explicit distinction between separable and inseparable PVs where it was appropriate and placed an asterisk (wildcard) character in places where separation could occur. Then, to every verb we assigned a number of different forms in which it could possibly appear in the text, depending on its tense. Table 3 illustrates an example phrasal verb pattern and all its corresponding variations. The pattern-based representation was used to drive queries to search engines.

## V. Potential Ambiguities and Other Problems

There are a few corner cases in counting the number of documents containing a given phrasal verb and they are all a consequence of how text information retrieval methods (implemented in search engines) work. In simplest terms, search engines transform a document into a vector of individual words and their *weights* (relative importance of a given word to the document). This representation of text is called the vector space model [7]. A query to a search engine returns all documents that contain a union of the query’s set of words (possibly ordered), but it is rarely possible to specify deeper contextual constraints. Let us explain the possible side-effects of this process on a few examples.

The first problem is that not every word pattern corresponds to an actual phrasal verb. For example, *[to] be in* can appear as *I’m in*, but the sole appearance of this sequence of words without the knowledge of the context may be a false hit (*I’m in Poland right now.*). Unfortunately this will be the case with most verbs that have transitive and intransitive forms. Another issue is caused by multiple meanings of a single phrasal verb, compare *throw up* (vomit) and *throw up* (an idea). Detecting and separating the meaning of these two expressions seems impossible assuming the measurement technique we agreed to use.

The final example concerns separable forms of phrasal verbs. What we intend to do is to query for patterns (sequences of words) that have a few words in between (but not too many). For example, *sign me in* should be counted as an occurrence of *sign in*. However, simply allowing words to appear in between components of a phrasal verb may lead to many mistakes. For instance, as Figure 2 illustrates, the three top-ranked documents for a query *ask out* separated by three other words, are basically wrong. There seems to be no way of filtering out this noise without more complex linguistic analysis (if we had access to whole document content, as in a controlled corpus, we could use POS tags for getting rid of such errors).

Regardless of the above problems, we decided to calculate occurrence statistics and proceed with the experiment. It is our assumption that the number of false matches for less than three wildcards can be neglected compared to the number of true matches (at least for common phrasal verbs). As for phrasal verbs with multiple meanings, all occurrences of these meanings sum up to one figure which reflects the aggregated use of a given sequence of words. Since so, the final ranking

position is to some extent indicative of the need to learn a given phrasal verb (even if it is ambiguous).

## VI. Collecting occurrence statistics

We collected occurrence statistics from several search engines: Google (`www.google.com`), Yahoo (`www.yahoo.com`), AllTheWeb (`www.alltheweb.com`), Gigablast (`www.gigablast.com`) and Microsoft Live (`www.live.com`). With the exception of Gigablast and Microsoft Live, the remaining providers all support the so-called *wildcard queries*, i.e., a query for all documents containing a given phrase separated by one or more unrestricted words inside. With wildcard queries we could estimate the number of occurrences of separable phrasal verbs by querying for the exact phrase, phrase with one, two and three extra words at the point of possible separation. For example, the entry (to simplify, we only show one verb form here):

```
ask * out
```

would result in the following queries to a search engine:

```
ask out
ask * out
ask * * out
ask * * * out
```

An exact format of queries submitted to each search engine varied depending on the service provider's syntax and we omit it here, although we found out that such details are quite crucial because search engines employ various optimizations and query expansion techniques that, in our case, distorted the output. As previously observed in [5], the returned estimation counts have some significant variance within the same query (the same search engine would return a different document count for consecutive executions of an identical query). We took this into account and put together 10 identical query lists, randomized their order and executed all queries at different times and from different machines. Finally, we paid particular attention to restricting the search to documents in the English language and to searching within document content only (exclude links pointing to the page).

The process of querying search engines was partially automated and performed in accordance with each search engine's policies and terms of use specifications (timeouts between queries, use of automated programming interfaces when possible).

## VII. Results

Overall, we collected frequency counts for 10 633 various separable and inseparable forms of 991 phrasal verb patterns (some of these were closely related, like *blend in* and *blend into*). For each form, we stored the estimated document count for each of the 10 'samples' made to each single search engine. Even though the querying process was semi-automatic, it lasted over three days (because we had to add the required timeouts between queries) and involved over 30 machines (with different IP addresses). If we had been given access to the search engine's infrastructure, such processing could be made much faster and more accurately by running shallow grammar parsing on the content of each document, splitting the process over multiple machines using the map-reduce paradigm.

We describe the results from several angles in sub-sections below.

### A. Differences between search engines

Every search engine is a bit different—these differences usually concern the number of indexed documents, ranking algorithms and technical aspects of estimating the number of matching documents. Our first step was to cross-compare the numbers returned from various search engines to see if they share similar distribution and what shape this distribution is.

We took one sample out of the ten made and for each phrasal verb form we compared document counts between search engines by sorting all forms according to the number of documents returned by Yahoo, placing them (in this order) on the horizontal axis and plotting document counts on the vertical axis. Figures 4–7 demonstrate the results. The overall distribution shape for all search engines is for the most part exponential (vertical axis is on logarithmic scale). Exponential distribution confirms our initial intuition that a small number of phrasal verbs occurs frequently and a great deal of them are relatively infrequent on the Web.

Back to differences between search engines, we can observe notable differences in average document counts between different search engines, but highly correlated distribution shapes. This validates our assumption that search engines are a methodologically sound tool to 'probe' the Web. If (theoretically) we consider the Web to be a global population of documents, then the index of each search engine is basically a random sample taken from this population. If so, the average count of documents between two search engines should be linearly proportional to the degree of a constant multiplier. Another way to put it is that the *ordering* of phrasal verb forms imposed by all search engines should be very similar between search engines. A look at Figures 4–7 and especially at log-log plots in Figure 8 reveals that all search engines returned correlated results. For example, Yahoo and AllTheWeb's results are almost identical (Figure 4) because AllTheWeb's index is powered by Yahoo; minor differences may be a result of different search query routing inside Yahoo's infrastructure. There is also an evident high similarity between Yahoo, Gigablast and Microsoft Live's results (see log-log plots in Figure 8, although Microsoft and Gigablast have an order of magnitude smaller index. The only visibly different engine is Google—not only has it fewer documents compared to Yahoo, but also its count distribution is strikingly different compared to other search engines (although still correlated). Narrowed to only non-wildcard forms, the distribution difference is even more strange because it shows two different 'traces' of frequency distribution in the area of more frequent phrasal verbs (see Figure 8).

We initially thought this difference in Google's case might be caused by the fact that it has the largest infrastructure and queries may be routed to separate index sections, leading to

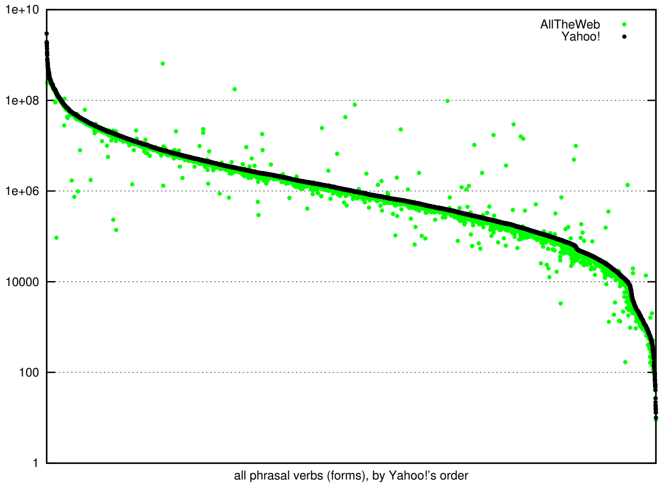

Fig. 4. Document counts for results acquired from AllTheWeb and Yahoo (sorted by Yahoo's results—the black line).

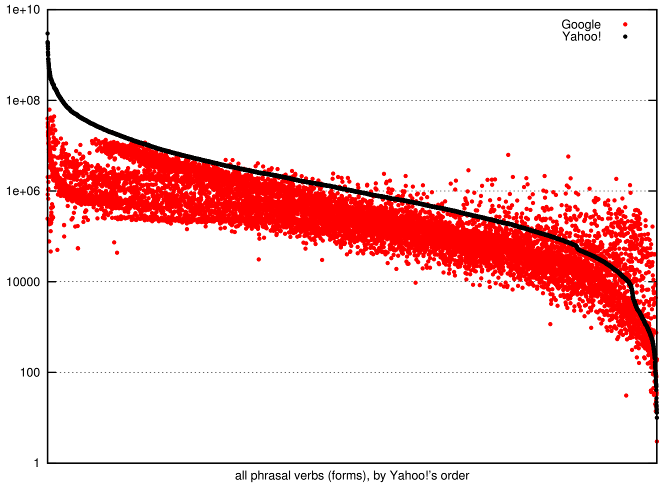

Fig. 5. Document counts for results acquired from Google and Yahoo (sorted by Yahoo's results—the black line).

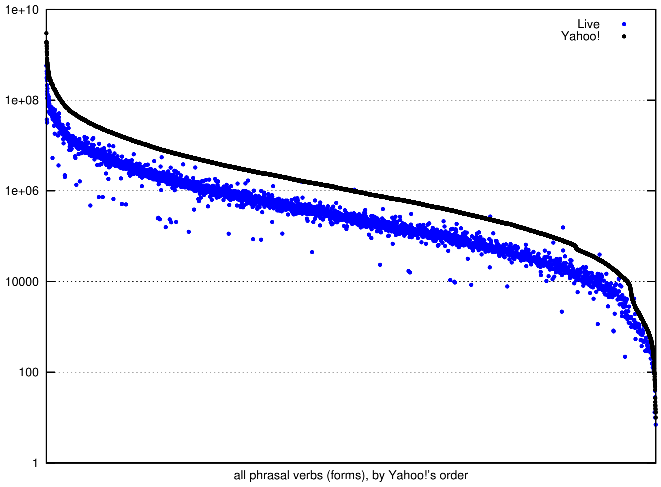

Fig. 6. Document counts for results acquired from Microsoft Live and Yahoo (sorted by Yahoo's results—the black line).

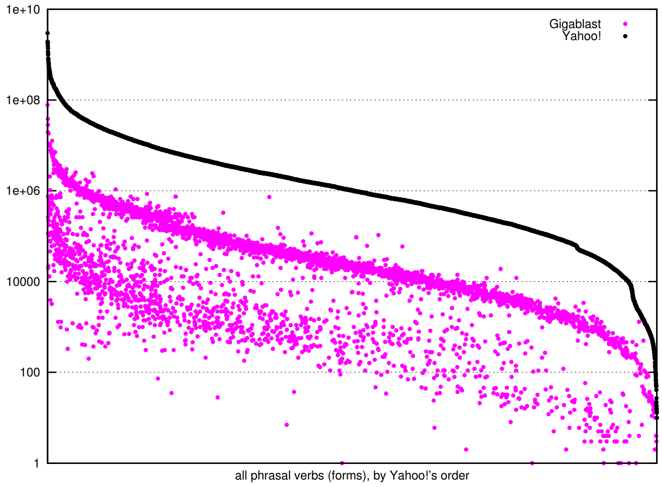

Fig. 7. Document counts for results acquired from Gigablast and Yahoo (sorted by Yahoo's results—the black line).

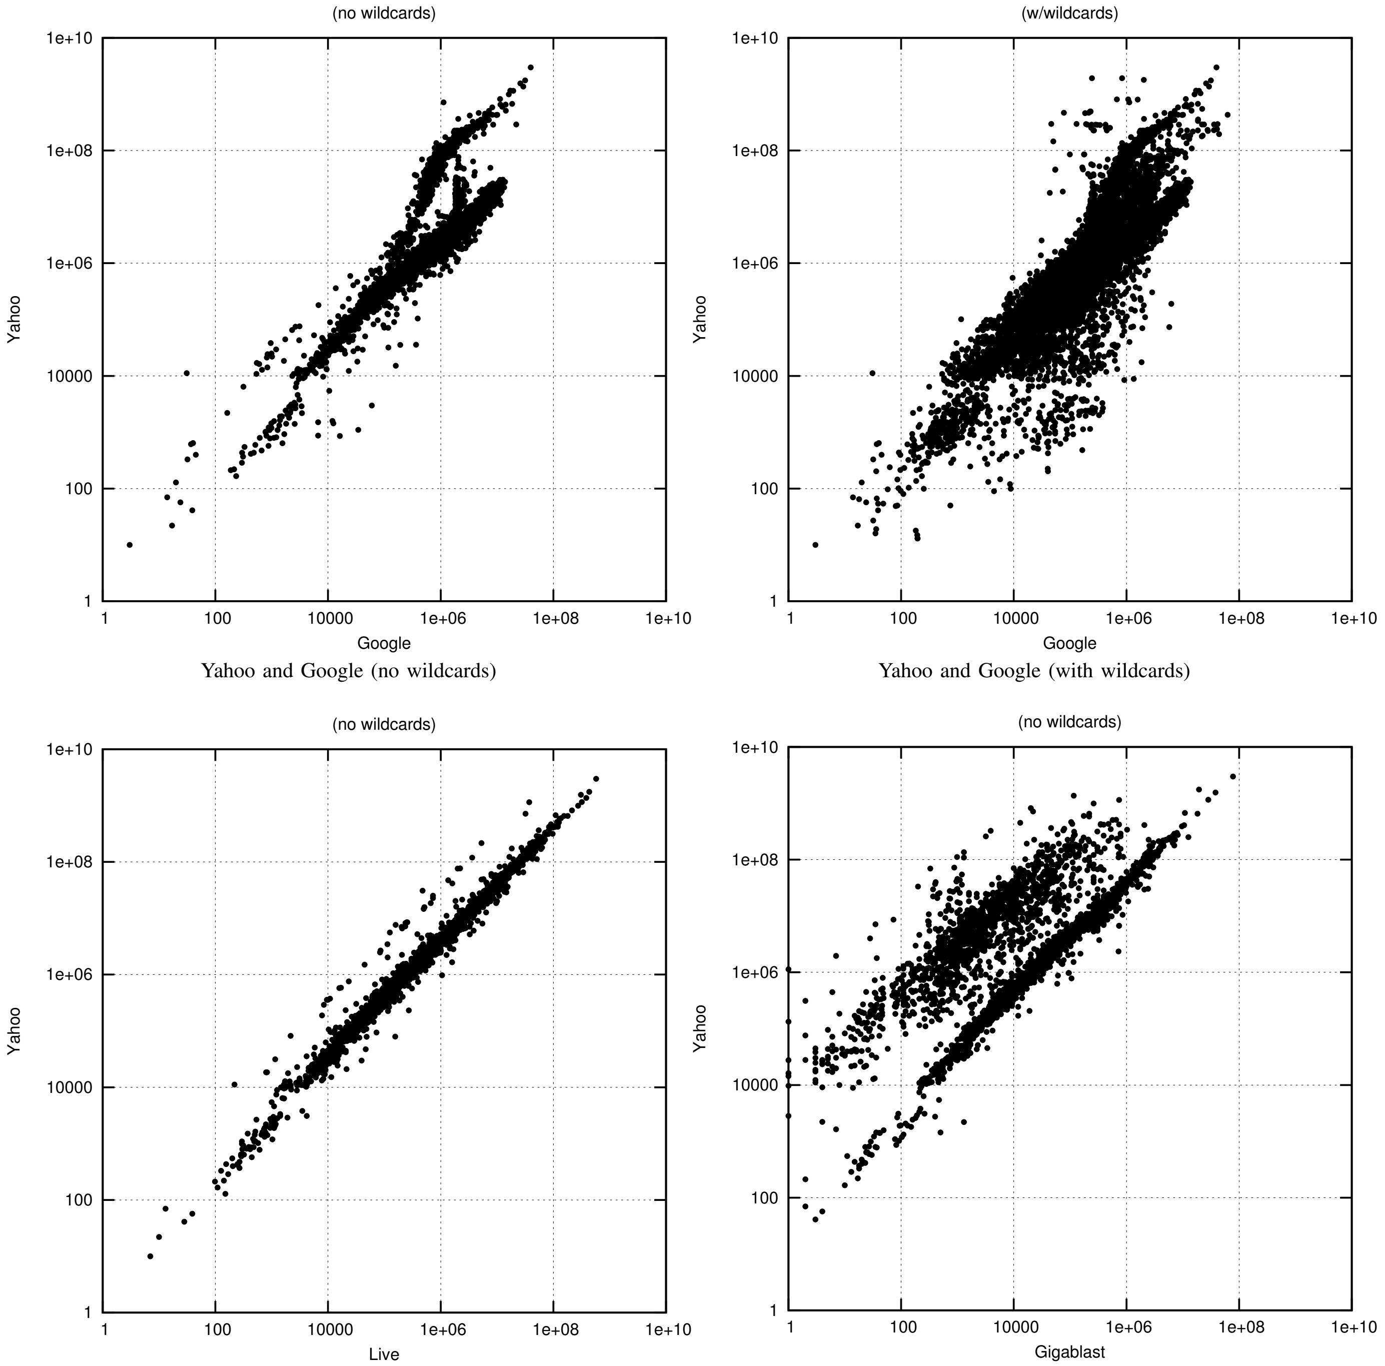
different estimated count of results. We took a closer look at all ten samples for each query, calculating minimum, maximum, median and a truncated average (average of 6 samples after sorting and removing two minimum and maximum outliers). The outcome of this analysis is that, again, Google has the largest variation between estimated result count for a single query (refer to technical report [8] for a more in-depth analysis). In case of Yahoo the difference between minimum and maximum number of results is relatively small, usually the same. Microsoft Live returns a fairly consistent range of difference—usually in the order of magnitude—with the truncated average usually equal to the maximum. For Google, the difference between min and max is again the order of magnitude, but the average is less predictable and is usually in between min and max (see Figure 9).

### B. *Phrasal verb rankings (groups)*

We constructed a *ranking* of phrasal verbs according to their totaled frequency of occurrence on the Web. Note that actual positions in this ranking are a product of multiple heuristics and their values should not be compared directly. The overall ordering should merely help to distinguish subgroups of frequent and infrequent phrasal verbs, as was our initial motivation for this research.

We experimented with many different ways of aggregating information from all samples and forms of each phrasal verb. We produced multiple possible rankings based on the following algorithm steps:

1) for every search engine, aggregate all samples for each phrasal verb form `form_id`, calculate minimum, maximum, median and truncated average (`avg2`) from document counts;
2) consider all variations: forms with <= 0, 1, 2 and 3 wildcards;



Yahoo and Google (no wildcards)

Yahoo and Google (with wildcards)

Yahoo and Live (with wildcards)

Yahoo and Gigablast (no wildcards)

Fig. 8. Log-log plot of document counts between Yahoo and other search engines.

3) sort in descending order all forms according to minimum, maximum, median and avg2 column, assign a rank to each `form_id`;
4) assign a minimum rank of any of its forms to each phrasal verb `pv_id`.

The above procedure has several variables which cause numerous possible variations of output rankings (depending on the engine, number of wildcards and the order column being considered). These rankings, consistently with our previous observations, demonstrate close similarity to each other within a single search engine and between Yahoo, AllTheWeb and Microsoft Live. Only Google is an exception. To give a few examples, the choice of the sorting column did not have much impact on the actual ranking within a single search engine. Cross-engine ranking consistency is shown on plots in Figure 10. The correlation of ranks (measured with correlation coefficient, which in this case equals to Spearman's rank coefficient) between AllTheWeb, Yahoo and Microsoft Live

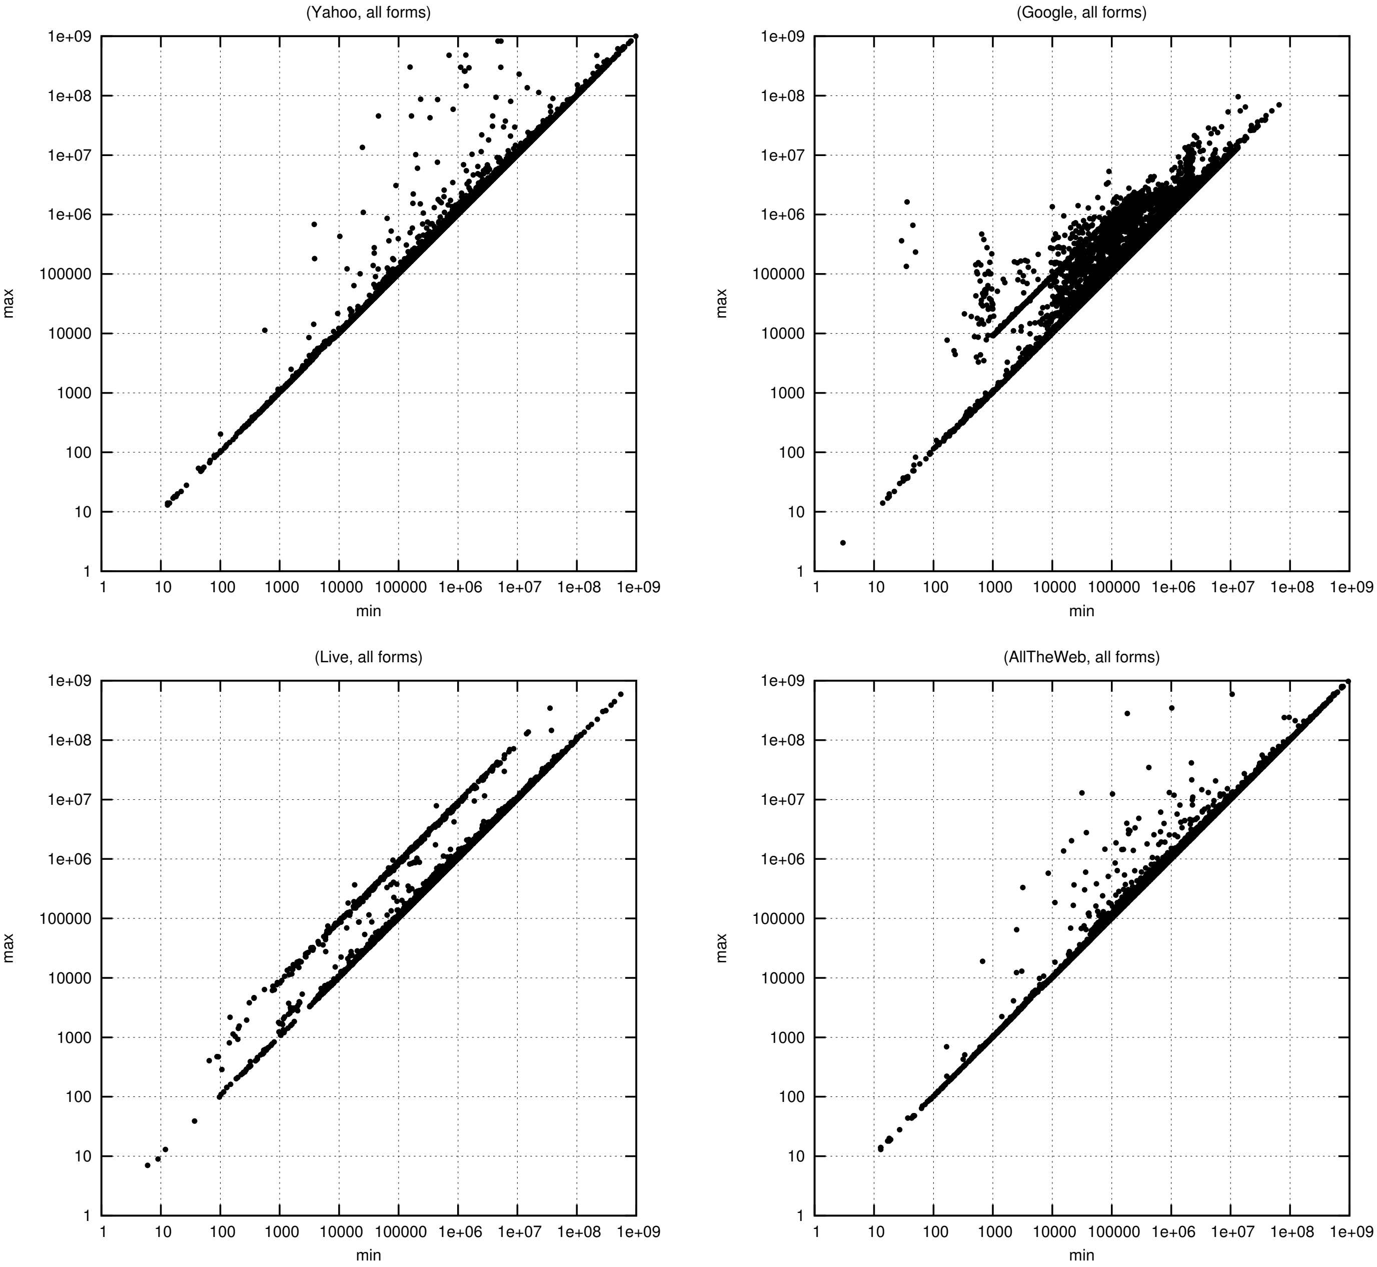


Fig. 9. Relationship between minimum and maximum number of results out of 10 samples for each phrasal verb form (Yahoo, Google, Microsoft Live and AllTheWeb).

was evident and larger than 0.9 for all considered combinations of rank computations. Google is distinctly different from other search engines, but the correlation coefficient is still quite high—between 0.7 and 0.8. We have no clear explanation as to why Google's results turn out to be slightly different than obtained from other search engines.

Even though all rankings were highly correlated, they were still a bit different from each other, so there is no ultimate one answer to our initial question of 'frequent' and 'infrequent' phrasal verbs. Without a doubt the rankings themselves reflect the nature of Web resources (see Table I) by, e.g., boosting phrases common in e-commerce (*sign up*, *check out*). Yet, a tentative and subjective feeling is that the top entries are indeed something that every native user of English should be familiar with and bottom ranking entries are extremely rare, uncommon or denote mistakes in the data set (see Table II).

## VIII. Summary and conclusions

We tried to create a ranking of phrasal verbs according to their frequency of actual use on the Web. We designed and performed a computational experiment, measuring estimated document count using several independent search engines. We think the outcomes are interesting from two different viewpoints: the linguistic one and the one concerning (dis)similarities across contemporary search engines, which turn out to be quite intriguing.

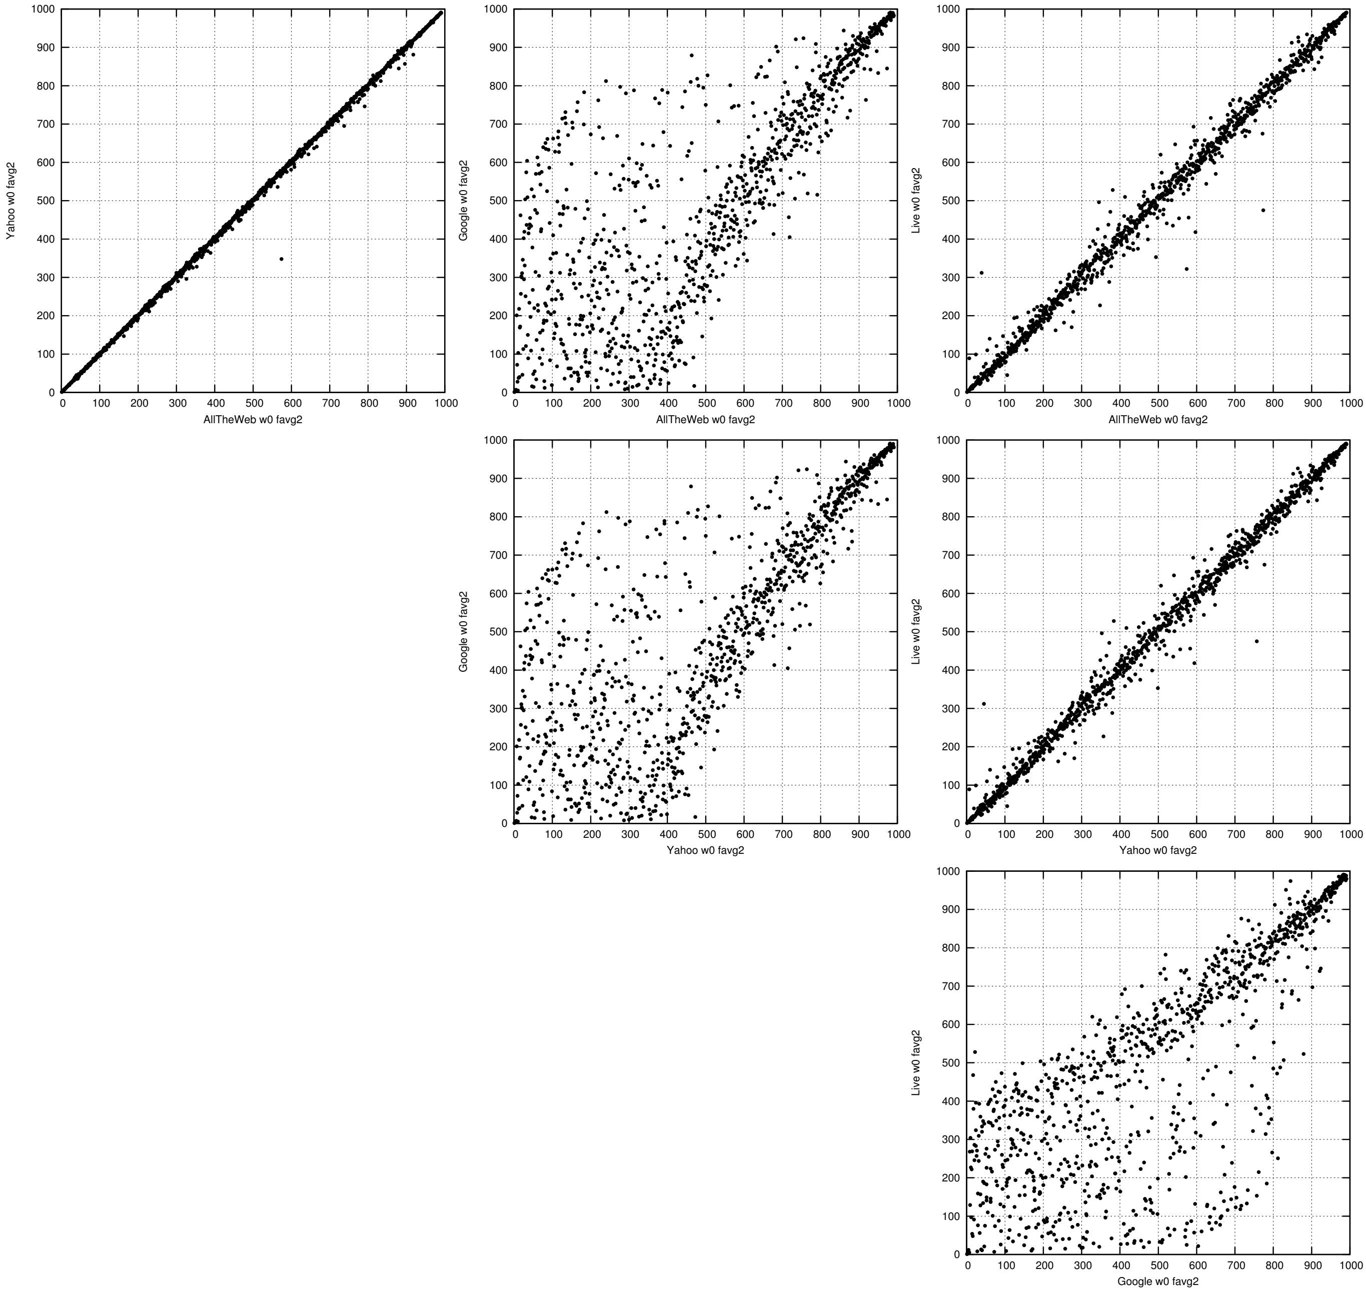

Fig. 10. Relationship between phrasal verb ranks depending on the search engine (search engine on horizontal and vertical axes fixed for rows and columns). Other parameters fixed to: `avg2` column used for sorting, zero wildcards.

As for the linguistic aspect, we are not aware of such search engine based measurement of the frequency of phrasal verbs, although search engines have been used for conducting linguistic experiments before. We think there are clear indications to believe that such an analysis can yield valid results, allowing one to separate frequent and infrequent phrasal verbs. A number of challenging problems remain unsolved:

- Even though the Web is very large, it is also biased; especially phrases that relate to e-commerce are boosted high up the ranking (*sign up*, *check out*). In our case this was not a problem because the rankings (groups) were edited manually for the final application after they were acquired anyway, but in other scenarios this is a problem.
- We currently see no way of disambiguating multi-sense phrasal verbs or no-object phrasal verbs. Given access to the full content of search engine's documents, shallow NLP techniques could be employed here.
- We used wildcard queries and multiple tenses for fetching various potential forms of phrasal verbs. It turned out that this had very little influence over final rankings; is such a step necessary or would it be enough

TABLE I
TOP 10 PHRASAL VERBS ACCORDING TO YAHOO, GOOGLE AND LIVE (0 WILDCARDS, AVG2).

| be bombed out | sponge down | rap put |
| slog out | ravel out | scorch along |
| hiss off | scorch along | stream down upon |

to just limit the analysis to present-tense forms?

- The distribution of document counts returned from search engines is exponential, so one could make groups of phrasal verbs each falling into bins related to the frequency's order of magnitude. However, there is no clear dividing line between these bins and there is certainly some room for improvement here.

From the point of view of a researcher interested in search engines, this work provides an interesting insight into differences between major search providers, especially with regard to the estimated matching document set size.

- Yahoo is by far the most *consistent* search engine and its returned estimation does not vary much between the same queries issued at different times,
- Yahoo and Microsoft Live show very correlated counts—nearly identical, in fact. This follows our intuition about 'sample from a large corpus', but is contradicted by results returned by Google. We cannot explain why Google is so much different compared to Yahoo and Live.
- Google and Live return document counts (for the same query) that vary by an order of magnitude.

As for further work on this subject, it would be quite interesting to examine phrasal verb distribution using exact NLP methods (or shallow, but with linguistic context taken into account) on a larger free corpora (such as Wikipedia or a free crawl of the Web) and compare the rankings with those we acquired from search engines. Such effort would allow validating and deriving further conclusions concerning the accuracy of our method. Alternatively, one could try to estimate the estimation error by taking the results returned from a search engine, manually tagging the returned documents as false/ true matches and then establishing true/false hit ratio. This method is used successfully in software engineering to establish the true number of software defects given a number of unreliable referees assessing code quality. Access to input lists of phrasal verbs, crawl results and rankings is given at the following address: http://www.cs.put.poznan.pl/dweiss/research/pv/.

**Acknowledgment** We are very grateful for anonymous reviewer feedback and his or her constructive suggestions and comments. The work was carried out with the financial support of Polish Ministry of Science and Higher Education.

# 8th International Multidisciplinary Conference on e-Commerce and e-Government

WE WOULD like to invite original papers on all aspects of electronic commerce, electronic government and related issues. The conference is meant to address the academic community as well as representatives of business, industry, government, NGOs and information technology sector. Thus—apart from research papers—practical presentations of existing solutions are very welcome, too. This year we specifically added the EGOV component as we would like to explore the e-government research and applications.

The areas of e-Commerce, e-Governance, e-Government etc. are interdisciplinary by nature: they involve people with their background in economy, management, artificial intelligence, computer science, sociology, psychology, law and so on. We feel that a meeting of specialists in those areas may help to cross the boundaries between the traditional disciplines, but also between the communities of theorists and practitioners. And to create a better understanding of the mechanisms underlying electronic markets, electronic administrations and networked organizations.

The general list of topics includes:

- electronic markets and electronic marketing
- business models and processes in e-Commerce and e-Government
- languages and models for e-Commerce and e-Government
- artificial Intelligence in e-Commerce and e-Government
- electronic contracting and public procurement
- legal aspects of e-Commerce and e-Government
- electronic interaction and negotiation
- virtual enterprises and knowledge management
- technology for e-Commerce and e-Government
- Internet computing, networked enterprises and networked governments
- social aspects of e-Commerce and e-Government
- futurology of e-Commerce and e-Government
- e-Inclusion and its influence on e-Commerce and e-Government
- national and cross-boarder e-Government services
- productivity and efficiency in e-Commerce and e-Government

***Abstract*—The paper presents the desk research on interdependences between individual use of e-government services and group of selected socio-economic indicators, results from public opinion polls on S&T, and work requirements in EU27 countries. We identified six distinct groups of indicators that are significantly correlated with use of e-government services: national innovativeness and competitiveness, regular use of Internet, demanding and autonomous work, interest in innovations and S&T, data protection and security and personal trust. Among others, research opens questions about possible role of social capital in public acceptance of e-governments services. Deeper insight into interdependences between studied indicators also reveals that old EU15 and the new EU member states in some cases demonstrate different behavior patterns.**

## I. Introduction

SUCCESSFUL implementation of e-government projects depends on public acceptance of new services. Practical experiences and researches [1][2][3] confirm that users' acceptance is not granted per se. Public approval is quite often below what developers expected [4]. To understand what motivates citizens to use e-government services is equally relevant issue for policy-makers and for developers [5]. Public providers cannot "force" individual citizens to use their services, as governments or corporations can do with their own employees. Motivation of citizens is often underestimated and many governments believe that it is enough to passively offer new services. Providers of e-government services should be more aware also of users' absorption ability for new technologies and applications. Some categories of citizens like elderly population [6] and people with special needs are already studied, but we are referring to general population.

From this point of view, it is attention-grabbing to see that the use of e-government services strongly vary across different European countries [7][8] The usage is clearly correlated with economic power of particular country and its ability to invest into development of e-government. But, economy cannot explain all regional differences. There are also other forces that can influence use of public services [9][10].

We were particularly interested in the role of socio-economic environment and citizen's perception of new technologies, as unseen forces behind innovativeness and consequently use of e-services [11]. Many researches confirm that social capital and other social characteristics strongly influence individuals' behavior and make them more or less opened for new ideas [12][13]. We still lack comprehensive definitions of social capital and variables, so we are using many substitutes like general trust. We took similar approach in our research, including results from selected public opinion polls in EU27.

## II. Research and hypothesis

In the paper we present a part of a wider research on interdependences between socio-economic environment and national performance indicators. In the focus of this particular research was the question which social and citizens' characteristics identify an environment that is favorable for use of e-government services by individuals. We were also interested in regional differences between EU countries, partly because it was relevant issue for policy-makers, and partly because there were available data on EU level. Socio-economic diversity in the EU is very high and offers an opportunity to study its influence and interdependences between different national performance indicators. In our desk research we also searched for possible dissimilarity between old EU15 and new EU member states.

Research hypothesis were based on prevailing perception of users' behavior like: high national innovativeness and positive attitude towards science and technology, high public interest in Internet and new on-line technologies, trust and awareness on personal data protection they all stimulate use of e-government services. In our previous researches [1] we noticed that in many cases old and new EU member states behaved differently, so we were interested to see if they follow the same pattern or not.

Main information sources for research were EUROSTAT data bases and public opinion polls published in Eurobarometers (Table 2). Our research sample was set of EU27 member states. Research was conducted in three steps:

- With factor analysis we reduced number of variables, considering only variables that load on the first principal component associated with use of e-government services by individuals (we started with nearly 50 indicators and ended with 24);
- In the second step we calculated correlations between remaining variables and the use of e-government services by individuals;

- To get a deeper insight into the structure of some particularly interesting correlations we decided to use also graphical presentations to visualize behavior of individual countries and their eventual clustering.

## III. Presentation of results

Correlations between use of e-government services and the most relevant economic indicators have been already recognized and interpreted (Table 1). These correlations just confirm that economically more developed countries can invest relatively more into e-governments than others, and consequently increase its usage. It is evident that innovativeness and national competitiveness are the most prominent characteristics of environments with high use of e-government services. Other correlations are not that high, so there is still a room for other often hidden forces that influence e-governments.

Less recognized and studied are correlations between use of e-government services and social indicators or public opinion which determine socio-economic environment that that can also significantly influence behavior of individuals. The Table 2 presents correlations with such indicators and

Table I
Correlations between e-government use by individuals and selected national performance indicators for EU27 member states

| | Source of data | Correlation with e-government use by individuals |
|---|---|---|
| Innovativeness (SII) | European Innovation Scoreboard | 0,881 ** |
| National competitiveness | IMD World CompetitivenessYearbook | 0,848 ** |
| GDP per capita in PPP | Eurostat | 0,724 ** |
| Economic performance | IMD World CompetitivenessYearbook | 0,653 ** |
| Labor productivity | Eurostat | 0,651 ** |
| Spending on human resources | Eurostat | 0,519 ** |
| Science and technology graduates | Eurostat | 0,376 * |

** Correlation is significant at 0,01 level.
* Correlation is significant at 0,05 level.

Table 2
Correlations between e-government use by individuals and selected socio-economic indicators for EU27 member states

| | Source of data | Correlation with e-government use by individuals |
|---|---|---|
| Share of individuals recently used e-commerce | Eurostat | 0,901 ** |
| Share of individuals regularly using Internet | Eurostat | 0,892 ** |
| High individuals' level of computer skills | Eurostat | 0,860 ** |

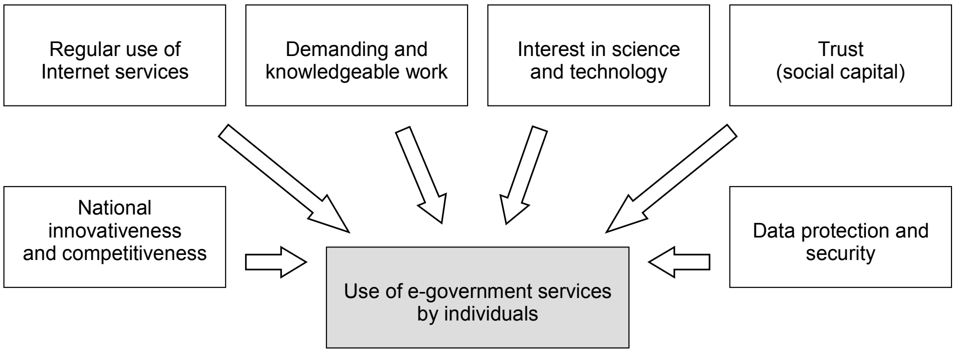
| Interested in economics and social sciences | Spec. Eurobarometer 273 | 0,560 ** |
| Interested in Internet | Spec. Eurobarometer 273 | 0,456 ** |
| Globalization is opportunity | Eurobarometer 63 | 0,433 * |
| Well informed about inventions and S&T | Spec. Eurobarometer 282 | 0,381 * |
| Interesting in IT news in media | Spec. Eurobarometer 282 | -0,282 |

** Correlation is significant at 0,01 level.
* Correlation is significant at 0,05 level.

results of public opinion polls that were selected with factor analysis out of nearly 50 subjective selected indicators. They load on the first principal component which is associated with use of e-government services.



Regular use of Internet services
Demanding and knowledgeable work
Interest in science and technology
Trust (social capital)
National innovativeness and competitiveness
Data protection and security
Use of e-government services by individuals

Fig. 1 - Groups of indicators influencing use of e-government services by individuals

The first three top ranking indicators confirm high interdependence between use of internet services and use of e-government by individuals. It confirms that from user point of view e-government services are just ordinary e-services as others. More intriguing is high correlation with personal trust. It indicates a potential role of social capital (trust is an important part of social capital) that has not been really studied in connection with e-governments issues. It is also noteworthy that the next four places occupy indicators describing individuals' work conditions and professional demands. Extensive work at home and high demand for knowledge and personal initiative at work make individuals keener for use of e-government services. Similar effect has an intensive lifelong learning.

Public believe that personal information are properly protected is in the middle of the list with medium correlation (R=0,670). It is similar with public perception that transmitting data over Internet is sufficiently secure. It indicates that concern for data protection and security are relevant drivers for use of e-government services, but it is not decisive. Citizens tend to believe that their data will not be misused.

The next group of three indicators talks about individual awareness of S&T and Internet. Interest in S&T is much stronger motivator (R=0,67) than interest in Internet alone which demonstrate surprisingly low correlation (R=0,46). We can hypothesize that people accept Internet just as an useful tool, but they don't need to be very enthusiastic and interested in the tool itself. On the other side, general interest in S&T indicates a general innovative environment that is favorable also for implementation and use of innovative e-government services. Public perception that globalization is an opportunity is again a sign of open-minded society for new challenges. However, the correlation is already very low and it is statistically not really relevant.

Fig. 1 schematically presents six main clusters of national indicators and public opinions that are the most significant indication of stimulative environment for use of e-government services.

Correlations are just statistical figures and cannot reveal details in the structure of interdependences. For that reason we visually investigated positioning and eventual clustering of individual countries. As we already mentioned, the correlation between public interest in Internet and use of e-government services was low. This result contradict our common believe that sole interest in internet powers its use.

However, in the Fig. 2 we can notice two clusters of countries. In the first cluster are the most developed EU countries (Denmark, Netherlands, Sweden, Luxembourg, Finland, Germany, France and UK). They demonstrate high use of e-government services but a wide range of interests in internet, from very low to very high. We can conclude that these variables are nearly independent for this cluster. On the other side, in all other EU countries we can witness much lower use of e-government services, but much stronger correlation between it and interest in Internet. We can hypothesize that in the beginning of e-government implementation public interest in Internet plays a relevant role, but not in the more mature development phase when Internet becomes a "normal" and widely accepted technology. It indicates a nonlinearity that can be noticed in many other cases, too.

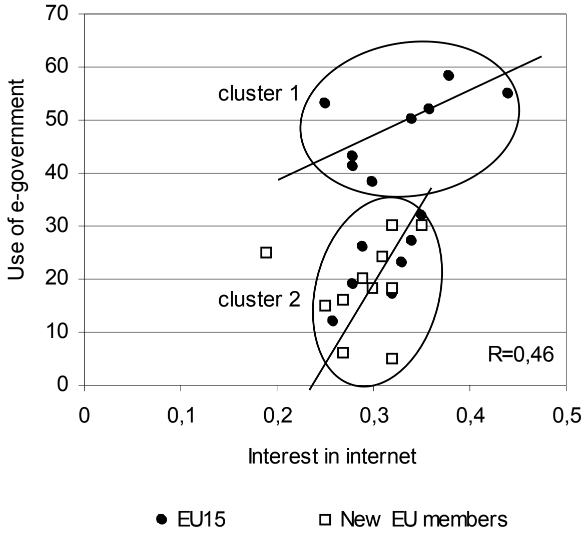


Fig. 2 - Interdependence between public interest in internet and use of e-government services

Stronger motivator for use of e-government services than interest in Internet is a general public interest in S&T (Fig. 3). In this case too, behavior of old (EU15) and new EU member states shows different pattern. In contrast to the old EU member states (full line in Fig. 3), in the new EU members higher interest in S&T doesn't result in considerably higher usage of e-government services (dotted line in Fig. 3). Relatively high interest in S&T in new EU member states is noticed in many researches and is attributed to educational system and some historical reasons. However, this interest alone cannot significantly raise use of e-government services because there are other, particularly economic brakes.

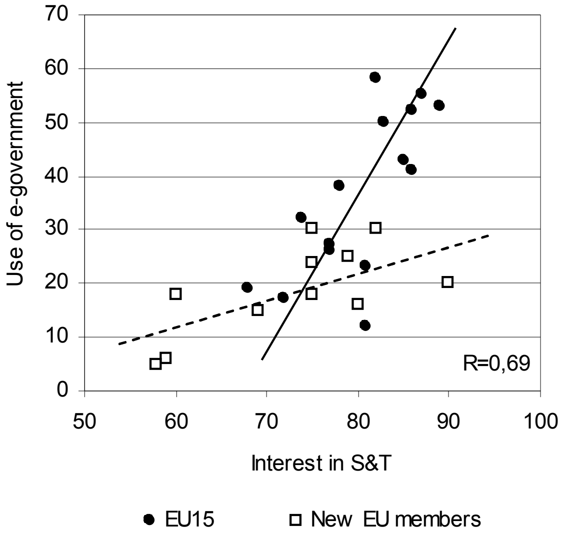

Fig. 3 - Interdependence between citizens' interest in S&T and use of e-government services

One of the strongest motivator for use of e-government services is a general national innovativeness. It identifies environment in which individuals are more attracted and opened to new ideas and ready to experiment with new technologies. So, it is not a surprise that such environment significantly stimulates use of e-governments. Investigating this interdependence in more details we can notice (Fig 4) that the most developed EU countries (marked cluster) have significantly higher level of innovativeness which is very likely one of the main reasons for their higher use of e-government services. However, we have to additionally comment this issue. The European Commission annually evaluates and ranks national innovativeness through Summary Innovation Index which also includes infrastructure issues and economic power that enable innovative processes in particular country. So, even national innovativeness is not just state of the mind, but reflects the strength of national economy. The circle is so closed, because the economic power makes possible higher investments into e-government projects and their higher use Table 1).

Correlation between the level of computer skills and use of e-government services by individuals is high (R=0,86), but again we can see two clusters of countries (Fig. 5). Trend lines are parallel but shifted indicating that at the same level of computer skills in northern EU countries exhibits higher level of e-government usage than in other countries that are on a lower "development" trajectory. In the new EU members, including Spain, Portugal, Italy and Greece, we see that even high level of computer skills results with lower use of e-government services. We can just guess that in the first phase of e-government development computer skill are more important and simulative than later stages.

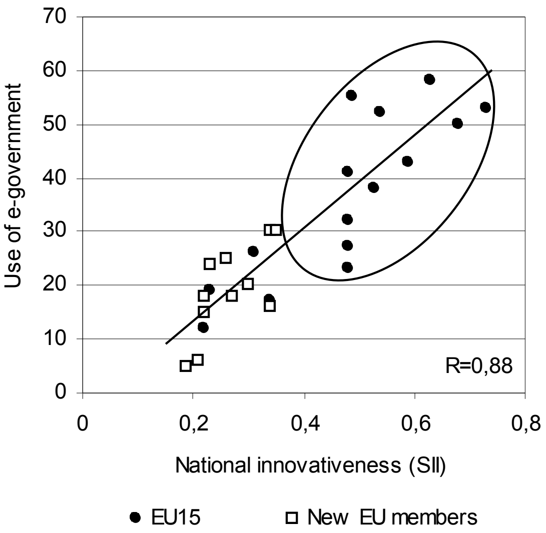

Fig. 4 - Interdependence between national innovativeness (Summary Innovation Index) and use of e-government services

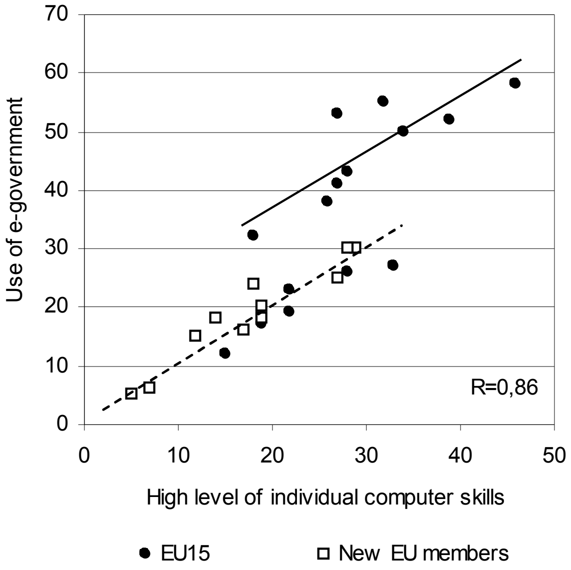

Fig. 5 - Interdependence between citizens' level of computer skills and use of e-government services

To summarize, figures from 2 to 5 illustrate four typical patterns in behavior dissimilarity in the old EU15 and new EU member states:

**P1:** In the most developed EU member states the use of e-government services is not very sensitive on changes in studied indicators (Fig. 2), but it is very sensitive in new EU members (and also for old EU15 members from the Southern Europe).

**P2:** The second pattern defines the opposite situation (Fig 3). In the new EU member states the use of e-government services is not very sensitive on changes in studied indicators.

**P3:** In the third pattern all EU member states demonstrates similar behavior (Fig. 4).

**P4:** The last pattern indicates different development trajectories for the most developed EU members and the rest, including all new member states and few old EU15 member states from Southern Europe (Fig. 5).

## IV. Conclusions

In the research we identified six distinct groups of national indicators and public opinions that are significantly correlated with use of e-government services by individuals. Two of them are quite evident (National innovativeness and competitiveness, and regular use of Internet), the next are data protection and security , and other three are less obvious (demanding and autonomous work, interest in innovations and S&T, and personal trust).

Particularly intriguing is high correlation between use of e-government and personal trust. It opens many questions about possible role of social capital in acceptance of new e-government services. As we already mentioned, this issue have not been really studied in connection with e-governments'. We could hypostatize that high social capital in Scandinavian countries and UK significantly increase use of publically available e-government services and that it is one of the main reasons for regional differences.

Another interesting feature is clustering of countries with different behavior. Deeper insight into interdependences between discussed indicators reveals that the old EU15 and new EU member states often demonstrate different behavior patterns. It would be interesting for some future research to find out if these differences are caused by nonlinearities in functional interdependences between use of e-government services by individuals and presented socio-economic indicators, or by other reasons. We indicated that in early development and usage phases of e-government services some correlations are different than in more mature phases. But, we could also offer another possible explanation. Lower level of e-government usage is characteristic of all new EU member states and some old EU15 member states from the Southern Europe, so we could hypothesize that their different attitude towards governments is relevant motivating factor in the use of e-government services. Particularly in Central European countries we could still see some public reluctance against government that has deep historical roots.

***Abstract*—This paper presents the basic assumptions of the Collaboration@Rural project (C@R) supported by the EU's 6th Framework Programme for Research and Technological Development. Apart from discussing primary objectives of the project—focused on supporting the development of rural areas by providing network-based collaboration environment—it also shows basic assumptions of a 3-layer reference model serving as the foundation for C@R architecture. As an example of service rendered available within such network collaboration environment, the implementation of a notification service component is presented herein.**

## I. Introduction

Accounting for more than 90 percent of the EU's territory, rural areas are inhabited by almost 60 percent of its population. For this reason, the development of rural areas has long been one of the major priorities of EU's policy [5]. Despite that, many of those areas are still challenged by serious problems.

In the world of globalisation, dynamic competition and free-market economy, agriculture and forestry-related enterprises must continue to improve their competitiveness. What is a serious issue in this context, the average income per capita in rural areas is usually lower compared with cities, skills resources being lower as well, and the services sector—poorly developed. Nevertheless, rural areas have much to offer too. First and foremost, they are the source of basic raw materials. Because of the natural resources they are also a valuable place of rest and recreation. Many people are considering living or working in the country, as long as they can count on access to proper services and infrastructure (including ICT infrastructure). Bearing the above in mind, the objective of EU's policy relating to the development of rural areas is to overcome the challenges facing the population of such areas, and to utilise their potential [5, 6].

Chapter 2 of this paper presents a general concept behind the Collaboration@Rural project, together with its main objectives. Chapter 3 contains the characteristics of a layer-structured reference model of C@R architecture, while the next one describes the concept of implementing the e-mail based notification service within the framework of this project. The final chapter contains a summary and some information about the policies of further actions.

## II. Objectives of the Collaboration@Rural project

Collaboration@Rural[1] project (C@R) is a 3-year-long project carried out since September 2006 as part of the EU's 6th Framework Programme for Research and Technological Development. The project is being implemented by a multinational consortium comprising over 30 partners—universities and research centres, companies (both market leaders like Nokia or SAP, and representatives of the SME sector) and international organisations (including FAO and ESA). Poland is represented by Adam Mickiewicz University from Poznań.

The goal of this project is to accelerate the implementation of Collaborative Working Environments (CWE) in the context of sustainable development of rural areas. According to this concept, C@R encompasses a number of R&D actions (from analyses to validations), which have been grouped in three major interest areas, also defining the framework of technical solution—C@R service architecture (layers): Collaborative Core Services (CCS), Software Collaborative Tools (SCT) and Living Labs (see 1).

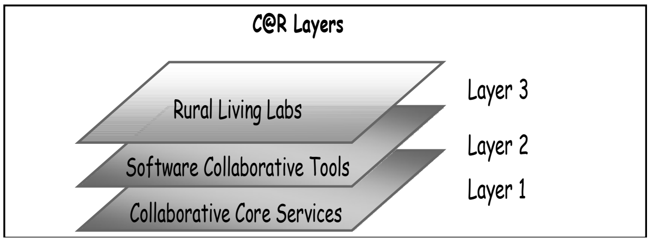

Fig. 1 C@R Architecture

C@R project implementation aims to complete five basic objectives, which have been defined in the following way [3]:

[1] Full title: *„A collaborative platform for working and living in rural areas*"

978-83-60810-14-9/08/$25.00 © 2008 IEEE

Obj 1: C@R will deliver collaboration environments to rural communities, to be defined in relation with the remaining network collaboration environments (CWE)

Obj 2: C@R will present the method in which three types of users can utilise the shared platform that integrates various hardware and software tools

Obj 3: C@R will promote the use of Open Collaborative Architecture (OCA) to cater for the needs of implementing new industrial and business projects in the rural sector, at the same time showing its usability and suitability for this type of actions

Obj 4: C@R will develop a concise methodology serving the development and assessment of obtained Rural Living Lab results

Obj 5: C@R will provide support to policy makers in the context of designing new strategies of development and innovation for rural areas after 2010.

## III. Layer-Based Reference Model for ICT Collaborative Environment

IT tools and technologies supporting group work and facilitating the creation of network collaboration environments (both for individual and group entities) have been the subject of studies, analyses and numerous research papers in the recent years. Owing to the continuous development and spread of technologies improving the efficiency of use of IT tools, it has lately become possible to carry out many specialist tasks (e.g. real-time positioning, teleconferences, telework, mobile workers' support, etc.) and reach communities that used to be marginalised (living in sparsely populated areas, rural areas, etc.)

The following 3-layer reference model has been approved for C@R, serving as the basis for the creation of an ICT collaboration environment for rural areas, comprising (see Fig. 2):

- Collaborative Core Services (CCS)—layer 1;
- Software Collaborative Tools (SCT)—layer 2;
- Rural Living Labs (RLL)—layer 3.

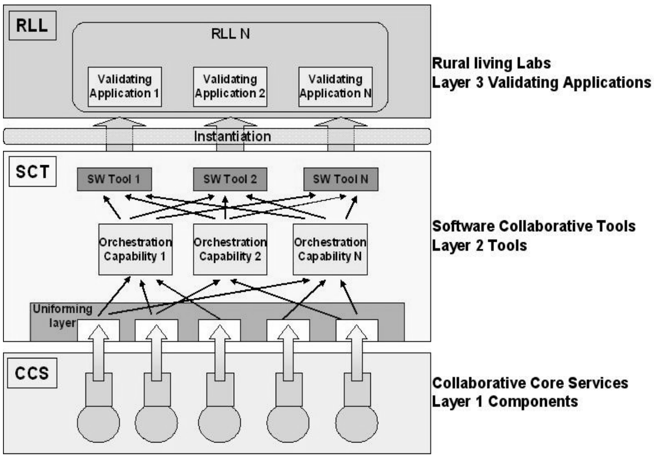

Fig. 2 Layered reference model for C@R [3]

The CCS layer includes software modules that allow to use all key platform services and resources (e.g. networks, sensors, devices, etc.). These modules can be freely combined with one another, and utilised with layer 2 SCT tools. With such flexibility, the C@R service architecture will be capable of cooperating with any solution and tool from outside the scope of the project (irrespective of its openness), which will allow the project to contribute significantly to defining the concept of Open Collaborative Architecture (OCA). The third layer—Living Labs—will render real environments available for the purposes of developing and validating solutions meeting specific needs of users from rural areas.

### *I. Collaborative Core Services Layer*

The layer of collaborative core services (CCS) is the first one in the 3-layer C@R reference model. It focuses on basic or low-level services and resources, which are indispensable for building a collaborative working environment (CWE). Consequently, elements of this layer comprise all mechanisms and technical means allowing to e.g.: provide access to ICT network, use advanced network services, render subject location service available, use the geographical information system, provide notification services and web services, deliver dispersed processing environment, etc.

All services available in this layer should be encapsulated in single programme components (CCS components) with specific objects defining data, protocols and API interface, so that they can form the basis for the structure of more complex services at the second layer of the model (comp. Fig.3).

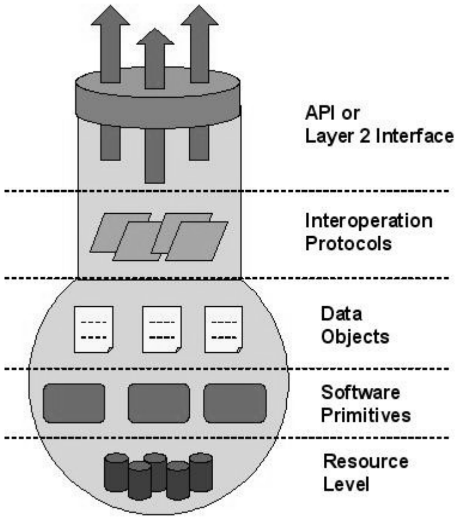

Fig. 3 CCS component construction [3]

The following CCS component classes have been defined in the C@R project:

- communications—comprising:
  - all possible network access systems (WiFi, WiMAX, UMTS, etc.);
  - advanced network services (QoS, multicast, etc.);
  - advanced services available via signal protocols (SIP/IMS, forwarding, multimodality, etc.);
- related to environmental and context data capture :
  - ICT infrastructure and devices (GSM/GPRS, GPS/Galieo, positioning services, terminals, etc.);

  - sensors and sensor networks providing data on environment variables, and allowing to identify subjects (e.g. data from RFID sensors required to identify goods, animals, etc.);
  - biometric devices and protocols (advanced methods of subject verification based on individual characteristics of eye retina, fingerprints, voice recognition, etc.);
- related to user experience :
  - all elements used directly by parties cooperating in rural areas, e.g. advanced graphic interfaces, computers built into tools, wardrobes, etc.;
- related to informati—on management:
  - all information sources;
  - data repositories—also dispersed ones;
  - data access technologies;
  - notification services;
  - web services.

### *II.Software Collaborative Tools Layer*

The second layer—Software Collaborative Tools (SCT)—is responsible for delivering the following three functionalities:

- Uniforming Middleware:

  it is a conceptual middle layer for CCS components, its goal being to harmonise, unify and adapt to existing standards; with this functionality, the C@R architecture gains flexibility and power, owing to improved integration with existing and newly developed standards;
- Orchestration Capabilities:

  this layer is responsible for delivering—within the network collaboration environment (CWE)—complex services, such as dispersed working environment, conditioning action and context; implementation of this objective consists in delivering mechanisms that allow to integrate elementary CCS components into more complex elements; key research issues relating to this functionality revolve around such elements as ontologies for collaboration environments, semantic compatibility, flows, synchronisation and coordination of middleware;
- Software Tools:

  they contain all necessary software components (scripts, programmes, intelligent agent programmes) in order to supply the end user with a component able to deliver specific services; basic components are related with synchronisation protocols, middleware orchestration protocols, dispersed repositories, context identification, multimodal interfaces and security.

### *III.Validation layer—Living Labs*

The concept behind a *Living Lab* is a methodology of conducting research and implementation activities in Knowledge-Based Economy and Information-Based Society conditions, where innovative products, services or applications are designed, tested and improved in real conditions, in interdisciplinary teams comprising all interested entities—from engineers and researchers, through entrepreneurs, local authorities and social organisations, to citizens.

A Living Lab is also a place (usually some area of a town, university campus, technology park, etc.) where innovation is developed—not merely in terms of technology, but also society, economy, etc.—focusing on the needs of the recipient. This unique anthropocentrism relating to the method of conducting research—i.e. focusing on people (citizens) as well as their requirements and expectations—is a characteristic feature of Living Labs methodology: man is the source of innovation here rather than the subject of testing, or the source of feedback needed to improve products. Moreover, the process of creating innovation is open [1,2] (i.e. based on a broad partnership of many different organisations) and democratic [4] (i.e. involving entire communities of end users). What is also important, each Living Lab is based on the collaboration of players of key importance to a given region (including local administration), owing to which it can engage in the completion of the strategic goals more efficiently.

The concept of Living Labs (LL) was developed within the framework of *AMI@Work Family of Communities* [7], the international expert group closely cooperating with the European Commission since 2004. Beginning from the Finnish Presidency (end of 2006) regions, cities and organisations which develop their own Living Labs (more than 50 currently) have been associated in the European ENoLL network (*European Network of Living Labs*). EnoLL, together with a number of projects co-financed by the European Commission (i.e. C@R accompanied by CoreLabs, CLOCK, COLLABS and others), have provided the background for creating numerous tools, guidelines and procedures aimed to facilitate developing and supporting the operation of Living Labs. Besides receiving support from the European Commission, this initiative has been supported by successive EU Presidencies and particular regions.

The role of Rural Living Labs (RLL) in the third layer of the C@R model consists in activating the Collaborative Working Environment—not merely in the final stage, being the validation of designed solutions, but also at the research level, e.g. when domain ontologies are being developed. C@R project entails continuous active involvement of RLL community members who are to be an important source of information about the accuracy of courses of research undertaken in each of the middle stages of the project, or allow to estimate the effectiveness of approved solutions at the level of individual system components. Another key role of RLL's is their social dimension, namely they allow to monitor social reception on an ongoing basis, along with the effectiveness of utilising proposed solutions.

Consequently, the third layer of this model is responsible for implementing the following tasks:

- causing a Collaborative Working Environment to acquire specific characteristics required by each of the RLL labs;
- selecting appropriate infrastructure or adapting existing infrastructure to each RLL, allowing to fully utilise the capabilities of lower layers;

- designing appropriate applications adjusted to specific needs and activities of each RLL;
- implementing a validation process based on action scenarios existing in each RLL, along with typical users' activity, in order to supply feedback to the designers of layer 1 and 2 components.

## IV. An Exemplary Implementation of the CCS Component—a Notification Service Based on Electronic Mail

One of the benefits notification services offer to entrepreneurs is the possibility of an immediate transfer of almost any information to a defined group of registered users. In particular, the entrepreneur or business partner is able to transfer their messages to cooperators and customers in the natural course. What is important is the fact that messages can be addressed to a selected group of recipients; thus, their content may be personalized and suited to the relation binding the entities, as well as to current needs.

Most entrepreneurs have already appreciated the benefits offered by this type of services and use them actively. Nevertheless, the fact remains that the solutions available today are characterized by a number of problems limiting the potential scope of their application. Among the commonly noticed drawbacks of the available solutions are: limited scanning possibilities, high dependence on the equipment and program platform, limited possibilities of configuration and management.

For these reasons, a CCS component allowing any entity reporting such functionality needs to benefit from the advantages of notification services is to be developed within the C@R project.

In order to demonstrate the possibilities of creating notification services integrated with the C@R platform, an SMTP-CCS component, allowing for sending e-mails, was developed. Its main element is the CCS, containing a Server capable of sending SMTP messages to an e-mail Server. The service provided by the SMTP-CCS component is available through the *Web Service* interface.

In order to take advantage of the possibilities offered by SMTP-CCS and the C@R platform, a client component needs to be implemented, which would enable access to the provided service.

### *IV.Resources included in the component*

The following resources were included in the components in order to create the notification service:

- SMTP-CCS contains a server capable of sending SMTP messages to an appropriate e-mail server; this server and the component are located in the same local network, thus facilitating communication. CCS makes the Web Service which allows for sending messages, available to the world (SendEmail);
- Client CCS contains a simple text interface enabling registration on the platform and the sending of basic e-mail messages with the use o the service provided by SMTP-CCS.

### *V. Component Specification*

- The server

The purpose of the SMTP-CCS component is to mediate between different C@R platform elements and the electronic mail server sending e-mail messages. The server is an element passively awaiting customer demands, which are serviced as they are sent.

The component implements the following functions:

- o Web Service client, which enables registration on the platform;
- o Web Service interface, which allows for obtaining connections with other elements of the platform;
- o Web Service interface which enables the reception of demands for a notification email.

- The client

The client component is an active element, which establishes connections with the server component for the purpose of sending notifications.

- o The component implements the following functions:
- o Web Sernice client which enables registration on the platform;
- o Web Sernice interface which allows for obtaining connections with other elements of the platform;
- o Web Sernice client which allows for sending connection demands to a different component;
- o A client servicing the data channel (it this particular case Web Service) which enables the sending of a notification through SMTP-CCS.

### *VI. The integration of the notification service with the C@R platform.*

In order to integrate the notification service with the platform, the following steps were taken:

The CCS core was fed with appropriate data enabling registration; “Notify e-mail” was indicated as the name of the provided service, being an available “WebService.SendEmail” data channel;

- The component’s Specific Options service was complemented with the necessary parameter of Web Service SendEmail address;
- The SendEmail service, which processes data, was implemented
- The SMTP-messages-generating functions were implemented;

In order to integrate the service client with the platform, the following steps were taken:

- CCS component framework was fed with the appropriate data enabling registration;
- The notification service search criteria were set for “e-mail”,
- A simple text interface allowing for testing client’s operations was implemented.

### *VII. Component interactions*

Figure 4. demonstrates the way in which components communicate. The sending of a notification entails realization of the four following stages:

1. The client component registers on the platform and sends an inquiry for availability of the server component (SMTP-CCS) and access parameters (protocol, address, etc.)
2. The client prepares a message including information describing the e-mail to be sent for SMTP-CSS. Once the message has been prepared, a suitable Web Service is called up (in this particular case SendEmail).
3. The SMTP-CCS server prepares and sends the SMTP message to the e-mail server.
4. The e-mail server is responsible for delivering the message to the addressee.

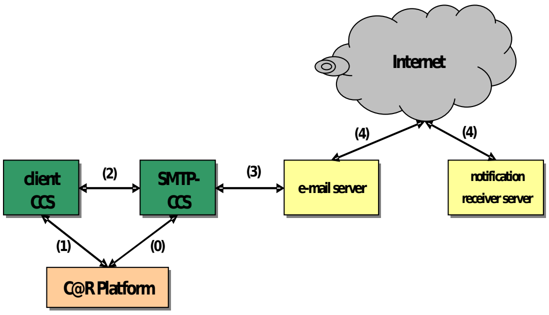

Fig. 4 Service components communications

Apart from the steps presented above, the SMTP-CSS registration on the platform (marked with "0") is required for the proper functioning of the service. This step enables other components to find the server and use the service it provides.

## V. Summary and further work

The article presented the IT platform of cooperation and its role in the process of rural areas development support. The basic assumptions of the Collaboration@Rural (C@R) project, implemented under the 6th Research and Technical Development Framework Programme of the European Union, were discussed as an important contribution to the support of stimulation of rural areas and preventing the phenomenon of digital exclusion. The three-layer reference model composed of the following layers: Collaborative Core Services (CCS), Software Collaborative Tools (SCT), and the so-called Living Labs was described in detail.

Moreover, a diagram of implementation of a selected component within the CCS layer was presented—a notification service using electronic mail.

Further works within the C@R project, which has entered into the second stage of its existence, will involve the validation of the results obtained within the CCS and SCT layers in the environment of RLL laboratories.

# Corporate blogs—innovative communication tool or another internet hype? empirical research study

Grzegorz Mazurek, Ph.D.
Koźmiński University
ul. Jagiellońska 59, 03-301 Warsaw, Poland
e-mail: gmazurek@wspiz.edu.pl

***Abstract*—In the following paper the role, potential and perception of corporate blogging among key marketing decision makers from the companies listed on Warsaw Stock Exchange have been presented. The topic of blogs has been widely promoted in recent theoretical and practical publications, however very little information can be found on the scope of blogs usage and real impact of such modern communication tool on the business. Such issues as limitations in corporate blogs implementation, the perception of the blogs' information value or the expected potential of blogs usage have been identified and explained. Author describes various models of corporate blogs and tries to find out whether blogs are truly used as modern communication tool for business or it is just another hype which soon is replaced in media by another ideas and concepts.**

## I. Introduction

BLOGS, defined as web pages that serves as a publicly accessible personal journals [1] have been attracting media and public eye for the last few years. The amount of registered blogs is huge and still increasing - by the end of 2007, Technorati.com was tracking more than 107 million blogs [2]. Such phenomenon, appreciated and popularized by many internet users, has also been regarded in literature as innovative communication tool for business. That is why the new term has been coined – corporate blog.

A corporate blog is a weblog published and used by an organization to reach its organizational goals [3]. The purposes of blog usage can be grouped in three fields – brand building (incl. leadership), customer service (inc. product development) and promotion (incl. sponsorship and advertising) [4].

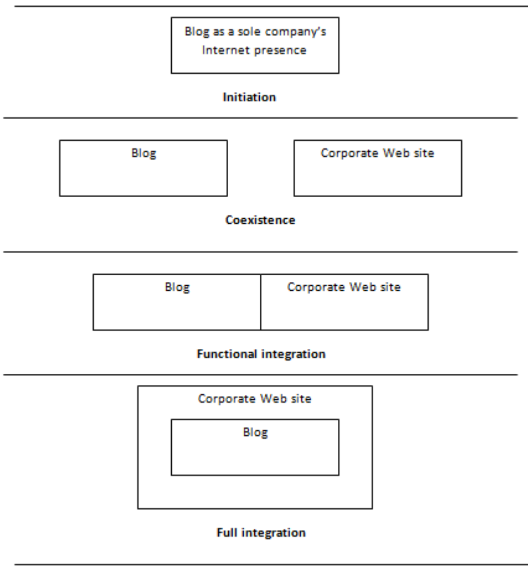
Corporate blogs have some unique features which make them perfect alterative or upgrade to typical corporate web pages which are usually exemplified by minor usage of user generated content (UGC) – i.e. the communication is one-sided or asymmetric and the users do not have many opportunities to provide company with valuable information, not mentioning about the possibility of having on-line dialogue with company's employees and other clients.

The key prerequisites for successful corporate blogs are [5]:

- symmetric communication (incl. using comments)
- informal language
- dialogue with readers which results in creating virtual community,
- regular postings,
- integration with other media and other content,
- clear rules and purpose of publishing (regulations).

Setting-up corporate blog often leads to challenges concerning the coordination of the overall on-line communication as companies use various other tools: corporate web pages, product or event sites and co-branded content via e-media presence. That is why 4 models of blog implementation are distinguished.

Scheme 1. Blogs and corporate web site – models of implementation



Source: [5], p.22.

The abovementioned characteristics of blog and media attention devoted to the issue should encourage companies to implement such innovative communication tool and widely popularize it among enterprises.

However, even rough market analysis proves that the usage of corporate blogs is very narrow – few companies in fact use corporate blogs. It shows that although blogs have unlimited opportunities and benefits, they have to face also many challenges as, for example: privacy and accountability issues [6], risk of loosing control over the communication strategy [7] or other issues raised in the presented empirical research.

Because corporate blogging seems to have huge potential in fulfilling various organizational roles, it is important to examine whether managers and specialists – taking into account their company's specific situation – perceive corporate blogs as tools they should use. That is why the second part of the article presents the corporate blog usage and its image among marketing decision makers in companies listed on the Warsaw Stock Exchange.

## II. Background—Blog Potential

There are different types of blogs. Dearstyne defines blogs on the basis of their source and impact and distinguishes two dimensions: external, internal [8]. Mazurek groups blogs on the basis of the three factors: function of blog, topic of blog and blog authorship [9]. In the following study the below mentioned corporate blog typology has been implemented:

- Leadership corporate blogs—in which particular person from company is thoroughly chosen to represent the company not only for brand building, but also for presenting company's views on various aspects. Such blogs are mainly used by companies which are market leaders.
- Group corporate blogs—in which all employees have right to participate in the development of company's blog. In such case, company uses only one blog, which is usually incorporated within the structure of company's corporate web site and the blog has many co-authors.
- Corporate blogs platform - consisting of many blogs written by employees or company's business partners. Such blogs can promote particular individuals as specialists in given fields and are often used as customer service support.
- Promotional blogs – such as sponsored blogs, advertising and contest blogs where the leading role is played by product, event or other marketing action, not by an author.

## III. Methodology

The findings presented below are taken from a survey conducted between May – 10 June, 2008 which was focused on the perception and usage of business blogs among marketing managers and specialists from the companies listed on the Warsaw Stock Exchange (GPW). Two research methods have been implemented in the survey. Firstly, corporate web sites of the listed companies have been examined in order to find out whether corporate blogs are used and what are their basic characteristics. Secondly, on-line and off-line questionnaire has been distributed among the marketing specialists and managers from the companies.

The overall research study was focused on five key areas:

1. Usage of corporate blogs—existence, function, model, aims
2. Reasons—why are the corporate blog used and why not
3. Perceived benefits—what are the top advantages of corporate blogs mentioned by those who don't use them yet
4. Blog information value—perceived value of information from corporate blogs for readers
5. Potential usage—whether respondents consider using corporate blogs in their companies.

## IV. Results

### *A.Population*

In the first part of research, 332 corporate web sites have been analyzed by experts which comprise ca. 98% of all listed companies. In the second part of research, based on on-line questionnaire supported by telephone and e-mail invitations, 57 managers and specialists from the listed companies responded to the survey. In addition, the off-line questionnaire has been answered by 39 managers and specialist from the total sample of 332 companies. In general, the response rate of answered questionnaire can be estimated on 29% of the total population (96 respondents).

### *B. Usage of corporate blogs*

All analyzed web sites were corporate sites, which means that the main aims they fulfill are: company brand building and information providing. Therefore, corporate blogs could have been perfectly implemented in such web pages in order to widen the scope and character of corporate communication with the environment. As the research shows, the companies using blogs as corporate communication tool are in vast minority. Only 17 (5% of the sample) of them use such tools and among them:

- 4 use leadership blogs,
- 4 use blog platform,
- 7 use promotional blog,
- 2 use corporate blog platform.

All the implemented blogs come from companies which deal with service sector. In particular, the blogs are published in companies from media, finance and insurance markets.

What is interesting, only few of the blogs noted significant comment publishing, most of them have had posts without any feedback from the readers—10 out of 17 identified corporate blogs have entries practically without any comments.

### *C. No usage of blogs—reasons*

Managers and marketing specialists from the listed companies are aware of corporate blogs potential (96% of respondents declares to know what corporate blogs are). Among the main reasons which were mentioned as important, very important or crucial in discouraging them from using blogs are:

1. Company's organization culture which doesn't accept such tools and informal way of communication ("closed companies")
2. Perceived problems with disclosure of important, secret information from the company to the public.
3. Lack of topics to write about which in consequence would lead to project failure.

The complete list of results are shown in Table I.

Among other reasons the respondents mentioned a few times were also: risk of spamming and flooding through comments function, black PR danger, no need as company uses other modern communication tools (discussion groups, chat rooms) and waiting for competitors and avoiding their mistakes afterwards.

TABLE I.
OPINION ON POTENTIAL CORPORATE BLOG BENEFITS

| Reason why to use blog in the future | 1 | 2 | 3 | 4 | 5 | Resp. | Total score | Average |
|---|---|---|---|---|---|---|---|---|
| 1. Improve basic e-marketing results (increased popularity among users) | 1 | 5 | 17 | 44 | 29 | 96 | 383 | 3,99 |
| 2. New, informal way of communicating with the environment (less formal) | 1 | 6 | 23 | 32 | 34 | 96 | 380 | 3,96 |
| 3. Create the leadership and innovative brand image | 3 | 10 | 41 | 23 | 19 | 96 | 333 | 3,47 |
| 4. Alternative way of customer service | 1 | 23 | 39 | 19 | 14 | 96 | 310 | 3,23 |
| 5. Get feedback from customers | 9 | 29 | 38 | 12 | 8 | 96 | 269 | 2,80 |
| 6. Promote the best employee and company's personalities | 1 | 48 | 29 | 11 | 7 | 96 | 263 | 2,74 |
| 7. Improve media relations | 10 | 33 | 39 | 5 | 9 | 96 | 258 | 2,69 |
| 8. Create virtual community | 1 | 53 | 28 | 8 | 6 | 96 | 253 | 2,64 |
| 9. Improve SEM position | 10 | 49 | 18 | 12 | 7 | 96 | 245 | 2,55 |
| 10. Sell products on-line | 41 | 29 | 16 | 7 | 3 | 96 | 190 | 1,98 |

Scale: 1 = Not a factor, 2 = Some, 3 = Important, 4 = Very important, 5 Primary reason

### *D. Perceived potential benefits*

Another issue raised by decision makers is the perceived advantages of corporate blogs usage. The results of the study shows that respondents considering corporate blog usage appreciate mainly the basic e-marketing benefits – increased traffic of users, information providing  and on-line brand image creating. Such issues as: another channel for customer service, valuable information feedback from the readers or improvement of media relations on-line are not widely appreciated, whereas – potential community building, search engine positioning and selling on-line are practically unnoticed by respondents.

The complete list of results are shown in Table II on the following page.

Among other potential benefits mentioned a few times by respondents we can find: employee integration, creating corporate identity among employees and reducing costs of traditional PR activities.

### *E. Information value*

The problem of reluctance in corporate blog implementation probably also comes from the managers' and specialists' opinion on the value of information they have from reading other blogs. 76% of respondents declare to read or scan through blogs and 45% of them are disappointed with the value them get from blogs. The respondents indicate that among the negative characteristics of blogs they have contact with, there are such disadvantages as:

- the entries are not interesting  (54%),
- the entries are irregularly updated (45%),
- the communication is one-sided (not comments or without comment option) (37%),
- the entries are heavily promotional (23%),
- the same texts can be found in other sources (12%).

In general, the perceived value of information gained from blogs the respondents read is estimated of 3.5 on 1-5 scale (1—not valuable, 5—very valuable).

On the other hand, perceived credibility of the massages presented on the read corporate blogs is estimated of 2,7 on 1-5 scale (1—not credible, 5—very credible). Such results prove that the blogs the respondents have contact with cannot be perfect examples of blog usage as they do not encourage the marketers to use the same tools in their companies.

### *F. The perspective of blogs usage*

The abovementioned results show that the image of blogs can hardly be called as very positive. However, more than 33% of respondents consider establishing corporate blog till the end of the coming year.

TABLE II.
DEFINING REASONS FOR NOT USING CORPORATE BLOGS

| Reason why not use blog | 1 | 2 | 3 | 4 | 5 | Resp. | Total score | Average |
|---|---|---|---|---|---|---|---|---|
| 1. Company's "closed" organization culture | 8 | 6 | 10 | 27 | 45 | 96 | 383 | 3,99 |
| 2. Perceived problems with disclosure of important information | 3 | 3 | 24 | 32 | 33 | 95 | 374 | 3,94 |
| 3. Prospective lack of topics to write about | 8 | 12 | 13 | 34 | 29 | 96 | 352 | 3,67 |
| 4. Employees reluctance to write | 2 | 8 | 38 | 25 | 23 | 96 | 347 | 3,61 |
| 5. Risk of receiving many negative comments and difficulty with dealing with them | 10 | 18 | 21 | 25 | 22 | 96 | 319 | 3,32 |
| 6. Having seen bad examples and users disappointment with blogs | 12 | 22 | 19 | 33 | 10 | 96 | 295 | 3,07 |
| 7. Risk of legal rights to text and other legal issues | 24 | 18 | 31 | 20 | 4 | 97 | 253 | 2,61 |
| 8. Lack of know-how in blog project management | 37 | 21 | 16 | 17 | 4 | 95 | 215 | 2,26 |
| 9. Risk of loosing valuable employees who promote themselves through blogs (head hunting) | 27 | 38 | 21 | 2 | 8 | 96 | 214 | 2,23 |
| 10. Budget constraints | 34 | 36 | 15 | 4 | 6 | 95 | 197 | 2,07 |

Scale: 1 = Not a factor, 2 = Some, 3 = Important, 4 = Very important, 5 Primary reason

50% of respondents who want to set up corporate blog in that time think about the promotional blog, 28% consider establishing group blog, 16% declare to create the blog platform for employees whereas only 6% think about the leadership blog.

On the other hand, more than 41% of respondents don't intend to implement any blogs in their e-marketing strategy.

In general, 57% of respondents agreed that the role of corporate blog usage will be increasing in the next years, 30% have opposite opinion, 13% couldn't say.

## V. Conclusion

The research study clearly illustrates that using corporate blogs can be described as being in the embryonic stage and the overall results – in the context of the advancement in corporate blog usage - are similar with the conclusions deriving from the analysis of corporate blogs in Fortune 500 companies where only 3.6% of companies used such tool in 2005 [10]. In 2008, among 332 companies listed on Warsaw Stock Exchange only 17 use corporate blogs (5% of the sample). The marketing managers and specialists from the researched companies very critically look at the real potential of corporate blogs for their specific situation – they acknowledge mainly brand building, web traffic improvement and information providing. Worth mentioning here is the fact that the most important reasons for postponing the corporate blog implementation in the listed companies were: the unfavorable organizational culture of company and perceived problems with disclosure of important information.

The respondents also declared that the value and credibility of information they receive from other blogs are not very high – such issues – combined with the others also mentioned in that study lead to the conclusion that the real image of blogs among marketing decision makers differ from the media hype around virtual diaries.

On the other hand, such critical view on blogs doesn't discourage the decision makers from using corporate blogs— still many of them consider using the tool—33% of respondents think about setting up corporate blog till the end of next year and 57% of respondents agreed that the role of corporate blog usage will be increasing in the next years

Those results are in fact encouraging as indicate that if corporate blogs emerge, they will by based on good situation analysis and critical view instead of short term fascination.

# An examination of factors affecting bidders' choice in electronic auctions

Costantinos Rougeris
Department of Business Administration
University of Patras
GR-265.00, Rio, Greece

George S. Androulakis
Department of Business Administration
University of Patras

Email: gandroul@upatras.gr

***Abstract*—The increment of number of services provided in World Wide Web lately drives more and more consumers to e-commerce. During the last years and due to the vast increase of e-stores (B2C), electronic marketplaces and electronic auction sites became more popular. Many researchers examined how buyers interact with the auction facts and sellers during the procedure. Questions such as "how do millions of users decide about their e-bidding" and "what are the factors affecting them and what is their order of importance" are amongst the most significant ones in current research.**

**In this paper these factors are initially located using auction literature and eBay interface as well as expanded with the addition of a new factor (communication with seller). Their weights derive from the statistical analysis of the answers given in a questionnaire that was filled electronically by eBay users during the period of February – March 2007.**

## I. Introduction

E-AUCTIONING has raised some really interesting questions during the later years including the following:

- What are the unrelated factors affecting the eBay users to bid on an item?
- How important is each one of them for the decision maker?
- Do these factors have the same weight or does it change under different circumstances?

E-commerce latest standards instead of the traditional e-shops and on-line catalogs are e-auctions web sites. On-line auctions allowed a brand new model of data interchanging (C2C) to grow up rapidly during the last years. Consequently, a new theoretical and research field has been inaugurated, trying to interpret the physiology of on-line auctions.

Initially, there was an effort to describe e-auctions in comparison to traditional physical auctions and an analysis of the characteristics of the seller was also made [1], [2], [3], [4]. As the e-auctions evolvement continued, it was necessary that the factors affecting the buyer and their results being analyzed [5], [6], [7]. An interpretation of the buyer's behavior was also made based on those factors and on how can he or she decide for the same item between 2 auctions [8], [9].

In this paper e-auctions are examined from the buyer's view. All factors affecting the buyer that were examined previously are gathered and ranked by importance according to users' opinion. For the statistical facts, we are based on the results deriving from the comparison of 2 different questionnaires, one filled in September/October 2006 and the second filled in February/March 2007.

In section II the electronic auctions literature so far is presented while in section III the factors investigated in this paper are analyzed and how they affect the buyer to bid on an item. In sections V the results of the statistical analysis are presented and finally, conclusions and further research for future discussion are incorporated in section VI.

## II. Auction Theory

As Milgrom and Weber pointed, [9], introducing affiliated values (AVs), evaluation of an item under-auction is a result of objective but also personal factors. Especially when the item is bought not for resale but for personal and often collective purposes it is clearly a subjective issue, [3]. Therefore electronic auctions must be criticized not only on auction but on the bidder level too.

The various characteristics of on-line auctions and sellers investigated in [3], [10], where explained how they are converted into factors affecting the buyer in comparison to a physical auction.

Vakrat, [6], expanded the research on how much consumers were willing to pay for identical products offered through on-line auctions instead of on-line catalogs. The authors findings suggest that bidders prefer shorter auctions and expect larger discounts for expensive items, while their second study [7] concludes that most bids are made during the first half of the on-line auction, and that high starting bids result in fewer bidders and vice verse.

Bapna, [11], later categorized the bidders into types—evaluators, participators and opportunists—and describes their behavior during bidding.

Seller feedback rating has been widely discussed as a factor in many studies, [12], [10], [13], as well as long-time users usually bid on an item before the auction ends, [14].

It is also known, [8], that the starting bid of an auction, the number of negative comments and the length of the auction all affect the final price of the item.

In the same paper, [8], using data from 55,000 bids over a 3 years period, auctions of identical items that took place during different periods are examined. Kauffman and Wood found factors that affect bidders making them willing to pay more for the same item that are the existence of an image,

Fig. 2. Bidders can read comments about all the seller's past transactions. They will give notice to the negative ones.

seller experience, whether or not the auction ends on weekend and previous bids (herd effect).

## III. Factors affecting an eBay auction

In this paragraph the most important factors affecting the buyers on an on-line eBay auction are introduced.

As presented in Fig. 1, a typical eBay bidding screen, bidders show all the information about the item and the seller in order to bid for an item. Items current price, time until auction ends (and the exact date and time it will end), seller feedback, description, item images, payment methods and other users bids are all there. Note that asking the seller a question about the product and the transaction is always an option for the bidder until the auction ends.

It is already known that the price of the item listed is the most important factor affecting an eBay auction. In this paper the desired price satisfying the bidder so as to buy online is to be located, expressed as a percentage of a physical store's price for the same item (discount). Moreover, we are trying to ascertain whether or not the bidder has a different discount requirement in comparison to the final price and also according to the item condition.

Time is also considered to be an important factor concerning eBay auctions, while it is connected with both price and the number of bids. More specifically, time is observed since the beginning of an auction and we are trying to locate the moment most buyers chose to bid.

In Fig. 2 a full seller's transaction history is presented and bidder is given the opportunity to read all the comments other bidders made about their purchases from the seller, positives or negatives. After each won item of an auction and the end of the transaction between buyer and seller, the former is obligated to leave a positive, negative or neutral comment (feedback) about the seller and the services he or she provided. The percentage of positive over negative comments is the seller feedback rating, which we is used to examine how it affects the buyer so as to bid for an auction.

Another recently introduced factor is how prior bids from other possible buyers on the same auction affect the bidder; thus it is interesting to find the bid ratio required to confirm our hypothesis. Supposing two auctions of the exact same item exist and share 10 bids, it is examined for what proportion will the buyer prefer one of them (i.e. 6 bids for the first auction over 4 for the second or 8 for the first over 2 bids for the second).

screenshots

Fig. 3. Several high resolution photos are needed between words.

In Fig. 3, a sample of large resolution images of the item used in the item's description can be observed. Note that images are "real" (of the specific item auctioned) and not taken from the item's manufacturer (i.e. from the company site). Image existence is also significant to the buyer's opinion on the item. The current findings on the topic is expanded by examining how it affects the buyer and whether or not more than one photo affects more. There is also a classification concerning the item condition (new item / used item in excellent condition / used item in good condition).

Except for the item's image existence and length, it is of equal importance to examine what is the item's description specific role in the bidders decision. Fig. 4 shows the importance of the description's extent in an auction. In this auction case, seller uses a large description of the item auctioned to persuade other users to bid on it, explaining the item's specifications and condition. It is examined (in relation to the item's condition: new item / used item in excellent condition / used item in good condition) whether and how a more detailed description in the item's presentation affects the buyer against a more concise one with less information about the item.

One factor that always influences eBay buyers is the way they have to pay for an item they bid on. The most popular way to pay for an eBay item is examined. It is noted that every auction on eBay can have one or more accepted payment methods that affect the bidder's choice.

Brand New FULLY SIM UNLOCKED 8GB Quad-Band Apple iPhone - Tested working with T-mobile and any other GSM network, also with Youtube and every features working!

We help international buyer for every International shipment, it will be declare as gift with low value, but we do not guarantee duty is not going to be charged.

Unlocked With the stealthsim V4(included in auction), you dont need to worry about the upgrading of the firmware as long as the activation is avaiable!

iPHONE IS BEEN UNLOCKED WITH StealthSim V4(which is included in this auction) THAT ALLOWS YOU TO USE GLOBALLY IN ANY NETWORK PROVIDER. JUST FOR YOU TO KNOW THAT YOUR SIM CARD HAVE TO BE CUT AND THE StealthSim NEEDS TO BE ADDED IN ON TOP TO ACCEPT THE SIGNAL.

THIS WILL COME WITH THE iPHONE WHEN DELIVER TO YOU.

iTS REALLY EASY TO PUT ON, EVERYTHING IS READY TO WORK

Fig. 4. Description can be up to several pages, so as to persuade the bidder that "it's the real thing".

In holidays (non-working days) Web and thus eBay traffic is increased while users have more free time. It is attempted to investigate the effect of the phenomenon and whether or not the probability of a buyer to make o bid for an item auctioned on eBay is also increased on holidays.

Finally, another important factor affecting on-line auctions is the communication during the auction between the 2 parts (buyer and seller). The seller's ability to respond to the buyer's questions about the item auctioned affects the prospect of the latter to bid for it.

## IV. Methodology

This essay is based on answers collected by eBay users using a questionnaire and examines the factors that affect the bidder during his/her decision to bid on an eBay auction item. Although all the factors mentioned by previous authors are gathered, we again examine all points of an auction that could possibly irritate the bidder. We also rank them by levels of importance based on our results, being able finally to find how much does each of the factors affect the bidder on his decision. Whether the factors remain stable or have different weights according to the circumstances is also to be examined. A primary sample survey was created to evaluate the final questionnaire form; 21 questions were categorized in 12 categories investigating the factors affecting the bidder's decision. The questionnaire was anonymously filled out, while participating was completely volunteering. The type of questions used was multiple choice with one answer accepted and throughout the questionnaire clarity was the main goal, which is one of the most popular questionnaire issues. Answer-driven questions were also avoided, creating neutral and clear expressions. The questionnaire was available in two language versions (English and Greek), using the questionnaire developing software LimeSurvey, (www.limesurvey.org, 2007) and was hosted on a University of Patras server. The questionnaire is presented in Appendix A.

All 218 surveys were filled out between February and March 2007 by eBay users. The sample emanated from users that maintain accounts in various interest forums. Finally, for the statistical analysis of the questionnaire results was used the R-Project [15].

TABLE I
FACTORS' STATISTICAL MEASURES ACCORDING TO ITEM'S CONDITION.

| Category | Mean | Std | Skewness | Kurtosis |
|---|---|---|---|---|
| Item Price | | | | |
| $K_1$ | 2.624 | 0.6620 | 0.2050 | -0.4144 |
| $K_2$ | 3.234 | 0.6892 | -0.4222 | 0.5459 |
| $K_3$ | 3.569 | 0.6349 | -1.2794 | 0.9465 |
| Seller Feedback | | | | |
| | 3.023 | 1.0089 | -0.6352 | -0.7981 |
| Item Image | | | | |
| general | 3.362 | 0.6935 | -1.6184 | 2.5490 |
| $K_1$ | 3.479 | 1.5488 | -0.4451 | -1.3740 |
| $K_2$ | 4.561 | 0.9561 | -2.3700 | 4.8722 |
| $K_3$ | 4.706 | 0.8946 | -3.1528 | 8.9813 |
| Item Description | | | | |
| general | 4.280 | 0.9929 | -1.6184 | 2.5490 |
| $K_1$ | 3.688 | 1.3556 | -0.6743 | -0.8102 |
| $K_2$ | 4.390 | 0.9205 | -1.7233 | 2.8864 |
| $K_3$ | 4.541 | 0.9261 | -2.3723 | 5.3896 |
| Communication | | | | |
| | 4.518 | 0.8102 | -2.2330 | 6.0759 |
| Time until auction ends | | | | |
| | 3.908 | 1.3305 | -0.9194 | 0.4865 |
| Prior bids (herd effect) | | | | |
| | 2.683 | 1.3563 | 0.1304 | -1.2204 |

To evaluate the weight of each factor, every questionnaire participant was asked to rank the factors in decreasing order of importance. Furthermore, in order to discover whether or not more undiscovered factors affecting the the bidders' existence, the participants were also asked to and rank them among the others.

Another observed fact is that bidders change their stance on bidding depending on item's condition. For example, real images are strongly needed in cases of used items. In order to measure the changes in factors' weights a discrimination of 3 item condition categories was made:

$K_1$: new items
$K_2$: used items in excellent condition and
$K_3$: used items in good condition

## V. Survey Findings

In Table I all the factors investigated are listed with statistical results for each one of them. Factor results are discriminated when needed in our three condition categories ($K_1$, $K_2$ and $K_3$) and mean, standard deviation, skewness, kurtosis are shown based on our questionnaire answers.

A glance at the factors results can lead us to some early conclusions. First of all, according to the majority of the studies, price mean increases as the item condition deteriorate. The same increase appears also in item image and item description with the largest difference between new and used item (slightly or heavily used). This strongly endorses the bidder's need for large images and description of the item. Whatever the item's condition is, when it is not new, bidder has to be reassured that he knows what he is investing on. Concerning seller feedback, it is notable that there is no important disaggregation between highly feedback rated sellers (most ratings are over 95%) which might make a negative comment rating more usable for the bidders.

Essential in order to create a complete view of the factors' literature are the results of a question in which bidders were asked to rank the factors by importance. In Table I the results of this question are presented along with each factor's calculated weight. The sample of the survey was adequate to present a ranking between the factors. Nontrivial is the existence of another unidentified factor which always ranks last.

As expected, price is clearly the most important fact about bidding, while seller feedback is the secondimportant. Places three and four (the order is not statistically clarified) are occupied by item's image and description which could be also easily predicted. The surprise was that communication with seller during the auction ranked fifth or sixth along with payment method. This factor has not been examined in other research cases and seems to be quite important for the bidder. Time until auction ends and herd effect ranked seventh and eighth, while auction end day ranked ninth.

### A. Answer's facts

The survey results lead us to hypothesis testing in order to present more concrete conclusions. Therefore, for each important observation we introduced a null hypothesis in order to accept or reject:

$H_1$: the average discount in *item price* is the same in all 3 item categories.

$H_2$: users do not care about *seller feedback* rating.

$H_3$: one third of bids are placed during the last hour of the auctions (*time until auction ends* factor).

$H_4$: users are not affected by prior bids (*prior bids* -herd effect factor).

$H_5$: the number of images is the same in all 3 item categories (*item image* factor).

$H_6$: *Item description* is equally important in all 3 item categories.

$H_7$: users do not care about the length of the *item description*.

$H_8$: users do not prefer using PayPal for their payments (*payment method* factor).

$H_9$: credit card payment and bank transfer are not equally preferred (*payment method* factor).

$H_{10}$: users do not care about the day the auction ends (*auction end day* factor).

$H_{11}$: users do not care about *communication with seller* during the auction.

All factors' hypotheses were rejected. Accordingly, we evaluate each factor's importance, while significant remarks are presented:

**a) Price:** statistical analysis shows that buyers require different levels of discount according to the item condition. The negative sign of kurtosis for item categories $K_2$ and $K_3$ show that a deeper inquiry of item categories is required.

**b) Seller feedback:** the investigation of the factors shows that 70% of buyers require seller feedback rating of at least 95% to make a bid. The fact that very high reputation rating is required for buyers so as to bid might lead to the conclusion that negative comments will have a much more significant effect on buyers choice than the positive ones. Thus, a negative comment rating approach in seller's feedback might prove more appreciated by eBay users.

**c) Item image:** item image is concerned from all buyers as necessary on an on-line auction. It was also expected that the necessity of the image increases as the condition of the item deteriorates.

**d) Item description:** statistical analysis also shows that a small percentage of buyers (less than 8%) is not affected by the length and the level of detailed presentation in description, while most buyers seem increasingly interested as the item condition deteriorates. This seems to agree with the findings of Kauffman and Wood [8] (more information on item leads to higher prices).

**e) Communication with seller during the auction:** in communication things are clear, although a small percentage (less than 13,5%) is observed not being affected by this factor or slightly affected.

**f) Payment Method:** the payment method ranking was as expected. Most users seem to seek PayPal for their item e-payment, while second most popular method is credit card use. Bank transfer is way the third most popular method and personal cheque fourth which seems to serve very few.

**g) Time until auction ends:** according to the questionnaire answers, about 50% of the bids for an item are placed during the last hour of the auction, 25% are placed 1 to 3 hours before the auction ends, 12,5% are placed 3 to 12 hours before the auction ends etc. The findings show that "bid sniping" [14] is a strategy many users will choose to apply, whilst others won't tend to bid during the last three hours until their auctions end.

**h) Prior Bids (herd effect):** from the answers given we observe that eBay users are divided into two categories:

- in a small percentage (less than 18%) which is indifferent to this factor and
- in the majority (greater than 82%) of the users that take it under consideration. 57% of them seem to be decisively influenced by the herd effect.

Our findings here again agree with the conclusion of Kauffman's and Wood's [9] work about the prior bids in an auction.

**i) Auction end day:** about the day the auction ends, the larger percentage (not larger than 60%) remains indifferent by the day they will bid for an item, while the remaining percentage (not less than 40%) seems influenced. Differences in results may occur about this factor between studies as internet usage and weekend habits change from country to country.

**k) Other factor(s):** from the statistical analysis it is found that even if other factors affecting bidding exist, they fall short of importance on contrast to the others mentioned.

TABLE II
FACTORS' RANKINGS.

| Ranking | Factor | Factor Weight |
|---|---|---|
| 1 | Item Price | 0.8119 |
| 2 | Seller Feedback | 0.0640 |
| 3–4 | Item Image | 0.0294 |
| | Item Description | 0.0294 |
| 5–6 | Communication | 0.0215 |
| | Payment Method | 0.0215 |
| 7–8 | Time (until auction ends) | 0.0087 |
| | Prior bids (herd effect) | 0.0087 |
| 9 | Auction end day | 0.0043 |
| 10 | Other factor | 0.0006 |

## VI. Conclusions and future research

In this paper, the factors affecting a possible buyer in his/her decision to bid in an electronic auction were thoroughly examined. The most important findings of our work are:

(a) the classification of factors depending on their importance,
(b) the analysis of each factor as well as the appearance of a new factor (communication with seller during the auction).

More specifically, the importance of communication between buyer and seller was evaluated for the first time. It was also clarified that the existence of item image is essential for the user, as well as the extent of the description of the item. Seller feedback rating could be improved as an eBay feature, projecting negative comments in percentage of total. It would also be interesting to embed the item's price category to eBay's feedback system. Simultaneously, it was observed that although most users watch the item that interests them in-3-days time before the auction expires, they wait for up to the last hour in order to bid for it. Moreover, statistical analysis of all factors showed an explicit and measurable differentiation depending on the category of product (age). In addition to that, a small portion of buyers presents neutrality and/or indifference for certain factors.

In future research we will examine the reliability of our findings based on actual data drawn with special software from eBay or other online auctions websites. Another main goal is to improve the efficiency of our survey based on our current answers. For that, an additional and improved survey may be important. Finally, important research interest presents the application of modern techniques of data mining for the configuration and analysis of potential different profiles of possible buyers.

## Appendix

### *A. Questions concerning the price of an item in auction.*

1) How lower should be the price of a brand new item be comparing to the price of a natural shop in order for you to bid for it on ebay.com?
   a) About the same price as the natural shop. (0–10% lower price)
   b) 10%-30% cheaper.
   c) 30%-50% cheaper.
   d) At least 50% cheaper (half price or lower).
2) How lower should be the price of a used item in excellent condition be comparing to the price of a natural shop's brand new one in order for you to bid for it on ebay.com?
   a) About the same price as the natural shop. (0–10% lower price)
   b) 10%-30% cheaper.
   c) 30%-50% cheaper.
   d) At least 50% cheaper (half price or lower).
3) How lower should be the price of a used item in good condition be comparing to the price of a natural shop's brand new one in order for you to bid for it on ebay.com?

a) About the same price as the natural shop. (0–10% lower price)
b) 10%-30% cheaper.
c) 30%-50% cheaper.
d) At least 50% cheaper (half price or lower).

### *B. Questions concerning the time until the auction ends*

4) In which exact time point during an auction would you bid for a product?
   a) Between 5 days and 24 hours until the auction ends.
   b) Between 24 and 12 hours until the auction ends.
   c) Between 12 and 3 hours until the auction ends.
   d) Between 3 and 1 hour until the auction ends.
   e) 1 hour or less until the auction ends.

### *C. Questions concerning the seller's reliability*

5) Which is the least acceptable seller's feedback rating in order for you to bid for a product in an auction on ebay.com?
   a) Not less than 90%-95% positive feedback rating.
   b) Not less than 95%-98% positive feedback rating.
   c) Not less than 98%-100% positive feedback rating.
   d) I don't care

### *D. Questions concerning the influence of prior bids in an auction in ebay.com.*

6) Please grade from 1 to 5 how important is for you the existence of prior bids from other possible buyers in an auction for a product in ebay.com:

   □1 □2 □3 □4 □5

7) Assume that there are 2 similar auctions of the same product with the same buying conditions. You have to decide on which one to bid. What should the adequate proportion between the prior bids be so as to be driven directly to bid in one of the auctions? (We assume that the prior bids are 10 in both the auctions) *Example: I would bid for the item that has at least 7 bids against 3 (meaning the one auction has 7 prior bids while the other has only 3, so I choose the first one)*
   a) 6–4
   b) 8–3
   c) 8–2
   d) 9–1
   e) 10–0

### *E. Questions concerning the influence of images during the auction.*

8) How many images in the item description do you consider as necessary enough for you to bid during an auction?
   a) None. The image is not a necessity for me to bid for an item.
   b) 1 image is enough.
   c) 2 images, 1 in the short and 1 in the extended description of the item.
   d) More than 2 images of the item.

9) Depending on the item condition how important is the existence of an image during an auction on ebay.com?

   For a brand new item.
   □1 □2 □3 □4 □5
   For a used item in excellent condition.
   □1 □2 □3 □4 □5
   For a used item in good condition.
   □1 □2 □3 □4 □5

### *F. Questions concerning the item description*

10) How much does a more detailed description of an item affect you in comparison to a shorter one during an auction in ebay.com?

   □1 □2 □3 □4 □5

11) Rate how much does a more detailed description of an item affect you in comparison to a shorter one during an auction in ebay.com depending on the item's condition:

   For a brand new item.
   □1 □2 □3 □4 □5
   For a used item in excellent condition.
   □1 □2 □3 □4 □5
   For a used item in good condition.
   □1 □2 □3 □4 □5

### *G. Questions concerning the Payment Method*

12) Which is your preferred payment methods in an ebay.com auction?
   a) PayPal
   b) Credit Card
   c) Bank Deposit / Transfer
   d) Personal Cheque

### *H. Questions concerning the bidding day*

13) During the non-working days (weekend-holidays) you more likely to bid on an item than the usual workdays?
   a) Not that I have observed.
   b) Maybe I little more like 0%-20% due to free time.
   c) During the holidays I use ebay.com 20%-50% more than the usual working days.
   d) I use Internet only on holidays so there is a 50% or more chance that I bid on an item these days than the usual working days.

### *I. Communication during the auction.*

14) How important do you consider the communication (quick and comprehensive answers about the price, shipping cost, item condition etc) between you and the seller before you bid for an item on ebay.com?

   □1 □2 □3 □4 □5

### *J. Other factors.*

15) Please describe any other factor not mentioned in current survey that could affect your choice for a bid in an auction on ebay.com

*K. Importance ranking of factors examined.*

16) Please rank the factors examined in the current survey according to each ones' importance. *(Please number each box in order of preference from 1 to 10)*

□ Item Price (including shipping costs).
□ Existence of one or more images in the description.
□ Time until the auction ends.
□ Positive seller rating.
□ Communication between buyer and seller.
□ Item description.
□ Payment method.
□ Bidding day.
□ Prior bids on an auction.
□ Other. (referring to question 15)

***Abstract*—This paper describes a "user-centred" approach to integration of services provided by the government in a "traditional" (i.e. face-to-face) or electronic way, applied in the EU R&D project Access-eGov. Individual ("atomic") services are integrated on semantic level (using semantic description of existing services – either traditional or e-services) into a scenario, realization of which leads to a solution of a problem faced by the end users (citizens or businesses) in a given life event (e.g. how to get a building permit, establish company etc.). Benefits for the end users are twofold: firstly they are provided with higher value-added services – a scenario of services (consisting of a series of services, including their dependencies), not just a single services; the services in the scenario are personalised (i.e. adapted to his/her personal data and/or situation). In case some services in the scenario are available electronically, they can be also executed online, increasing thus ultimate benefits to the end user. First prototype of the Access-eGov platform was test and evaluated in three pilot applications in three EU countries.**

## I. Introduction

INTEROPERABILITY was recognised as a precondition for the implementation of European eGovernment services in the eEurope Action Plan [1] and is explicitly addressed as one of the four main challenges in the i2010 EU strategy [2]. One of the most promising approaches to the interoperability is the employment of semantic technologies [3], [4]. Main advantage of this approach is the capability to formally describe meaning and context of government services, both traditional (i.e. face-to-face, "paper-based") as well as electronic ones (provided as electronic forms or web services), without necessity to modify the services themselves. The Access-eGov project (www.access-egov.org) builds on the use of semantic technologies with the aim to enable semantic discovery and semantic integration of governmental services into user specific scenarios. Integration of services into (user specific) scenarios (and the interoperability among them) is based on the WSMO technology (www.wsmo.org) used for description of process models by means of concepts defined in a knowledge model (ontology).

Access-eGov is a R&D project funded by the European Commission within the 6 th Framework Programme (FP6), Information Society Technologies (IST) programme. Within the Access-eGov project a SW platform supporting semantic interoperability of traditional as well as electronic government services in practical applications, together with methodological guidelines for introduction and management of such a platform, are being developed. In contrast to other projects, Access-eGov applies rather front office integration approach, i.e. no changes on the back office side are required.

The technological solution developed within the project is tested and evaluated within three pilot applications (in Slovakia, Poland and Germany) and one lab test (Egypt). The pilot application in Slovakia deals with the administration process of obtaining a building permission. The pilot application in Poland deals with the administration process of establishing an enterprise. The pilot application in Germany involves administrative and some non-administrative activities that are necessary to perform in a getting-married scenario.

## II. Semantic description of services

### *A. Web Service Modelling Ontology (WSMO)*

The WSMO framework (www.wsmo.org) provides a consistent conceptual model with the inclusion of mediators and distinction between goals and capabilities [9]. The Web Service Modelling Ontology (WSMO) is a conceptual model for describing semantic Web Services. WSMO consists of four major components: ontologies, goals, Web Services and mediators. Ontologies provide formal semantics to the information used by all other components. WSMO specifies the following constituents as part of the description of ontology: concepts, relations, functions, axioms, and instances of concepts and relations, as well as non-functional properties, imported ontologies, and used mediators. The latter allows the interconnection of different ontologies by using mediators that solve terminology mismatches.

A goal specifies objectives that a client might have when consulting a Web Service, i.e. functionalities that a Web Service should provide from the user perspective. In the WSMO, a goal is characterized by a set of non-functional properties, imported ontologies, used mediators, the requested capability and the requested interface.

A Web Service description in WSMO consists of five subcomponents: non-functional properties, imported ontologies, used mediators, a capability and interfaces. The capability of a Web Service defines its functionality in terms of preconditions, postconditions, assumptions and effects. A capability (therefore a Web Service) may be linked to certain goals that are solved by the Web Service via mediators. Preconditions,

978-83-60810-14-9/08/$25.00 © 2008 IEEE

assumptions, postconditions and effects are expressed through a set of axioms and a set of shared all-quantified variables. The service interfaces are described in the following chapter.

Mediators describe elements that aim to overcome structural, semantic or conceptual mismatches, which can appear between the different components that build up a WSMO description. Currently the specification covers four different types of mediators:

- OOMediators - import a target ontology into a source ontology by resolving all the representation mismatches between the source and the target;
- GGMediators - connect goals that are in a relation of refinement allowing the definition of sub-goal hierarchies and resolve mismatches between those;
- WGMediators - link a goal to a Web Service via its choreography interface meaning that the Web Service fulfils the goal; or link a Web Service to a goal via its orchestration interface meaning that the Web Service needs this goal to be resolved in order to meet the functionality;
- WWMediators - connect several Web Services for collaboration.

### *B. WSMO Choreography and Orchestration*

Interface of a Web Service provides further information on how the functionality of the Web Service is achieved. It describes the behaviour of the service from the client's point of view (service choreography) and how the overall functionality of the service is achieved in terms of cooperation with the other services (service orchestration).

A choreography description is semantically based on the Abstract State Machines (ASMs) [5] and consists of the states represented by ontology, and the if-then rules that specify (guarded) transitions between states. The ontology that represents the states provides the vocabulary of the transition rules and contains the set of instances that change their values from one state to another. The concepts of an ontology used for representing a state may have specified a grounding mechanism, which binds service description to a concrete message specification (e.g. WSDL).

For the Orchestration interfaces, it is planned by the WSMO authors to proceed as follows. The language will be based (note, that it is envisioned only, and the specification is not finished yet) on the same ASMs model as Choreography interfaces which - in order to link to externally called services or (sub)goals that the service needs to invoke to fulfil its capability - needs to be extended as follows:

- Goals and Services can be used in place of rules, with the intuitive meaning that the respective goal/service is executed in parallel to other rules in the orchestration
- The state signature defined in the choreography can be reused, i.e. external inputs and outputs of the service and the state of the choreography can be dereferenced also in the orchestration
- Additionally the state signature for the orchestration interface can extend the state signature of the choreography interface, with additional in/out/shared/controlled concepts which need to be tied to the used services and rules by mediators
- Respective WW or WG mediators need to be in place to map the in and out concepts defined in the orchestration to the respective out and in concepts of the choreography interfaces in the used services and goals, i.e. these mediators state which output concepts are equivalent to which input of the called service/goal and vice versa

### *C. Modifications in the Access-eGov project*

The life event approach [6] was adopted for modelling of government services, where the life event concept plays a central role – as a formal representation of user's point of view, his/her needs and requirements. Implementation of this approach resulted in the necessity to add the following top-level WSMO elements to the WSMO specification:

- Life Events – as formal models of user's needs, consisting from multiple goals and services organised into a generic scenario and expressed by orchestration construction consisting from shared variables (i.e. instances of concepts that are used within this life event) and transition rules that enable customisation of the generic scenario into a user specific scenario based on the user situation (i.e. instances describing this situation).
- Services as a generalisation of Web service concepts. This approach enables to describe both electronic and traditional government services by means of a service profile, containing functional and non-functional properties, capabilities, and interfaces. If there is no executable service available for a traditional service, the textual description of the required inputs (e.g. documents and forms, etc.) and requested actions (e.g. visit of a particular office) is specified as the non-functional property.

Requirement-driven approach [7] was developed within the Access-eGov project to guide semantic modelling and annotation (i.e. description of services by means of ontological models) of services provided by the government. While goals and life events are modelled in the ontologies (knowledge models) developed within this approach, the result of the annotation is a formalised WSML representation of the ontology containing all the definitions (concepts, classes) of services.

### *D. Process description in the Access-eGov*

The current WSMO specification for the process model based on the ASMs is, based on experience in the Access-eGov project, not structured in a way suitable for interaction with human actors, which is required for eGovernment applications especially those supporting also traditional services. For this reason, we have designed and implemented a workflow-based extension to the WSMO specification. Besides the objectives to guide citizens to achieve specific goals, and to coordinate activities performed by all actors - citizens, traditional public administration services and web services, the following facilities were identified as useful for a process model to provide support for modelling orchestrated scenarios:

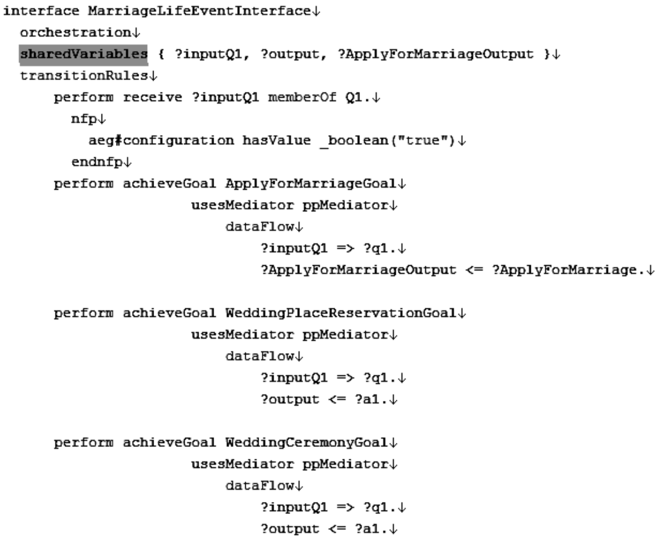
- compatibility with the standard process modelling notation (i.e. BPMN) in order to visualize scenarios to users and to use standard tools for modelling;
- compatibility with the proposed standard workflow modelling languages (i.e. WS-BPEL).

The Access-eGov model is based on the workflow CASheW-s model. The state signature is reused from the WSMO specification and replaces the ASMs transition rules with the workflow constructs. Shared ontology state signature allows reusing grounding of the input and output concepts to relevant communication protocols via WSDL for invocation of web services. Workflow model consists of activity nodes connected with the control or dataflow links. Each node can be either an atomic node (Send, Receive, AchieveGoal and InvokeService), or a control node (Decision, Fork and Join).

## III. Solution of life event

To put it simply, a WSML representation of a generic scenario is associated to the specified life event. This representation is then interpreted by the Acces-eGov system and presented to the user via SW tool called Personal Assistant client. The user answers relevant questions and if needed s/he chooses from a list of provided services.

The process of solving the life event situation consists of a set of specific goals that should be achieved, as well as from activities performed by all actors - citizens, traditional public administration services and web services. All these aspects are part of the process model (i.e. process ontology comprising generic scenarios) that is the core control (transition rules) and data (shared variables and data mediators) structure of the Access-eGov platform. Thus, process ontologies can be seen as an interface between the technical infrastructure design and the pilot applications. They provide a specification of the inner data structure for system components responsible for discovery, composition, mediation, and execution of services [8].



```

Fig. 1 Fragment of the process ontology of the pilot application of marriage in the new Access-eGov WSML notation

The above-presented figure is the high level process description of the life event getting marriage in Germany. The interface (MarriageLifeEventInterface) consists of two parts: sharedVariables and transitionRules. The first part defines variables (i.e. instances of concepts) that are visible within the whole interface of goal. Second part defines the process itself by using constructs from the set of the following constructs: if-then-enfIf, achieveGoal, send, receive. Note, that the example above uses only achieveGoal construct since it is high level process model (kind of complex goal) that is decomposed into three sub-processes (sub-goals).

In the Access-eGov syntax for process description the construct if-then-endIf is branching rule. This rule is used when we need to decide whether some constructs will be executed or not. The decision is done based on the evaluation of condition in the form of logical expression written in WSML syntax. When goal need to be decomposed into sub-goals the construct achieveGoal is used to address one of such sub-goal. There are three sub-goals of the presented goal (life event) marriage (ApplyForMarriageGoal, WeddingPlaceReservationGoal, WeddingCeremonyGoal). As can be seen the variables are mediated between goal and its sub-goals (construct usesMediator). The operator '=>' means that variable known in goal (that is on the left side of the operator) is known in sub-goal as variable on the right side of the operator (i.e. it's data mediation form goal to sub-goal). The operator '<=' means that variable known in goal (on the left side) holds data from variable known in sub-goal (on the right side) – i.e. data mediation form sub-goal to goal. The construct send means that process sends instance of specific concept to user. The construct receive means that the process needs instance of specific concept from the user side.

### *A. Presentation and interpretation*

Life Event Marriage

In order to best advise you what to do to solve you particluar life situation some questions need to be answered. Their answeres will then be processed by the system and the preliminary list of activities needed to progess in solution of your life situation will be presented on the left side.

Are you 18 years or older? * ○ Yes ○ No

What is your nationality? * ○ German ○ Slovak

Select values from combobox and add to table using "Add to list" button

Where is your place of residence in Germany?

State * [Select option]

Region *

Municipality *

Fig. 2 Fragment of the German pilot application presented to users, that is defined in the presented Access-eGov WSML notation

Customisation of the user situation is based on the answers obtained from the user side that are internally (i.e. in the system) held as values within the instances of the concepts that are used in the process ontology. In this case the instance ?q1 of the concept Q1 holds answers to the questions about age, nationality and place of residence of the user. These answers are then used for the process customisation (i.e. insertion of sub-goal(s) or possibly for withdrawal of sub-goal(s) – not use in the current Access-eGov yet-) as well as for the service filtration.

Note, that on one hand those goals that do not have sub-goals (that cannot be decomposed) are considered as goals that might be resolved with the atomic administration service, or they represent complex part of the process that are not modelled. The latter means for the user that it is not possible to identify specific type of governmental services (and thus there are not instances of such kind of services described semantically in the system). Textual description of such goal is intended for navigation of the user. The example may occur in the German pilot application (getting married) in case that the spouse was born outside the EU and does not have German citizenship. Such case is not very generic and the set of required goals (most likely achievement of specific documents by using specific services) is not modelled. Currently, it's modelled just for cases when spouse is from EU in the Access-eGov system.

On the other hand those goals that contain sub-goals are considered as solved via services that resolve their sub-goals and with services that resolve them. In German pilot application, the example is goal 'Registration for marriage' that contains sub-goal 'Get a certificate of registration'. There is a specific service for both of these goals and the first goal is solved via the use of both of these services.

Note, that the existence of the service(s) to the goal (i.e. the existence of the specific kind of service that might be used by the specific user – e.g. in terms of place of user residence) is known to the user by the picture of office window drawn in the rectangle representing goal. A screenshot of the Personal Assistant Client with identified service is depicted in Figure 3.

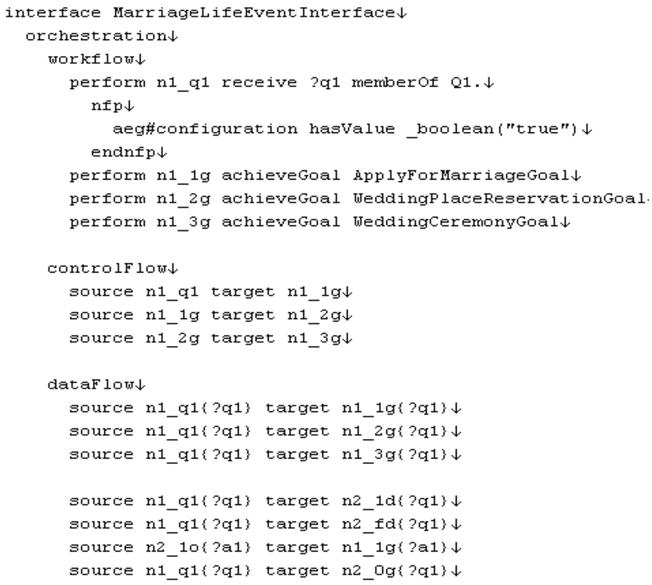
Fig. 3 Fragment of the German pilot application presenting service details of the identified service to the goal "Get a birth certificate"

Simply, after matching capabilities of the goal against capabilities of semantically described services the AeG system obtains service(s) that resolve goal. These capabilities are in the form of WSML logical expressions. The overall matching mechanism is not presented in this paper (more information can be found e.g. in [9]).

### *B. Practical experience with process description*

The evaluation of the first Access-eGov prototype was done within the first trial from October 2007 to the end of January 2008. Within this trial also quality of the ontologies and process models was evaluated. The results of this evaluation were analysed and implied changes that are currently being implemented. The second prototype will be tested and evaluated in the second trial in autumn 2008. The second prototype will incorporate also improved (easier) syntax for process description. Comparison of the old and new syntax is provided in Figure 1 (the fragment describes the life event getting married).



```
interface MarriageLifeEventInterface↓
  orchestration↓
    workflow↓
      perform n1_q1 receive ?q1 memberOf Q1.↓
        nfp↓
          aeg#configuration hasValue _boolean("true")↓
        endnfp↓
      perform n1_1g achieveGoal ApplyForMarriageGoal↓
      perform n1_2g achieveGoal WeddingPlaceReservationGoal·
      perform n1_3g achieveGoal WeddingCeremonyGoal↓

    controlFlow↓
      source n1_q1 target n1_1g↓
      source n1_1g target n1_2g↓
      source n1_2g target n1_3g↓

    dataFlow↓
      source n1_q1{?q1} target n1_1g{?q1}↓
      source n1_q1{?q1} target n1_2g{?q1}↓
      source n1_q1{?q1} target n1_3g{?q1}↓

      source n1_q1{?q1} target n2_1d{?q1}↓
      source n1_q1{?q1} target n2_fd{?q1}↓
      source n2_1o{?a1} target n1_1g{?a1}↓
      source n1_q1{?q1} target n2_0g{?q1}↓
```

Fig. 4 Fragment of the process ontology of the pilot application of marriage in the old Access-eGov WSML notation

The new syntax significantly simplifies the activity of process description. The most important positive aspect of the new syntax of process description is that it is not necessary to associate all usages of variables to the concrete node since the shared variables are known within the whole goal and the variables mediated between goal and its sub-goals are known within the whole sub-goals. This implies that identifiers of nodes are not needed. Another important aspect is that it is not necessary to define flow among the nodes. The process is read by the Access-eGov core system (execution mechanism) as a sequence as it is natural for the human reader too. Note, that the process description is done in the text based editor.

## IV. Conclusions

The Access-eGov system provides a consistent solution for description of processes within public administration, their interpretation and presentation to the user. This paper is focussed on the process description and some results of the first trial evaluation. The formalisms for the process description used in the Access-eGov project, represent an upgrade of the WSMO process description. This upgrade is based on the workflow CASheW-s model, therefore it is considered as compatible with the standard process modelling notation (i.e. BPMN) as well as compatible with the proposed standard workflow modelling languages (i.e. WS-BPEL). The first compatibility enables to visualize scenarios process models (scenarios) to the users and to use standard tools for modelling. Experiences gained so far within the Access-eGov show that the first version of the formalism proposed for the process description was difficult to read (understand) by public servants. For this reason, the syntax for process description was simplified, what will enable to check the correctness of the process description by public servants (i.e. not IT experts) and also to make corresponding changes (if needed). Thank to this, the administration of the Access-eGov system will be more flexible and easier, and the corresponding overheads lower.

## Acknowledgment

The Access-eGov project is co-funded by the European Commission within the contract No. FP6-2004-27020. The work presented in the paper was also supported by the Slovak Grant Agency of the Ministry of Education and Academy of Science of the Slovak Republic within the 1/4074/07 Project "Methods for annotation, search, creation, and accessing knowledge employing metadata for semantic description of knowledge".

# Access-eGov–Personal Assistant of Public Services

Magdalena Sroga
Cities on Internet Association, ul. Prądnicka 4/15, 30-002 Kraków, Poland
Email: m.sroga@mwi.pl

***Abstract*—Aim of this article is to present targeted research project Access-eGov, founded from the Sixth Framework Programme , priority 2 - Information Society Technologies. The article describes Access-eGov architectural and logical design and used technologies which enable to achieve the Project's aims. The Project introduces new, user-centric approach which uses predefined life events to solve citizens' problems which require from users implementation of public services. Project's approach enables users to perform complex executive scenarios instead of separated public services. This approach concentrates on user's needs and helps to build semantic interoperability among e-government services.**

## I. Introduction

Access-eGov (Access to e-Government Services Employing Semantic Technologies) is the acronym of a project pursued by a consortium of European organizations. The project started in January 2006 and is going to be finished in December 2008. The aim of the Access-eGov results from the action plan eEurope which formulated specific aims in the area of eGovernment to make public administration open, transparent, inclusive and productive. In this area the specific objective of the Project is to support semantic interoperability among e-government services across organisational, regional and linguistic borders what is being achieved by employing semantic technologies.

In “real life” situations citizens, as well as businesses usually do not need an atomic (singular) government service, but a (often non-linear) sequence (including if-then-else branches) – it means “scenario” of atomic services. Since we are still far away from the situation where 100% of government services are available on-line (and the level of the availability of e-services varies quite significantly across the EU member states), users usually have to deal with a combination of traditional services and e-services. Due to that fact Access e-Gov’s approach considers both electronic and traditional services from which the user scenario (usually “hybrid” one) is composed. Before identifying and executing a scenario, users are sometimes facing a more trivial problem – which public administration institutions are providing service(s) which they need in the given situation (context) and what inputs are required to execute this service independently on the way of provision.

To solve the first users’ problem using Access-eGov system, currently existing public services may be annotated using Annotation Tool and afterwards registered in the Personal Assistant platform. All accessible services are enhanced by the detailed description, links to relevant documents and guidelines on service providers, thus the user is provided with the complete information related to the particular service. The second problem is solved by composing a user scenario from available services relevant to user’s life situation. A significant issue is that the user is provided with complete, customised information relevant to her life case. Customisation is achieved by employing semantic technologies, particularly WSMO ontologies.

## II. Background

In the last years a number of significant developments have occurred that motivate the use of Semantic Technology in eGovernment. It is well-known that Semantic Technology enables federation, aggregation and inferencing over information, as well as helps to solve interoperability, integration, reusability, and accountability issues in and across different institutions. There are created new systems supporting public administrations by Semantic Technologies and applications based on ontologies. But not many systems adopt the approach of user’s life events, which is going to be the core Access-eGov strategy – to simplify users’ interactions with public administration as much as possible.

Web Services are supposed to be the technology which supports realisation of cross-governmental, integrated services. They constitute the common technology to fulfil application-to-application interoperability, based on XML message exchange that is capable of dynamically invoking remote software components with a minimum effort in interface description and customizing.

In semantically-enriched systems, ontologies or controlled vocabularies are used as conceptual support for providing information about resources and for accessing them. Therefore public servants shall be empowered by Access e-Gov technology to annotate their institutions’ services on their own, being provided with intuitive software and straight-forward reference manuals.

Modern e-Government landscapes can be categorized in many ways according to solutions offered to their customers or according to their technical implementations. Criteria that Access-eGov takes into consideration are notably the easy accessibility of government services for the customers and the extent to which information systems can interact with each other in modern e-Government landscapes. The criteria of interoperability mainly involve dedicated interconnection

978-83-60810-14-9/08/$25.00 © 2008 IEEE

of information systems between several agencies on the same administrative level of government. Only in a few scenarios in the UK and Australia cross-governmental information links on a mutual basis and on different levels of government can be observed. Openness to external partners also includes the ability to interact on a technical layer with non-governmental or private organizations. Most advanced examples of modern service-oriented architectures and usage of message-based information exchange services in order to communicate between back-end-systems are: open service interfaces with OIOXML in Denmark, Public Service Infrastructure (PSi) in Singapore, Government eLink in Sweden, and Government Gateway in the UK.

The evolution towards integrated IT-based public services shows the necessity to adopt new ways of interaction between administration institutions. Some EU projects have been already developing practicable solutions to problems deriving from interoperability issues. They mainly focus upon semantic enrichment of electronic services and their aggregation and orchestration towards combined “complex e-services”. Nevertheless, most of these projects focuses on the technical side and still lacks a citizen-centred point of view that could be taken by implementing software components tailor-made for the citizen’s attendance when applying for a public service. In these projects, citizens' needs take a background position compared to technical aspects. Therefore, new approaches in e-Government have to put the emphasis on easy service accessibility for customers, what is the main difference between Access-eGov and those projects and also an noticeable value added of the project.

## III. Access-eGov Functionality and Components

An Access-eGov software component is any piece of software that performs a specific technical task – i.e. it does not fulfil a user requirement by itself, but it solves a low-level problem specific to a domain.

An Access-eGov software module is any piece of software that performs a specific functional task – i.e. a task that fulfils a certain user requirement, thus solving a high-level problem specific to the user domain.

Whereas a component cannot operate individually without the tasks performed by other software components, a module should be able to work independently of other modules and when the module stops working, other modules are not affected.

### *A. Access-eGov Logical Architectures*

The figure 1 illustrates general architecture of Access-eGov platform which may be sub-divided into the three major parts: the Access-eGov Infrastructure, the Access-eGov Personal Assistant client, and Access-eGov Annotation services (not an integral, but an affiliated part of the Access-eGov Infrastructure).

The services are owned by public administration and thus located on its premises. They are simply made available via the Access-eGov system and thus they are not an integral part of the overall system. These can be both electronic services (provided directly via web service interfaces or web forms) and traditional ones (i.e. provided face-to-face). Executable services will dispose of an electronic XML-interface to the Access-eGov Infrastructure, whereas traditional ones are only described and registered in the Access-eGov platform. They are supposed to be annotated by public agencies which are responsible for them and want to expose them to the public.

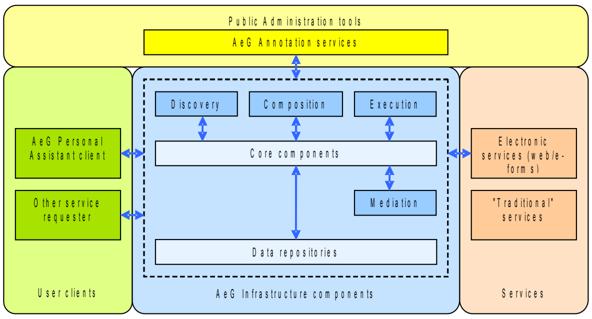

Fig 1: Overall architecture of the Access-eGov platform

Access-eGov Infrastructure components may be chosen by public agencies and installed on their premises or data centres dependently on which of them they wish to have. Such a “local” installation of the Access-eGov Infrastructure components is supposed to interact as a peer in the peer-to-peer overlay network that Access-eGov is likely to consist of.

### *B. Access-eGov Data View*

This section describes the relations between several data entities in order to provide a more detailed view on the platform data structures. The figure 2 presents structural correlations of data.

Life event denotes specific situation in user's life which requires performance of public services series. Life events can be categorized into groups and organized in multiple hierarchies. Using the Personal Assistant portal site, user may “browse” or navigate through life event categories in order to select an appropriate life event.

A life event may be assigned multiple goals, which will formalize user needs. Life event’s goals can have specified optional preconditions, which allow users to customize their specific life event. Preconditions are specified as logical expressions with input variables provided either explicitly by the user or from the user profile (preconditions are not dependent on service invocation).

Goal specifies objectives of the user who wants to perform a particular service, including functionalities that the service should provide from the user’s perspective. Goals formalize user needs by specifying the requested outputs and effects. This is declared in the same way as service functional properties.

Service profile specifies what the service does provide from user’s perspective and is used by the public administration to advertise services. Service profile consists of non-functional and functional properties.

Functional properties describe inputs, outputs, preconditions and effects of the service (IOPEs). They are specified as logical expressions, which consist of terms constraining type and property values of various resources required for or

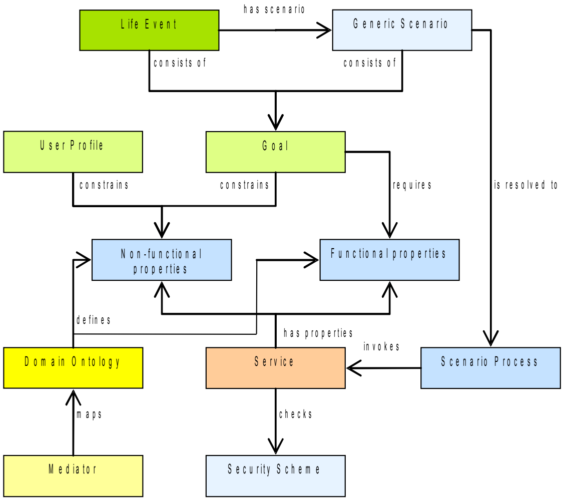

Fig 2: Logical data view on Access-eGov

provided by services. Types used to specify functional properties are defined in the domain specific resource ontologies.

Non-functional properties describe semi-structured information intended for requesters for service discovery, e.g. service name, description, information about the service provider and properties which incorporate further requirements for service capability (e.g. traditional office hours and office location, quality-of-service, security, trust, etc.). Structured non-functional properties are specified by domain specific ontologies.

The process model guides users to achieve specific goals and coordinates activities of users (citizens or businesses), traditional public administration services and web services. The process model is represented as a collection of activities designed to produce a specific output for a particular requester, based on a specific input. In that sense, activity is a function or a task that is carried out over time and has recognizable results.

### C. *Access-eGov Modules*

Most of the Access-eGov modules are derived from the needs implied by the use cases and they may be divided into three main groups: information provider related modules, information consumer related modules, and system management related modules.

#### 1) *Information Provider Related Modules*

Among the information provider related modules there are three separated modules: service annotation module, service discovery module, and service composition module.

The Annotation service module consists of a web-based application not being an integral part of the Access-eGov Infrastructure. Its main purpose is to enable domain experts to semantically describe their electronic or traditional services, by using relevant public service ontology. The web application provides also capabilities to allow annotation of traditional websites as well as an easy inspection of the existing content, which concurrently can be annotated.

Via web service interfaces, the Access-eGov Annotation module is able to access Ontology and Service Repositories within the Persistence Layer in order to register services and publish their descriptions. The creation, modification and editing of these semantic descriptions is controlled by the security subsystem.

Access-eGov system requires from the services to be semantically described and registered. For semantic description the Annotation service module uses the concepts and relationships from an appropriate ontology and to mark-up important aspects of the service or website.

Additionally that module is responsible for creating and managing goals and life events which are key idea of Access-eGov approach. Goals describe what user wants to achieve (similarly to WSMO vocabulary) and life events are situations happening to users which directly cause the need of executing some public services. Moreover goals and life events are workflow-like constructs that could be considered as outputs or interfaces provided by AeG system for users.

Service discovery module semantically matches functional properties of goals and services in the process of service discovery, in order to select services which are able to achieve the goals. Non-functional properties specified by the requester are then used to additionally filter or reorder the discovered services according to the requester preferences.

Service discovery task can be divided into two cases: “full-text search” and “semantic search”. The first case is a functionality provided in form of an interface to already existing full-text search engines in order to retrieve services and life events or goals from simply comparing the set of annotated properties. The second case is a functionality which allows to go beyond mere full-text matching for a semantic on-the-fly computation of an appropriate chain of services. The user input is then used to check preconditions and effects of registered services without invoking an already existing workflow.

Service composition module is used in case the service discovery module cannot find an atomic service which is able to achieve required goal. This module tries to orchestrate existing services to the new scenario to solve this goal. Although there are many initiatives to define industry standard languages for web service orchestration like BPEL, they have restricted capability to support only static service composition. Access-eGov Composition module provides support for dynamic composition of the services, which is not based on the static workflow pre-defined for the life event.

Automatic composition of services, which will solve these problems, is the subject of the current and future research. For this reason, current specification of the Access-eGov Composition component includes a semi-automatic approach based on the generic scenarios defined for the life event categories.

#### 2) *Information Consumer Related Modules*

Among the  information consumer related modules there are two modules: scenario execution module and personal assistant module.

Scenario execution module is responsible for executing user's scenario which is done via Personal Assistant. Service execution is invoked in case the user wants to achieve the goal, and in order to do it lets Personal Assistant start the execution of the retrieved service or workflow. The main activities of the scenario execution are as follows: invoke web service, invoke traditional service (special type of invocation, where activity is led back from the user - to the Personal Assistant. Executing of the scenario waits then for user to input the output of the traditional service.), resolve subgoal, and check timeout.

The personal assistant module is responsible for interaction with the user of the Access-eGov platform, but the user does not work directly with the module but with the Personal Assistant Client which is a web application which communicates to the Access-eGov platform and invokes its services through the module. Significant issue in this context is user's authentication through the user name and password which supports customisation of e-government services according to citizen's profile which may contain sensitive data.

#### *3) System Management Related Modules*

System management related modules cope with the core functionality of the Access-eGov platform and the only one module belongs to this category - system core module which is responsible for the interaction with the user of the Access-eGov platform and tasks relevant to the core platform functionality. That means manipulation with ontologies, connections management and security issues.

### *D. Access-eGov Components*

Each Access-eGov module consists of several components which perform its specific task and provide necessary functionality of particular parts of the modules. For example there is a group of components responsible for service annotation itself, for maintenance of life events and goals, for managing ontologies, for selecting services according to particular properties, or they provide e.g. interface to the full-text search of services.

### *E. Conceptual Architecture*

The basic functionality of Access-eGov is annotating services and store them in efficient way. Those services have to be retrieved according to certain citizen requirements and the administrators in public authorities ought to have a possibility to string such annotated services together to form new "meta services" - user scenarios. Therefore two different views may be considered: point of view of an administrator in a public institution as well as citizen's perspective.

An information provider has three main tasks, namely registering new services, annotating services and building generic workflows out of already defined services. A service consumer has two main possibilities of interaction with the platform: goal specification and request for executing the retrieved services. Communication with the platform always occurs through the personal assistant (or an equivalent user client interface).

## IV. Technologies Used

There is a variety of Semantic Technologies used for ontology creation. And then ontologies combined with semantic description are used for defining semantic web services. Access-eGov's approach required services platform to achieve semantic interoperability on different administration levels. Therefore, semantic technologies are mainly used to overcome language barriers in service description and annotation terms. In order to fulfil the goal, Access-eGov applies Semantic Web Services formalisms to create ontologies and semantically describe services. Four different formalisms were considered, namely: Web Ontology Language for Services (OWL-S), Web Service Modeling Ontology (WSMO), Web Service Semantics (WSDL-S), and Business Process Executions Language for Web Services (BPEL4WS). Before making the decision their advantages and disadvantages were considered.

### *A. OWL-S*

The structure of the OWL-S consists of a service profile for service discovering, a process model which supports composition of services, and a service grounding, which associates profile and process concepts with the underlying service interfaces. Moreover OWL-S distinguishes between atomic, simple, and composite processes. Atomic processes can be invoked, have no sub-processes, and are executed in a single step from the requester's point of view.

Two main OWL-S disadvantages are: usage of single modelling element (Service Profile) for requester and provider, and the problem with rule languages, which in spite of being recommended in the combination may lead to undecidability or leave semantics open (SWRL, DRS). There are also problems with ways of interaction between OWL and rule languages (e.g. KIF). The consortium saw a little apprehension before using OWL-S due to the fact the language must have been extended for traditional services.

### *B. WSDL-S*

WSDL-S is a small set of proposed extensions to Web Service Description Language (WSDL) by which semantic annotations may be associated with WSDL elements. WSDL-S defines URI reference mechanisms to the interface, operation and message constructs to point to the semantic annotations defined in the externalized domain models. WSDL-S defines following extensibility elements: *modelReference*, *precondition*, *effect*, *category*, and attribute – *schemaMapping*.

Significant advantage of WSDL-S is its independence on the semantic model languages. However, it has several weaknesses: new, being still in research phase approach and lacking explicit support of orchestration and choreography.

### *C. BPEL4WS*

BPEL4WS is a specification that models the behaviour of Web Services in a business process interaction. It is based on the XML grammar which describes the control logic required to coordinate Web Services participating in a process flow. An orchestration engine can interpret this grammar so it can coordinate activities in the process. BPEL4WS is a layer on the top of WSDL, which defines the specific operations and BPEL4WS defines how the operations can be sequenced.

Although BPEL4WS is very suitable for representing workflow, it needs to employ semantic into WSDL, what is a new approach. Also, there might have been problem with dealing with implementation of semantics.

### D. *WSMO*

The Web Service Modeling Ontology (WSMO) is a conceptual model for describing semantic Web Services. WSMO consists of four major components: ontologies, goals, Web Services and mediators.

Ontologies provide the formal semantics to the information used by all other components. WSMO specifies the following constituents as part of the description of ontology: concepts, relations, functions, axioms, and instances of concepts and relations, as well as non-functional properties, imported ontologies, and used mediators. The latter allows the interconnection of different ontologies by using mediators that solve terminology mismatches.

Goals specify objectives that a client might have when consulting a Web Service, i.e. functionalities that a Web Service should provide from the user's perspective. Goals are characterized by a set of non-functional properties, imported ontologies, used mediators, the requested capability and the requested interface.

A Web Service description in WSMO consists of five subcomponents: non-functional properties, imported ontologies, used mediators, a capability and interfaces.

A choreography description consists of the states represented by ontology, and the if-then rules that specify (guarded) transitions between states. The ontology that represents the states provides the vocabulary of the transition rules ant contains the set of instances that change their values from one state to the other. Concepts of an ontology used for representing a state may have specified the grounding mechanism which binds service description to the concrete message specification (e.g. WSDL). Like for the choreography, an orchestration description consists of the sates and guarded transitions. In extension to the choreography, in an orchestration can also appear transition rules that have the invocation of a mediator as post-condition. The mediator links the orchestration with the choreography of a required Web Service.

Mediators describe elements that aim to overcome structural, semantic or conceptual mismatches that appear between the different components building up a WSMO description.

After analysis WSMO proved to be formalism having the biggest range of advantages, as relying on loose coupling with strong mediation, combining conceptual modelling and rules, and providing opportunity for sophisticated goal-oriented discovery.

One of WSMO advantages crucial for Access-eGov is very clear distinction between functional and non-functional properties which are used within Access-eGov project very widely. WSMO enumerates all the relevant functional properties (for example Web service has Capability and Interface as its functional properties) and it allows flexible and easy to extend sets of NFPs everywhere. In WSMO conceptual model it is possible to enumerate all the parameters that are functional properties for the aim of WSMO. It is also possible to add different NFPs according to the own needs of the user.

WSMO provides a consistent conceptual model for the semantic description of web services, with the inclusion of mediators and the distinction between goals and services. In addition, the WSMO conceptual model fits best the proposed architecture and functionality of Access-eGov system.

However, some parts of the specification haven't been finished yet, what was considered as disadvantage, but consequently it offers possibility of specification development and conducting research. Moreover, orchestration and choreography is based on the abstract state machine where workflow is encoded and it also must be extended for traditional services.

Despite these inconveniences, consortium has decided to use WSMO technology as best suitable for Access-eGov's approach.

## V. Access-eGov Ontologies

### A. *Conceptual View of Ontologies*

Access-eGov ontologies are utilized to semantically express real-world concepts in a way defined and agreed upon by communities of users. “Ontology” in technical terms constitutes a formal specification of a shared conceptualization. Ontologies define an agreed common terminology by providing concepts and relationships between these concepts. In order to capture semantic properties of relations and concepts, ontology also provides a set of axioms (i.e. logical expressions in some structured language). Access-eGov uses three basic ontologies: life events ontology, service profiles ontology, and Acces-eGov domain ontology. Structure of ontologies is illustrated in the figure 3.

The domain ontologies are considered lower level ontologies within the system. They describe all the relevant pieces of domain information related to user’s scenarios. That means they describe functional and non-functional properties of a particular service. They are web based ontologies that are not necessarily relevant to the web services. The domain ontology describes  the lower (i.e. technical) level of the Access-eGov system.

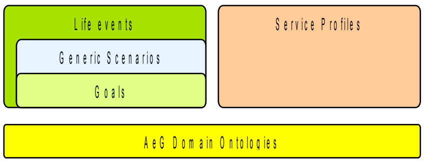

Fig 3: Conceptual data view in Access-eGov

The domain ontologies contain conceptual descriptions of domain-specific information for the pilot applications. It includes the concepts describing various forms, documents, certificates, location constraints, fees, questions, notification messages, etc., that are necessary to model the inputs and outputs of the provided governmental services.

The other two ontologies are “Life events” and “Service Profiles” ontologies which describe more abstract data. They are not simple web ontologies, but extended with semantic descriptions of possible life events (Life Events ontology) or (web) services (Services Profiles ontology). They denote more abstract system levels just as service description.

The Life events ontologies contain conceptual descriptions of life events, complex goals (also referenced as generic scenarios), and elementary goals for the pilot applications. The elements of the ontology are expressed by the WSMO choreography and orchestration interfaces.

The life events and goals described in the Life events ontology are used in the Personal Assistant client tool. The life events and goals of all the Access-eGov pilot applications specify a process model that will be composed and executed by the inner components of the Personal Assistant client according to the interactions with users.

All three Access-eGov ontologies describe several aspects and levels of the same real world data. All of them denote services (electronic or traditional) and the way of their usage.

### B. *Formalisms Used*

The WSMO conceptual model was adapted and modified to meet the requirements of the life event approach to modelling governmental applications. Thus the resource ontologies were formalised and implemented using the WSML (Web Service Modelling Language) representation. More precisely toolchain for ontology manipulation was designed, consisting of the specialised Annotation Tool and of the third-party WSMO Studio environment. The Annotation Tool was developed as a web application for user-friendly semantic annotation of governmental services. This tool, together with the resource ontologies, was tested by all the public administrations involved in the Access-eGov project.

The conceptual model contains a set of relevant entities - concepts, relations, properties, constraints, etc., that can serve as building blocks for the implementation of the system components as well as for the semantic annotation, i.e. the formal representation of potentially very complex governmental services and their relationships.

The WSMO conceptual model provides following top-level elements: ontologies which provide terminology used by other elements, web services which represent computational entities able to provide access to services, goals which describe aspects related to user's requirements, and mediators which describe elements handle semantic interoperability problems between WSMO elements.

Structural relations between the elements in the proposed conceptual model are depicted in figure 4. The parts reused from the original WSMO model are marked with grey colour.

### C. *Design of Ontologies*

The ontology-like structure needed to be formalised and expressed by WSML statements. It required fixing the meaning of the terms and relations defined in the controlled vocabulary, as well as verifying that the formal meaning reflects the informal description in the glossary.

The concepts and their relations were modelled by the following expressions:

```
concept ConceptName
  relationName RelaedConcept
```

For example, a hierarchy of certificates can be expressed in WSML notation as follows:

```
concept Certificate
  subConceptOf Document
concept Birth_certificate
  subConceptOf Certificate
concept Marriage_certificate
  subConceptOf Certificate
```

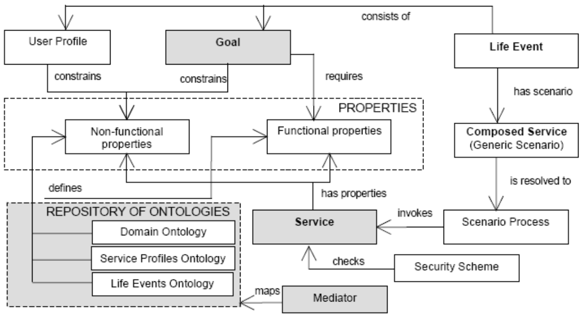

Fig 4: WSMO conceptual model adapted for the Access-eGov system

In addition, the external ontology resources, identified as relevant for the given domain, were used to standardise the ontology structure and to achieve a consistency between the semantic descriptions. The attributes of concepts were modelled as NFPs. Since the attributes are displayed in the client-side tools, they need to be localised to the proper languages. The localised values are modelled by Dublin Core's dc#title statements.

## VI. Access-eGov most important facts

Access-eGov provides a specific and new approach to the administrative issues – namely user's point of view. Realisation of such a perspective uses user's goals and life events, which exactly describe user's needs and take into consideration specific user's conditions deriving from user's characteristic context.

Executive scenario is dynamically composed on the basis of user's requirements as well as service capabilities. That is first of all user-friendly, and does not use administration-centric point of view which is not understandable by common users. Moreover, dynamic composition helps to create particular user's path consisted of separated atomic services, which are to be executed via Access-eGov platform in the meaning of web service execution or waiting for user input after realising traditional services has been completed.

Such an approach is directed towards the users – citizens or businesses, to facilitate their interactions with public administration and to make government services interoperable.

Administration-centric approach is comfortable only for institutions, because considers realisation of particular services, and user-centric approach constructs whole, unified processes built from atomic services. Such a process meets the whole path of realisation of particular life event, complying also tasks not related to public administration, but essential to complete user's goal.

The second important Access-eGov value added is usage of WSMO technologies, which are less popular among EU projects. It turns out that WSMO approach of user goals and service capabilities is strictly tailor-made for user-centric approach.

## Acknowledgment

The author expresses thanks to Access-eGov consortium for being involved in the Project and consequently having possibility of writing this article using Access-eGov deliverables as sources of knowledge.

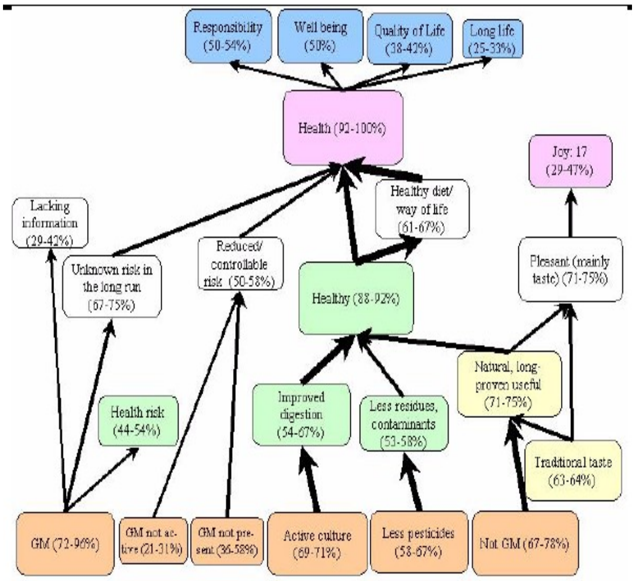
***Abstract*—Internet shopping becomes more and more popular. One of the most important questions for internet enerpreneurs seems to be how to encourage users to spend money. This is strictly connected with users' motivations. Therefore arises a strong need of learning, what they are and which factors, represented in product's features, are influencing them. One of most promising techniques in this field seems to be Hierarchical Value Maps. This paper describes the method and outcomes from preliminary research.**

## I. Introduction

As the number of internet shops is growing it is constantly harder and harder to gain customers that would like to do shopping. Many research is trying to find out what are motivations for certain human actions. One of newest methods, considered to be a promising one, are Hierarchical Value Maps. In this paper authors describe them – and present preliminary data, that may be used in the method.

## II. Value Maps

The Hierarchical Value Maps derive from the Means-end theory, which assumed that there always are some hierarchies in all human actions – so are in products and services perception and valuation. Users gain them from attribute experiences, which drives (through consequences) to personal values held by an individual. To have them illustrated better, later introduced graphical method, known as laddering, turned to be very helpful. Usually, in this technique, attributes are presented at bottom layer – and they reflect all important, perceived, features, that may influence users attitude to this product or service. Of course most important for users are their personal goals and habits. Therefore they are usually presented on top. Needless to say, in most cases they are different from product's features. But they have to depend (directly or indirectly) on product's features. These dependencies are usually shown in the middle layer – and in value maps are called consequences. The graphical form of these dependencies is known as a Laddering Technique. It became a commonly used form in search of consumers behavior structures and is widely used, especially in marketing research. Its final graphical form is known as Hierarchical Value Map (HVM). An example Hierarchical Value Map is shown on fig. 1 [2]



Responsibility (50-54%)
Well being (50%)
Quality of Life (38-42%)
Long life (25-33%)
Health (92-100%)
Joy: 17 (29-47%)
Healthy diet/ way of life (61-67%)
Lacking information (29-42%)
Reduced/ controllable risk (50-58%)
Unknown risk in the long run (67-75%)
Healthy (88-92%)
Pleasant (mainly taste) (71-75%)
Natural, long-proven useful (71-75%)
Health risk (44-54%)
Improved digestion (54-67%)
Less residues, contaminants (53-58%)
Traditional taste (63-64%)
GM (72-96%)
GM not active (21-31%)
GM not present (36-58%)
Active culture (69-71%)
Less pesticides (58-67%)
Not GM (67-78%)

Fig. 1: Sample Hierarchical Value Map

The Laddering Technique process that leads to such diagram, usually begins with semi-standardized, in-depth review series. During review session researcher should ask questions that may discover attribute-consequence-value chains. One of important difficulties is 'transparent' reviewing, which means that researcher can not suggest answers. This requires special training in question formulation, as commonly people tend to ask questions in such a way, that simple confirming is (awaited) positive information. Moreover, researcher needs to drive the review so that reviewed person may take initiative (which helps to find unexpected factors and value chains). It is very import ant, that each time an answer should be a starting point for researcher in search for new attribute-consequence-value chains. Therefore a very important is asking questions in such a way, that all vital associations may be discovered as a part of individual reflection of a person being under research. Achieving that requires all reviews to be individual and conducted by skilled researcher.

Obtained answers are presented as graphical chains between attributes, consequences and values later on. Connections are graphically represented by arrows, showing rela-

978-83-60810-14-9/08/$25.00 © 2008 IEEE

tions between linked elements. Usually, attributes come from features of product or service and may be directly observed and measured. Normally, they don't affect users values or preferences in a direct way. But theory assumes, that the product (or service) perceived usability reflects level of accomplishment of user's preferences or values (as users perceive products by satisfying user's needs) – and they come from features that are satisfied by product's attributes.

Consequences create a middle layer – between attributes and values. But what seems to be most important for user is a way in which physical attributes satisfy his/hers needs and respond to user's values (and not physical attributes of products). Therefore physical attributes need to be considered to be secondary in a process of product's definition formulation – and defined as implications of user needs reflected by consequences. Later on, consequences may be additionally described by weights reflecting importance of each consequence in order to fill user's value. The whole net of consequences allow to track which attributes are important in user's needs satisfying.

## III. Research

The above described technique is helpful in finding what is important for internet buyers. It is good to have a general outline of internet buyers' positions for having an idea how to conduct individual reviews. Therefore authors have done initial internet review, which outcomes are presented in this paper. They shall be used as a starting point in future, for individual reviews.

The research was done through a dedicated Web-questionnaire. Taking part in this research didn't require entering any personal data, unless person under research wanted to be informed of the current research statistics.

The questionnaire was split into two parts: main and demographic data imprint. 438 answers was collected during this research, of which 437 was accepted for further analysis (after verifying collected answers). On charts 2 to 4 characteristics of colleted group is presented (according to imprint).

The population and characteristics of group under research was not formally constructed to be a general one. However, it is satisfactory coherent with other researches and therefore one can assume its correctness. It was decided, that its outcomes can be used for further conclusions.

The research problem was set to find what factors (or instruments) are important during the process of making a decision on buying in internet shops. The starting point for this research was finding, that 87% of respondents has ever made a purchase in an internet shop. The frequency of internet purchases distribution is shown on fig. 5

Mostly respondents did their Internet shopping in two to four shops (50%) and next quarter of them – in less then 10 shops (26,6%). Only 9,5% of respondents did their shopping in more ten 10 shops.

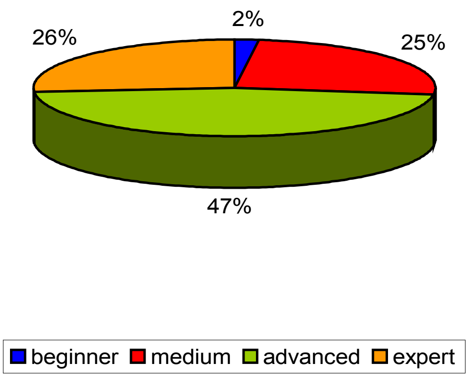


Fig. 2: Age structure of respondents

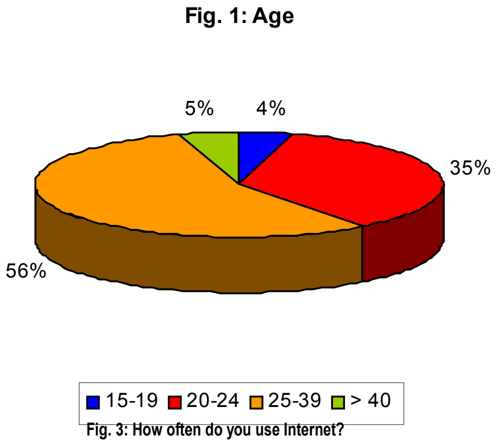

Fig. 3: IT competences of respondents

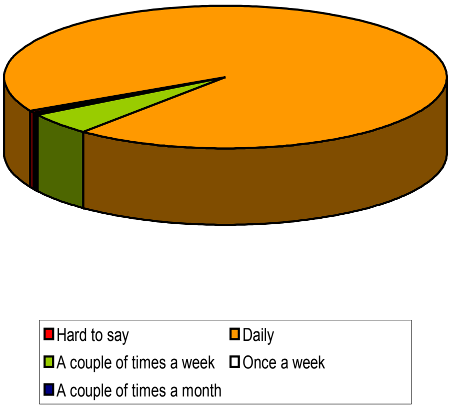

Fig. 4: How often do you use Internet?

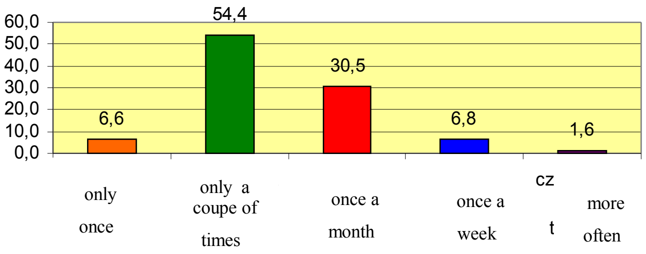

Fig. 5: How often do you buy products/services via Internet?

Next, respondents were asked about important features of internet shops. The most important one turned to be its functionality (27,2% of answers). Other important factors are company's offer (18,7%), delivery options (11,2%), price policy (10,6%) or communication with company (10,1%). The loyalty programs gained only 3,9% of votes. This shows that consumer loyalty may be strengthened with other then implicit instruments (like points, rebates, rewards).

It is worth to remind in this point, that internauts tend to build their trust with communication means, including personalization. Of course every internet shop would like customers to get back. So the next question was what is driving clients towards returning to the virtual shops. An answer to this question would be at a time a verification of basic features important for buyers. This verification was done in research a question: 'Indicate factors that may positively influence your decision on next transaction within the web site'. Outcomes are presented in Tab. 1

TABLE 1.
FACTORS INFLUENCING REPETIVE BUYING IN AN INTERNET SHOP.

| Factor | % |
|---|---|
| Price | 16,42 |
| Duration of Transaction | 12,56 |
| Delivery | 9,88 |
| Consumer service | 7,87 |
| Satisfactory previous transaction | 7,71 |
| Detailed description of the product | 5,86 |
| Oferring | 5,36 |
| Discounts for long-standing customers | 5,36 |
| Functionality | 4,52 |
| Communication | 4,52 |
| Quality of goods | 4,36 |
| Credibility | 3,52 |
| Promotions | 2,51 |
| Loyalty programs | 1,68 |
| Bonuses for customers | 1,34 |
| Diversity of payment methods | 1,34 |
| Seller 's competences | 1,17 |

As it might be seen in Tab. 1, factors that influence customers' return decision mostly are price, transaction time, conditions and delivery means, customer service and previous experiences. The fact, that four out of five of them were previously pointed as possible means of repetitive shopping, confirms correctness of presented conclusions. Moreover, we can consider correct consumer service to be a sine qua non condition of any consumer relations.

Considering that all these problems reflect in communication, it should be of great importance to find consumers' opinion on the most important issues of communication. That reflects in answers to the following questions:

1. Do you see need for contact with a seller before buying in an e-shop?
2. Do you expect seller to contact with you after buying in an e-shop?
3. Do you think that seller should investigate if selling process (goods, delivery, payment etc.) was satisfactory?

The outcomes are presented on Fig. 6.

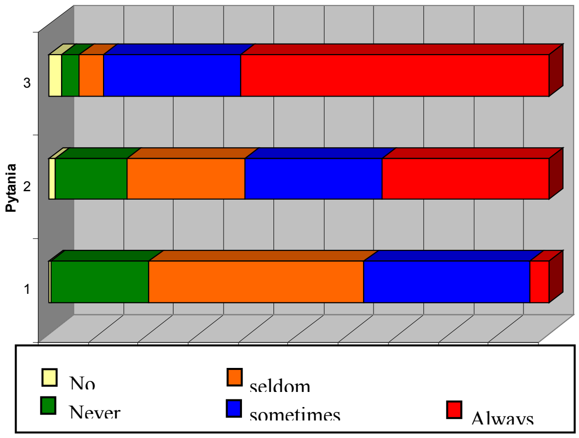

Fig. 6: Communication importance In customers' opinions

The outcomes show large consumer communication needs. Probably this is strictly connected with Internet specifics, which is highly of communicational and informational nature. The research shows dependency, which is very often overseen – both in literature and in practice – that communication importance increases as selling process advances. Before buying sees communication rarely (43,03%) or never (19,57%). Only 3,93% of buyers tends to find any form of contact before buying. Analyzing answers to the question about expected sellers contact after sale one can observe a strong shift in consumer attitude. In this case most of internauts (33,48% in every case and sometimes – 27,34%) do expect some form of contact – and therefore importance of communication increases. Moreover next 23,48% of internauts do expect some contact only rarely after sale.

## PRELIMINARY MODEL

After preliminary research it may be constructed preliminary Hierarchcal Value Map presenting consequences (relations) between universal web-product's features and abstract buyers values. Its first iteration of HVM is presented on fig. 7.

From this model we can see, that three features – quality, delivery and service seem to be most influential. There is also one identified feature – protection – which was not directly pointed by respondents, but is necessary for building expected by users value, safety namely.

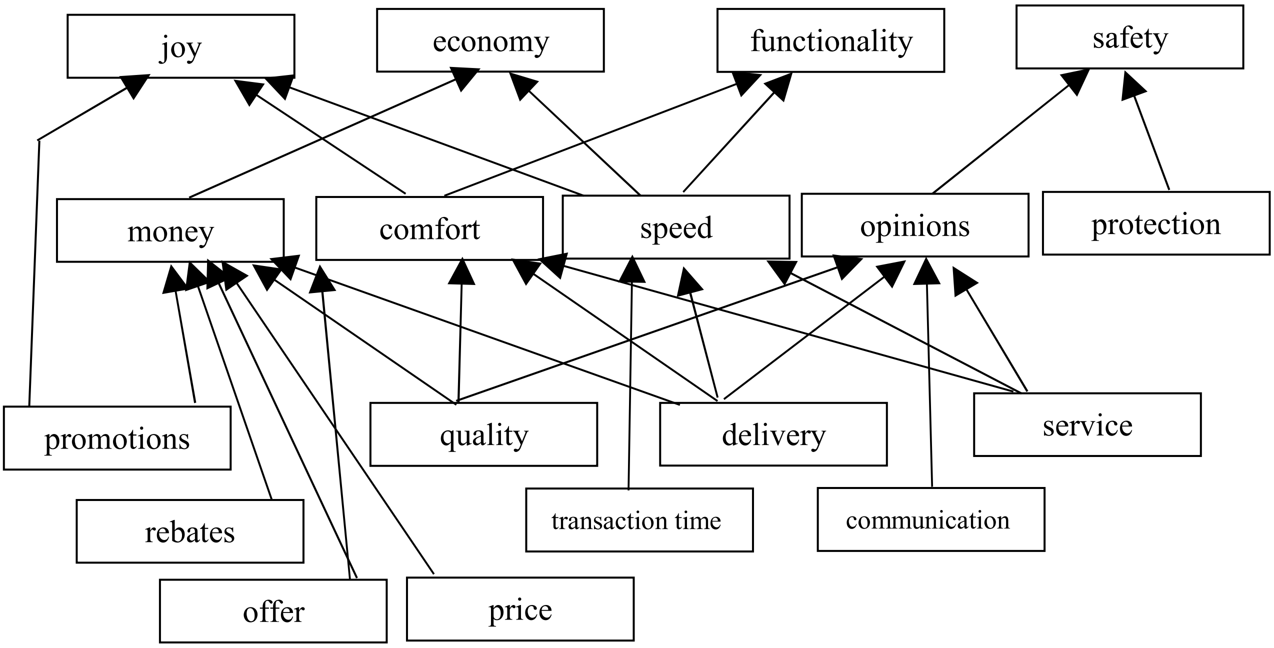

Fig. 7: Preliminary Hierarchical Value Map for web-enabled product or service

Of course this should be verified with a number of individual reviews – and for having them more understandable for people being reviewed – it seems it should be driven for a couple of characteristic web-enabled products and services.

*Abstract*—**The author assesses the suitability of virtual worlds for building effective selling environment . In analysis key features of virtual worlds are discussed and compared with the way of functioning the other type of virtual communities—social networks web-site.**

## I. Introduction

WHEN the idea of embedding virtual communities in business appeared in the mid 90's [1] the numerous virtual communities have grown in Internet space. N owadays many companies apply virtual communities [1] into their functioning, mostly in promotion and R&D, often resorting to social networks or sponsored web site. Among many different types of virtual communities, virtual worlds based on the new technology previously created for entertainment start playing important role in many business areas including distribution. Due to better description of virtual words even new marketing terms were invented like 'v-commerce' or 'v-CRM' [17]. Because 'pure' services [2] can be sold without material component, virtual worlds offering direct real-time communication with 3D graphics, become perfect venues in the Internet space for meeting customers and companies. Virtual world such as Second Life is still emerging new technology and their potential business users, such as companies operating in a real market, have limited knowledge about implementing virtual worlds' into their business environment. Many entrepreneurs perceive virtual worlds only as 'games', not discerning their potential in business areas. This article is focused on analysis of the role of virtual worlds in services. The analysis, based on qualitative research - netnographic studies, highlights the differences between implementation 'traditional' social networks and virtual worlds as a distribution channel.

## II. The main features of virtual worlds—example of Second Life (SL)

Second Life (SL) is a well-known virtual world with about 1.2 million of users, mostly from United States (about 36%) and from Germany, France, Brazil, Japan and United Kingdom[3]. Second Life is an example of Massively Multiplayer Online Games (MMOGs)[4], but significantly different from the goal-focused on-line games such as racing or fighting. This virtual world is also called 'metaverse' [7] in order to distinguish Second Life from non-social games. Second Life reflects 'real' life, therefore the avatars spend their money on entertainment such as shopping, going to clubs, disco, museums, parks.

Virtual world is an interface for people who want to meet, talk on-line with other users and play by creating their own world. SL also works as an Internet tool for companies looking for their potential customers, although the customers in Second Life (and virtual worlds as general) exist as avatars.

Depending on the connection with real world, the companies operating in Second Life can be classified into two groups:

1) Companies existing in the real market which aimed to strengthen their brands using virtual worlds:

- manufactures eg. Fiat, Peugeot, IBM, Adidas[5], Sony, Reebok, Sun Microsystems
- retailers e.g. Circuit City, Sears,
- service companies e.g. AOL, hospital: Palomar Pomerado Health [5]
- media ex. Reuters, National Public Radio NPR, Polish Radio Bis, Warner Bros

2) Companies which operate only in the virtual market e.g. language schools providing lessons via chat or voice, companies creating digital houses, garments etc. for avatars.

The varieties of business existing in Second Life is incredibly diverse: from companies connected with creation in SL such as custom avatar designer, jewelery maker, architect, freelance scripter, theme park developer [8] to companies using interface as a platform for delivering professional services such as education or architecture.

The business in Second Life flourishes due to the possibility of trading currency which is used inside the game (Linden

[1] The terms 'virtual community', 'virtual society' or 'social networks' are still unclear and authors use different criteria in analyzing this phenomenon

[2] Such as educational services or lawyer's advice

[3] Poland is 14-th in the ranking of active accounts with 4.426 avatars – less than 1% of all residents – April 2008 [9]

[4] There.com or Entropia Universe are other examples

[5] Adidas promoted their running shoes – the a3 Microride – creating the experimental store in Second Life, the project was successful: three out of every five visitors bought the product, virtual sales alone earned back 14.5% of total investment, also 3.750 on-line articles and TV interviews plus extensive magazine coverage were generated [15]

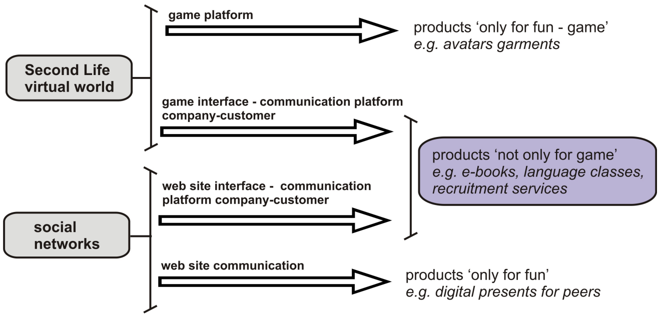
Dollars). It means that an entrepreneur who gains profit selling products or providing services inside a game, can exchange the earnings (Linden Dollars) into real money – American Dollars.

In the table 1 (see below) there are some main descriptions of Second Life and examples of social networks: Facebook, MySpace (global scale) and fotka.pl, Moja Generacja.pl, nasza-klasa.pl (regional market).

The products or services sold inside virtual communities can be classified into two categories [see the fig. 1]:

1. Products exclusively for entertainment. In Second Life these are new garments, houses, boats, cars and other products for avatars. In Facebook or in nasza-klasa there are some digital present for friends (like small pictures). In fotka.pl the user can buy 'being a star'. These products are useless for members of the community outside the game.

2. Products that can be used out with the gaming environment. In this case the virtual world is only an interface (environment) in providing services or selling products - these products/services could be sold in similar way using alternative Internet channels such as the web site. Providing language lessons or educational courses are the examples of services, but also digital products such as e-book, music, photos can be sold in this way.



game platform
products 'only for fun - game'
e.g. avatars garments
Second Life virtual world
game interface - communication platform company-customer
products 'not only for game'
e.g. e-books, language classes, recruitment services
web site interface - communication platform company-customer
social networks
web site communication
products 'only for fun'
e.g. digital presents for peers

Fig 1. The link between Second Life and social networks as distribution channels

Although Second Life is still in the early development phase, there are some examples of traditional companies using SL in their distribution. They successfully implemented SL in educational courses, consulting services, engineering and architecture projects or recruiting staff (see examples below)

1. Many schools use Second Life in teaching:
   (a) 43 universities in the United Kingdom work with Second Life organizing different kind of activities [6]
   (b) Insead provides MBA lecturers [20],
   (c) Ball State University in Indiana [19] , Montana State University-Bozeman and Harvard Law School [10] use the SL as a e-learning platform,
   (d) Standford University and University of Houston examine different aspect of functioning virtual world [10]
   (e) A group of schools in Barnsley resort to a virtual word to teach children writing and comprehension skills [21]
2. Non-profit institutions such as museums, art galleries, public radio organize educational events e.g.:
   (a) NPR Radio organizes Science Friday
   (b) The Royal Liverpool Philharmonic gives performances [4]
3. SL is useful in HR projects:
   (a) Novartis and Johnson&Johnson [4], Cisco Systems, BMW and Vodafone [23] use SL in the program of training their staff and company
   (b) Wipro Technologies receives submitted resume at Wipro's virtual campus [2]
   (c) Dutch bank ABN Amro is using the virtual world for one-to-one meetings with prospective employees [18],
4. Some engineers resort to Second Life as a platform for projects: 3D graphic is more convenient in presentation for clients than traditional architectural programs (e.g. Second Life allows customers experience walking through the house) [22]

Among many variables determining the potential of virtual communities in distribution, two groups of factors are especially important (see fig. 2):

1. factors connected with the technological environment
2. factors connected with characteristics of users

Apart from the characteristics of the community such as the age of members, the number of users or the intensity of communication, also the technical infrastructure affects the process of delivering services. Using only chat or instant

Table I.
Comparison of virtual worlds and chosen social networks

| Feature | Second Life | Facebook.com | Fotka.pl | Moja Generacja.pl | Nasza klasa.pl |
|---|---|---|---|---|---|
| Type of community | Virtual world | Social network - global | Social network - regional | Social network - regional | Social network - regional |
| Time founded | 2003 | 2004 | 2001 | 2006 | 2006 |
| Number of members [9], [11]-[13] | 13,7 mln users; 1,2 mln users logged during the last 60 days | 70 mln us | 3 mln users | 6 mln users | 6 mln users |
| Availability of Polish language | No | Yes, since December 2007 | Only Polish | Only Polish | Only Polish |

messaging is a more limited way of communication between entrepreneur and potential customer than voice communication.

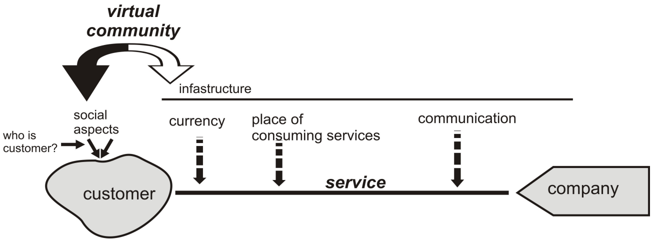


Fig 2. The factors influencing the process of delivering services

The following differences between social networks web site and virtual words can be pointed out [see table 2]:

1. Interaction with customers
2. Potential of creation
3. Currency

## III. Interaction with customers

The most significant advantage of Second Life is expressed by words of vice president ABN Amro's Bank: "The 2D Internet is excellent for simple human-machine interaction, but the 3D social Internet enables ready human-to-human interaction, or anonymous avatar-to-avatar communication" [3]. In the virtual word the environment allows the Internet user to see others' gestures, express emotions, hear voice and give indication that they really interact with others. Moreover the nature of interaction between avatars reflects the nature of human being interaction such as social norms of gender (the interaction between male and female avatars), interpersonal distance and eye contact [24]. On traditional 2D web-site of social networks, even if the communication goes smoothly, there is a significant delay in interaction.

The next issue is users' privacy. On most social networks web sites the posts and discussion are visible for all members. In virtual worlds the communication can be 'one-to-one' or provided among a chosen group.

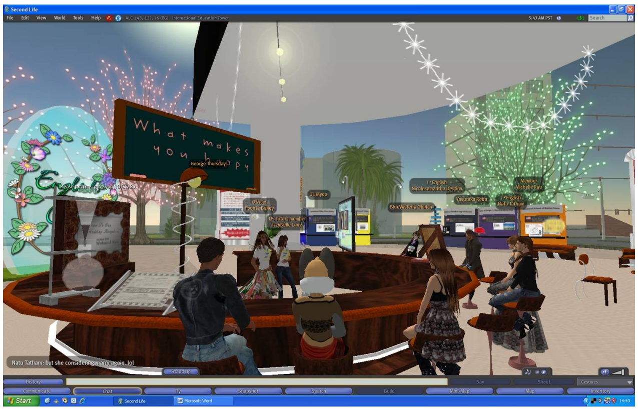

Fig 3. The English language course for avatars in SL – example of delivering service inside virtual world

## IV. Potential of creation – building effective selling environment
