Proceedings of the International Multiconference on Computer Science and Information Technology

October 18–20, 2010. Wisła, Poland

Volume 5 (2010)

Dear Reader, it is our pleasure to present to you Proceedings of the 2010 International Multiconference on Computer Science and Information Technology (IMCSIT), which took place in Wisła, Poland, on October 18–20, 2010. IMCSIT 2010 and was co-located with the XXVI Autumn Meeting of the Polish Information Processing Society (PIPS).

IMCSIT is a result of the evolutionary process. In 2005 a Scientific Session took place during the XXI Autumn Meeting of PIPS and consisted of 27 refereed presentations. After this relative success (we have advertised the Session very late in the year) we have decided to expand and extend it into a full-blown conference but continue cooperation (co-location) with the Autumn Meetings of PIPS. As a result of a steady growth, in 2010, IMCSIT consisted of the following events (and Proceedings are organized into sections that correspond to each of them):

- 5th International Symposium Advances in Artificial Intelligence and Applications (AAIA'10),
- Workshop on Agent Based Computing: from Model to Implementation VII (ABC:MI'10),
- International Workshop on Advances in Business ICT (ABICT'10),
- Computer Aspects of Numerical Algorithms (CANA'10),
- Computational Linguistics—Applications (CLA'10),
- 10th International Multidisciplinary Conference on e-Commerce and e-Government (ECOM&EGOV'10),
- International Symposium on E-Learning—Applications (EL-A'10),
- 6th Workshop on Large Scale Computations on Grids and 1st Workshop on Scalable Computing in Distributed Systems (LaSCoG-SCoDiS'10),
- 2nd International Workshop on Medical Informatics and Engineering (MI&E'10),
- 3rd International Symposium on Multimedia—Applications and Processing (MMAP'10),
- International Workshop on Real Time Software (RTS'10),
- 4th International Workshop on Secure Information Systems (SIS'10),
- International Symposium on Technologies for Social Advancement (T4SA'10),
- Workshop on Ad-Hoc Wireless Networks (WAHOC'10),
- Workshop on Computational Optimization (WCO'10).

Each of these events had its own Organizing and Program Committee (listed in these Proceedings). We would like to express our warmest gratitude to members of all of them for their hard work in attracting and later refereeing 201 submissions.

Maria Ganzha, Conference Chair, Systems Research Institute Polish Academy of Sciences, Warsaw, Poland, and Gdańsk University, Gdańsk, Poland.

Marcin Paprzycki, Systems Research Institute Polish Academy of Sciences, Warsaw and Management Academy, Warsaw, Poland.

TABLE OF CONTENTS

5$^{\text{TH}}$ International Symposium Advances in Artificial Intelligence and Applications:

Workshop on Agent Based Computing: from Model to Implementation VII:

International Workshop on Advances in Business ICT:

Computer Aspects of Numerical Algorithms:

Computational Linguistics–Applications:

10$^{\text{TH}}$ International Multidisciplinary Conference on e-Commerce and e-Government:

International Symposium on E-Learning–Applications:

6TH Workshop on Large Scale Computations on Grids and 1st Workshop on Scalable Computing in Distributed Systems:

2ND International Workshop on Medical Informatics and Engineering:

3RD International Symposium on Multimedia–Applications and Processing:

International Workshop on Real Time Software:

4TH International Workshop on Secure Information Systems:

International Symposium on Technologies for Social Advancement:

Workshop on Ad-Hoc Wireless Networks:

Workshop on Computational Optimization:

5th International Symposium
Advances in Artificial Intelligence and Applications

CELEBRATING 75TH BIRTHDAY OF PROFESSOR LEONARD BOLC

The AAIA'10 will bring researchers, developers, practitioners, and users to present their latest research, results, and ideas in all areas of artificial intelligence. We hope that theory and successful applications presented at the AAIA'10 will be of interest to researchers and practitioners who want to know about both theoretical advances and latest applied developments in Artificial Intelligence. As such AAIA'10 will provide a forum for the exchange of ideas between theoreticians and practitioners to address the important issues.

Papers related to theories, methodologies, and applications in science and technology in this theme are especially solicited. Topics covering industrial issues/applications and academic research are included, but not limited to:

- Knowledge management
- Decision Support System
- Approximate Reasoning
- Fuzzy modeling and control
- Data Mining
- Web Mining
- Machine learning
- Combining multiple knowledge sources in an integrated intelligent system
- Neural Networks
- Evolutionary Computation
- Artificial Immune Systems
- Ant Systems in Applications
- Natural Language processing
- Image processing and understanding (interpretation)
- Applications in Bioinformatics
- Hybrid Intelligent Systems
- Granular Computing
- Architectures of intelligent systems
- Robotics
- Real-world applications of Intelligent Systems

***Abstract*—Breast cancer is the second most common form of cancer amongst females and also the fifth most cause of cancer deaths worldwide. In case of this particular type of malignancy, early detection is the best form of cure and hence timely and accurate diagnosis of the tumor is extremely vital. Extensive research has been carried out on automating the critical diagnosis procedure as various machine learning algorithms have been developed to aid physicians in optimizing the decision task effectively. In this research, we present a benign/malignant breast cancer classification model based on a combination of ontology and case-based reasoning to effectively classify breast cancer tumors as either malignant or benign. This classification system makes use of clinical data. Two CBR object-oriented frameworks based on ontology are used *jCOLIBRI* and *myCBR*. A breast cancer diagnostic prototype is built. During prototyping, we examine the use and functionality of the two focused frameworks.**

***Index Terms*—Case-Based Reasoning, Case-Based Reasoning Frameworks, CBR, CBR Frameworks, jCOLIBRI, myCBR, Breast Cancer**

I. Introduction

BREAST cancer classification, diagnosis and prediction techniques have been a widely researched area in the past decade in the world of medical informatics. Several articles have been published which tries to classify breast cancer data sets using various techniques such as fuzzy logic, support vector machines, Bayesian classifiers, decision trees and neural networks. Classification accuracy as high as 98.8% has been achieved using a learning algorithm combining simulated annealing with the perceptron algorithm. Another study involving fuzzy modeling and cooperative co-evolution has gained an accuracy of 98.98% over one of the widely studied Wisconsin breast cancer database [16].

This research applies a new technique in the field of breast cancer classification. It uses a combination of ontology and case-based reasoning by using ontology based object-oriented case-based reasoning frameworks. Two frameworks are examined in building the classifier. One is the open source *jCOLIBRI* [5] system developed by *GAIA* group and provides a framework for building CBR systems based on state-of-the-art software engineering techniques. The other is the novel open source CBR tool *myCBR* [24] developed at the German Research Center for Artificial Intelligence *(DFKI)*. The objective of this classifier is to classify the patient based on his/her electronic record whether he/she is benign or malignant.

This paper is organized in four sections. Section 1 is this introduction. Section 2 gives a theoretical background about breast cancer, ontology, CBR and object-oriented frameworks. Section 3 illustrates the implementation of the breast cancer classifier on the two frameworks. Finally, section 4 discusses and concludes the results

II. Theoritical Background

A. Breast Cancer

Breast cancer is the form of cancer that either originates in the breast or is primarily present in the breast cells. The disease occurs mostly in women but a small population of men is also affected by it. Breast cancer is the most common form of cancer amongst the female population as well as the most common cause of cancer deaths [25]. Early detection of breast cancer saves many thousands of lives each year. Many more could be saved if the patients are offered accurate, timely analysis of their particular type of cancer and the available treatment options. Since the breast tumors whether malignant or benign share structural similarities, it becomes an extremely tedious and time consuming task to manually differentiate them. As seen in Figure 1 there is no visually significant difference between the fine needle biopsy image of the malignant and benign tumor for an untrained eye. Accurate classification is very important as the potency of the cytotoxic drugs administered during the treatment can be life threatening or may develop into another cancer. Laboratory analysis or biopsies of the tumor is a manual, time consuming yet accurate

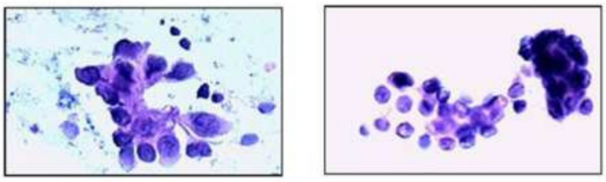

Fig. 1. Fine needle biopsies of breast. Malignant (left) and Benign (right) [25]

system of prediction. It is however prone to human errors, creating a need for an automated system to provide a faster and more reliable method of diagnosis and prediction for the patients.

B. Ontology

Ontology is a formal explicit description of concepts in a domain of discourse (classes (sometimes called concepts)), properties of each concept describing various features and attributes of the concept (slots (sometimes called roles or properties)), and restrictions on slots (facets (sometimes called role restrictions)). Ontology together with a set of individual instances of classes constitutes a knowledge base. In reality, there is a fine line where the ontology ends and the knowledge base begins [8].

C. Case-Based Reasoning

In case-based reasoning (CBR) systems expertise is embodied in a library of past cases, rather than being encoded in classical rules. Each case typically contains a description of the problem, plus a solution and/or the outcome. The knowledge and reasoning process used by an expert to solve the problem is not recorded, but is implicit in the solution. To solve a current problem: the problem is matched against the cases in the case base, and similar cases are retrieved. The retrieved cases are used to suggest a solution that is reused and tested for success. If necessary, the solution is then revised. Finally the current problem and the final solution are retained as part of a new case.

The CBR process can be represented by a schematic cycle, as shown in Figure 2 [1].

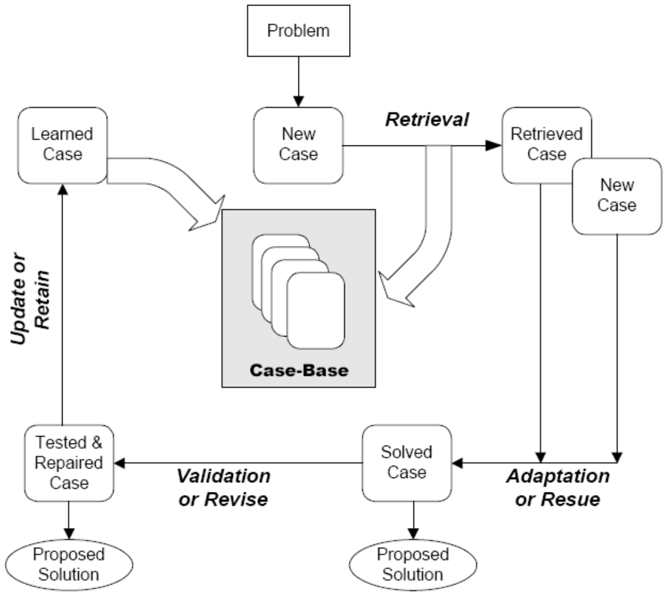

Fig. 2. The CBR Cycle

*R*epresentation: Given a new situation, generate appropriate semantic indices that will allow its classification and categorization. This usually implies a standard indexing vocabulary that the CBR system uses to store historical information and problems. The vocabulary must be rich enough to be expressive, but limited enough to allow efficient recall [2].

*R*etrieval: Given a new, indexed problem, retrieve the best past cases from memory. This requires answering three questions: What constitute an appropriate case? What are the criteria of closeness or similarity between cases? How should cases be indexed? Part of the index must be a description of the problem that the case solved, at some level of abstraction. Part of the case, though, is also the knowledge gained from solving the problem represented by the case. In other words, cases should also be indexed by some elements of their solution [11].

*A*daptation: Modify the old solutions to confirm to the new situation, resulting in a proposed solution. With the exception of trivial situations, the solution recalled will not immediately apply to the new problem, usually because the old and the new problem are slightly different. CBR researchers have developed and used various adaptation techniques [11].

*V*alidation: After the system checks a solution, it must evaluate the results of this check. If the solution is acceptable, based on some domain criteria, the CBR system is done with reasoning. Otherwise, the case must be modified again, and this time the modifications will be guided by the results of the solution's evaluation [11].

*U*pdate: If the solution fails, explain the failure and learn it, to avoid repeating it. If the solution succeeds and warrants retention, incorporate it into the case memory as a successful solution and stop. The CBR system must decide if a successful new solution is sufficiently different from already-known solutions to warrant storage. If it does warrant storage, the system must decide how the new case will be indexed, on which level of abstraction it will be saved, and where it will be put in the case-base organization [11].

Retaining the case is the process of incorporating whatever is useful from the new case into the case library. This involves deciding what information to retain and in what form to retain it; how to index the case for future retrieval; and integrating the new case into the case library.

D. CBR Object-Oriented Frameworks

The concept of object-oriented frameworks has been introduced in the late 80's and has been defined as a set of classes that embodies an abstract design for solutions to a family of related problems, and supports reuses at a larger granularity than classes [9].

The goal of a framework is to capture a set of concepts related to a domain and the way they interact. In addition, a framework is in control of a part of the program activity and calls specific application code by dynamic method binding. A framework can be viewed as an incomplete application where the user only has to specialize some classes to build the complete application [9].

Frameworks allow the reuse of both code and design for a class of problems, giving the ability to non-expert to write complex applications quickly. Frameworks also allow the development of prototypes which could be extended further on by specialization or composition. A framework once understood, it can be applied in a wide range of domain, and can be enhanced by the adding of new components [9].

Using frameworks for development of new applications helps improve software quality. It improves programmers' productivity and quality, performance, and reliability of software. It also enhances extensibility by providing the required methods that allow applications to extend its stable interfaces [20]. Figure 3 clearly shows the difference of the effort required for developing an application from scratch and using a framework [15].

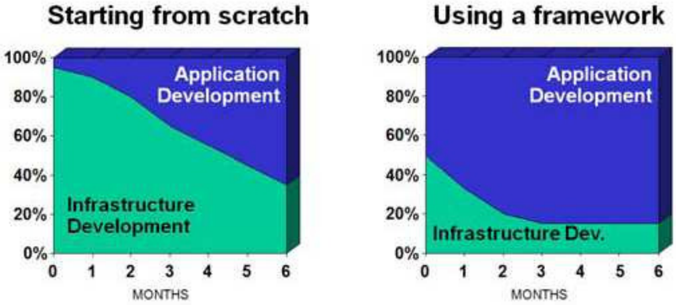

Fig. 3. Development Effort Reduction by using Frameworks

CBR researchers agree that the best way to satisfy the increasing demand of developing CBR application is by development of frameworks. Recently, some efforts within the CBR community have developed CBR frameworks [20]. This paper focuses on two of them *jCOLIBRI* developed by *GAIA* group and *myCBR* developed by *DFKI* group.

III. Experiments

A. Breast Cancer Classifications

Breast cancer has become the number one cause of cancer deaths amongst women. Once a breast cancer is detected, it can be classified benign (not cancerous tissue) or malignant (cancerous tissue). In this study, the two compared CBR frameworks are tested by developing a CBR application that classifies the condition of the breast cancer tumor whether it is benign or malignant. Wisconsin breast cancer data set was used for building the case-bases. It is obtained from the University of Wisconsin Hospitals, Madison from Dr. William H. Wolberg [14]. Samples inside the data set arrive periodically as Dr. Wolberg reports his clinical cases. The number of instances inside the dataset is 699 (as of 15 July 1992). Each record contains ten attributes plus the class attribute. Table I shows the attributes and their possible values. 65.5% of the elements belong to the benign class and 34.5% to the malignant class. 16 elements are incomplete (an attribute is missing) and have been excluded from the database.

TABLE I
Wisconsin Breast Cancer Dataset

No.	Attribute	Possible Value
1	Sample code number	id number
2	Clump Thickness	1 – 10
3	Uniformity of Cell Size	1 – 10
4	Uniformity of Cell Shape	1 – 10
5	Marginal Adhesion	1 – 10
6	Single Epithelial Cell Size	1 – 10
7	Bare Nuclei	1 – 10
8	Bland Chromatin	1 – 10
9	Normal Nucleoli	1 – 10
10	Mitoses	1 – 10
11	Class	(2 for benign, 4 for malignant)

B. jCOLIBRI

1) Overview: *jCOLIBRI* is an evolution of the COLIBRI architecture [7], that consisted of a library of problem solving methods (PSMs) for solving the tasks of a knowledge-intensive CBR system along with ontology, CBROnto [8], with common CBR terminology. COLIBRI was prototyped in LISP using LOOM as knowledge representation technology. This prototype served as proof of concept; was very useful but it is not helpful for non-expert users. Then, people at *GAIA* group have started to develop a new complete framework with the name of *jCOLIBRI*. It stands for Cases and Ontology Libraries Integration for Building Reasoning Infrastructures. CBR ontology assumes the same vocabulary provided by any CBR system. In *jCOLIBRI*, ontology is not represented as a new source. All concepts of CBR are mapped into classes and interfaces of framework. Classes that represent the concept of ontology serve as templates where new CBR types should be added. They also provide the tasks and abstract interface of the methods. The design of the *jCOLIBRI* framework comprises a hierarchy of Java classes plus a number of XML files. The framework is organized around the following elements [2]:
Tasks and methods: The tasks supported by the framework and the methods that solve them are all stored in a set of XML files.
Case-base: Different connectors are defined to support several types of case determination, from the file system to a database.
Cases: A number of interfaces and classes are included in the framework to provide an abstract representation of cases that support any type of actual case structure.
Problem solving methods: The actual code that supports the methods included in the framework.
The *jCOLIBRI* comes in two major releases version 1 and version 2. According to the tutorial [19], version 2 is a new implementation that follows a new and clear architecture divided into two layers: one oriented to developers and other oriented to designers. Unfortunately, the only available distribution of version 2 is the one that is oriented to the developers which is out of scope of this paper. *jCOLIBRI* version 1 is the first release of the framework. It includes a complete Graphical

Fig. 4. Implementation in *jCOLIBRI*

User Interface (GUI) that guides the user in the design of a CBR system. This version is recommended for non-developer users that want to create CBR systems without programming any code which is exactly the scope in this study. As a result, version 1 is selected to implement the required application. Downloading of the *jCOLIBRI* is an easy task; it can be obtained through the web page of GAIA group. It comes in a compressed distribution that can be easily extracted to have the full package. To run *jCOLIBRI*, there is a ready batch file (we are using MS Windows® platform) that can be invoked directly to run jCOLIBRI. It is required to have JAVA Virtual Machine installed before running the batch file. By invoking this batch file we get the first screen of the framework GUI.

2) Implementation: By the help of the multimedia tutorials provided and the GUI of the *jCOLIBRI*, users can go through five steps to implement and deploy a CBR System. These steps are

- Definition of case structures
- Building the case-base
- Managing similarity measures
- Configuring the behavior of the CBR process
- Testing and deploying the CBR application

Definition of Case Structures: By using *jCOLIBRI* GUI users are able to create the case structure defining simple and compound attributes that describe the cases together with their types, weights, similarity measure -that is chosen from a library of existing similarity functions and parameters. The case structure can be saved or loaded in and from a XML file. Figure 4(a) shows the definition of the patient case parameters.

Building the case-base: *jCOLIBRI* introduces the concept of Connectors which cases persistence is built around. Connectors are objects that know how to access and retrieve cases from the storage media and return those cases to the CBR system in a uniform way. Therefore connectors provide an abstraction mechanism that allows users to load cases from different storage sources in a transparent way [24] [21]. Defined connectors can work with plain text files, XML files, or relational data bases. The graphical interface helps mapping the defined case structure with the tables and columns from the storage scheme. Figure 4(b) shows how the patient case structure is mapped to columns in a text file containing the Wisconsin data set patient records.

Managing similarity measures: When two cases are compared, the local similarity functions are used to compare simple attribute values. Global similarity functions are linked to compound attributes and are used to gather the similarities of the collected attributes in a unique similarity value. At last, the similarity value of two cases is computed as the similarity of their description concepts. The available similarity measures are listed in a configuration file, and can be managed using the GUI. Since our problem is simple, we leave the default similarity assigned by *jCOLIBRI*.

Configuring the behavior of the CBR process: As introduced, *jCOLIBRI* formalizes the CBR knowledge using CBR ontology (CBROnto), a knowledge level description of the CBR tasks and a library of reusable Problem Solving Methods (PSMs) [21]. Configuration of tasks is done in an interactive approach by choosing from a library of reusable methods one that is suitable to solve the selected task. Constraints of the selected task are being tracked during the configuration process so that only applicable methods in the given context are offered to users. In our comparison we focus only on the retrieval task. Figure 4(c) shows the configured tasks in the breast cancer application.

Testing and deploying the CBR application: The CBR application is finished when all the tasks have been configured. Users can test the system from inside the graphical interface. The first task of the CBR system, (Obtain query task)ÿ obtains the query that is going to be used to retrieve the most similar cases. Figure 4(d) shows the GUI after a query. We tested the 16 records that are excluded from the dataset according to one missing value. Only two missed classifications are obtained. Documentation mentions that it is possible to deploy the developed CBR application by generating a code template with most of the code required to run the developed system as an independent application. We have tried this process but it is completely failed.

C. *myCBR*

1) Overview: myCBR is an open-source plug-in for the open-source ontology editor Protégé [6]. Protégé is based on Java, is extensible, and provides a plug-and-play environment that makes it a flexible base for rapid prototyping and application development [4]. Protégé [4] allows defining classes and attributes in an object-oriented way. Furthermore, it manages instances of these classes, which *myCBR* interprets as cases [22]. So the handling of vocabulary and case base is already provided by Protégé. The *myCBR* plug-in provides several editors to define similarity measures for an ontology and a retrieval interface for testing [24]. As the main goal of *myCBR* is to minimize the effort for building CBR applications that require knowledge-intensive similarity measures, *myCBR*

(d) Breast Cancer as a Stand-Alone Application

Fig. 5. Implementation in *myCBR*

provides comfortable GUIs for modeling various kinds of attribute specific similarity measures and for evaluating the resulting retrieval quality. In order to reduce also the effort of the preceding step of defining an appropriate case representation, it includes tools for generating the case representation automatically from existing raw data [22]. The novice as well as the expert knowledge engineer are supported during the development of a myCBR project through intelligent support approaches and advanced GUI functionality [22]. Downloading *myCBR* requires two steps of downloading. The first is to download *myCBR* plug-in files; this can be done directly through *myCBR* web page. The second step is to download the Protégé ontology editor; this can be done through the Protégé web page. Downloading Protégé is not an easy task. Users need to do some readings on the site to be able to select the suitable version to download. Since *myCBR* is a plug-in inside Protégé, users need to install Protégé first. It is required to have JAVA Virtual Machine installed before proceeding in installation, or users may choose to download the version that includes the JAVA. To install the *myCBR* plug-in for Protégé, users need to copy the *myCBR* plug-ins into Protégé's plug-ins directory. Then to start Protégé and create new projects, users need to enable the myCBR plug-ins from the configuration menu of Protégé. After installing and activating the myCBR plug-in, the user interface of Protégé is extended with additional tabs to access the *myCBR* modules. After developing a CBR application using the Protégé plug-in, *myCBR* can also be used as a stand-alone Java module, to be integrated in arbitrary applications, for example, JSP5-based web applications. In this application phase, the retrieval engines of *myCBR* just read the XML files of the created project generated using the plug-in interface and perform the similarity-based retrieval [24]. For Protégé manuals and tutorial, users may consult the documentation section of the Protégé web site for available documentation. Among other things, users may find the Protégé User's Guide, a "getting started" tutorial, and information on ontology development. The manual for *myCBR* is available on its web page as HTML version or a PDF version. The manual covers installation and different usage issues. No multimedia tutorials are available for the usage of *myCBR*.

2) Implementation: Four steps are required to develop a CBR application:

- Generation of case representations
- Modeling similarity measures
- Testing of retrieval functionality
- Implementation of a stand-alone application

Generation of case representations: One powerful feature provided by *myCBR* is the easiness of the case representation by CSV data import module [24]. Users have the choice to import data instances in an existing Protégé class or to create a new class that is suitable for their raw data. Figure 5(a) shows how Wisconsin dataset is arranged in a CSV file. *myCBR* allows also slots to be added manually using Protégé. Figure 5(b) shows myCBR screen after importing the dataset into a new class Patient which will be used as query and case values for retrieval step.

Modeling of similarity measure: *myCBR* follows the local-global approach which divides the similarity definition into a set of local similarity measures for each attribute, a set of attribute weights, and a global similarity measure for calculating the final similarity value. This means, for an attribute-value based case representation consisting of n attributes, the similarity between a query q and a case c may be calculated as follows

$$Sim(q,c) = \sum_{i=1}^{N} w_i \times Sim_i(q_i, c_i) \qquad (1)$$

Here, sim_i and w_i denote the local similarity measure and the weight of attribute i, and Sim represents the global similarity measure [24]. The dataset used in this experiment is simple so we leave the similarity measure definition as the default of myCBR. We only change the weight values of the Id and Class slots from one to zero. However, users may consult myCBR tutorial for more options in defining local and global similarity measure.

Testing of retrieval functionality: *myCBR* includes an easy to use GUI for performing retrievals and for analyzing the corresponding results. By providing similarity highlighting and explanation functionality, *myCBR* supports the efficient analysis of the outcome of the similarity computation. We tested the 16 records that are excluded from the dataset according to one missing value. Only two missed classifications are obtained. Figure 5(c) shows one query of these records after retrieving the most similar cases. Another alternative of performing case retrieval is to use a query from cases. This is also tested and gives a similar result as shown in Figure 5(d).

Implementation of stand-alone application: *myCBR* can also be used as a stand-alone Java module, to be integrated in arbitrary applications. In this application phase, the retrieval engines of *myCBR* just read the XML files of the created project generated using the plug-in interface and perform the similarity-based retrieval. Figure 5(d) shows the breast cancer stand-alone application.

IV. Discussion and Conclusion

In this paper, we examined two object-oriented ontology based CBR frameworks *jCOLIBRI* developed by *GAIA* group and myCBR developed by *DFKI* group. A breast cancer classifier is built by using the two selected frameworks.

During the implantation of the breast cancer diagnostic application using jCOLIBRI we found that *jCOLIBRI* is user-friendly and efficient to develop a quick application. The classifier was successful in classification of the selected data set. During the implantation of the breast cancer classifier using *myCBR* we noticed that *myCBR* is a really a tool for rapid prototyping of a new CBR application. In seconds, users may have a running standalone CBR application by using the CSV importing feature. *myCBR* is intelligent enough to build the case structure and the case base by parsing the provided CSV file. *myCBR* avoids reinventing the wheel by making the development of a new CBR application done inside Protégé. The classifier was successful in classification of the selected data set.

In conclusion, two CBR frameworks are very useful to develop CBR base breast cancer classifier that can play a very important role to help for early detecting the disease and hence right medications can be used to save lives.

Abstract—**The capability of the classification SVM, Tree Boost and Tree Forest in analyzing the DDSM dataset was investigated for the extraction of the mammographic mass features along with age that discriminates true and false cases. In the present study, SVM technique shows promising results for increasing diagnostic accuracy of classifying the cases witnessed by the largest area under the ROC curve (area under empirical ROC curve =0.79768 and area under binomial ROC curve =0.85323) comparable to empirical ROC and binomial ROC of 0.57575 and 0.58548 for tree forest while least empirical ROC and binomial ROC of 0.53452 and 0.53882 was accounted by tree boost. These results are confirmed by SVM average gain of 1.7323, tree forest average gain of 1.5576 and tree boost average gain of 1.5718.**

***Keywords*- Breast Cancer, Classification Support Vector Machine (SVM), Decision Tree, Receiver Operating Characteristic Curve (ROC), Tree Boost, Tree Forest, Gain.**

I. Introduction

CANCER can develop when cells in a part of the body begin to grow out of control. These extra cells form a mass of tissue, called a growth or tumor. Tumors can be benign or malignant. The scientific discipline whose goal is the classification of objects into a number of categories or classes can be called Pattern Recognition. Objects can be images, signal waveforms or any type of measurement that needs to be classified [11].

The importance of the study is that; the breast cancer refers to life-threatening malignancies that develop in one or both breasts and is the most common form of cancer among women in developed countries. According to American Cancer Society one in eight women will develop breast cancer during their lifetime.

The problem with Breast Cancer Diagnosis is that despite radiographic breast imaging and screening has allowed for more accurate diagnosis of breast cancer, 10% to 30% of malignant cases are not detected for various reasons. There are two errors typical in examining mammograms. They are False Positives (FP) and False Negatives (FN).

The Computer-Aided Diagnosis (CAD) can reduce both the FP and the FN diagnosis rates. CAD is an application of pattern recognition aiming at assisting doctors in making diagnostic decisions. The final diagnosis is made by the doctor. Our aim is to utilize a pattern recognition system in order to assist radiologist with a "Second" opinion by concluding the mammographic mass features that most indicates malignancy.

II. Data Set

This part of the study includes shedding light on the case study used and the collected data description.

An image may be defined as a two-dimensional function, $f(x, y)$, where x and y are spatial (plane) coordinates, and the amplitude of f at any pair of coordinates (x, y) is called the intensity or gray level of the image at that point. When x, y, and the amplitude values of f are all finite, discrete quantities, we call the image a digital image. The field of digital image processing refers to processing digital images by means of a digital computer. Note that a digital image is composed of a finite number of elements, each of which has a particular location and value. These elements are referred to as picture elements, image elements and pixels. Pixel is the term most widely used to denote the elements of a digital image [11].

Computers cannot handle continuous images but only arrays of digital numbers. Thus it is required to represent images as two-dimensional arrays of points. A point on the 2-D grid is called a pixel or pel. Both words are abbreviations of the word picture element. A pixel represents the irradiance at the corresponding grid position. In the simplest case, the pixels are located on a rectangular grid; the position of the pixel is given in the common notation for matrices. The first index, m, denotes the position of the row, the second, n, the position of the column [4].

The principal goal of the image segmentation process is to partition an image into regions of interest that are homogeneous with respect to one or more homogeneity criteria(s) or features. Segmentation is an important tool in medical image processing, and it has been useful in many applications. A segmentation algorithm, in a mammographic context, is an algorithm used to detect something, usually the whole breast or a specific kind of abnormalities, like micro-calcifications or masses [8].

A wide variety of segmentation techniques have been proposed. However, there is no one standard segmentation technique that can produce satisfactory results for all imaging applications. The definition of the goal of segmentation varies according to the goal of the study and the type of image data. Different assumptions about the nature of the analyzed images leads to the use of different algorithms [7].

This section provides the general mammographic image information explaining the mammographic abnormalities then introduces techniques, operations and statistics that form the tools for the development of comprehensive analysis/ diagnosis algorithms.

The digital database for screening mammography (DDSM) is a resource for use by the mammographic image analysis research community. The primary purpose of the database is to facilitate sound research in the development of computer algorithms to aid in screening. Secondary purposes of the database may include the development of algorithms to aid in the diagnosis and the development of teaching or training aids. The database contains approximately 2,500 studies [15].

The most effective method of early detection of the breast cancer is mammograms, certain characteristics in the mammograms determines whether cancer exists or not, breast cancer often presents as a mass with or without presence calcifications.

The location, size, shape, density, and margins of the mass are useful for the radiologist in evaluating the likelihood of cancer. Most benign masses are well circumscribed, compact, and roughly circular or elliptical. Malignant lesions usually have a blurred boundary, an irregular appearance, and sometimes are surrounded by a radiating pattern of linear spicules. Masses are categorized by their shape, density, and margins.

The mass shape is described with a four-point assessment: round, oval, lobular and irregular. The mass margins modify the boundaries. For example the overall shape may be round, but close inspection may reveal scalloping along the border, which may indicate a degree of irregularity or a lobular characteristic. The margins are rated with a 5-point system: circumscribed (well-defined or sharply-defined) margins, microlobulated margins, obscured margins, indistinct margins and spiculated margins as shown in Fig. 1.

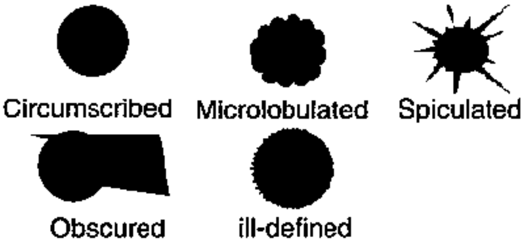

Fig. 1 Mass descriptors for margin

The intensity or the x-ray attenuation of the mass tissue region is described as density. The density here is the relative density, i.e. higher, lower or similar relative to the surrounding tissue. The density is rated on 4-point system:

High density, equal density, low density (lower attenuation, but not fat containing) and fat containing – radiolucent [10].

Numerous statistics can be developed from digital images which aid in describing and analyzing images. This section provides an introduction to a selected group of image statistics. The selected group represents those used in this research; however, they are far from exhaustive. In fact, a significant amount of researches continues developing new statistics for describing and analyzing images. This research is primarily interested in the application of existing statistics. .

(1) Age

(2) Variance

The variance of an image is a measure of the variation of pixel intensities in the image.

(3) Area

The area is defined as the total number of pixels belonging to the object.

(4) X-centroid, Y-centroid

The coordinates of the geometrical center of the object defined with respect to the image origin.

$$x_{centroid} = \sum_{i \in object} i \div A \qquad (1)$$

$$y_{centroid} = \sum_{j \in object} j \div A \qquad (2)$$

where i and j are image pixel coordinates and A is the area of the segment or region of interest (ROI) [9].

(5) Compactness

Compactness is another measure of the object's roundness and is calculated as:

$$compactness = p^2 \div 4\pi \mathrm{A} \qquad (3)$$

where P is the object perimeter. Compactness gives the minimal value 1 for circles [12].

(6) Circularity

Area and perimeter are two parameters which describe the size of an object. In order to compare objects which are observed from different distances, it is important to use shape parameters which do not depend on the size of the object on the image plane. The circularity c is defined as:

$$c = p^2 \div A \qquad (4)$$

The circularity is a dimensionless number with a minimum value of 4π ≈ 12.57 for circles. The circularity is 16 for a square and 12√3 ≈ 20.8 for an equilateral triangle. Generally, it shows large values for elongated objects.

(7) Eccentricity

This is a measure similar to the circularity but with a better defined range. The parameter is extracted from the second-order moments as:

$$\varepsilon = \frac{\left(m_{2,0} - m_{0,2}\right)^2 + 4\mathrm{m}_{1,1}^2}{\left(m_{2,0} + m_{0,2}\right)^2} \qquad (5)$$

The eccentricity ranges from 0 to 1, it is zero for circular object and one for line shaped object [3].

III. Statistical Techniques

One of the most useful applications of statistical analysis is the development of a model to explain the relationship between the variables; many types of models have been developed, including classification support vector machines, tree boost and tree forest. This part will focus on the deployed analytical techniques.

SUPPORT VECTOR MACHINES

Methods for analyzing and modeling data can be divided into groups; supervised learning and unsupervised learning. Supervised learning requires input data that has both independent variables and a dependent (target) variable whose value is to be estimated. By various means, the process learns how to model predict the value of some variable, then supervised learning is recommended approach.

Unsupervised learning does not identify a dependent variable (target), but rather treats all of the variables equally. In this case, the goal is not to predict the value of a variable but rather to look for patterns, groupings or other ways to characterize the data that may lead to understanding of the way the data relate. Cluster analysis, correlation, factor analysis (principle components analysis) and statistical measures are examples of unsupervised learning.

One of the most useful applications of statistical analysis is the development of a model to represent and explain the relationship between variables. One of the best state-of-the-art modeling methods including support vector machines (SVM).

In the manner of speaking of SVM literature, a predictor variable is called an attribute, and a transformed attribute that is used to define the hyper plane is called a feature. The task of choosing the most suitable representation is known as feature selection. A set of features that describes one case (i.e., a row of predictor values) is called a vector. So the goal of SVM modeling is to find the optimal hyper plane that separates clusters of vector in such a way that cases with one category of the target variable are on one side of the plane and cases with the other category are on the other side of the plane. The vectors near the hyper plane are support vectors.

To illustrate classification SVM, let us assume that there is a linear relationship with N observations. The independent variable is x_i and the dependent variable is y_i given that i=1, 2, 3……N. The goal of classification SVM is to produce a linear function which can make the best fit of the dependent variable y_i. The linear function can be expressed as follows:

$$y = f(x) = \langle b \cdot x \rangle + a \qquad (6)$$

Where a and b are the classification parameters and is the dot product of b and x.

The dot product of two vectors is defined as:

$$b \cdot x = \sum_{i=1}^{N} b_i x_i = b_1 x_1 + b_2 x_2 + \dots . b_N x_N$$

The optimum classification function can be found by minimizing the following function:

$$M(b, S) = 0.5\|b\|^2 + C\sum_{i=1}^{N}\left(S_i^- + S_i^+\right) \qquad (7)$$

The constraint can be as follows:

$$\begin{aligned} & y_i - \langle b, x_i \rangle - a \leq \varepsilon + S_i \\ & \langle b, x_i \rangle + a - y_i \leq \varepsilon + S^*_i \qquad (8) \\ & S_i, S_i^* \geqslant 0 \end{aligned}$$

Where C is a constant greater than zero, and can be used to determine the trade off the smoothness of f and the amount up to which deviations larger than ε are accepted. and S_i^+ are two slack variables, which can be used to represent the upper and the lower constraints of the classification function. is norm of b. the norm can be as follows:

$$\|b\| = \sqrt{b_1^2 + b_2^2 + \dots b_N^2}$$

To find the optimum solution of M function, loss function must be determined. Loss function is a function shows the maximum allowed deviation of the predicted values from the observed one. The most recommended loss functions are four. These four functions are: Huber, ε-insensitive, quadratic and Laplace [13]. Fig. 2 shows the difference between the four types of loss functions.

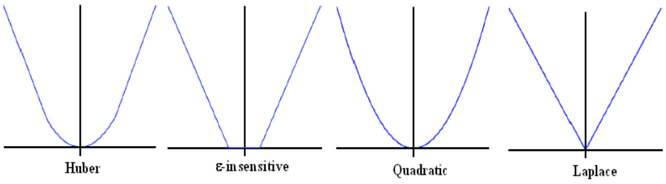

Fig. 2 The four types of loss functions

The first loss function is Huber loss function: it is a robust loss function that has optimal properties when the underlying distribution of the data is unknown. The second one is ε-insensitive loss function; it is an approximation to Huber's loss function but it can reduce sensitivity to the outliers. The third one is quadratic loss function: it corresponds to the predictable least squares error measure. The fourth one is Laplace loss function: it is less sensitive to outliers than the quadratic loss function.

In this paper, the ε-insensitive loss function was selected. For classification SVM model which depends on ε-insensitive loss function: the difference between the estimated values and the observed values of the dependent variable y_i can be calculated. If the difference is less than ε, the classification function is considered to be most popular and accurate [13]. The ε-insensitive loss function can be expressed as follows:

$$|S|_{\varepsilon} = \begin{cases} o & if\ |S| < \varepsilon \\ |S| - \varepsilon & otherwise \end{cases} \qquad (9)$$

Most modeling techniques are trying to find the best fit between the observed and predicted values, however, SVM'S ε-insensitive loss function focuses on optimizing a bound around the classification function thus making it stronger against the outliers.

To find the solution of equation 7, Lagrange optimization must be used, the solution to this optimization problem can be expressed as follows: Minimizes the target function as follows:

$$\varepsilon \sum_{i=1}^{N} \left(\alpha_i + \alpha_i^*\right) + 0.5 \sum_{i=1,j=1}^{N} \left(\alpha_i - \alpha_i^*\right)\left(\alpha_j - \alpha_j^*\right)\left(x_i \cdot x_j\right) + \sum_{i=1}^{N} y_i\left(\alpha_i - \alpha_i^*\right) \qquad (10)$$

The constraints can be as follows:

$$\sum_{i=1}^{N} \left(\alpha_i - \alpha_i^*\right) = 0{,}0 \leq \alpha_i,\ \alpha_i^* \leq C \qquad (11)$$

SVM models are built around a kernel function that transforms the input data into an n-dimensional space where a hyper plane can be constructed to partition the data.

There are four kernel functions, linear, polynomial, radial basis function (RBF) and sigmoid (S-shaped). There is no way in advance to know which kernel function will be best for an application.

The RBF kernel non-linearity maps samples into a higher dimensional space, so it can handle nonlinear relationships between target categories and predictor attributes; a linear basis function cannot do this. Furthermore, the linear kernel is a special case of the RBF. A sigmoid kernel behaves the same as a RBF kernel for certain parameters. The RBF function has fewer parameters to tune than polynomial kernel, and the RBF kernel has less numerical difficulties.

This is the case of linear classification, but to illustrate the classification case of non-linearity, the data must be firstly linearized by mapping it into a higher dimensional space, called "feature space" by using kernel functions, that linear classification functions can be applied. The most recommended kernel function is the RBF Kernels [6]. The RBF kernel is defined as:

Given that is a kernel parameter.

Insert kernel function in the previous model (10), this model can be adjusted as follows:

The same constraints in (8) can be used, minimize:

$$\varepsilon \sum_{i=1}^{N} \left(\alpha_i + \alpha_i^{¿}\right) + 0.5 \sum_{i=1,j=1}^{N} \left(\alpha_i - \alpha_i^*\right)\left(\alpha_j - \alpha_j^*\right) K\left(x_i \cdot x_j\right) + \sum_{i=1}^{N} y_i\left(\alpha_i - \alpha_i^*\right) \qquad (12)$$

DECISION TREES

A decision tree is a logical model represented as a binary (two-way split) tree that shows how the value of a target variable can be predicted by using the values of a set of predictor variables. There are many techniques for decision trees. In this paper the authors selected two techniques which are Boosting Trees and Tree Forest.

A decision tree can be used to predict the values of the target variable based on values of the predictor variables.

Each node represents a set of records (rows) from the original dataset. Nodes that do not have child nodes are called "terminal" or "leaf" nodes. The topmost node called the "root" node. Unlike a real tree, decision trees are drawn with their root at the top. The root node represents all of the rows in the dataset.

A decision tree is constructed by a binary split that divides the rows in a node into two groups (child nodes). The same procedure is then used to split the child groups. This process is called "recursive partitioning".

DECISION BOOSTING TREES

"Boosting" is a technique for improving the accuracy of a predictive function by applying the function repeatedly in a series and combining the output of each function with weighting so that the total error of the prediction is minimized. In many cases, the predictive accuracy of such a series greatly exceeds the accuracy of the base function used alone.

The TreeBoost algorithm is optimized for improving the accuracy of models built on decision trees. Research has shown that models built using TreeBoost are among the most accurate of any known modeling technique.

The TreeBoost algorithm is functionally similar to Decision Tree Forests because it creates a tree ensemble, and it uses randomization during the tree creations. However, a random forest builds the trees in parallel and they "vote" on the prediction; whereas TreeBoost creates a series of trees, and the prediction receives incremental improvement by each tree in the series.

Mathematically, a TreeBoost model can be described as:

$$\mathrm{PT} = F_0 + \mathrm{B}_1 T_1(X) + \mathrm{B}_2 T_2(X) + . + B_M T_M(X) \qquad (13)$$

Where *PT* is the predicted target, *F*$_0$ is the starting value for the series (the median target value for a regression model), *X* is a vector of "pseudo-residual" values remaining at this point in the series, $T_1(X)$, $T_2(X)$ are trees fitted to the pseudo-residuals and B_1, B_2, etc. are coefficients of the tree node predicted values that are computed by the TreeBoost algorithm.

The first tree is fitted to the data. The residuals from the first tree are then fed into the second tree which attempts to reduce the error. This process is repeated through a chain of successive trees. The final predicted value is formed by adding the weighted contribution of each tree.

Usually, the individual trees are fairly small, but the full TreeBoost additive series may consist of hundreds of these small trees. TreeBoost models often have a degree of accuracy that cannot be obtained using a large, single-tree model. TreeBoost models are often equal to or superior to any other predictive functions including neural networks. TreeBoost models can handle hundreds or thousands of potential predictor variables. Irrelevant predictor variables are identified automatically and do not affect the predictive model. TreeBoost uses the Huber M-regression loss function which makes it highly resistant to outliers and misclassified cases. TreeBoost procedures are invariant under all (strictly) monotone transformations of the predictor variables. So transformations such as (a*x+b), log(x) or exp(x) do not affect the model. Hence, there is no need for input transformations. The sophisticated and accurate method of surrogate splitters is used for handling missing predictor values. The stochastic element in the TreeBoost algorithm makes it highly resistant to over fitting. Cross-validation and random-row-sampling methods can be used to evaluate the generalization of a TreeBoost model and guard against over fitting. TreeBoost can be applied to regression models and k-class classification problems. TreeBoost can handle both continuous and categorical predictor and target variables.

DECISION TREE FOREST

A Decision Tree Forest is an ensemble of decision trees whose predictions are combined to make the overall prediction for the forest. A decision tree forest is similar to a TreeBoost model in the sense that a large number of trees are grown. However, TreeBoost generates a series of trees with the output of one tree going into the next tree in the series. In contrast, a decision tree forest grows a number of independent trees in parallel, and they do not interact until after all of them have been built.

Both TreeBoost and decision tree forests produce high accuracy models. Decision tree forests use the out of bag data rows for validation of the model. This provides an independent test without requiring a separate data set or holding back rows from the tree construction. The sophisticated and accurate method of surrogate splitters is used for handling missing predictor values. The stochastic element in the decision tree forest algorithm makes it highly resistant to over fitting. Decision tree forests can be applied to regression and classification models.

The primary disadvantage of decision tree forests is that the model is complex and cannot be visualized like a single tree. It is more of a “black box” like a neural network. Because of this, it is advisable to create both a single-tree and a decision tree forest model. The single-tree model can be studied to get an intuitive understanding of how the predictor variables relate, and the decision tree forest model can be used to score the data and generate highly accurate predictions.

IV. Analysis and Results

The measures in Table I were used for comparison purposes. These measures can be used as an indicator of the mean difference between the measured and estimated values.

Table I.
The Results of Applying Classification SVM and Decision Trees

Measures	Classification SVM		Forest Tree		Boosting Tree	
	Training	Validation	Training	Validation	Training	Validation
CV	0.796	0.922	0.852	0.958	0.922	0.988
NMSE	0.479	0.644	0.550	0.695	0.643	0.738
MSE	0.118	0.158	0.135	0.170	0.158	0.181
MAE	0.331	0.346	145.125	169.396	155.113	181.055
MAPE	32.870	37.414	37.675	39.542	47.142	53.658
Var%	36%	30%	42%	36%	69%	58%

Root mean squared error (RMSE) is a quadratic scoring rule which measures the average magnitude of the error. RMSE is the difference between predictions and corresponding observed values are each squared and then averaged over the sample. Finally, the square root of the average is taken. Since the errors are squared before they are averaged, the RMSE gives a relatively high weight to large errors. This means that RMSE is most useful when large errors are particularly undesirable.

The normalized root mean squared error (NMSE) is the RMSE divided by the range of observed values; the value is often expressed as a percentage, where lower values indicate less residual variance.

Mean absolute error (MAE) measures the average magnitude of the errors in a set of predictions, without considering their direction. The MAE is the average over the verification sample of the absolute values of the differences between predictions and the corresponding observation. The MAE is a linear score which means that all the individual differences are weighted equally in the average.

Proportion of variance (Var%) explained by model variables; this is the best single measure of how well the predicted values match the actual values. If the predicted values exactly match the actual values, then the model would explain 100% of the variance.

According to the previously discussed measures of C.V, NMSE, MSE, MAE and MAPE, the classification SVM was the optimum technique declared by the lowest values of 0.796, 0.479, 0.118, 0.331 and 32.870 respectively for the training set among techniques applied and validated with values of 0.922, 0.644, 0.158, 0.346 and 37.414 respectively.

To determine the importance of the independent variables of the suggested model; the misclassification rate for the model using the actual data values for all predictors must be calculated. Then for each predictor, it randomly rearranges the values of the predictor and computes the misclassification rate for the model using the rearranged values. The difference between the misclassification rate with the correctly ordered values and the misclassification rate for the rearranged values is used as the measure of importance of the predictor. Table II shows the variables importance for both techniques.

Table II.
The Variables Importance of Classification SVM and DEcision Tree

Variable	SVM	Forest Tree	Boosting Tree
Age	100	100	100
Variance	22.462	49.36	36.11
Circularity	11.044	45.758	34.152
Compactness	11.018	50.444	31.032
Eccentricity	8.72	35.175	17.044
Centroid X	7.66	40.385	23.212
Centroid Y	3.48	36.636	17.332
Area	1.429	36.503	18.607

The importance score for the most important predictor is scaled to a value of 100. Other predictors will have lower scores. Variance, Circularity, Compactness, Eccentricity, Centroid X, Centroid Y and Area are the less important variables for both SVM and Boosting tree, their importance ranges from 1.429 to 36.11 which is less than 40, then these variables could be ignored in the analysis [14] while Age, Compactness, Circularity and Centroid X possess the highest importance for the Forest Tree with importance of 100, 50.444, 49.36, 45.758 and 40.385 respectively.

The lift and gain is a useful tool for measuring the value of a predictive model. The basic idea of lift and gain is to sort the predicted target values in decreasing order of purity on some target category and then compare the proportion of cases with the category in each bin with the overall proportion. The lift and gain values show how much improvement the model provides in picking out the best of the cases. A gain chart displays cumulative percent of the target value on the vertical axis and cumulative percent of population on the horizontal axis. Cumulative gain is the ratio of the expected outcome using the model to prioritize the prospects divided by the expected outcome of randomization. The straight, diagonal line shows the expected return if no model is used for the population. The curved line shows the expected return using the model. The shaded area between the lines shows the improvement (gain) from the model. The gain of 1.00 means we are not doing any selective targeting.

Figures 3, 4and 5 exploits that by applying boosting tree we get 1.5718 times better outcome than the expected return of no model or randomization comparable to an average gain of 1.5576 for forest trees while the highest average gain is due to applying SVM of 1.7323.

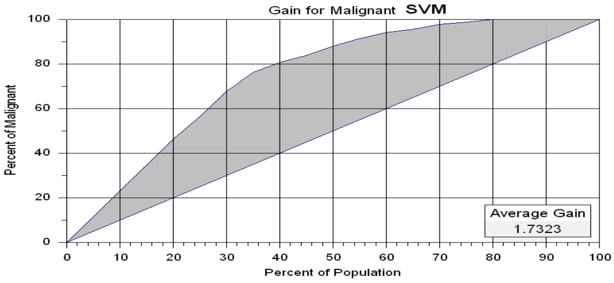

Fig. 3 The gain chart for classification SVM

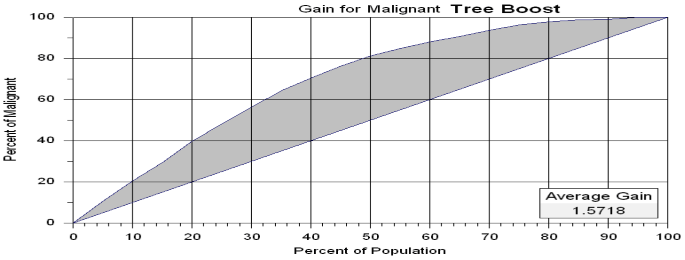

Fig. 4 The gain chart for boosting tree

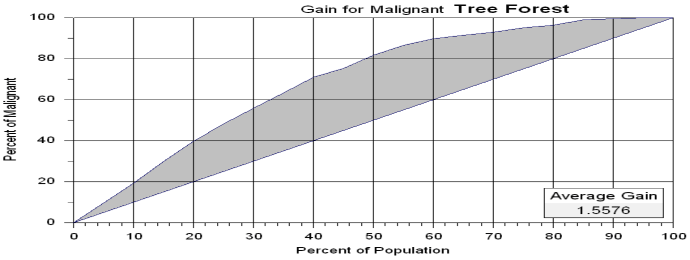

Fig. 5 The gain chart for forest tree

A receiver operating characteristic curve (ROC) curve is a graphical representation of the tradeoff between the false negative and false positive rates for every possible cutoff. Equivalently, the ROC curve is the representation of the tradeoffs between sensitivity and specificity. The area under the curve is a measure of test accuracy. It shows the tradeoff between sensitivity and specificity (any increase in sensitivity will be accompanied by a decrease in specificity). The closer the curve follows the left-hand border and then the top border of the ROC space, the more accurate the test. The closer the curve comes to the 45-degree diagonal of the ROC space, the less accurate the test. The slope of the tangent line at a cut point gives the likelihood ratio for that value of the test.

The accuracy of the test depends on how well the test separates the group being tested into those with and without the disease in question. Accuracy is measured by the area under the ROC curve. An area of 1 represents a perfect test; an area of 0.5 represents a worthless test.

The empirical estimate of area under the ROC curve (±SE) for the SVM was (0.79768±0.02762) while the binomial estimate of area under the ROC curve was (0.85323±0.02537). Empirical estimate of area under the ROC curve of the boosting tree was (0.53452±0.03474) while the binomial estimate of area under the ROC curve was (0.53882±0.03900). Empirical estimate of area under the ROC curve of the forest tree was (0.57575±0.03439) while the binomial estimate of area under the ROC curve was (0.58548±0.03843).As discussed above and illustrated in fig. 6, SVM possess the highest area under the curve among the discussed techniques.

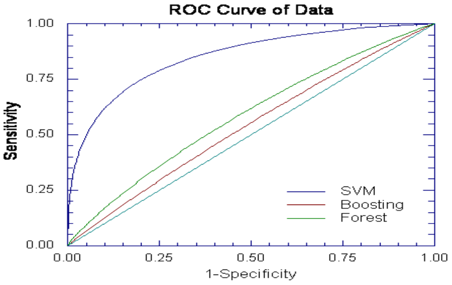

Fig. 6 The ROC for SVM, Forest Trees and Boosting Trees.

IV. Conclusion and Future Work

The results of applying the three classification techniques for extraction of the most important mammographic mass features showed promising and superior results for classification SVM over decision trees witnessed by minimal error measures ans maximum average gain.

Other risk factors could be used to aid the analysis such as genetic risk factors, previous breast radiation, and previous abnormal breast biopsy. Other proposed mammographic mass features includes: center of gravity, sphericity, inertia-shape, mean radius and max radius. Automated detection and classification of other types of mammographic lesions as micro calcifications and distorted architecture. The use of automated detection and segmentation techniques not only in mammographic images but also in MRI.

***Abstract*—This paper presents analysis of a model for car brand recognition. The used method is an invariant keypoint detector - descriptor. An input for the method is a set of images obtained from the real environment. The task of car classification according its brand is not a trivial task. Our work would be a part of an intelligent traffic system where we try to collect some statistics about various cars passing a given area. It is difficult to recognize objects when they are in different scales, rotated or if they are low contrasted or when it is necessary to take into count high level of details. In our work we present a system for car brand recognition. We use scale space invariant keypoint detector and descriptor (SURF – Speeded-up Robust Features) for this purpose.**

I. Introduction

THIS paper presents a model for car brand recognition. Not many works have been published for such problem yet. We discuss a model for scale, space invariant car brand detection and recognition. The goal of our work is to provide information about car type approaching monitored region. For example car brands as “Ford”, “Kia”, “Volkswagen” etc. are considered. Recently, some promising approaches to detect foreground objects from images have been published: SIFT - Lowe (Scale Invariant Feature Transform) [1] and SURF - Bay et al. (Speeded Up Robust Features) [2]. Both methods detect interest points, called features, and also propose a method of creating an invariant descriptor for these features. The created descriptor is used as vector, uniquely identifying the found interest points. It has to be distinctive and robust for various scale-space deformations. Vectors can be used for matching of detected interest points even under a variety of disturbing conditions like scale changes, rotation, changes in illumination and viewpoints or image noise. The invariance is the most important ability of these keypoint detectors. The car brand can be in various representation in the image. An example is shown in the Fig.1.

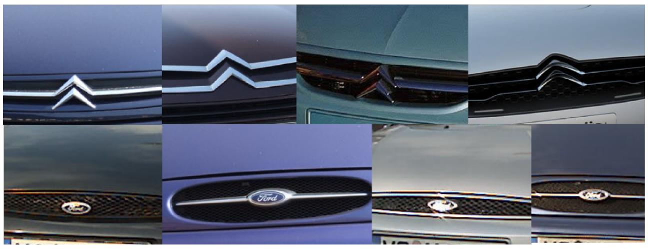

Fig 1: A series of images to show various car brand invariances for the same car brand.

The purpose of this paper is to review and investigate a method referred to as SURF. The SURF detector-descriptor method for our problem is analyzed. We use the OpenSURF library which we integrated into our software demo. In [3] we proposed a possibility to use the SIFT method for the same problem. It showed some positive results but average percentage of successful classification was not to high. The number of different car brands was 7 and the final percentage moved around 60%. Some car brands were classified with better results than others. As far as we know, no other works exist for car brand recognition problem. We focus on scale-space invariant detectors and descriptors. These seem to be a good compromise to other methods. The SIFT and SURF in various problem are used where patterns or objects from database in given scene (unknown image) are searched. Results from other types of common work are motivation for our problem. In [4] authors measure visual similarities between different visual entities with SIFT. In [5] the SIFT is used for face detection. In [6] the SURF is used for foreground detection. Comparative work done by Mikolajczyk and Schmid in [7] is a good reference for other types of interest points detectors and descriptors. The authors of SURF [2] claims SURF to be a superior to SIFT in terms of runtime execution while it is still providing good results with regards to feature point quality. The goal of this paper is not to compare SIFT against SURF or otherwise, but the goal is to analyze the possibility of using the SURF for car brand recognition from images taken in a natural outdoor environment.

In the second part the SURF is discussed in more details. First the algorithm is analyzed from a theoretical standpoint, to provide a brief overview of how it works and what was the motivation of using it. In the third part a brief overview of preprocessing procedures for region of interest specifying is discussed. The 4th proposes experiments for the problem of car brand recognition. The paper is concluded in 5th part.

II. Speeded-Up Robust Features (SURF)

The SURF is scale and rotation invariant interest point detector and descriptor. It is designed to overcome relatively low computation time which SIFT has, by providing the

978-83-60810-27-9/09/$25.00 © 2010 IEEE

same functionality. Much of the performance increase in SURF can be referred to the use of an special image representation known as the “Integral Image" [2]. The SURF is three step process:

- Interest points detection and localization.
- Feature vector construction – descriptor (interest point description).
- Descriptors matching.

A. Interest Point Detection and Localization

The SURF uses Fast – Hessian features detector and it is based on determinant *D(H)* of Hessian matrix *H(f)*. The Hessian matrix is the matrix of partial derivatives of two dimensional function *f(i,j)* (see eq. 1) [8][9].

$$H(f)=\begin{bmatrix} \frac{d^2 f}{di^2} & \frac{d^2 f}{didj} \\ \frac{d^2 f}{didj} & \frac{d^2 f}{dj^2} \end{bmatrix} \qquad (1)$$

The determinant of this matrix *(H)*, known as the discriminant, is calculated by:

$$D(H)=\frac{d^2 f}{di^2}\cdot\frac{d^2 f}{dj^2}-\left(\frac{d^2 f}{didj}\right)^2 \qquad (2)$$

Equations (1) and (2) are defined for continuous function f, but we work with images, so it means discrete space. Then *f(i,j)* as discrete function is considered which represents image. Point at *(i,j)* coordinates is a pixel intensity for the image. Approximated derivatives are computed by convolution with appropriate kernel (*H'* is approximation of *H*). For determinant approximation *(D')* formula is used:

$$D'(H')=D_{ii}.D_{jj}-(0.9\mathrm{D}_{ij})^2 \qquad (3)$$

Determinant computation is necessary for interest point detection (which are maxims in determinant matrix). In order to be able to detect interest points in scale space the notion should be introduced. A scale-space is a continuous function which can be used to find an extrema across all possible scales [10]. In SIFT scale-space as an image pyramid is used where the input image is iteratively convolved with Gaussian kernel in reduced size and so repeatedly sub--sampled. In SURF we do not need to resize images. Instead the convolution mask is re-sampled to ensure size invariance. This allows for multiple layers of the scale-space pyramid to be processed simultaneously and negates the need to subsample the image hence providing performance increase [8]. The idea is shown in Fig. 2. For appropriate and accurate interest point selection some other steps are processed. Firstly a treshold is applied, secondly non maximum supression is done and next step is interpolation. Fo more details see [2],[8].

B. Interest Point Descriptor

The SURF descriptor describes how the pixel intensities are distributed within a scale dependent neighborhood of each interest point detected by the Fast-Hessian [8]. The process of descriptor extraction consists of two parts. At first a reproducible orientation to each interest point is assigned. Secondly around each interest point a square window in appropriate scale is constructed. In this square a 64 value vector is computed which is the descriptor for given interest point. For more details see the Fig. 3. The SIFT extracts 128 values for one interest point compared to the SURF.

C. Descriptors matching

If descriptors of database items and new query are known, they are matched each other. We use simple principle and its modification. For each item in database find all keypoints. For each keypoint from the query image find the keypoint from database with the smallest distance (MSE). Two keypoints are considered as the same if the error of the best match is at least a factor of α smaller than the distance to the next closest descriptor. If not take another. Then count the number of descriptors that successfully matched.

III. Image preprocessing

In this part a brief introduction to preprocessing is discussed. The main purpose is to reduce image to a size which contains all the necessary information but the image remains as small as possible. The car brand represents just a small part compared to the whole image. Reducing an input image to the region around car brand has positive effect namely in two aspects: Lower number of detected interest points leads to more accurate computation (less error rate) and it improves the execution time. From the Fig. 4 is clear that we use license plate for image reducing into region of interest. The license plate is found and according its position a car brand is searched. We suppose that the car brand is above the license plate. It is not a rule but almost all cars satisfy this condition. In next part experiments are discussed.

IV. Experiments

In this part, we study whether SURF features are suitable and robust enough for our problem. Since we have chosen a typical pattern classification approach for solving the problem of car brand recognition, it is necessary to have a suffi-

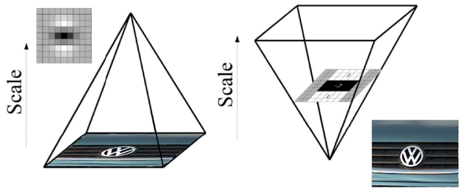

Fig 2: Pyramid. On the left - traditional approach (SIFT), on the right approach used in SURF.

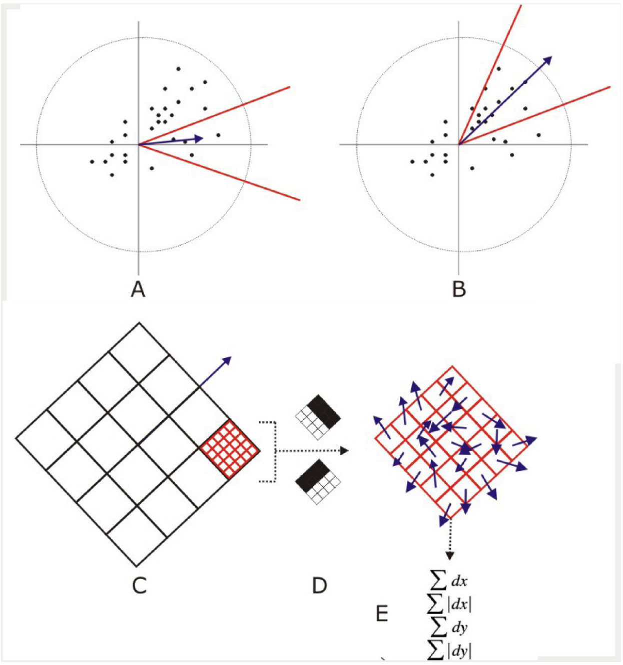

Fig 4: The SURF - descriptor. A, B represent orientation assignment. C is square around interest point with orientation. D and E show 64 value descriptor computation.

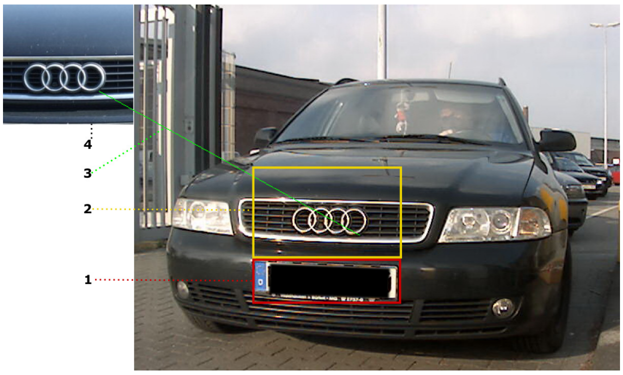

Fig 3: Process of initialization region of interest. At first license plate is found (1). Then above the license plate region of interest which holds car brand is set (2). Next the matching process is initialized (3,4) after descriptors are extracted.

Table I

pospis

Car brand	Num. Of samples
Audi	21
BMW	22
Citroen	8
Ford	16
Kia	12
Mercedes	16
Opel	24
Peugeot	14
Renault	19
Skoda	8
Volkswagen	29

cient data set. The data corpus of altogether 189 different samples was collected in the entrance to a car park. Table 1 shows number of samples for each brand. Our database consisted of 11 different car brands. Original image size was 640x480. When the region of interest was reduced the size moved around 200x200 pixels.

For given set of samples we tested the SURF method. Before experiments a template database was created. The database contained one sample for each brand. We chose the image which seemed to be optically the "best" (without noise, rotation, well visible etc.) for each class (see Fig. 5). From samples the SURF descriptor was computed and saved to file. Detected interest points which did not affect the car brand were deleted (see Fig 6.). The criteria used to evaluate

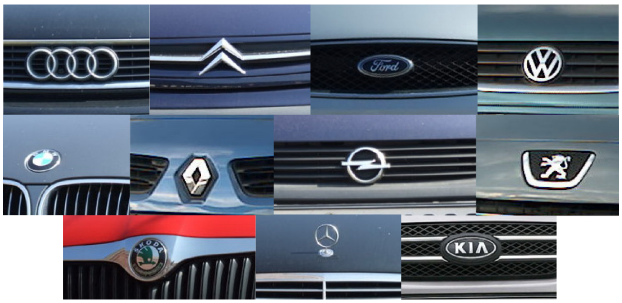

Fig 5: Samples in database. Each image represents one class. These samples are considered as templates for matching.

Table II

Experimental results.

Car brand	Result (α=0.6)	Result (α = 0.8)
Audi	0.52	0.9
BMW	0.14	0.09
Citroen	0.63	0.5
Ford	0	0
Kia	0.08	0.33
Mercedes	0.06	0
Opel	0.71	0.88
Peugeot	0.43	0.29
Renault	0.21	0.42
Skoda	0.25	0.38
Volkswagen	0.66	0.66

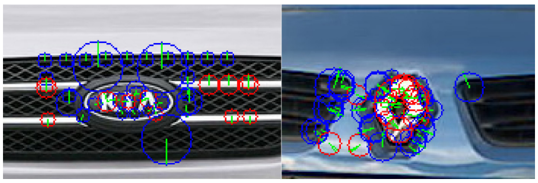

Fig 6: Detected interest points. Interest points which do not affect the car brand are deleted. Most of them describe the mask.

the performance of the detector is number of correctly matched samples from the database to samples from available testing dataset (new queries). We created tests based on average error and tests based on number of descriptor matches for certain class. The second approach provided better results but it was unfair because not all samples had the same number of detected keypoints. Summary is shown in table 2. We modified also the α constant (distance between the best and the next closest descriptor). Better results were achieved with α=0.8 (default values was 0.6) but this fact is clear because we are not so strict to coincidence. Descriptor which fitted the most produces smaller error (the same descriptors produce error equals to 0).

An average result for all samples moved around 45%. Table 1 shows interesting results. Some car brand are recognized with high percentage but the other ones are recognized poorly. The reason could be for example a small database of samples. For some car brands just low number of interest points was detected (see Fig. 7) and therefore they are recognized with insufficient result. The SURF method is quite strong tool from various aspects. Similar (the same) objects were found with almost 100%. Objects in different scales were also recognized with high percentage. Fig. 8 shows some results where the best matched keypoint as an example is depicted. Images on the left are samples from the database and images on the right are new queries.

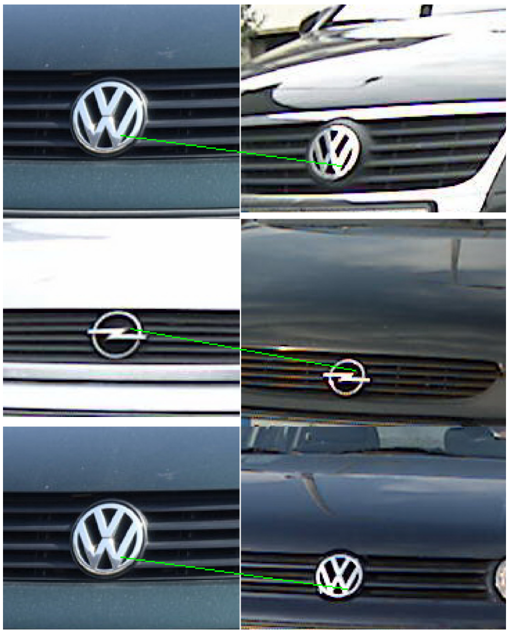

Fig 7: An example of positive matching. The same interest points were detected in different images.

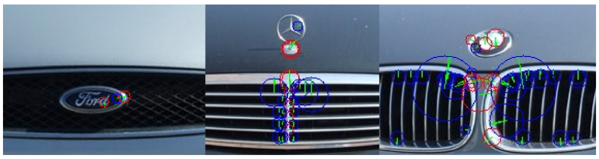

Fig 9: An example of detected interest points for some car brands. In all image low number of keypoints is detected. It is also shown that the mask is quite informative (or noisy) for some car brands (bmw and mercedes). If we would consider the mask, result could improved but the mask is not standardized.

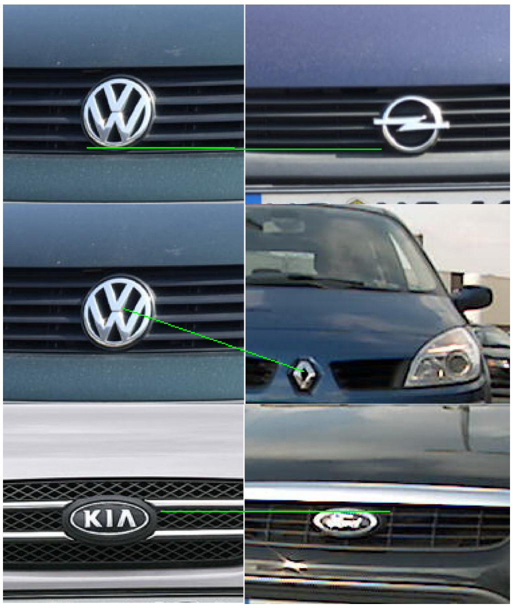

Fig 8: An example of negative matching. Even if the images are not matched, some similarities can be found for highlighted interest point.

V. Conclusion

In this work, we investigated the usage of SURF descriptors for car brand recognition. The final percentage was not very high. The main purpose was to analyze the possibility of this method for our problem and from this standpoint we obtained some valuable results. As the future work a new strategy for creating database is necessary to build. It would be also appropriate to analyze descriptor values and that especially for car brands with small amount of detected interest points. For some brands, which were recognized very poorly, different invariant key point detector should be tested (MSER – maximal stable external regions).

Evaluation of Clustering Algorithms for Polish Word Sense Disambiguation

Bartosz Broda, Wojciech Mazur
Institute of Informatics, Wrocław University of Technology, Poland
bartosz.broda@pwr.wroc.pl, wojciech.mzr@gmail.com

***Abstract*—Word Sense Disambiguation in text is still a difficult problem as the best supervised methods require laborious and costly manual preparation of training data. Thus, this work focuses on evaluation of a few selected clustering algorithms in task of Word Sense Disambiguation for Polish. We tested 6 clustering algorithms (K-Means, K-Medoids, hierarchical agglomerative clustering, hierarchical divisive clustering, Growing Hierarchical Self Organising Maps, graph-partitioning based clustering) and five weighting schemes. For agglomerative and divisive algorithm 13 criterion function were tested. The achieved results are interesting, because best clustering algorithms are close in terms of cluster purity to precision of supervised clustering algorithm on the same dataset, using the same features.**

I. Introduction

WORD Sense Disambiguation (WSD) deals with contextual resolution of lexical ambiguity. Most words in natural language have more than one lexical meaning (sense), but usually only one of them is active in a given context. Typical example of ambiguous word is *line*, which according to WordNet (an electronic thesaurus, cf. [1]) has 36 senses. WSD is important problem for applications in domain of Natural Language Processing (NLP). Machine translation cannot work without some form of disambiguation, but WSD can be helpful also for information retrieval, information extraction and computer aided lexicography among others [2].

WSD is a hard problem. Most difficulties arise from the fact that the concept of a meaning is vague. Usually, there are no clear boundaries between one sense or the other [3]. Typically, the problem of defining meaning is tackled with using dictionaries (which are called *sense inventory* in a context of WSD). I.e., from the algorithmic point of view sense inventories are used to enumerate all the meanings that a given word has. Now, the goal of WSD can be stated as choosing appropriate sense from sense inventory in a given context of a word.

There are two main approaches to WSD based on machine learning: supervised and unsupervised [2].[1] Supervised learning focuses on the usage of manually disambiguated examples of text snippets containing ambiguous words. We need to choose an appropriate sense inventory in advance, at early stages of the construction of supervised WSD system. Some features are extracted from those text snippets (or contexts[2]) and classifiers are trained using this manually labeled data. Most of the time, supervised approaches are superior to unsupervised in terms of accuracy of automatic disambiguation when used on the same type of texts that the systems were trained on.

Nevertheless, there is another issue connected with the problem of the definition of a meaning, i.e., an issue of creation of other resources used for automatic system performing WSD. This is especially evident in creation of corpora[3] manually annotated (tagged) with senses, which are used for training machine learning classifiers in a supervised setting. There are two important problems during manual sense tagging of a corpus: low *interannotator agreement* (IA) and high cost of annotation process. IA is a way of measuring how much annotations assigned by one annotator differers from annotations assigned by another annotator. IA is used for estimation of an upper bound on performance on automatic WSD. Typically, it is not enough to give a value of percentage agreement, because agreements and disagreements may arise by chance. Cohen's κ is widely used in computational linguistic community for this purpose, but there are also other measures [5]. The cost of annotation is high, because large effort is required during manual annotation. Mihalcea estimated that a construction of a corpus with sufficient amount of data for supervised classification algorithms for 20 000 ambiguous words would require 80 man-years of work [6].

On the other hand, unsupervised and semi-supervised algorithms can be used. The amount of manual labor required is much lower in learning without supervision. Unsupervised approaches to WSD tend to use unlabeled data and automatically find sense distinctions. Usually those methods involve some form of clustering. Harris' distributional hypothesis [7] can be used as a theoretical foundation for unsupervised methods of WSD. It states that "meaning of entities (...) is related to the restrictions on combinations of these entities relative to other entities.". In this context entities can be understood as words.

The main goal of this work is to compare various clustering algorithms in the task of unsupervised Word Sense Disambiguation for Polish data. In unsupervised WSD system deals with grouping of contexts for given word that express the

[1] There is a plethora of other approaches to WSD, e.g., based on translational equivalence or hand-written rules. We omit those for brevity. For extensive overview of other methods see, e.g., [2], [4].

[2] We will use term *context* to denote a passage of text containing ambiguous word.

[3] Here we define a corpus as a collection of texts prepared for linguistic processing

same meaning without providing explicit sense labels for each group (e.g., without using a dictionary) [8]. Also, this work is motivated by the fact that clustering is important for semi-supervised WSD algorithm called Lexicographer Controlled Semi-automatic word Sense Disambiguation [9], [10]. So far, the selection of the algorithm used in LexCSD was motivated by the performance of the given algorithm in other tasks and its analytical properties, because analysis of the performance of different clustering algorithms in similar settings (i.e., using similar dataset and features) for Polish WSD is difficult to find.

There are a few differences when dealing with WSD data in comparison to classical applications of clustering. To name just a few: the distributions of classes (senses) are skewed[4], data is represented in spaces of very large number of dimensions (thousands or even hundreds of thousands), for some classes only very specific, often overlapping among classes features are important and sometimes there is difficulty in distinguishing between two close classes.

The paper is organized as follows. First the selected clustering algorithms are briefly described. Evaluation section starts with the analysis of evaluation metrics used. Next, the corpus and experimental settings are described. Section III-D provides discussion of results. Section IV gives a summary of performed experiments and overviews direction of further works.

II. Selected algorithms for testing

For this work we have selected a few classical clustering algorithms, but we tried to choose algorithms representing a few different approaches to the problem of clustering. We started with *K-means* and *K-medoids* algorithms, which represent simple, hard and flat clustering methods. We choose *Growing Hierarchical Self-Organising Map* (GHSOM) as a representative of family of clustering using neural networks. GHSOM is also a hierarchical clustering algorithm. We experiment with standard hierarchical clustering algorithms with different criterion functions, both from agglomerative and divisive families of algorithms. Last but not least, we test also graph-based clustering algorithm. We have reimplemented K-means, K-medoids and GHSOM and use existing implementation of other algorithms [11].

We are focusing on clustering for WSD so we will use NLP-related terminology during description of algorithms. As a task of WSD is a contextual one, we will cluster *contexts* (text snippets) containing ambiguous word. From the context some real-valued features are extracted. So the context is a vector of features $\vec{v}$ in high dimensional space. We will use term *context* and *context vector* interchangeably. The exact nature of context and feature extraction process are described in Sec. III-B.

A. K-means and K-medoids

K-means is one of the simplest clustering algorithm. K-means defines cluster as a centers of mass of contexts being clustered [12]. Those centres are represented as centroids. Initially random contexts are chosen as centroids. Then we assign most similar contexts to each centroid. After this step new centroids are computed as a mean of all the contexts in a group. This process is then repeated until some stopping criterion is reached, e.g., number of iteration reaches some predefined threshold or the clustering solution do not change significantly between subsequent iterations.

K-medoids is similar in concept to K-means algorithm. The most fundamental difference between the two algorithms is that K-medoids uses real contexts from the dataset as a basis for clustering in contrast to centroids used in K-means (which are artificial contexts). One of the realisations of K-medoids is an approach called *Partition Around Medoids*, or PAM [13]. In PAM one starts with randomly selection of initial medoids. Then every swapping of every medoid with every context is tested in terms of decreasing *cost* of whole clustering solution. This approach has its drawbacks in terms of computational complexity, i.e., $O(k(n-k)^2)$, where n is number of contexts to cluster and k is number of medoids. Thus a few extensions have been proposed that, e.g., employ sampling (CLARA) or randomized search (CLARANS) [13]. Nevertheless, we use classical PAM, as both mentioned algorithms can have negative impact on quality in comparison to PAM. This approach is applicable in our experiments, as we use relatively small datasets.

B. Growing Hierarchical Self-Organizing Map

The Growing Hierarchical Self-Organizing Map (GHSOM) [14] is a natural extension of Kohonen's idea of Self-Organizing Maps (SOM) [15]. SOM is an *artificial neural network* consisting of many neurons. Every neuron consists of a weight vector. Training SOM is done in an unsupervised manner applying *winner takes most* strategy. Every feature vector is delivered to the network input several times. For every input vector the similarity with the neuron weight vector is computed. Weights of the most similar neuron (the winner) and its neighbourhood are updated to be even more similar to the input pattern. The learning algorithm is constructed in such a way, that the neighbourhood and the degree of the weight updating is decreasing over time.

GHSOM address one of the most important drawback of SOM — the a priori definition of the map structure. Rauber *et al.* proposed an algorithm for growing SOM both in a terms of the number of map neurons and the hierarchy [14]. After the training stage of SOM mean quantization error for every neuron i (mqe_i) is calculated as the average distance of every context recognised by the neuron i to its weight vector. The average MQE_j for whole map on level j is computed, too. If $MQE_j \geq \tau_1 \cdot MQE_{j-1}$ then the additional row or column of neurons is added to the map and the training stage is repeated. In the other case the mqe_i for every neuron is compared to MQE_j. If $meq_i \geq \tau_2 \cdot MQE_{j-1}$ then another layer of the map is created for contexts recognised by the neuron i.

[4] Not all senses are represented in the data equally; distribution of senses is biased towards a few frequent senses.

C. Agglomerative and Divisive Clustering

Agglomerative and divisive clustering algorithms produce *hierarchical* clustering trees called dendrograms. Agglomerative clustering starts in a situation that each context is contained in a separate cluster, then in each step two clusters maximising *criterion function* are merged. On the other hand, divisive algorithms starts with all contexts in one cluster which are repeatedly bisected according to the criterion function. We are using existing implementation of hierarchical algorithms from CLUTO[5] [11]. We use *rbr* variant of divisive algorithm, i.e., standard bisecting clustering is employed and is further optimized according to criterion function [16].

Criterion function is very important aspect of both agglomerative and divisive clustering algorithms as it drives the whole process. There are many criterion function available [17]. We have tested standard criterion functions used with agglomerative algorithms, i.e.: single link (slink), complete link (clink), average link (upgma) and weighted variants of single (wslink), complete (wclink) and average links (wupgma).

The second group of criterion function including $i_1, i_2, \varepsilon_1, G_1, G_1', H_1, H_2$ can be used with both agglomerative and divisive algorithms. The exact form of those functions are given by [11]:

$$I_1 = \text{maximize} \sum_{i=1}^{k} \frac{1}{n_i} \Big(\sum_{\vec{v},\vec{u} \in S_i} sim(\vec{v},\vec{u}) \Big) \quad (1)$$

$$I_2 = \text{maximize} \sum_{i=1}^{k} \sqrt{\sum_{\vec{v},\vec{u} \in S_i} sim(\vec{v},\vec{u})} \quad (2)$$

$$\varepsilon_1 = \text{minimize} \sum_{i=1}^{k} n_i \frac{\sum_{v \in S_i, u \in S} sim(\vec{v},\vec{u})}{\sqrt{\sum_{v,u \in S_i} sim(\vec{v},\vec{u})}} \quad (3)$$

$$G_1 = \text{minimize} \sum_{i=1}^{k} \frac{\sum_{v \in S_i, u \in S} sim(\vec{v},\vec{u})}{\sqrt{\sum_{v,u \in S_i} sim(\vec{v},\vec{u})}} \quad (4)$$

$$G_1' = \text{minimize} \sum_{i=1}^{k} n_i^2 \frac{\sum_{v \in S_i, u \in S} sim(\vec{v},\vec{u})}{\sqrt{\sum_{v,u \in S_i} sim(\vec{v},\vec{u})}} \quad (5)$$

$$H_1 = \text{maximize} \frac{I_1}{\varepsilon_1} \quad (6)$$

$$H_2 = \text{maximize} \frac{I_2}{\varepsilon_1}, \quad (7)$$

where k is total number of clusters, S is total number of contexts to cluster, S_i is a set of contexts assigned to i-th cluster, $n_i = |S_i|$, and $sim(\vec{v},\vec{u})$ is similarity between two context vectors $\vec{v}$ and $\vec{u}$.

D. Graph Partitioning Based Clustering

We use an implementation of min cut graph partitioning algorithm from CLUTO [11]. This algorithm starts with creation of neighbourhood graph based on similarities between contexts and then applies min cut to partition the graph into disjoint regions. Min cut uses approach that the size of graph edges in a partition is minimal.

This approach achieved high quality in research on semi-automatic extension of Polish WordNet [18] and was also used in Polish WSD based on weakly-supervised settings using LexCSD algorithm [10].

III. Experiments

A. Evaluation Measures

Evaluation of clustering algorithms can be done in many ways [19]. Some of them are based on *external criteria*, i.e., the comparison of the resulting clustering solution with some pre-existing categories that were created manually. On the other hand, one can use an *internal criteria* without resorting to gold standard clustering. The most important drawback of evaluation using internal criteria is that good score does not always corresponds to good results of clustering in a given application [20]. As we have developed semantically annotated corpus (SCWSD, see Sec. III-B) we can use it for the need of evaluation. The problem with SCWSD is its small size, so there is a risk of not capturing all of the peculiarities and biases of some large corpora in SCWSD.[6]

We used several measures for evaluation to capture different aspects of created groups. For measuring how homogeneous clusters are we used *Purity*:

$$Purity(\Omega, C) = \frac{1}{N} \sum_{k} \max_{j} |\omega_k \cap c_j|, \quad (8)$$

where $\Omega = \{\omega_1, \omega_2, \ldots, \omega_k\}$ is a set of clusters, a $C = \{c_1, c_2, \ldots, c_j\}$ — a set of pre-existing categories. In our setting C is a set of contexts with ambiguous word annotated with the same sense. $Purity(\Omega, C) \in \langle 0, 1 \rangle$, where 1 is the best case. A drawback of $Purity$ is its preference for solutions with large number of groups. Assigning every context to a singelton cluster gives Purity of 1 [20].

The *Rand Index* measures accuracy on the basis of decisions performed for the subsequent context pairs. If we use TP for *true positive*, TN for *true negative*, FN for *false negative* and FP for *false positive.* the Rand Index is given by the following equation:

$$R_I = \frac{TP + TN}{TP + FP + FN + TN} \quad (9)$$

One of the drawbacks of using R_I for evaluation is the equal treatment of false positives and negatives. Using decision for context pairs we can also use standard measures of information retrieval, i.e., precision P, recall R and the harmonic mean of precision and recall F_β:

[5] CLUTO is a free software package implementing several clustering algorithms including partitioning, agglomerative and graph-based. Available at: http://glaros.dtc.umn.edu/gkhome/views/cluto/

[6] On the other hand, the total size of the dataset, i.e., 1344 contexts (Tab. I), is not very small in comparison to, e.g., [16], where the smallest dataset has 878 elements and the largest — 4069 elements.

$$P = \frac{TP}{TP + FP} \quad (10)$$

$$R = \frac{TP}{TP + FN} \quad (11)$$

$$F_\beta = \frac{(\beta^2 + 1)PR}{\beta^2 P + R} \quad (12)$$

Another way of measuring clustering quality is to use *Normalized Mutual Information* (NMI). NMI takes into account the trade off between quality and number of clusters as opposed to Purity.

$$NMI(\Omega, C) = \frac{MI(\Omega; C)}{[H(\Omega) + H(C)]/2} \quad (13)$$

$$MI(\Omega, C) = \sum_{k,j} P(\omega_k \cap c_j) log \frac{P(\omega_k \cap c_j)}{P(\omega_k)P(c_j)} \quad (14)$$

$$H(\Omega) = -\sum_k P(\omega_k) log P(\omega_k), \quad (15)$$

where mutual information $MI(\Omega, C)$ is normalized by entropy $H(\Omega)$ and probabilities can be counted using maximum likelihood estimation (MLE). The normalization by entropy is performed for penalizing clustering solutions with large number of clusters, as entropy tends to increase to maximum with number of clusters. Thanks to the normalization $NMI \in < 0, 1 >$, where 0 corresponds to random clustering.

Last method used for evaluation is a variation of F-Measure used by Kulkarni and Pedersen in SenseCluster system [21]. Its main idea is contained in a sentence: "One sense—one cluster". It means that each cluster must have unique sense label. The label of each cluster is determined by most frequent class of cluster members, but one sense label cannot be assigned to multiple clusters. In particular, having more clusters than senses force us to treat members of unlabeled groups as unclustered. With that assumption in mind the standard measures of precision P_p and recall R_p are defined as:

$$P_p = Purity(\Omega', C) \quad (16)$$

Where Ω' is set of labeled clusters, C is set of classes defined above.

$$R_p = \frac{\#hits}{\#total\ instances} \quad (17)$$

Where *#hits* is number of elements with sense accordant to cluster sense label, *#total instances* - number of all elements including outliers.

Having P_p and R_p, we use F_β, with $\beta = 1$:

$$F(P)_1 = \frac{2 P_p R_p}{P_p + R_p} \quad (18)$$

B. Corpus Description

For the need of evaluation we have used recently developed, manually disambiguated corpus called *Korpusik US*[7] (rough English translation: Small Corpus for WSD, henceforth SCWSD) [10].

The corpus consists of parts of IPI PAN Corpus [22]. Only 13 ambiguous words were annotated. The chosen words represent the variety of different problems for WSD; some of the senses have homonymous character, i.e., they represent separate homonyms of the same morphological base form. The sense inventory was based on extended version of Polish WordNet [18]. Performing evaluation only on limited set of words is called *Lexical Sample Task* [2]. The following words were chosen for annotation:

- agent: a person who represents a company or artist, secret agent, chemical agent
- automat: automaton, machine, telephone, a coin-operated automatic machine, submachine gun, automatic car transmission ;
- dziób: beak, bow, nose, front part of a ship, informal mouth, face (semantically marked)
- język: tongue, natural language
- klasa: category, class, rank, classroom, mathematical category, savoir-vivre, social class, subject, excellence
- linia: line, route, edge, line separating two areas, power line, assembly line, telephone line, row, lineage, contour, figure, ruler, line of defence, line of products for sale, credit line, geometric line.
- pole: field, area, playing field, physical field.
- policja: police (organization), police station, 'policemen'.
- powód: reason', plaintiff.
- sztuka: art, act of craftsmanship, item, a beautiful girl, dramatic play, theatrical performance of a play, an amount of fabric (for example wool), bale, a piece of meat.
- zamek: castle, lock, zipper, breechblock, trap in hockey, a part of machine or any device that stops its action.
- zbiór: set, group, mathematical set, collection, harvest, an act of harvesting, an exercise book, file.
- zespół: team, band, group of machines, complex of buildings, syndrome, sport team, botanical 'association'.

The annotation of the corpus was done by two native speakers of Polish: a professional linguist and a computational linguist. The exact corpus statistics are show in Tab. I. There are 1344 annotated examples. After the annotation process we measured interannotator agreement using Cohen's κ [23]. The agreement is surprisingly high, 0.88 for whole corpus. Such an agreement is very high in comparison with other corpora annotated with fine-grained WordNet-based senses [2].

SCWSD was previously used in research on WSD for Polish [10]. Its previous version (sense inventory base on early version Polish WordNet) was also used in [9], [24]. The best reported precision in [10] using supervised classifiers is 72.42%. There is also a baseline associated with a corpus called Most Frequent Sense baseline (MFS), i.e., using a heuristic classifier that chooses always the most frequent sense. For SCWSD the MFS baseline is 44.56% (weighted average for all the words).

[7] The corpus is available for browsing http://nlp.pwr.wroc.pl/webann

TABLE I
SMALL CORPUS FOR WSD (SCWSD) — STATISTICS

C. Experimental Settings

The experimental settings are the same as in experiments presented in [10], where approaches based on supervised and weakly supervised were tested. We use only small manually annotated corpus because we want to have a clear point of comparison with previous work. We use the same features as in [10], i.e., bag of words, to simplify discussion. Contrary to [10], there is no need to split the data into training and test sets for evaluation because of unsupervised nature of clustering algorithms, cf [16], [17], [20].

This features are extracted from text in the following process. First a text window surrounding ambiguous word of ±20 segments (tokens) is constructed.[8] Then the occurrence of a word[9] is noted in a feature vector. Every dimension corresponds to different word. The resulting vectors are sparse. Instead of using raw frequencies we tested a few weighting schemes coupled with *cosine* function for measuring similarities between contexts. The following measures were tested:

- Term frequency, inversed document frequency (henceforth, *tf.idf*), see [20]. We assume, that document is the same as context in this measure.
- *Logent* — values were scaled with logarithm and divided by entropy of a context (standard Shanon entropy counted as $\sum p \log p$, where p is estimated using MLE). This technique was proposed in *Latent Semantic Analysis* by Landauer and Dumais [26].
- Mutual information (definition following work of Lin [27]). We use *lin_cos* for denoting this measure.
- Discounted pointwise mutual information (*pmi*), see [28]. The most important difference between pmi and lin_cos is that pmi uses discounting factor to address the problem of overestimation of mutual information in case of infrequent events.
- Rank Weight Function (RWF) based on mutual information defined by Lin (*rwf_lin*), see [18].
- Rank Weight Function (RWF) based on pointwise mutual information (*rwf_pmi*), see [18].

Both RWF function works by using ranks instead of exact feature values. It allows for certain level of generalization from word occurrence frequencies, which can be accidental. RWF approach was previously used in a task of finding similar words in large corpus with very good results [18].

D. Results

Tab. II-VII present results averaged for all the words using different weighting schemes. The first thing to notice is that the results are very hard to grasp. We have noticed several regularities. Firstly, the results of GHSOM evaluation are high in terms of Purity, NMI and Rand Index and very low in terms of F-Measures. Secondly, the amount of data to analyse is very high: 5 weighting measures $\times$ 5 evaluation measures $\times$ 25 algorithm variants. And last but not least, there is no "best" algorithm, i.e., an algorithm that would rank highest in all the different evaluation measures.

To tackle the first problem we will analyse GHSOM in isolation from the other algorithms. We can observe, that the Purity measure for GHSOM has always got the highest values (over 70%). In case of growing hierarchical SOM, we cannot simply define desirable number of clusters, which is strictly determined by number of neurons in each layer. In our — relatively small — set of input data, reading results from all network layers leads to a number of singleton clusters. As was written above, Purity of such clusters equals 1. This fact artificially increases results and clearly shows the weakest side of the Purity measure. Evaluation using F-Measures shows totally opposite results, discarding GHSOM as a efficient clustering method.

There are also some *not available* results (*n/a*) for logent weighting in GHSOM rows. In this particular case, we observed uncontrolled growing of first layer of neural network. Tunning the parameters was also not helpful. The size of the layer reaching 20x20 (which represents 400 clusters), while having data set with only several groups was obviously too big, so we decided to discard such results. The growth of the network might be caused by the nature of logent weighting on this particular dataset. By taking logarithms of feature values the vectors become extremely sparse, because of large number of ones in the features.

One of the most important properties of GHSOM, i.e., not having to specify number of clusters in advance, becomes its most important drawback using standard evaluation measures. To overcome problems with GHSOM two steps can be taken: analysing the resulting network for searching the desired number of clusters or using evaluation measures that can capture other positive properties of GHSOM, most importantly the spatial relations between neurons.

For resolving the second problem with large amount of data to analyse we tested whether some of the evaluation measures are correlated to each other. We used Spearman rank correlation coefficients[10]. The results of this evaluation were

[8] A segment (token) is defined as word, words separators, but some words can be split onto several segments. For discussion see [25].

[9] A word is a fuzzy concept, more specifically we use a base forms of a word coupled with its flexemic class.

[10] We tested also Pearson's correlation coefficient. The results were also suggesting high correlation among measures, but rank correlation coefficient is more robust to outliers, in our case — GHSOM.

interesting: in most cases correlation was very high between Purity, NMI and RI. Average Spearman's $\rho = 0.83$ and the two-tailed p-value were always lower then 0.0001. Correlation between F_1 and $F(P)_1$ is lower, but also high ($\rho = 0.64$), where usually F_1 is a little bit lower. As $F(P)_1$ allows only for assigning given sense label to cluster only once, we will focus only on decision-based F_1, which scores every pair of clustered contexts.

Reducing the measures to only two (i.e., Purity and F_1) does not solve the problem of choosing the best combination of clustering and weighting scheme. Thus we created two rankings of all the pairs of <clustering algorithm, weighting scheme> ordered by Purity (R_1) and F_1 (R_2). To rank different weighting schemes we use a sum of average of both ranks. This approach can be interpreted as choosing a weighting scheme for which on average the clustering solutions are better then the other. The best weighting scheme is pmi, followed by lin_cos, tf.idf, rwf_lin, rwf_pmi and logent. The difference between pmi using discounting factor and without discounting factor (lin_cos) is minor. The same applies to RWF versions of mutual information based measures. The best results were achieved by agglomerative clustering with weighted average link criterion function while using pmi weighting (Agglo(wslink) in Tab. V). Following are measures using both agglomerative and divisive clustering using (weighted and unweighted) average link criterion for Agglo and e1, h2 and g1 for Rbr. The worst performing algorithms are K-means and K-medoids, which is not surprising—we are using them as another way of setting a baseline.

Those results are interesting, because in related tasks graph partitioning was performing better then the other algorithms. Also, best result achieved for pmi-based weighting scheme is interesting, but not as surprising as these family of measures achieves very good results in the task of finding similar words [18].

The results can be compared to precision of supervised algorithms, because precision corresponds to Purity in our evaluation. All the algorithms beat the baseline of selection always most frequent sense. The best supervised classification algorithm tested on the same dataset, using the same feature set achieved precision of 72.42% as reported by [10], the best clustering algorithm have Purity=71.36%. These results is very high, as usually unsupervised approaches have troubles with beating MFS baseline [2]. This can be explained with high quality of corpus annotations, small corpus size and partially balanced sense distribution in corpus.

TABLE II
AVERAGE RESULTS FOR TF.IDF WEIGHT

	Purity	**NMI**	**RI**	**F_1**	**$F(P)_1$**
Agglo(clink)	49,80	0,137	0,515	41,03	42,43

IV. CONCLUSIONS AND FURTHER WORKS

This paper presented evaluation of selected clustering algorithms in task of Word Sense Disambiguation for Polish. We have used simple lexical features to represent contexts of ambiguous words. The features were weighted using different weighting schemes. Using pointwise mutual information as a weighting scheme gave best results on average.

Evaluation of clustering was performed on manually disambiguated corpus using five standard evaluation measures [20], [21]. Interestingly, in our settings some of the measures are highly correlated, thus it is only necessary to use two of them, e.g., Purity and F-Measure. This might be caused by the fact, that we know how many clusters are in the data in advance, but one of the problem that the more elaborated measures are trying to address is the problem with generation of large number of clusters.

The results of evaluation are interesting. Divisive clustering algorithm are not worst then agglomerative. Previously used graph partitioning approach is sub-optimal. Not surprisingly, K-means and K-medoids produce clustering of lowest quality.

In the future we are planing to extend this work in a few ways. We want to evaluate some clustering algorithms that were tailored to a problem of Word Sense Disambiguation (e.g., Clustering by Committee [29]). Testing using more elaborated features can give more insight into nature of different clustering schemes. Evaluation of the algorithms on large corpus is needed (f.e., using whole IPI PAN Corpus [22]), because used corpus is small and potentially does not capture peculiarities of large amount of unrestricted texts. Of course, such evaluation has to be performed manually, based on examination of only statistical significant samples of results.

Application-based evaluation of clustering in performing WSD in weakly-supervised settings is also needed. We plan to use LexCSD algorithm for this purpose [9], [10]. This is especially important, as we have used graph partitioning clustering, which occurred to be a sub-optimal according to evaluation presented in this work.

Generation of First-Order Expressions from a Broad Coverage HPSG Grammar

Ravi Coote and Andreas Wotzlaw

Abstract—**This paper describes an application for computing first-order semantic representations of English texts. It is based on a combination of hybrid shallow-deep components arranged within the middleware framework Heart of Gold. The shallow-deep semantic analysis employs Robust Minimal Recursion Semantics (RMRS) as a common semantic underspecification formalism for natural language processing components. In order to compute efficiently first-order representations of the input text, the intermediate RMRS results of the shallow-deep analysis are transformed into the dominance constraints formalism and resolved by the underspecification resolver UTool. First-order expressions can serve as a formal knowledge representation of natural text and thus can be utilized in knowledge engineering or textual reasoning. At the end of this paper, we describe their application for recognizing textual entailment.**

Index Terms—**recognizing textual entailment; logical inference; HPSG-based text analysis; first-order logics**

I. Introduction

MANY applications depend on a formal representation of natural language sentences in form of *first-order logic* (FOL). For instance, in recognizing textual entailment [1] the approaches based on logical inference depend on FOL formulas as a semantic representation of the input texts. Furthermore, enhanced first-order knowledge representations of natural language sentences can be accomplished by integrating knowledge from resources like the lexical base *WordNet* [2] or the ontological database *YAGO* [3] into FOL formulas. Other applications can be found in the area of *knowledge engineering* and *information integration* (see, e.g., [4]).

Basically, for a production of fine-grained FOL expressions a broad coverage of syntactic structures and English words is preferable. To this end, the *English Resource Grammar* (ERG, see [5]), a broad-coverage, linguistically precise *Head-driven Phrase Structure Grammar* (HPSG) of English can be used. ERG utilizes *Minimal Recursion Semantics* (MRS, see [6]) as a formalism for building scope underspecified semantic representations from HPSG grammars.

Combining deep parsing techniques with shallow ones can make parsing processes more robust, i.e., less error-prone and faster [7]. For that reason, we use *Heart of Gold* (HOG, see [7]), a framework for combining NLP components like, e.g., shallow statistical parsers, named entity recognizers, and deep syntactic parsers.

Neither literature nor implemented systems producing FOL from an HPSG grammar with RMRS as semantic formalism could be found so far. For that reason, we decided to build such a system which we present in this paper.

Related work: Other approaches of wide coverage syntactic and semantic analysis with FOL output as input for textual entailment were presented in [8]. However, in contrast to our approach they are not based on a purely linguistically motivated grammar formalism with a broad coverage like, e.g., ERG. Furthermore, our formula generation system has successfully been employed as underlying analysis basis in a framework for recognizing textual entailment (see [9]).

II. Semantic Representation Formalisms

In this section we describe shortly the semantic formalisms MRS and RMRS on which our application builds.

Minimal Recursion Semantics: Scope underspecification is a well-known technique in computational semantics of natural language [10]. MRS is a description language over formulas of FOL languages with *generalized quantifiers*. For instance, the sentence *"Every wizard acts in a circus"* illustrates the well-known problem of scopal ambiguity. Is it one and the same circus in which every wizard acts or are there possibly several different circuses in which the wizards act? Thus, the sentence has two scopal *readings* which can be represented by the following FOL formulas:

$$a(x_9, circus(x_9), every(x_5, wizard(x_5), and(act(e_2, x_5), in(e_2, x_9)))) \quad (1)$$

$$every(x_5, wizard(x_5), a(x_9, circus(x_9), and(act(e_2, x_5), in(e_2, x_9)))). \quad (2)$$

MRS allow multiple formulas, which differ only in their scopal configuration like, e.g., (1) and (2), to be expressed with exactly one single compact formula. To achieve this, in MRS predicates of the formulas are decoupled from each other by removing any nesting of predicates, assigning different *labels* $l_1, l_2, ...$ to them, and adding *holes* $h_1, h_2, ...$ to scope relevant predicates. A single scope underspecified representation of (1) and (2) above can then be given as an MRS by

$$\begin{aligned} < \{ & l_3 : every(x_5, h_6, h_4), l_7 : wizard(x_5), \\ & l_8 : act(e_2, x_5), l_8 : in(e_{10}, e_2, x_9), \\ & l_{11} : a(x_9, h_{13}, h_{12}), l_{14} : circus(x_9)\}, \\ & \{h_6 \ qeq \ l_7, \ \ h_{13} \ qeq \ l_{14}\} > \end{aligned} \quad (3)$$

978-83-60810-27-9/09/$25.00 © 2010 IEEE

More specifically, (3) contains a set of labeled (decoupled) first-order predicates ($l_3 : every, l_7 : wizard, ...$) with holes ($h_6, h_4, ...$) and a set of *qeq-constraints* ($h_6\, qeq\, l_7, ...$). A *qeq-constraint* states a directive enforcing a particular label l to be in the scope of a particular hole h. In (3), the first qeq-constraint enforce label l_7 to be in the scope of h_6. Scope specified formulas are obtained by assigning, or *plugging*, labeled predicates to holes in a manner that is consistent with the qeq-constraints. For instance, (1) is obtained by plugging l_7 into h_6, l_{14} into h_{13}, l_3 into h_{12}, and l_8 into h_4. Such formalized assignments are called also pluggings.

Robust Minimal Recursion Semantics: RMRS is a generalization of MRS. It can not only be underspecified for scope as MRS, but also partially specified, e.g., when some parts of the text cannot be resolved by a given NLP component. Furthermore, in RMRS due to possible lack of morphological analysis, predicates are allowed to lack for their arguments. Hence, it can be used as a semantic representation formalism of shallow NLP components. HOG supports integration of shallow NLP components by using RMRS as an exchange format. Additionally, RMRS defines an in-group relation ing which describes conjunctively connected labels, e.g., the in-group relation $\{h8\ ing\ h10001\}$ in Figure 2. For a detailed description of MRS and RMRS see [6] and [11], respectively.

III. Generation of FOL Formulas

The application for generation of FOL formulas illustrated in Figure 1 consists of two parts:

a) Semantic analysis with the shallow-deep approach realized by HOG, and
b) Resolving of RMRS realized by UTool.

Aditionally, a graphical user interface (GUI) enclosing these parts was developed to control the analysis process and to inspect the results of the analysis components.

HOG is configured to control the overall workflow of the hybrid shallow and deep analysis. In particular, it transforms and transports data among various NLP components of the application. First, HOG processes the input text and computes its semantic representation as RMRS. Afterwards, the generation of *pluggings* representing readings of the RMRS is performed with the underspecification solver *UTool* [12]. Finally, the FOL formulas are constructed out of the computed pluggings and the original RMRS. In the following the processing steps are described in more detail.

Syntactic-semantic analysis: Shallow parsing techniques are used to retrieve superficial information from the sentences without a deep structure. In our system shallow parsing begins with tokenization by JTok (distributed with HOG) which splits the sentence by its tokens. Those tokens are passed to the statistical part-of-speech tagger TnT [13]. In parallel to these two components, SProUT [14], a finite state machine named entity recognizer, prepares information about named entities found. The results from TnT and SProUT are merged together via XML-transformation from HOG and prepared for input to the deep HPSG parser PET [15]. In that manner, PET is supplied with information for words which possibly are not contained in the deep HPSG lexicon (e.g., unusual named entities). Afterwards, PET parses the pre-annotated input text by employing the HPSG grammar ERG. With the help of this processing step, a fully syntactic annoted phrase structure is computed, from which predicate argument structures can directly be established. During the deep HPSG analysis, PET composes (robust minimal recursion) semantics according to the semantic algebra for HPSG grammars [16]. According to the analysis procedure described above, HOG produces the RMRS in Figure 2 for the following example sentence:

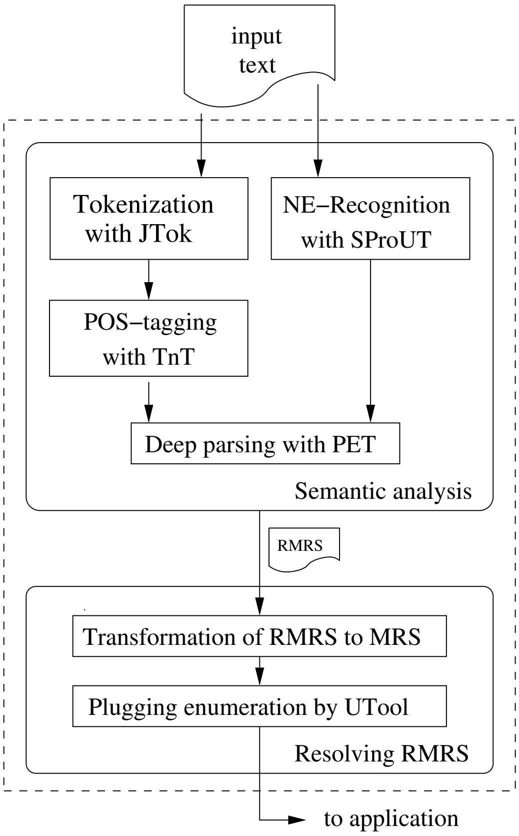

Fig. 1. Overall system for formula generation.

```
A wizard acts in a circus show in Paris.
```

Resolving RMRS: Unfortunately, a sentence with n quantifiers can have up to $n!$ readings [6], e.g., RMRS in Figure 2 with the quantifiers a_q, $udef\_q$, and $proper\_q$ has 4! scopal readings. More adverse is that about 8% of the sentences of the Rondane treebank provided with ERG have more than 100,000 readings according to the ERG analyses, and about 4% have more than one million readings [17]. Thus, it is required to enumerate all readings efficiently and to eliminate those which are logically equivalent. These tasks are performed by UTool in time of $O(n^2)$ per solved form (see [18]).

As in Section II described, for MRS the scopal readings are obtained by plugging labels l to holes h. RMRS has to be resolved analogously. However, in its standard configuration, UTool resolves only MRS. Therefore, by following the in-

$$\begin{bmatrix}
\text{TEXT} & \\
\text{TOP} & h1 \\
\text{RELS} & \left\{ \begin{array}{lll}
\begin{bmatrix} \textit{\_a\_q} & \\ \text{LBL} & h3 \\ \text{ARG0} & x5 \\ \text{RSTR} & h6 \\ \text{BODY} & h4 \end{bmatrix} &
\begin{bmatrix} \textit{\_wizard\_n} & \\ \text{LBL} & h7 \\ \text{ARG0} & x5 \end{bmatrix} &
\begin{bmatrix} \textit{\_act\_v} & \\ \text{LBL} & h8 \\ \text{ARG0} & e2 \\ \text{ARG1} & x5 \end{bmatrix} \\
\begin{bmatrix} \textit{\_in\_p} & \\ \text{LBL} & h10001 \\ \text{ARG0} & e10 \\ \text{ARG1} & e2 \\ \text{ARG2} & x9 \end{bmatrix} &
\begin{bmatrix} \textit{\_a\_q} & \\ \text{LBL} & h11 \\ \text{ARG0} & x9 \\ \text{RSTR} & h13 \\ \text{BODY} & h12 \end{bmatrix} &
\begin{bmatrix} \textit{compound\_rel} & \\ \text{LBL} & h14 \\ \text{ARG0} & e16 \\ \text{ARG1} & x9 \\ \text{ARG2} & x15 \end{bmatrix} \\
\begin{bmatrix} \textit{udef\_q\_rel} & \\ \text{LBL} & h17 \\ \text{ARG0} & x15 \\ \text{RSTR} & h19 \\ \text{BODY} & h18 \end{bmatrix} &
\begin{bmatrix} \textit{\_circus\_n} & \\ \text{LBL} & h20 \\ \text{ARG0} & x15 \end{bmatrix} &
\begin{bmatrix} \textit{\_show\_n} & \\ \text{LBL} & h10002 \\ \text{ARG0} & x9 \\ \text{ARG1} & u21 \end{bmatrix} \\
\begin{bmatrix} \textit{\_in\_p} & \\ \text{LBL} & h10003 \\ \text{ARG0} & e23 \\ \text{ARG1} & e2 \\ \text{ARG2} & x22 \end{bmatrix} &
\begin{bmatrix} \textit{proper\_q\_rel} & \\ \text{LBL} & h24 \\ \text{ARG0} & x22 \\ \text{RSTR} & h26 \\ \text{BODY} & h25 \end{bmatrix} &
\begin{bmatrix} \textit{named\_rel} & \\ \text{LBL} & h27 \\ \text{ARG0} & x22 \\ \text{CARG} & \text{Paris} \end{bmatrix}
\end{array} \right\} \\
\text{HCONS} & \{h6 \text{ qeq } h7, h13 \text{ qeq } h14, h19 \text{ qeq } h20, h26 \text{ qeq } h27\} \\
\text{ING} & \{h8 \text{ ing } h10001, h8 \text{ ing } h10003, h14 \text{ ing } h10002\}
\end{bmatrix}$$

Fig. 2. RMRS of shallow deep analysis of the example sentence as attribute value matrix.

structions from [11], we developed an XSLT-based procedure for transforming RMRS into MRS to make the output RMRS of HOG suitable for resolving with UTool. Afterwards, UTool can automatically compute the assignments according to which the labels should be linked to holes. In particular, the following procedure is applied (see [17] for details):

1) Translation of MRS into *dominance constraints* [17], a closely related underspecification formalism, and
2) Efficient enumeration of solved forms of the dominance constraints.

Dominance constraints can be represented as *dominance graphs*. Thus, an MRS corresponds to a dominance graph. In a dominance graph originating from an MRS, nodes correspond to MRS labels h whereas (dashed drawn) dominance edges correspond to MRS qeq-constraints. For instance, the RMRS from Figure 2 which was produced by HOG is translated by UTool into dominance constraints which is shown as a dominance graph in Figure 3.

UTool computes all solved forms of the dominance graph according to the algorithm that is based on graph connectivity (see [17]). One possible reading of the dominance graph from Figure 3 (and simultaneously of the RMRS in Figure 2) is given as a solved dominance graph in Figure 4.

Consequently, from each solved dominance graph, UTool recursively generates a set of pluggings. The plugging for Figure 4 looks like the following one:

```
h24(h27,h11(h17(h20,h14),h3(h7,h8)))
```

Finally, we parse all pluggings sequentially and replace each label by its corresponding predicates according to the original MRS. After that procedure is finished, we get the formula for the first plugging:

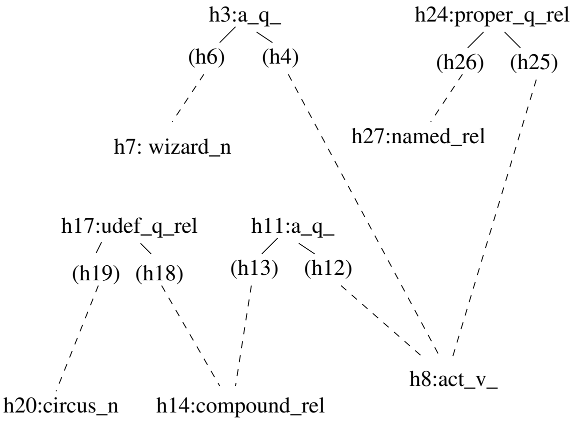

Fig. 3. Dominance graph.

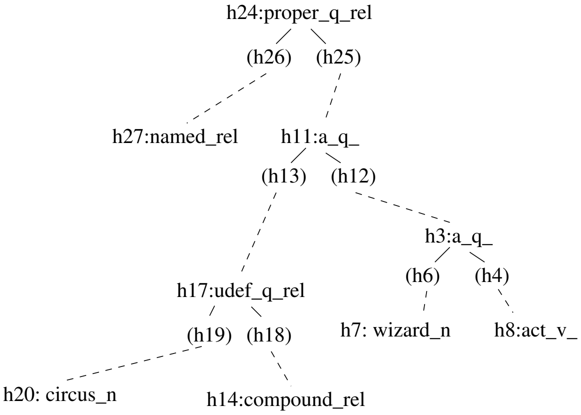

Fig. 4. Solved dominance graph.

```
proper_q_rel(X22,
    named_rel(X22,paris),
    a_q_rel(X9,
        udef_q_rel(X15,
            circus_n_1_rel(X15),and(
            compound_rel(E16,X9,X15),
            show_n_of_rel(X9))),
            a_q_rel(X5,
                wizard_n_1_rel(X5),and(
                act_v_1_rel(E2,X5),and(
                in_p_rel(E10,E2,X9),
                in_p_rel(E23,E2,X22))))))
```

IV. Applications Using FOL Expressions

There are many applications depending on a logical representation of natural language (see, e.g., [1] or [4]). The application presented here was successfully implemented in our experimental system for recognizing textual entailment (RTE) [9]. In RTE [19], the aim is to identify the logical relations between two texts, thesis T and hypothesis H, e.g.,

```
T: A wizard acts in a circus show in Paris.
H: Some magician remains in a capital
   town of France.
```

In particular, given a pair $\{T, H\}$, our system was designed to find answers to the following conjectures [20]:

1) T entails H,
2) $T \wedge H$ is inconsistent, or
3) H is informative with respect to T, i.e., is H a new and consistent information in relation to T?

In the example above, T entails H. To prove it, our system uses model-theoretic approach combined with logical inference. Syntax and semantics of the texts representing T and H are first analyzed with HOG and the resulting semantic representations in form of RMRS are translated into FOL as described in Section III. Afterwards, they are passed to external automated reasoning tools like *model builders* and *theorem provers* which check what kind of logical relation between T and H holds.

V. Conclusion and Future Work

In this paper an application based on a combination of linguistic resources and tools is presented that enable for an efficient generation of first-order logic formulas from a broad coverage HPSG grammar combined with shallow analyses. Since the semantic composition is performed by a deep HPSG parsing, it is required for a successfull generation of FOL expressions that the deep parsing succeeds. Unfortunately, it can fail if well-formedness of syntactical structures is too weak, e.g., in SMS dialogues or transcriptions of spontaneous speech.

The application can be improved through integration of coreference resolvers, so that different object variables pointing to the same individual can be identified. Finally, the application could be supplemented with statistical models describing scopal position settings in natural language sentences, so that scope resolved readings are produced in order of descending probability of their occurrence.

Furthermore, RMRS is the common semantic formalism for the HPSG grammars within the context of the *LinGO Grammar Matrix* [21] like the Japanese HPSG grammar *JaCY* [22], the *Korean Resource Grammar* [23], the *Modern Greek Resource Grammar* [24], the Norwegian *NorSource Grammar* [25], and the Spanish Resource Grammar *SRG* [26]. Because all of these grammars interface to RMRS, an exchange of the ERG in our system can be considered and a high degree of multilinguality achieved.

Acknowledgment

The authors would like to thank Matthias Hecking for many fruitful discussions on the work presented in this paper.

***Abstract*—Modeling of optimized motion controller is one of the interesting problems in the context of behavior based mobile robotics. Behavior based mobile robots should have an ideal controller to generate perfect action. In this paper, a nonlinear identification Takagi-Sugeno fuzzy motion controller has been designed to track the positions of a moving object with the mobile platform. The parameters of the controller are optimized with Particle swarm optimization (PSO) and stochastic approximation method. A gray predictor has also been developed to predict the position of the object when object is beyond the view field of the robot. The combined model has been tested on a Pioneer robot which tracks a triangular red box using a CCD camera and a laser sensor.**

I. Introduction

OBJECT detection and tracking is an essential ingredient of any motion planning controller employed for mobile robot navigation. Mobile robot navigation is known as the ability of a robot to act based on its knowledge and sensor values in order to reach its goal position as efficiently and as reliably as possible [1]. Wide variety of sensors such as sonar, laser range finder, infra-red, Global Positioning System (GPS) and vision are used for mobile robot navigation. The vision based navigation is widely used [2], since vision gives the rich information about the surroundings. Vision is an attractive sensor as it helps in the design of economically viable systems with simpler sensor limitations. It facilitates passive sensing of the environment and provides valuable information about the scene that is unavailable to other sensors [3].

An ample of work has been done on vision based object tracking. Ramesh et.al. in [4] proposed the Mean shift algorithm for object tracking that can be used for the images with static distribution. The Continuously Adaptive Mean Shift Algorithm (CAMShift), which is an adaptation of the Mean Shift Algorithm has been proposed by Bradski [5] to track the head and face movement using a one dimensional histogram (hue) consisting of quantized channel from the HSV color space. CAMShift operates on a probability density image obtained by histogram back-projection. In this paper, a hybrid CAMShift algorithm [6], that overcomes the assumption of single hue, has been used for object tracking. The computational cost of mean matching algorithm used in the hybrid CAMShift algorithm is high. So, instead of using mean matching algorithm for the detection of object when the CAMShift fails to detect the object, a gray predictor has been used to predict the position of the object. Gray predictor re-initializes the CAMshift window not only when CAMshift fails to detect the object but also when the object goes out from the robot's view.

The outputs of the hybrid CAMShift algorithm are the centroid coordinates of the object in the image frame. In order to obtain the global position and orientation of the object or even just to determine their relative pose, various algorithms of calibration and transformation are required. All the proposed approaches formulate the vision-based navigation problem as a two-step process: first, to transfer the visual features back to pose information, and then make a motion plan in the pose space. The calibration techniques, that transfer the visual features from image space to pose space introduce unnecessary uncertainty into the system. In this paper, a simple transformation technique has been proposed to transfer centroid coordinates of the object from image frame to the robot frame.

Once the coordinates of the object centroid are known in the robot frame, the next task is to design motion controller to effectively track the object. Since the primary focus of machine intelligence and advanced robotics is to capture the human faculties in the robot, fuzzy logic controllers are often a good choice. These controllers are developed to utilize human expert knowledge in controlling various systems and they have capability to express knowledge in the form of linguistic rules. Among various fuzzy modelling themes, the Takagi-Sugeno (T-S) model has been one of the most popular frameworks as it exhibits both high nonlinearity and simple structure [7][8]. In this paper, a T-S fuzzy controller has been modeled to control the motion of the robot while tracking the object. The structure identification of the premise part (i.e. membership functions) of rules of T-S fuzzy controller is carried out using PSO [9], while the identification of consequent part (i.e. weight parameters) of rules of T-S fuzzy controller is carried out using stochastic approximation method [10].

II. Outline of our approach

The goal of this work is to design a vision and laser sensor based optimized motion controller for the mobile robot to make it track the moving object in an effiecient manner. The outline of our approach for tracking the moving object is illustrated in figure 1. The first step inculdes the initialization of the robot and selection of object in the current frame. Next, frames are captured from the resulting video stream and the hybrid CAMShift algorithm is run over to detect the presence of the object in the scene. In case object is detected the algorithm returns the centroid coordinates of the object in image frame. If hybrid CAMShift fails to detect the object then the output of algorithm will be origin coordinates. Failure of the algorithm occurs either due to fast motion of the object or when the object goes out from the robot's view. In case of failure of the algorithm, a gray predictor is used to predict the centroid coordinates of the object. If the predicted x-coordinate lies in the range of image width, then the failure of the algorithm is due to fast motion of the object. In this case, the center coordinates of the CAMShift window are replaced by the predicted coordinates of the gray predictor. In case, when predicted x-coordinate does not lies in the range of image width, the reason of the algorithm failure is the absence of the object in the robot's view. The robot is then commanded to turn by an angle, calculated using the predicted x coordinate as follows:

$$\beta = -\frac{\phi}{2} + \frac{x}{x_{max}}.\phi \qquad (1)$$

where, β is the required turning angle, x_{max} is the maximum x coordinate of the image (width of the image in pixels), ϕ is the view angle of the camera.

The CAMShift window is then reinitialized with the center x coordinate of the window as $(x_{max}/2)$ and center y coordinate of the window as the predicted y coordinate of the gray predictor. In both the cases, the CAMShift window size is taken to be equal to its initial window size. Once the object centroid coordinates are obtained in the image frame, a coordinate converter, as described in section IV, is used to transform the object centroid coordinates from the image frame to the robot frame. The object centroid coordinates in the robot frame are then sent to an optimized T-S fuzzy motion controller, described in section VI, to generate desired translational and rotational velocities for the robot. The robot is then commanded to move with the translational and rotational velocities as generated by the controller.

Rest of the paper is organized as follows. In section III, the gray fuzzy predictor is discussed to predict the position of the object when it goes out from the robot's view or the hybrid CAMShift algorithm fails to detect the object. Section IV gives the details of the transformation of object coordinates from the image frame to the the robot frame. Section V briefly explains the PSO method and the T-S fuzzy model. Section VI presents modelling of the T-S fuzzy controller for the object tracking using PSO and stochastic approximation method. Experimental results are presented in section VI and finally the paper is concluded in section VII.

III. Gray predictor

A system with partial known information and certain unknown information is defined as a gray system. The gray theory, originally developed by Deng [11], employed the method of data generation instead of statistic regulation, to obtain more regular generating sequence from those initial random data. The gray prediction is to establish a gray model extending from the past information to the future based upon the past and present known or undeterminate information. Then the gray model can be used to predict the future variation trend of the system.

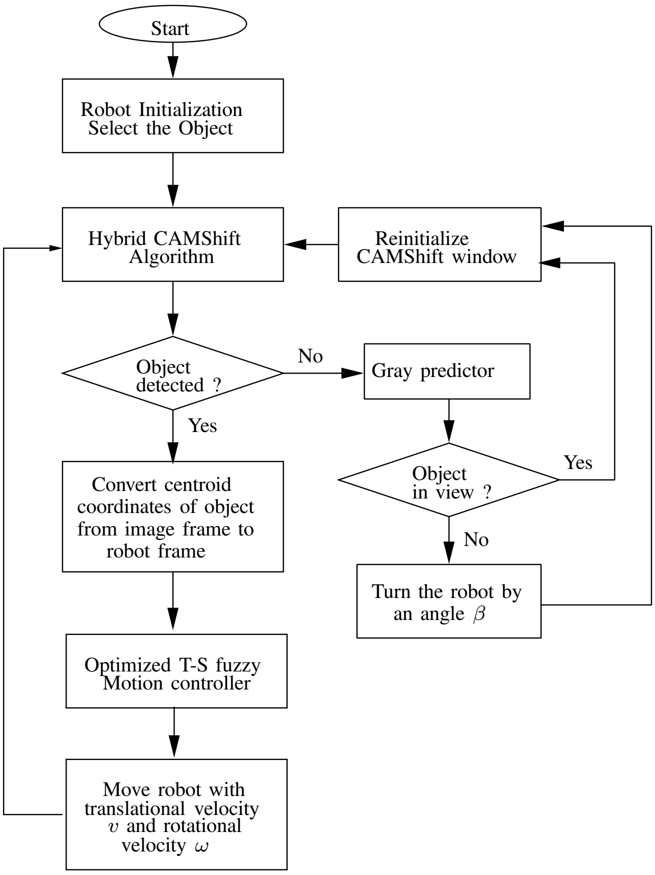

Fig. 1. flow diagram of our approach

Gray Prediction model for tracking The procedure of gray prediction model is as follows:

- Establish the initial sequence from observed data

$$\mathbf{x}^{(0)} = (x^{(0)}(1), x^{(0)}(2), x^{(0)}(3), ..., x^{(0)}(n) \qquad (2)$$

where, $x^{(0)}(i)$ represent the base line data with respect to time i.

- Generate the first-order accumulated operation sequence (AGO) sequence $\mathbf{x}^{(1)}$ based on the initial sequence $\mathbf{x}^{(0)}$

$$\mathbf{x}^{(1)} = (x^{(1)}(1), x^{(1)}(2), x^{(1)}(3), ..., x^{(1)}(n) \qquad (3)$$

where,

$$x^{(1)}(k) = \sum_{i=0}^{k} x^{(0)}(i) \qquad (4)$$

- Compute the mean value of the first-order AGO sequence:

$$z^{(1)}(k) = 0.5x^{(1)}(k) + 0.5x^{(1)}(k-1) \qquad (5)$$

- Define the first-order gray-differential equation of sequence $\mathbf{x}^{(1)}$ as:

$$\frac{dx^{(1)}(k)}{dk} + az^{(1)}(k) = b \qquad (6)$$

  where, a and b express the estimated parameters of gray prediction model.

- Utilize the least square estimation, we can drive the estimated first-order AGO sequence $\hat{x}^{(1)}(k+1)$ and the estimated inversed AGO sequence $\hat{x}^{(0)}(k+1)$ as follows:

$$\hat{x}^{(1)}(k+1) = \left[x^{(0)}(1) - \frac{b}{a}\right]e^{-ak} + \frac{b}{a} \qquad (7)$$

$$\hat{x}^{(0)}(k+1) = \hat{x}^{(1)}(k+1) - \hat{x}^{(1)}(k) \qquad (8)$$

  where, parameter a and b can be conducted by following equations:

$$\left[\begin{array}{c} a \\ b \end{array}\right] = (B^T B)^{-1} B^T y \qquad (9)$$

$$B = \left[\begin{array}{cc} -\frac{1}{2}(x^{(1)}(1) + x^{(1)}(2)) & 1 \\ -\frac{1}{2}(x^{(1)}(2) + x^{(1)}(3)) & 1 \\ \cdots & .. \\ -\frac{1}{2}(x^{(1)}(n-1) + x^{(1)}(n)) & 1 \end{array}\right] \qquad (10)$$

$$y = \left[x^{(0)}(2), x^{(0)}(3), x^{(0)}(4), ..., x^{(0)}(n)\right]^T \qquad (11)$$

In this paper, we modeled two gray predictor to predict the x and y coordinate of the object centroid. We used last six centroid coordinates to generate accumulated operation sequence.

IV. Transformation of the object coordinates from the image frame to the robot frame

To design any motion controller for the robot, it is necessary to transform the coordinates of the gravity center of the object from the image frame to the robot frame. As x coordinate of the object in the image frame is invariant to the size (width) of the object, it can be used to calculate the direction of the object with respect to the robot. But y coordinate of the object in the image frame varies with the size (height) of the object, so, it cannot be used to determine the distance of the object with respect to the robot. To get the accurate coordinates of the gravity center of the object in the robot frame, x co-ordinate of the object in the image frame and laser sensor data are used. As view angle of the camera and size of the image are known, direct relationship between the x coordinate of the object in the image frame and angle of the object w.r.t. the robot can be established as:

$$\alpha = -\frac{\phi}{2} + \frac{x}{x_{max}}\phi \qquad (12)$$

α is the angle of the of the object w.r.t. the robot at a particular x coordinate of the object in the image frame. In our case, camera view angle is $40°$, and size of image is 640×480.

Once the angle of the object w.r.t. the robot is obtained, the distance of the object can easily be measured with the help of the laser data. Laser can give the distance reading from $-90°$ to $+90°$ with a resolution of $0.5°$. The nearest integer value of the angle α is choosen and the minimum of the three laser reading at $\alpha - 1$,α and $\alpha + 1$ is taken. As the object is in motion, so it may happen that at a particular angle α, the laser ray may not come back from the object. So, $1°$ offset is put to get the accurate reading. Using this transformation, the polar coordinates (α, r) of the gravity center of the object in the robot frame are obtained.

V. Description of particle swarm optimization and T-S fuzzy model

A. Particle swarm optimization

PSO is an optimization technique developed by Kennedy and Eberhart [9]. It is inspired by the formation of swarms by animals such as bird flocking and fish schooling. The principle behind PSO is that each individual in the swarm, called a particle, will move towards the best performing particle in the swarm while exploring the best experience each particle has [12]. The particle update their velocities as follows [13]:

$$\begin{aligned} v(k+1) &= \eta(k+1).v(k) \\ &\quad + c_1(k+1).r_1.(P^{lbest}(k) - P(k)) \\ &\quad + c_2(k+1).r_1.(P^{gbest}(k) - P(k)) \end{aligned} \qquad (13)$$

where, k is the generation number, v denote the particle velocities, η denotes the inertia weight, $r_1$and r_2 are random numbers between 0 and 1, c_1 is the cognitive parameter, c_2 is the social parameter, P^{lbest} is the local best solution and P^{gbest} is the global best solution of the group.

The inertia weight η represents the degree of momentum of the particles. This parameter is used for balancing between local and global explorations. In early generations, it is set higher, so that the particles are allowed to have much exploration capability and pursue an aggressive search of the solution space. Once the algorithm is found to converge towards the optimum, this coarse tuning is gradually converted to finer tuning by making η smaller in later generations. In this paper, a linearly adaptable inertia weight is employed [14], which starts with a high value η_{max} and linearly decreases to η_{min} at the maximum number of generations. This means that $\eta(k+1)$ is calculated from

$$\eta(k+1) = \eta_{max} - \frac{\eta_{max} - \eta_{min}}{Gen_{max}}.Gen \qquad (14)$$

where, Gen_{max} is the maximum number of generations and Gen is the current generation number.

The constants c_1 and c_2 represent the weights of the stochastic acceleration terms that pull each particle toward the local best and global best positions. With a large cognitive component and small social component at the beginning, particles are allowed to move around the search space, instead of moving toward the best solution. In the latter part of the optimization, a small cognitive component and large social component are used, to allow the particles to converge on the global optima. In this paper, we use linearly time-varying acceleration coefficients over the evolutionary procedure. Therefore, the acceleration coefficients $c_1(k+1)$ and $c_2(k+1)$ can be expressed as follows [15]:

$$c_1(k+1) = c_{1max} - \frac{c_{1max} - c_{1min}}{Gen_{max}}.Gen \tag{15}$$

$$c_2(k+1) = c_{2min} - \frac{c_{2min} - c_{min}}{Gen_{max}}.Gen \tag{16}$$

To limit the searching space v is limited to be within a certain range of $v_{min} \leq V \leq v_{max}$.

The particle positions is updated as:

$$P(k+1) = P(k) + v(k+1) \tag{17}$$

Where, P is the positions of the particle. P should also be limited to be within a certain range of $P_{min} \leq P \leq P_{max}$ for limiting the searching space.

The evaluation of the particle performance is based on a problem specific fitness function that decides the 'closeness' of the particle to the optimal solution. The particle which has the best fitness in any generation till the current generation is known as global best particle and its position is known as global best solution (P^{gbest}). For each particle, there is a local best solution (P^{lbest}), which is the position of the particle at generation g in which that particle has the best fitness till the current generation.

B. The T-S Fuzzy Model

The T-S fuzzy model constructs a map from input space to output space through a fuzzy average of local models. The local models can be either linear or nonlinear. In this paper, the map is built using local linear models. The i^{th} rule in a T-S fuzzy model with k inputs has the following form:

$$R^i : IF\ x_1\ is\ A_1^i\ and\ x_2\ is\ A_2^i\ ....x_k\ is\ A_k^i$$
$$THEN \qquad y_i = w_i^T x + b_i$$

where, R^i is the i^{th} rule (i = 1,2....m); m-is the number of rules; x =$[x_1$,x_2,.....$x_k]^T$ is a input vector; $w_i \in \mathbf{R}^{1\times k}$; b_i is the constant; A_1^i,A_2^i,....,A_k^i are fuzzy sets and y_i is the consequence of the i^{th} rule.

The possibility that the i^{th} rule will fire is given by the minimum of all the membership functions associated with the i^{th} rule (Mamdani's implication [16]).

$$\mu_i = \min(\mu_1^i, \mu_2^i, ...\mu_k^i) \tag{18}$$

where, μ_i is the membership value for the i^{th} rule and μ_k^i is the membership value of the k^{th} input in the A_k^i fuzzy set. The weighted membership value for the i^{th} rule is given by:

$$\sigma_i = \frac{\mu_i}{\Sigma_{i=1}^k \mu_i} \tag{19}$$

By using center of gravity method for defuzzification, the overall output of the T-S fuzzy system is given by:

$$y = \sum_{i=1}^{k} \sigma_i * y_i \tag{20}$$

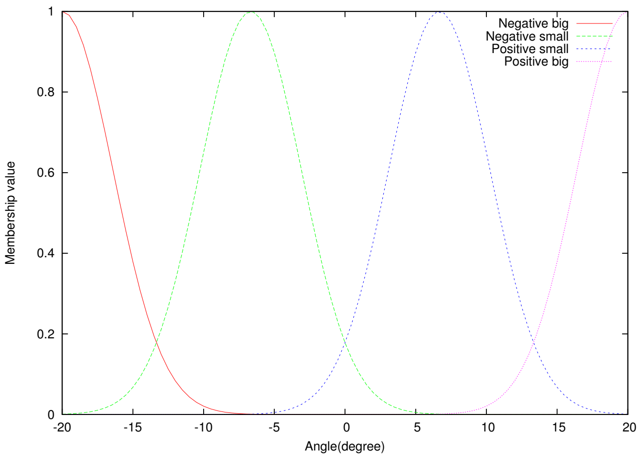

Fig. 2. Fuzzy zones for angle α

VI. Modelling of the T-S fuzzy controller for object tracking

Modelling of the T-S fuzzy controller required the followings steps:

1) Acquisition of real-time data for training and testing the T-S fuzzy model.
2) Design and develop the T-S fuzzy model using training data.
   - Identification of the parameters of the premise part of the rules.
   - Identification of the parameters of the consequent part of the rules.
3) Verification of the designed T-S fuzzy controller to demonstrate the desired object tracking behavior on the Pioneer robot.

A. Acquisition of real-time data for training and testing

To collect the training and testing data, the robot had driven manually using a joystick to set both translational and rotational velocities, guiding the robot to follow the moving red box. The human driver had no visual contact with the object and the robot, he used the robot's camera video stream and his sensor motor coordination to steer the robot towards the box.

The robot was driven in this manner for one hour. During this time, the placement angle of the object w.r.t. the robot and the distance of the object from the robot, and the robot's translational and rotational velocities were logged every $500ms$. The robot's maximum translational velocity is set to 750 mm/sec.The object position w.r.t. the robot was estimated with the hybrid CAMShift algorithm and laser data, as discussed in section II and IV.

B. Design of T-S fuzzy controller

For object tracking behavior the inputs to the T-S fuzzy model are the object position in the robot frame, i.e., object placement angle w.r.t. the robot and the object distance from

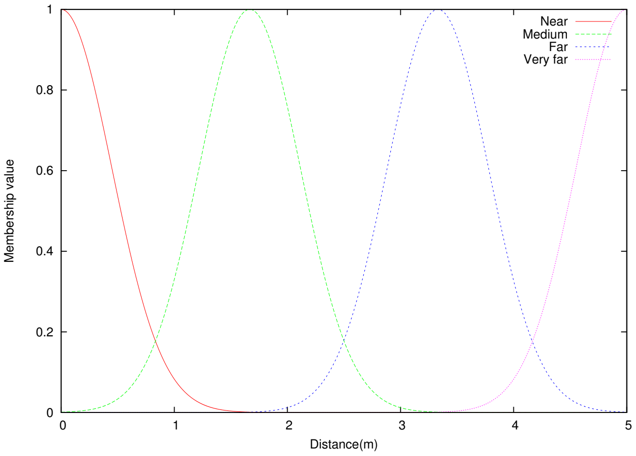

Fig. 3. Fuzzy zones for distance d

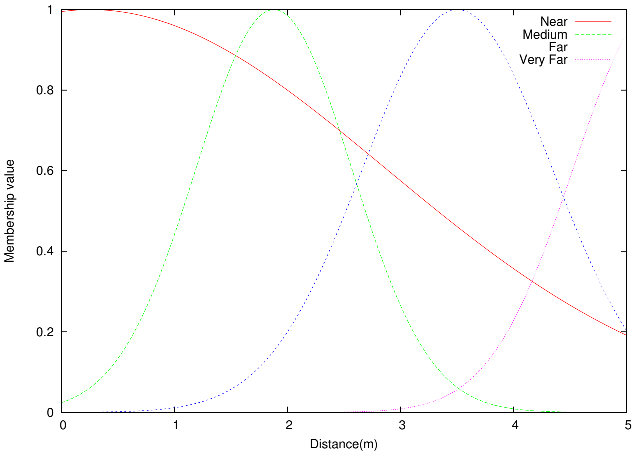

Fig. 4. Fuzzy zones for distance d

the robot, and the current translational and rotational velocities ($V(t)$,$\omega(t)$) of the robot. Outputs of the T-S fuzzy model are desired translational and rotational velocities ($V(t+1)$,$\omega(t+1)$) of the robot required to reach the object.

Placement angle (α) and distance (d) of the object are fuzzified into four zones each as shown in figure 2 and 3 respectively. Initially, a Gaussian membership function is taken for each zone and later on membership functions are updated using particle swarm optimization. The total number of rules (k) is equal to the product of number of zones for α and number of zones for d ,i.e., 4 ×4 = 16. For each rule the membership value is calculated as follows:

$$\mu_i = \prod(\mu_{\alpha_i}, \mu_{d_i}) \tag{21}$$

where, μ_{α_i} is the membership value of α in i^{th} rule and μ_{d_i} is the membership value of d in i^{th} rule.

For each rule the outputs are given as:

$$V_i(t+1) = w_i^T x + b_i \tag{22}$$

$$\omega_i(t+1) = w_i^{'T} x + b_i' \tag{23}$$

where, x = $[d$,α,$V(t)$,$\omega(t)]^T$ is a input vector; w_i and w_i' are parameter vectors to be updated to make the model for a given behavior and b_i and b_i' are constants.

The overall outputs of the T-S fuzzy system are given as:

$$V(t+1) = \sum_{i=1}^{k} \sigma_i * V_i(t+1) \tag{24}$$

$$\omega(t+1) = \sum_{i=1}^{k} \sigma_i * \omega_i(t+1) \tag{25}$$

After defining the structure for the T-S fuzzy controller, the parameters of the structure are identified as follows:

1) Identification of the parameters of the premise part of the rules using particle swarm optimization: The membership functions used in the premise part of the T-S fuzzy controller are all of Gaussian forms. The parameters that define the Gaussian membership function are mean m and the deviation σ. The Gaussian membership function is defined as:

$$G_{mf}(x) = e^{-\frac{(x-m)^2}{2\sigma^2}} \tag{26}$$

Since, we have defined 2 inputs each having 4 zones, so there are 8 membership functions and a total of 16 parameters that need to be updated. Therefore, in the PSO, each particle is to have 16 dimensions. We have defined 20 particle in the swarm and total searching iterations has been set to 2000. The minimum and maximum value of inertia weight have been set to be 0.1 and 0.9 respectively. For weights of the stochastic acceleration minimum and maximum value have been set to 0.5 and 2.5 respectively. The fitness function that evaluates the fitness of each particle has been defined as:

$$f(x(k) = \sum_{g=0}^{G_{max}} \epsilon^2 \tag{27}$$

where, $x(k)$ is the k^{th} particle of the swarm, $Gmax$ is the maximum number of generation and ϵ is the output error. At the completion of the all iterations, the membership functions for the inputs of the T-S fuzzy controller have been modified significantly as shown in figure 4 and 5.

2) Identification of parameters of the consequent part of the rules using stochastic method: There are several methods described in the literature for the parameters estimation [17]. Least-mean square algorithm based on the idea of stochastic approximation is widely used. It was developed by Widrow and Hoff [18] and is used for adjusting the weights in a liner adaptive system. For consequent part parameters identification we have used stochastic approximation method, as described by the Jelena in [10]. Once the training is over, the learned T-S fuzzy model with 16 rules is validated using test data. One sample rule of the learned T-S fuzzy model is given here:

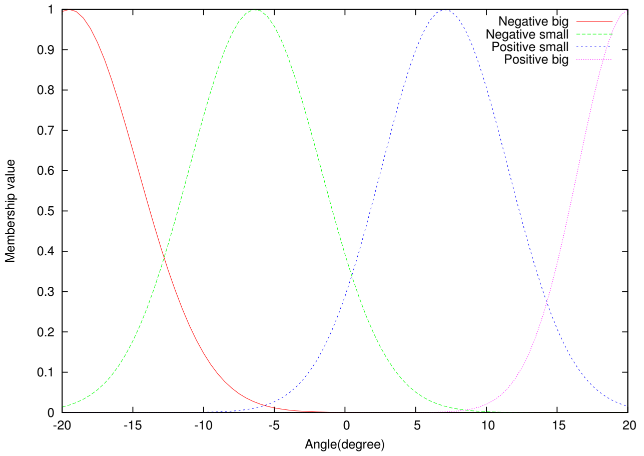

Fig. 5. Fuzzy zones for angle α

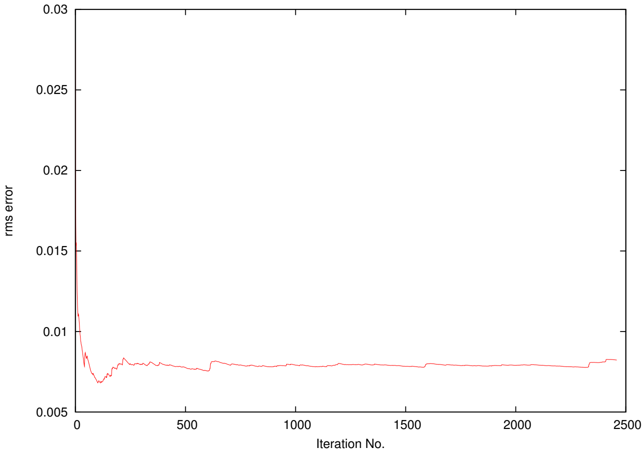

Fig. 6. RMS error during testing

- If α is Negative big and d is Near, then

$$\begin{aligned} V_1(t+1) &= 0.6506d - 0.00009\alpha - 0.00173V(t) \\ &\quad +0.00007\omega(t) - 0.0169 \\ \omega_1(t+1) &= 0.0046d + 1.37\alpha - 0.0295V(t) \\ &\quad -0.026\omega(t) - 0.173 \end{aligned}$$

C. Experimental results and Observations

We applied the testing data set and observed the error. The RMS error during testing of the model is shown in figure 6. Figure 7 shows the desired and actual translational velocities of the robot for the object tracking behavior during testing. Desired and actual rotational velocities of the robot for the object tracking behavior during testing is shown in figure 8. As compared to our previous work [19], the rms error has reduced significantly. The reason of error reduction is the updation of the parameters of the membership functions in this work. Searching mode for the robot, which is a slow process is not required in this case, as the grey predictor predict the position of the object quite efficiently, when the algorithm fails to detect the object. A test run of the designed model in action can be seen in the following video [20].

VII. Conclusion

This paper has presented a T-S fuzzy model based sensor-motor coordination scheme for object tracking. The object is detected using vision sensor and the laser is used to transform the image coordinates of the object into the robot frame coordinates. Particle swarm optimization is used to optimized the parameters of membership functions of the T-S fuzzy model. Since the robot behavior is expressed as if-then rules, the behavior modelling can be easily interpreted. A gray predictor is developed to predict the position of object, when it is not in the view of the robot. The control scheme has been implemented on a Pioneer robot for tracking a triangular box. The experimental result shows that the robot is able to track any object in any arbitrary trajectory using the proposed controller.

Abstract—**In this paper, we have introduced a hierarchical object categorization method with automatic feature selection. A hierarchy obtained by natural similarities and properties is learnt by automatically selected features at different levels. The categorization is a top-down process yielding multiple labels for a test object. We have tested out method and compared the experimental results with that of a nonhierarchical method. It is found that the hierarchical method improves recognition performance at the level of basic classes and reduces error at a higher level. This makes the proposed method plausible for different applications of computer vision including object categorization, semantic image retrieval, and automatic image annotation.**

I. Introduction

IN computer vision, object categorization is the problem of deciding the class of an object present in a given image. The major challenge in object categorization is the extraction of suitable features from the images with consideration of geometric and photometric transformations of an object in different image planes, intra class variations, object deformations, partial occlusions, and background cluttering etc. Different kinds of extractable features have been proposed over the last three decades [1]. It is generally agreed that a particular feature may not be suitable for all classes of objects. Some features may be specialized for discriminating between certain classes while being useless in the general cases. Hence, dividing the problem into sub-problems and selecting the appropriate subset of extractable features for each of them may be useful.

Different classes of objects could be clusterized by their natural superclass-subclass relationships and can be represented by a hierarchical (parent-child) structure. For example, taxonomy of biological objects is generally arranged in such a structure. In a hierarchy, a subclass by definition has the same properties and constraints as the superclass plus some additional properties or constraints. Human is capable to perceive such superclass-subclass relationship. Findings of visual neuroscience [2] also show that a combination of several kinds of features is used in primate cerebral cortex for categorization. Features are used in a hierarchical fashion starting from simple features and later using a combination of several features. Our work is motivated by these two observations: firstly it is assumed that there exists a hierarchical relation between object classes and secondly visual categorization is a hierarchical process by using a combination of suitable features.

In general, a hierarchy (e.g. taxonomy) is a result of long time research in the scientific community. The hierarchies, discovered by different researchers, may vary depending on the available data, resources, and method of analysis of data using striking features. Learning of a hierarchy (e.g. taxonomy of biological objects) is a different problem than discovering it. Basically, the learning is a supervised process - it is a process of becoming a specialist in the domain. Such a specialist can be relied on for authentic specification of an unknown instance of an object class (i.e. determining Kingdom, Phylum, Class, Order, ..., Species). In visual object categorization, we learn a given hierarchy by automatically selecting a suitable subset of extractable features and a classification function for each of the superclasses. Once such a hierarchy is learnt the classification method provides a detail specification of an unknown test object (e.g. the given sample is a ‘fruit’ and an ‘apple’). An overview of the method can be found in Fig. 1.

In this work, we have proposed a method of learning a given hierarchy by automatic selection of a set of suitable features for each of the superclasses. The main contribution of this work is to automatically select non uniform features for categorization of diverse class of objects. We consider the superclasses at different levels of hierarchy as independent multi-class classification problems. Then an appropriate classification function (model) is learnt with the selected features. The specification process is carried out in a top-down approach which starts from the root of the hierarchy and follow a single branch of the hierarchy depending on the decision at each internal node until we get a decision about the basic class. This yields a detail specification of the given sample. The proposed method has been tested on different hierarchies and promising results have been obtained.

There are several potential advantages of a hierarchical method [2], [3] such as faster model selection and flexible features choice for improved classification. However, an important objective of hierarchical categorization is to achieve better classification performance on the basic classes. In addition to this we get a detail specification of a

This work was not supported by any organization

given sample with multiple labels. In many applications the ontology of a certain domain may be encoded in terms of object class hierarchy based on their semantic meanings [4]. That is why, hierarchical categorization may be useful for such applications including object classification, semantic image retrieval, image annotation by assigning multiple concepts (i.e. labels) etc.

The outline of the remaining of the paper is as follows. We first review the related work in Section II. We discuss recent advances in hierarchical methods of object classification and learning of such a hierarchy. In Section III we describe our method of hierarchical object categorization. In this section, we also briefly discuss about features and hierarchies used. In section IV, we present the experimental setup, database used, and results. Section V concludes the paper with a discussion of the limitations of current work and our future directions.

II. Related Works

Hierarchical approaches for object categorization have become increasingly popular over the years as it has been regarded as a mean to improve the performance of object classification [3], [5]. Particularly, in pursuit of a general categorization system capable of recognition a vast number of object categories, a need for such a hierarchical structuring has emerged. Hierarchical systems combine existing classes into more complex entities (i.e. superclasses) to achieve more compact object representation enabling fast and robust categorization with better generalization properties [6].

Decision tree [7] based approach is an earlier example to exploit hierarchical feature selection method. Decision tree use heterogeneous and diverse types of features and select them dynamically at different levels. However, this obtained structure does not necessarily follow the semantically meaningful hierarchy (e.g., the subtrees of a decision tree not necessarily correspond to semantically meaningful superclasses.) An extension of this method can be found in [8] where the classification system rather pursuits the hierarchy which is obtained by the semantic information of object class. However, this method uses manually selected features at different levels of hierarchy. In order to improve classification performances, several classification models are also combined together by using them at different levels [5].

The primary concern is how to find the hierarchical relation among the basic classes. Natural hierarchy could be a good choice. Handcrafted hierarchy based on the natural similarity is used for classification in [5]. Hierarchy is constructed through a statistical analysis of elementary similarity in [8]. Some works are also dedicated to discover such a relation automatically. Both supervised and unsupervised learning methods have been investigated. Supervised learning has shown a significant generalization for small sample sets by sharing features between object classes [9]. Recently, unsupervised learning, based on common visual elements also shows comparable performance [4].

III. Hierarchical Categorization

There are two basic steps in object categorization: training and testing. In a regular nonhierarchical object recognition method some train samples for each of the classes are provided. Features are extracted from the training samples and used to learn a classifier (a pre-specified function). For example, *n* SVMs (assuming one-versus-rests approach) are learnt for an *n* class problem. In the testing process, the classifier determines the class of a test object and assigns a label to it. In a simple model, a few specific features (sometimes only one) are used for classification [10], [11]. Recently, automatic feature selection method has emerged [12], where a subset of features from a given set is selected before the training process. However, these selected features remain fixed and are used to learn the classification function. Briefly, in these methods of categorization, all the classes are treated equivalently with the same set of features.

In hierarchical categorization, we assume that a hierarchical relation of the basic object classes is provided in addition to the training samples of each of them. Then, the original classification task is divided into some (hierarchically defined) superclasses. Each of these superclasses is learnt with a suitable subset of features. The two basic steps of hierarchical learning are as follows:

1. Automatic selection of a set of features for each of the superclasses
2. Learning the appropriate classification function for each superclass with the selected features.

Unlike in the regular method, the automatically selected features become non uniform for different superclasses. Once the hierarchy is learnt, a novel test object is categorized in a top-down fashion by assigning multiple labels. Hence we rename the testing process as ‘specification’ which gives a detail description of the test object. The basic idea of hierarchical categorization is show by the block diagram in Fig. 1.

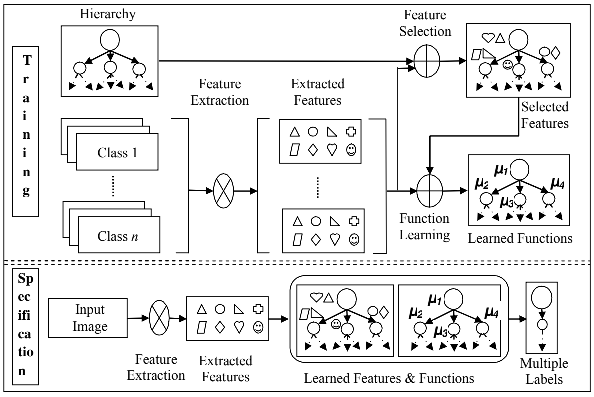

Fig. 1 Block diagram of hierarchical object categorization

We describe the different steps of hierarchical object categorization below. The first step of learning and classification is the extraction of features for respective images. A brief introduction about the image features is given in subsection *A*. A short description of hierarchical representation is given in subsection *B*. The learning and specification methods are described in subsection *C* and *D* respectively. Finally, we discuss the computation cost of the proposed method in subsection *E*.

A. Image Features

For object categorization, we consider locally defined low-level image features. For the recognition of a partially occluded object in cluttered environment, local image features are preferable. These features are generally invariant to different kinds of geometric and photometric transformations as well.

Features are generally extracted from affine covariant interest regions (image patches) by computing different kinds of descriptors of such an image patch. They are represented as a vector of *m* dimensional features space $\Re^m$. An up-to-date review of different methods of local feature detection and description can be found in [1]. All these features are indeed quite successfully used for many applications such as wide baseline matching for stereo pairs [13], content based image and video retrieval (CBIR) from large databases [14], model based object recognition [15], etc. However, it is generally believed that the local-feature-based nearest-neighbor classification method can overcome the intra-class variation of objects to some extent.

Local features are utilized in two different ways in different applications: (i) unquantized features, which comprises two basic steps: feature extraction and feature matching; (ii) quantized bag-of-features and hyperfeatures, which includes the following four steps: feature extraction, feature clustering, frequency histogram construction, and feature matching. Matching approaches depend on distance matrices. For unquantized features, Euclidean distance and Mahalanobish distance are generally preferred. On the other hand Chi-squared (χ^2) distance and Earth Movers Distance (EMD) are popular for histogram comparison [11].

B. Hierarchical Representation

As discussed in section II, three approaches can be identified in the literature to obtain a hierarchy for a given set of object classes: handcrafted, statistical, and learning-based. The final outcome depends on the similarity and dissimilarity among object classes. These similarities and dissimilarities are rather abstract ideas. However, given a measure of similarities and dissimilarities, we can obtain a hierarchy for a give dataset following any of these methods. The hierarchy could vary depending on the designer's perspective and application as well.

In this work, we intuitively group some of the apparently similar classes into a superclass. Two alternative hierarchies are depicted in Fig. 2 for ETH-80 [7] database. As shown in Fig. 2(a); dog, cow, and horse classes are put into a superclass named 'animal' which shares some common shapes. These superclasses always may not have common perceivable shape features rather some other common properties. For example, different types of artefacts may not have any shape similarity; instead they share a common properties of being man-made (e.g. car and cup). Similarly 'small' and 'big' (Fig. 2(b) superclasses have vague shape similarities. These super-classes can be further clustered into the higher-level super-superclasses, and so on. Eventually, we obtain a multilevel hierarchy. For simplicity, we consider only a two-level hierarchy in this work.

A hierarchy can be represented by a general tree where each node can have a different number of children. The root (considered as the first level of decision making) corresponds to the world under consideration. The leaves are the basic classes and each of the internal nodes represents a superclass. Suppose, we have a set of *n* classes $\{C_i \mid i = 1\ldots n\}$, i.e. a tree with *n* leaves. We clusterize the set $\{C_i\}$ into *k* subsets (superclasses) $\{S_j \mid i = 1\ldots k\}$. Thus we form a subtree for each superclass where the root is represented by the superclass, and the basic classes under the superclass become leaves. We may further cluster superclasses into super-superclasses and add another level in the hierarchy and so on. Finally, we add the root which corresponds to the world (database) to form the tree.

C. Automatic Feature Selection

Suppose we have a categorization function (μ) and the input image *X* of an object belonging to class $y \in \{+1, -1\}$. If $\hat{y} = \mu(X)$ then for an ideal classification function we always expect that $|y - \hat{y}| = 0$. As discussed above, the function may have different choices of features. Let us assume we have *l* features $\{f_1, \ldots, f_l\}$ extractable for the function, and an arrangement of features $\alpha(\{f_1, \ldots, f_l\})$ is feasible. We wish to find an α which minimizes categorization error. Now the problem of feature selection is to automatically decide an arrangement α on a given training set such that

$$\arg\min_{\alpha} \sum | y - \hat{y} | \qquad (1)$$

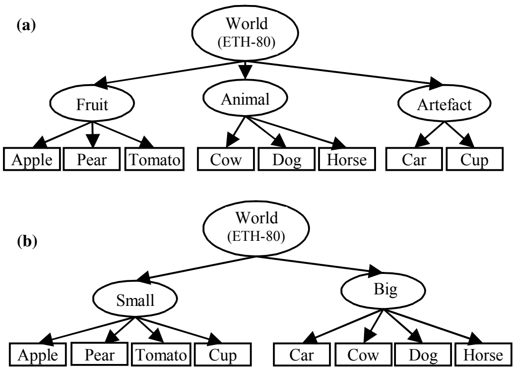

Fig. 2 Two different object class hierarchies for ETH-80 database. (a) HRC-1, (b) HRC-2

The arrangement α could be defined in many ways such as a subset of the features or a weighted contribution of all the features [12], [16].

In this work, we consider the use of SVM classification with multiple kernels as proposed in [12]. Each of the kernels uses a particular feature. The k-th kernel using feature f_k can be written as $K_k(\mathbf{x}, \mathbf{y})=\exp(-\gamma_k f_k(\mathbf{x}, \mathbf{y}))$, where the kernel matrices are strictly positive definite. The basic idea of multiple kernel method is to concatenate the contribution of the features by summing up the individual kernels. The contribution of each of the features is weighted as follows:

$$K = \sum_k d_k K_k \tag{2}$$

An optimal kernel K is learnt from a given training set by leaning the weight parameters d_k; $k = 1, \ldots, l$. The optimization is carried out in the SVM framework to achieve the best classification on the training set.

D. Learning a Hierarchy

Suppose we are given a hierarchy and a set of training images of each of the n basic classes. The hierarchical structure divides the learning problem into $O(n\text{-}1)$ independent sub-problems. We consider each of the internal nodes (superclasses) including root of the tree as a separate learning problem. Suppose S is such a node having c children. For a child $C_i \in \text{Children}(S)$ we obtain the training set T_i by concatenating the training samples of all basic classes under this branch. Now it becomes a c class problem with T_i training images for each, where $i = 1, \ldots, c$. If we consider the one-versus-rest method, we need to train c SVMs. The learning consists of the following two steps

1. Feature learning: in this step the weights d_k, $k = 1, \ldots, l$ for the features are learned from the training samples. The features having significant contribution are retrained and associated with the node.
2. Function learning: in this step the parameters of c SVMs are learnt and associate them with the node.

The learning process of a hierarchy is summarized in the following Algorithm 1. Here, the input is the hierarchy (H) represented as a tree and the set of training features (F) for all basic classes. The algorithm returns the tree with associated features and functions for each of the internal nodes.

E. Specification

In this step, we obtain a detail specification of a given test object. We start from the root of the hierarchy tree. From the learning process we already know the relevant features for this node and we extract only them for the input object. Then, the associated learned function is used to decide the subclass (the next level super-class in the hierarchy). We repeat the process until we reach a leaf (the basic class). Hence, the method follows a particular branch of height $O(\log_2 n)$ of the tree (i.e. goes through $O(\log_2 n)$ decision processes) yielding a specification with $O(\log_2 n)$ labels.

The specialization method is described by Algorithm 2. Here we supply the hierarchy associated with learned features (H') and classification functions (H'') together with a test object X. The algorithm returns a list of labels denoted by the set S.

Algorithm 1:

```
Hierarchy_Learning ($H$, $F$)
    Initilalize($Q$)          // initializes an empty queue
    $H' = H'' = H$;           // initialization
    $T$ = Root($H$)           // function Root returns the root of tree $H$
    EnQ($Q$, $T$)             // function EnQ enqueues $T$ into the queue
    while $Q \neq$ Empty
        $T$ = DeQ($Q$)     // function DeQ returns top element in the queue
        if Is_Leaf($T$) = false  // Is_Leaf determines whether $T$ is a leaf
            for all $C_i \in$ children ($T$)    // for all children of the node $T$
                EnQ ($Q$, $C_i$)
                // union of all training features of leaves for the subtree
                $F_i$ = Find_all_Training_Features ($C_i$)
            $d_k$ = Learn_weight ($\{F_i\}$)  // learn weight $d_k$ for k = 1, …, $l$
            $\alpha = \{□\}$                 // initialize $\alpha$ (a set of selected features)
            for all $k$ = 1 to $l$
                if $d_k$ > Threshold   // user defined threshold
                $\alpha = \{\alpha \cup f_k\}$      // adding significant features in the set
            $H'$ = Associate ($\alpha$, $H'$, $T$)   // associate $\alpha$ with the node $T$
            $\mu$ = Learn_Function ($\alpha$, $\{F_i\}$) // learn classifier for the node $T$
            $H''$ = Associate ($\mu$, $H''$, $T$)  // associate $\mu$ with the node $T$
    return $H'$, $H''$.
```

Algorithm 2:

```
Specification ($H'$, $H''$, $X$)
        $T$ = Root($H'$)    // function Root returns the root of tree $H'$
        $S = \{□\}$       // initialize the empty set of labels
        while Is_Leaf($T$) == false
            // function Is_Leaf determines whether $T$ is a leaf or not.
            $\alpha$ = Get_Ftrs ($H'$, $T$)   // Get_Ftrs returns learned features at $T$
            $F$ = Extract_features ($\alpha$, $X$) //extracting relevant features
            $\mu$ = Get_Func ($H''$, $T$)  // Get_Func returns learned function
            $T = \mu(F)$        // decision at current node
            $S = S \cup$ Label ($T$)    // append the node label
        $S = S \cup$ Label ($T$)        // append the leaf label
        return $S$.
```

F. Computational Cost

Consider the one-vs-rests method used in a regular nonhierarchical categorization process we need to train n SVMs for a n class problem. Similarly, we need to evaluate n function for testing process. The hierarchical method does not decrease the computational efficiency for the learning process which still remains $O(n)$. However, the real computational cost in the train process is multiplied by a constant depending of the branching factor of the tree. One the other hand, the specification process become $O(\log_2 n)$ instead of $O(n)$ in a nonhierarchical categorization process. This is a desirable property in many cases of categorization problem where training is merely an off-line process but the specification is rather online.

IV. Experimental Setup

We have tested the hierarchical method and compared the performance with a regular nonhierarchical method of object categorization. We have chosen a multiple kernel learning (MKL) SVM framework with automatic features selection. An implementation of this method is available online (http://www.robots.ox.ac.uk/~vgg/software/MKL). It combines SIFT [17], *self-similarity* [18], and *geometric blur* [10] features with the multiple kernel learning of Varma and Ray [12] to obtain state-of-the art performance. SIFT and self-similarity features are quantized into Bag-of-Words and then spatial histograms are computed. Geometric Blur feature is used without any quantization. Here, seven RBF kernels are combined linearly. For matching, χ^2 distance is used for former two features and correlation-based distance measures [10] are used for the later feature. One-versus-rests SVMs are trained and classification results are obtained by assigning each image to the class that obtains the largest SVM discriminant score.

Our implementation of hierarchical categorization was based on this MKL implementation. Algorithms 1 and 2 were implemented on the top of this implementation with the same set of parameters for the SVMs. For the convenience of comparison, we used the same set of features and kernels. The basic difference was that the features are selected independently for each node of the hierarchy and it was non-uniform. We tested the method on ETH-80 database for the two hierarchies (HRC-1 and HRC-2) in Fig. 2 and compared the results with the nonhierarchical MKL method.

A. Database

The methods were tested on ETH-80 database [7]. In this database, there are eight classes of both biological and artificial objects. In each of the classes there are ten objects. Fig. 3 shows the eight classes with ten objects for each of them. Each object is represented by 41 views with uniform background spaced evenly over the upper viewing hemisphere.

For this database, the suggested test mode is leave-one-object-out crossvalidation. Here all the 79 objects (i.e. 79×41 images) are used as training set and test is carried out with the remaining one unknown object (i.e. 41 images). The results are averaged over all 80 possible test objects.

For more effective evaluation, we carried out experiments with different numbers of training objects. For three different sets of experiments we use two objects, five objects and eight objects of each class. The remaining objects are used as a test set for the respective experiment. For instance, with the eight training objects, for each class we use 8×41 images as the training set and 2×41 images as the test set. In all these experiments we carried out multiple tests for a particular number of training objects. These training objects were selected randomly but kept the same for all the corresponding experiments.

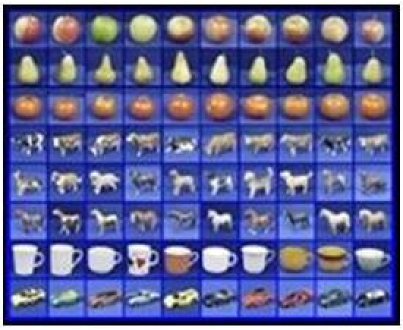

Fig. 3 Ten objects of each of the eight classes in ETH-80 database

B. Results

Fig. 4 shows the recognition rate for both of the methods. This was obtained by averaging the two tests for each experiment with different numbers of training objects. Here we carried out experiments with 2, 5, and 8 training objects. The performance of MKL method is compared with our hierarchical method using two hierarchies (HRC-1 and HRC-2). It can be seen that the hierarchical method has performed somewhat better than the regular MKL method in most of the cases. In these three experiments HRC-1 and HRC-2 are in average superior by 1.0% and 0.8%, respectively, than the nonhierarchical MKL method.

In Fig. 4 the comparison is performed on the basic classes. We have also performed some analysis on the higher levels of hierarchy (only the level just above the leave exists in the given hierarchies). For example, in HRC-1 in Fig. 2(a) there are three superclasses (fruits, animals, artifacts). We compared the recognition error at this level with MKL method. For the nonhierarchical MKL method we obtained equivalent results just by concatenating (bottom-up) the results on basic classes. Here a misclassification within the same superclass is not counted. For example, if an apple is classified as tomato, it is not considered as a misclassification.

Fig. 5 shows the error rate for the second level of hierarchy. Here we need to put the results in separate graphs due to the difference in superclasses in second level. For example, the superclass fruit has three basic classes but the superclass small has four. Thus, to make the result comparable with MKL method, we concatenate the results of the respective three and four classes. It can be seen that hierarchical methods results less error in the higher level of hierarchy. It means that if we wish to retrieve objects of a superclass (e.g. fruits) we will achieve better accuracy. In these three experiments HRC-1 and HRC-2 have average error rates lower by 2.7% and 2.3%, respectively, compared to a nonhierarchical MKL method.

V. Conclusion

This paper describes a method of automatic feature selection for hierarchical object recognition. Automatic feature selection and hierarchical object categorization techniques have evolved recently. We are motivated by biological vision systems to put them together to improve recognition performance. In this work, we have tested our proposed method on two hierarchies, given for an ideal database. The hierarchies are based on natural similarities and properties of the basic object classes. We wanted to investigate feasibility of the proposed method. In fact, the experimental results are found consistent with our expectation. With the same parameters of a SVM based classification framework, we achieved better categorization performance without any increase in computational costs. This was true for both of the hierarchies. More importantly, we obtained less error in categorization on the superclass level. All these implicate the potentiality of this method especially in object categorization, semantic retrieval, automatic annotation, and other areas.

At the primary stage, we have tested our method on a small database. Here we assumed that the objects in all basic classes and superclasses are unimodal. This is an unrealistic assumption indeed. So trying with multimodal classification method at different levels of hierarchy should further improve the categorization performance. Furthermore, we have used the same classification model at different levels of hierarchy. A method which is capable to automatically select different models of categorization could further improve the results.

***Abstract*—In this paper, we propose the use of the pairwise comparisons (PC) method for selection of strategies for software certification. This method can also be used to rank alternative software certification strategies. The inconsistency analysis, provided by the PC method, improves the accuracy of the decision making. Some current methods of software certification are presented as they could be modified by the proposed method. Areas of potential future research are discussed in order to make the software certification process more feasible and acceptable to industry.**

I. Introduction

THE PROCESS of software certification is time consuming and hence expensive. Most software systems, since they are usually not critical, never go through a certification process. Thus software is still being developed without any consideration given to software certification [1]. In most modern systems, software is one of the most complex components. At the same time it is considered as one of the most error prone, despite the increasing demand for reliable software. As a result, there is an apparent need for a viable dynamic software certification process which can adjusted to the dynamic demands of the rapidly evolving software industry [2]. We propose to use the pairwise comparisons method as a means of selecting a strategy for a software certification process. It is quite likely that a certifying body would need to adjust their certification strategy for almost every project. This is because projects are different, especially when they are designed for different domains. A better software certification strategy may require a smaller amount of resources in order to adjust to new scenarios. The use of this approach will provide insight and understanding of the software certification process. For every project, some properties will be more important than others, while some properties will be completely irrelevant. The pairwise comparisons method can provide a scheme where the software certification strategy can be modified easily and adapted to different scenarios.

II. Product Based Certification

The objective of product based certification is to deduce whether the product conforms to requirements and provide an evaluation of the developers abilities to produce new products while conforming to requirements [3]. ISO IEC 14598 provides instructions on how to evaluate a software product. It uses the ISO IEC 9126 standard which describes how general attributes can be subdivided into less general attributes. In practice, both standards are applied in parallel. ISO IEC 14598 has four phases: defining the evaluation requirements, identifying the evaluation, building the evaluation schedule and executing the evaluation schedule. In defining the evaluation requirements, attributes and sub-attributes for the product evaluation are defined. These attributes and sub-attributes could be taken from the McCall's and Blundell's quality models [4], [5]. In identifying the evaluation, a collection of metrics are defined for the evaluation of all attributes and sub-attributes. In addition, metrics which will evaluate relationships between a product and its environment are also defined. While building the evaluation schedule, a detailed evaluation plan is constructed. Finally, the evaluation schedule is executed [6].

III. Process Based Certification

The IEC 61508 (Functional safety of electrical/electronic/programmable electronic safety-related systems) and DO-178B (Software Considerations in Airborne Systems and Equipment Certification) standards follow a process based methodology and thus implicitly view the software certification process as one that places the emphasis on checking that an approved process was adhered to. These standards describe the collection of practices which should be followed during software development. They claim that it would be easier to achieve validation and verification of software by following the proposed practices. The IEC 61508 and DO-178B standards should be followed in correlation with other regulations where they outline the significance of software failure. The Development Assurance Levels (DALs), from the domain of civil aerospace, are an example of this correlation which dictate levels of criticality. The automotive and European rail industries use Safety Integrity Levels (SILs). The (DALs) and (SILs) are not similar in their applications, despite the strong tendency for them both to focus on risk reduction. The more critical the software, the greater the need for risk reduction to be an essential attribute of the software. Greater demands upon the (SILs) and (DALs)

978-83-60810-27-9/09/$25.00 © 2010 IEEE

lead to stricter demands from the software development process. The DO-178B argues that the verification of a system should be accomplished through extensive testing, while highly emphasizing the need for a good traceability process and a manual review of the components [7]. The verification process supported by DO-178B is subdivided into four levels. There are twenty eight properties at the lowest level, D. They validate tools, high level requirements, and the configuration of the development process. The next level, C, deals with twenty nine properties. They validate low level requirements, testing and code coverage. The next level, B, deals only with eight properties and logic. The highest level, A, is responsible for sixty six attributes. At this level, while the overall quality of the product is evaluated, a significant focus is allocated to traceability [7].

IV. Motivation

In situations where it is difficult or infeasible to use an algorithm, we revert to the use of heuristics in order to find solutions. There are a large number of attributes which should be considered during the certification process. As projects evolve rapidly and grow in complexity we need mechanisms to assign consistent weights to attributes and properties. The pairwise comparisons method is ideal for this task because it can reduce inconsistencies while still maintaining some acceptable margin of error. We describe a process on how to assign consistent weights to attributes and properties. Once inconsistency is minimal, preferably not zero, the developed software certification strategy can be used as a dynamic entity in the software certification process [8], [9].

V. Pairwise Comparisons Method

The pairwise comparisons method was used for the first time in 1785 by Condorcet. He used this method in the election process where voters rank candidates based on their preference [10]. The method was a voting system which used matrices for particular pairwise comparisons with rows representing each candidate as a runner and columns representing each candidate as an opponent. It was Fechner who specified pairwise comparisons as a scientific method in 1860, although only from the psychometric perspective [11]. Thurstone, in 1927, provided a mathematical analysis of this method and called it the *law of comparative judgments* [12]. The *law of comparative judgments* can be used to scale a collection of attributes based on simple comparisons between attributes taken two at a time. Although, Thurstone referred to it as a law, it can be more appropriately identified as a measurement model which could be of important use for software certification. This model allows experts to synthesize diverse procedures involved in software certification. The hierarchy reduces the number of comparisons from $O(n^2)$ to approximately $O(n \ln n)$, making it applicable to a wide variety of problems. For example, a moderate case with 49 features would require 1,176 comparisons without a hierarchy and only 168 comparisons if these 49 features are arranged into a hierarchy by grouping seven features. Measurements of length, such as a meter or foot, or by mass and weight are commonly used and accepted. Society has become accustomed to having standards for the majority of tasks, and sometimes it is difficult to understand standards, which often occur in the software industry, without an acceptable universal measuring method. In the case of software certification, many strategies may need to be developed for a single project. It is safe to conclude that developing a single certification strategy is not feasible and would not work for all types of projects, because some projects have very little in common [9], [13], [14].

TABLE I: Comparison scale

Code	Definition of intensity or importance
1	Equal or unknown importance
2	Weak importance of one over another
3	Moderate to essential importance
4	Demonstrated importance
5	Absolute importance
3.5 etc	Intermediate importance

A. Inconsistency Analysis

The pairwise comparisons method does not impose any limit on the number of criteria. Setting the maximum number of entities on one level to seven is accepted as a heuristic, because seven items gives 21 distinct pairs to compare. The first step in pairwise comparisons is to establish the relative preference of two criteria for situations in which it is impractical or irrelevant to provide absolute estimations. The relative comparison coefficients a_{ij} for criteria $C_1, C_2, \ldots, C_n$ are expected to satisfy $a_{ii} = 1$ and $a_{ij} = 1/a_{ji}$. The first constraint is related to comparing a given attribute with itself. The second constraint is a consequence of the obvious fact that $x/y = 1/(y/x)$ for $x, y \neq 0$. A scale from 1 to 5, as demonstrated in Table I, is used for expressing the importance of one attribute over others. This is accomplished in a pair. Other scales also exists, but as described by [8] larger values lose meaning in the comparison process.

The absolute estimation of the weights defining the importance of analyzed software certification criteria is practically unobtainable through either statistical or formal procedures. It would be beneficial to have experiments which may contribute to the accuracy of the estimates. However, it is unrealistic to expect such experiments to take place. This approach allows us to improve the processing of often subjective expert assessments in the certification process. We propose the use of a comparison scale that is demonstrated in Table I for the subjective expression of relative preference.

Fig. 1: Relative importance of considered software quality attributes

The values of relative importance, which are given in Figure 1, have been entered by a single person solely for demonstration of the method. We have used the concluder software which can be download from the website that is maintained by W. W. Koczkodaj. [1] The values were deduced from the comparison in pairs. In a real scenario, the values should be reasoned about by a team of experts. The attributes have been taken from the ISO/IEC 9126 software standard. They are also known as the top six level attributes, which are considered to be key attributes for software quality [15]. Now we consider the process to identify the best alternative. Let us denote the attributes by $A_1, A_2, \ldots, A_n$ (n is the number of compared attributes), their actual weights by $\gamma_1, \gamma_2, \ldots, \gamma_n$, and the matrix of the ratios of all weights by $\Gamma = [\gamma_i/\gamma_j]$. The matrix of pairwise comparisons $\mathrm{M} = [a_{ij}]$ represents the assessments between individual pairs of alternatives ($\mathrm{M_i}$ versus $\mathrm{M_j}$, for all $i, j = 1, 2, ...n$) chosen usually from a given scale. The elements a_{ij} are considered to be estimates of the ratios γ_i/γ_j, where γ is the vector of actual weights of the attributes. All the ratios are positive and satisfy the reciprocity property $a_{ij} = 1/a_{ji},\ i, j = 1, 2, \ldots, n$. The inconsistency concept was explained in [16]. The distance based inconsistency indicator is defined as the maximum over all triads $\{a_{ik}, a_{kj}, a_{ij}\}$ of elements of M (with all indices i, j, k distinct) of their inconsistency indicators. It is defined as:

$$ii = \min\left(\left|1 - \frac{a_{ij}}{a_{ik}a_{kj}}\right|, \left|1 - \frac{a_{ik}a_{kj}}{a_{ij}}\right|\right) \tag{1}$$

Three is the minimal number of attributes which may cause inconsistency. Comparing two attributes will often lead to inaccuracy. The distance based inconsistency is the minimum distance from three ideal triads with no inconsistency when the third value is substituted using the consistency condition $a_{ij} \times a_{jk} = a_{ik}$. Since we are not in a position to determine which ratio is incorrect, all three assessments must be reconsidered before we attempt finding a consistent approximation for a given pairwise comparisons matrix. The stress on localizing the most inconsistent assessments is expressed by adding the *consistency-driven* to the name of the method since it is easier to remedy implications of an error when we are able to localize it. There is no practical reason to continue decreasing the inconsistency indicator to zero. Only the high values of the inconsistency indicator are considered as unacceptable and harmful. A very small value, or zero, may indicate a faked result rather than a true estimate. The practical challenge in working with the pairwise comparisons method comes from the lack of consistency of the pairwise comparisons matrices. Depending on the strategy it may take some time to get the matrix consistent [9], [13], [14], [17].

VI. Demonstration of the Matrix Adjustment

Assume the following attributes are considered for evaluation: safety, security, reliability, resilience, robustness, knowing, testability, adaptability, modularity, complexity, portability, usability, reusability, efficiency and learn-ability. They are considered in [18] as a general group of attributes of any software. All the attributes are subdivided into two main categories, such as development and maintenance. These groups are subdivided further and weights are assigned as demonstrated in Table II. It is safe to assume that some areas of software evolution are based on intuition and experience. In situations where there is more than just one person making decisions there is a greater possibility for inconsistency to occur. Industry must rely on the subjective judgments of experts in situations where practical methods of measure are unknown [9], [13].

TABLE II: On the left inconsistent strategy and on the right consistent strategy

Attribute	Percent	Attribute	Percent
development	**80%**	**development**	**80%**

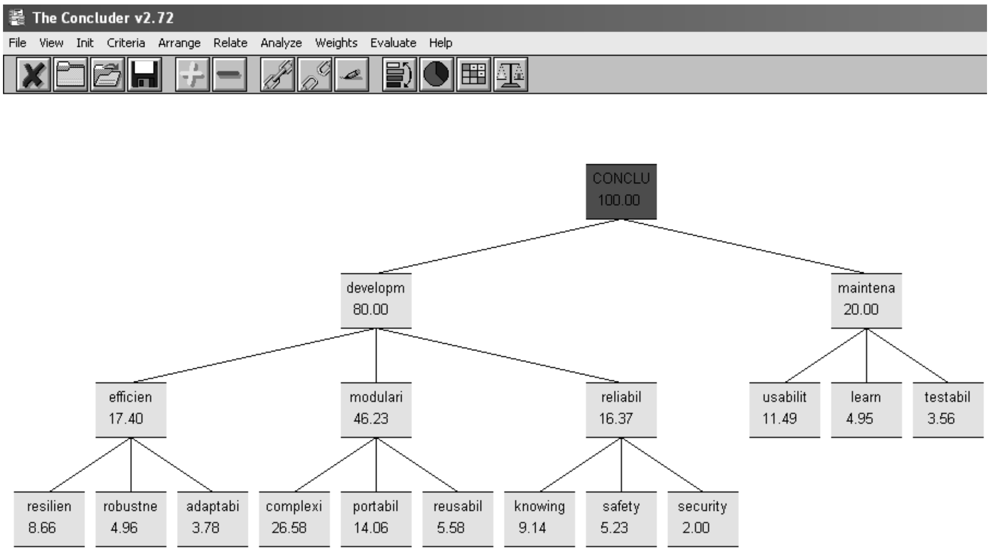

Fig. 2: Inconsistent strategy.

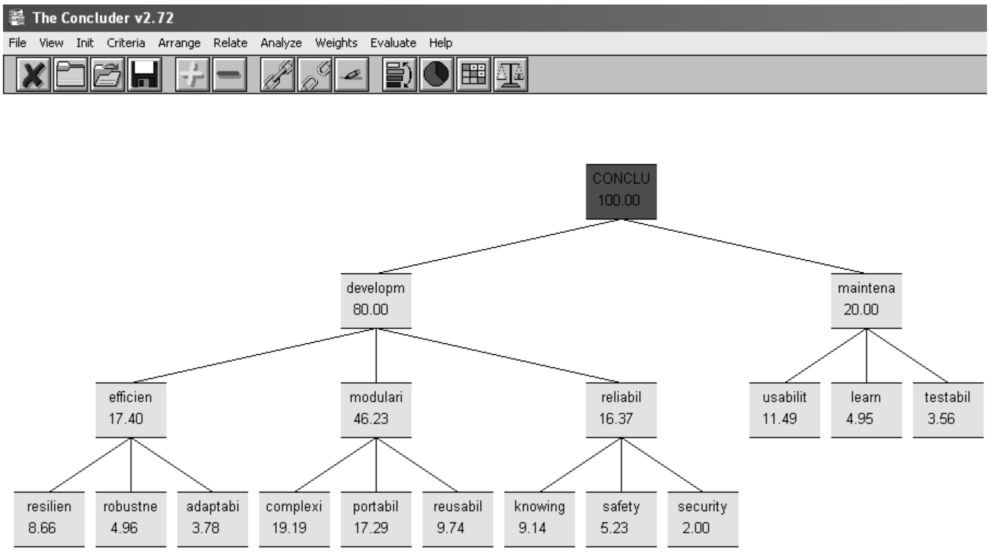

Fig. 3: Consistent strategy.

From Table II we can evaluate the complexity, portability and reusability triad where C_1 = complexity, C_2 = portability and C_3 = reusability. This triad has an inconsistency of 0.75 which is shown in Figure 4. As described in [8] it is not recommended. According to [8] the acceptable inconsistency is around 0.33. We have to adjust the values in order to bring the inconsistency down. After the adjustment, and as demonstrated in Figure 5, the inconsistency has decreased to 0.3 which is more acceptable.

In Table II, the weights of the attributes are allocated based on the significance of each attribute, and the most important criteria is complexity. After the correction we can see a new percentage redistribution, which is shown in Table II. The appropriate concluder's strategy models which demonstrate the percentage redistribution are given in Figure 2 and Figure 3. The redistribution could be evaluated and adjusted by many experts in order to achieve a situation in which the redistribution is accepted by all experts [19]. We think the consistency method is a preferred choice for the construction of consistent software certification strategy. The statistical evidence of the accuracy improvement with pairwise comparisons from approximately 15% to 5% for the one dimensional case (randomly generated bars) in [20], and from approximately 25% to 15% for randomly generated 2D shapes [21] support our expectations of improvement.

VII. CONCLUSIONS

This study demonstrates how the use of pairwise comparisons to relate such intangible software attributes as resilience

	C1	C2	C3
C1	1.00	3.00	3.00
C2		1.00	4.00
C3			1.00

Maximum Inconsistancy: 0.75

or reusability can result in computing weights that may be useful in establishing a software certification strategy.

Software systems are developed for different purposes. Properties such as safety, reliability and modularity could have different priorities for different projects. Software providers are obliged to provide a guarantee that their software will operate reliably, but a certification process can not imply nor guaranty that the software will not fail in all unexpected situations [22].

The desire for companies to certify their software may be driven by their ability to increase sales and to maintain a competitive advantage in the industry. This comparative advantage could be achieved if companies would develop their products while conforming to the product's requirements and industry regulations [23], [24]. A more effective software certification strategy, in terms of better resource allocation, contributes to software development cost savings. We expect that certification methods which were utilized for past projects would fit, with some minor modifications, into our software certification strategy where we use the pairwise comparisons (PC) method. This may allow for a more accurate and consistent software certification process.

***Abstract*—A problem of extrapolation of a large class of processes and of their future states forecasting based on their occurrence in the past is considered. Discrete-time discrete-value processes are presented as instances of relations subjected to the general relations algebra rules. The notions of relative relations, parametric relations and non-deterministic relations have been introduced. For extrapolated process states assessment relative credibility levels of process trajectories are used. The variants of direct one-step, indirect one-step and direct multi-step process extrapolation are described. The method is illustrated by numerical examples.**

I. Introduction

EXTRAPOLATION of processes is a basis of decision making in control, management, administration, social and/or economical planning, governing, etc. Roughly speaking, it consists in predicting future states of a process on the basis of its known current and past states as well as of some knowledge concerning influencing the process circumstances. Even extrapolation of deterministic processes, whose form can a priori be calculated using some analytical rules, may become a non-trivial problem. A process described by nonlinear differential equations may not only need high computational costs for being predicted but in certain cases it cannot be for long periods exactly predicted because of extreme equations' sensitivity to the initial conditions which with limited accuracy only can be established [1]. Extrapolation of non-deterministic processes is charged by inevitable uncertainty. In the simplest case of stochastic processes extrapolation the uncertainty takes the form of a statistical extrapolation error [2]. The rate of the error can be calculated when the probability distribution of the process is a priori known; otherwise, it should be experimentally evaluated [3, 4]. However, when non-probabilistic indeterminism of the processes takes place, the problem of based on the decision making, including extrapolation, becomes much more complicated [5]. On the other hand, namely non-deterministic processes whose future states are to be predicted in many application areas play an important role. The effectiveness of statistical methods of process extrapolation is satisfactory when the analyzed process's behavior depends on numerous unknown factors of approximately comparable strength. In a more general case of non-deterministic processes, some of the factors may be dominating, while their number and individual properties (e.g. nature, parameters, way of influence on the extrapolated process, etc.) remain unknown their existence by final effects only being manifested. Effective predicting of future states of such processes, on one hand, depends on making use of all available and relevant information, and on the other one, on neglecting all side information making the prediction incorrect. Till now, no commonly accepted definition of non-deterministic processes, excepting some of their particular cases, exists. In this paper an attempt to non-deterministic processes extrapolation based on extended theory of relations [6,7] is presented. Roughly speaking, it is assumed that the past, current and future states of an analyzed process as elements of an universe *U* are instances of a fuzzy multivariable relation; the problem of process extrapolation can thus be interpreted as the one of conditional relation identification when its instances are partially known. Moreover, some general concepts of relative logic (more widely presented in [9,10]) to an evaluation of the extrapolated states of the processes are used. The aim of this paper is to show that extrapolation of non-deterministic processes even if no numerical their instances' logical value is available is still possible. Such conclusion seems to be important in the case of extremely high indeterminism level of the considered processes.

The paper is organized as follows: preliminary extended relation theory concepts are described in Sec. II; in Sec III process extrapolation rules based on relations are presented. An example of process extrapolation under uncertainty is also given there. Conclusions and suggestions concerning future works are presented in Sec. IV.

This work was partially supported by the Ministry of Science and Higher Education of Poland.

II. Extended Fuzzy Relations

It will be considered a countable and linearly ordered family F of mutually isomorphic sets $U^{(i)}$, $i\in[\ldots-2,-1,0,1,2,\ldots]$. Within this paper the indices i will be interpreted as discrete: negative – past, null – current, positive – future time-instants. The family F will be called an universe, the sets $U^{(i)}$ – instant state repertories and their elements $\mathbf{u}^{(i)}_k$ – instant states. Any subfamily $F^{(m)}\subseteq F$, m = 1,2,3,…, preserving the linear order of F will be called its sub-universe; the family of all sub-universes of F (including F itself as well as empty subfamily $\varnothing$) will be denoted by Ω_F. For each sub-universe $F^{(m)}$ a Cartesian product of its instant state repertories:

$$C^{(m)} = \times_{(i)} U^{(i)},\quad U^{(i)}\in F^{(m)},\ F^{(m)}\in \Omega_F, \tag{1}$$

will be called a repertory of scenarios. Any subset

$$R^{(m)} \subseteq C^{(m)} \tag{2}$$

is a relation described in the sub-universe $F^{(m)}$ called below a process while its instances $\mathbf{y}\in R^{(m)}$ will be called process trajectories. A process is thus defined as a set of trajectories described in a given universe F or in any its sub-universe $F^{(m)}$. Any subset $R^* \subset R^{(m)}$ is called a partial process (a partial relation) of $R^{(m)}$ while any projection $R^{(p)} = R^{(m)}{}_{C(p)}$ of $R^{(m)}$ on a repertory of scenarios $C^{(p)}$ corresponding to a sub-universe $F^{(p)}\subset F^{(m)}$ is called a sub-process (a sub-relation) of $R^{(m)}$. A partial process consists thus of selected trajectories while a sub-process consists of cancelled (e.g. to a shortened time- interval) sub-trajectories of $R^{(m)}$. In the above-mentioned cases $R^{(m)}$ is called a broadening of R^* and an extension of $R^{(p)}$.

For a given sub-universe $F^{(m)}$ we denote by $\Omega^{(m)}$ the family of all processes, including an empty process $\theta^{(m)}$ and a "trivial" process $C^{(n)}$, that on $F^{(m)}$ can be defined. Similarly, it will be denoted by Ω_F the family of all processes that can be defined on any sub-families $F^{(m)}$ of the universe F. Then, an extended algebra of relations that can be described on F and its sub-universes is given by a quintuple [7]:

$$A_F = [F, \Omega_F, \underline{\cup}, \underline{\cap}, \underline{\neg},] \tag{3}$$

where $\underline{\cup}$, $\underline{\cap}$, $\underline{\neg}$, stand, respectively, for extended sum, intersection and negation of relations. Let us remark that an extended difference of relations $R^{(m)} \underline{\setminus} R^{(n)}$ is given by the formula:

$$R^{(m)} \underline{\setminus} R^{(n)} = R^{(m)} \underline{\cap} (\underline{\neg} R^{(n)}). \tag{4}$$

All concepts of the extended algebra of relations can thus directly be applied to the processes.

Example 1

Let I be a countable set of real integers i called time-instants and let U be a countable set of elements u_k, $k\in[\ldots,-2,\ -1,0,1,2,\ldots]$ called states. Then any function:

$$f_\nu:\ I \rightarrow U \tag{5}$$

$\nu\in N$, where N denotes a set of natural numbers, describes a discrete process trajectory (whose interpretation depends on a given application area). We take into consideration four time-instants: $i_1, i_2, i_3, i_4 \in I$ such that $i_1 < i_2 \le i_3 < i_4$ and two discrete time-intervals: $I', I''\subseteq I$, $I' = [i_1,\ldots,i_3]$, $I'' = [i_2,\ldots,i_4]$. Evidently, it is $I' \cap I'' \neq \varnothing$ where $\varnothing$ denotes an empty set. We shall denote by $f_\nu|_{I'}$ and $f_\nu|_{I''}$ the function f_ν cancelled, respectively, to the time-interval I' and I''. The above-described notions can also be interpreted in the relations theory terms. For this purpose an universe takes the form of linearly ordered family of sets $F = U^{\,I}$. Their Cartesian product C_F plays the role of a multidimensional discrete space whose elements (discrete vectors) correspond to the process trajectories. We also shall denote by $F' = U^{\,I'}$ and $F''=U^{\,I''}$ the sub-universes of F consisting of the sets marked by indices belonging, respectively, to the discrete time-intervals I' and I''; the corresponding Cartesian products (repertories of scenarios) will be denoted by C' and C''. Any process trajectory $\mathbf{y}\in C_F$ outlines thus in unique way in C' and C'' process sub-trajectories $\boldsymbol{y'}$ and $\boldsymbol{y''}$ called, respectively, the projections of $\mathbf{y}$ on the intervals I' and I'' as shown in Fig. 1 (the sub-trajectories are marked in gray, their common part is shown in black color). On the other hand, the process trajectory $\mathbf{y}$ will be called an extension of $\boldsymbol{y'}$ (respectively, of $\boldsymbol{y''}$) on the interval I.

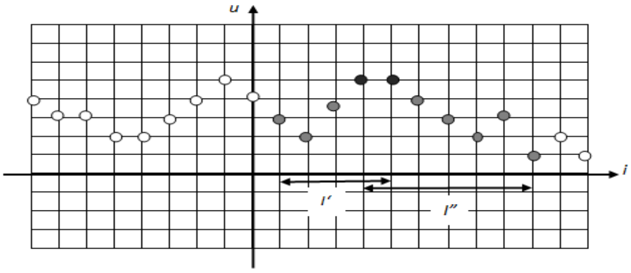

Fig. 1. Example of a discrete process trajectory **y** and its sub-trajectories ***y'*** and ***y''***.

Any set of discrete process trajectories $\mathbf{Y^*} = \{\mathbf{y}^{(\nu)}\}$, $\nu\in N$, described on a given interval $I^* \subseteq I$, is a subset of Cartesian product $\mathbf{Y^*} \subseteq C^*$; hence, it defines a relation in the family of sets F^*. On the other hand, each relation defined in F^* describes a discrete process whose trajectories constitute the instances of the relation. As it has been mentioned above, on the basis of the family Ω_F of all relations that can be defined on the sub-families of F it can be defined an extended algebra A_F of relations; it also becomes an algebra of discrete processes described in C_F.

Let us denote by $\boldsymbol{Y'}$ and $\boldsymbol{Y''}$ two discrete processes described, respectively, on the (not obviously disjoint) intervals I' and I''. Then:

a) an extended sum $\boldsymbol{Y'}\ \bar{\underline{\cup}}\ \boldsymbol{Y''}$ of the processes is a discrete process defined on the interval $I' \cup I''$ as a set of all trajectories $\mathbf{y}^{(\nu)}$ such that their projections on I' are the trajectories of Y' or their projections on I'' are the trajectories of Y'';

b) an extended product $Y' \underline{\cap}\ Y''$ of the processes is a

c) discrete process defined on the interval $I' \cup I''$ as a set of all trajectories $\mathbf{y}^{(\nu)}$ such that their projections on I' are the trajectories of Y' and their projections on I'' are the trajectories of Y'';

d) an extended difference $Y' \underline{\setminus}\ Y''$ of the processes is a discrete process defined on the interval $I' \cup I''$ as a set of all trajectories $\mathbf{y}^{(\nu)}$ such that their projections on I' are the trajectories of Y' and their projections on I'' are not the trajectories of Y''.

The following example will illustrate the above-given notions. Two discrete time-intervals are defined as follows (see Fig. 1):

$$I' = [1,2,3,4,5], \quad I'' = [4,5,6,7,8,9,10];$$

(the intervals are overlapping at the time-instants 4 and 5).

In these intervals two discrete processes are given by their trajectories:

$$Y' = \{[3,2,4,5,5], [2,3,4,5,4], [5,3,4,6,5]\},$$
$$Y'' = \{[3,2,4,5,5,6,4], [5,5,4,3,2,3,1], [6,5,0,3,4,5,5], [1,2,0,3,4,6,7]\}.$$

Their algebraic combinations will be described as processes in a joint time-interval:

$$\mathrm{I} = [1,2,3,4,5,6,7,8,9,10].$$

Then one obtains the following algebraic combinations of the processes:

$$Y' \underline{\cup}\ Y'' = \{[3,2,4,5,5,*,*,*,*,*], [2,3,4,5,4,*,*,*,*,*], [5,3,4,6,5,*,*,*,*,*], [*,*,*,3,2,4,5,5,6,4], [*,*,*,5,5,4,3,2,3,1], [*,*,*,6,5,0,3,4,5,5], [*,*,*,1,2,0,3,4,6,7];$$

where * denotes any element (instant state) of U;

$$Y' \underline{\cap}\ Y'' = \{[3,2,4,5,5,4,3,2,3,1], [5,3,4,6,5,0,3,4,5,5]\};$$
$$Y' \underline{\setminus}\ Y'' = \{[2,3,4,5,4,*,*,*,*,*]\},$$
$$Y'' \underline{\setminus}\ Y' = \{[*,*,*,3,2,4,5,5,6,4], [*,*,*,1,2,0,3,4,6,7]\}.$$

Negations of relations (complements of relations) can be defined as extended differences of trivial relations and the relations under consideration:

$$\underline{\neg} Y' \equiv \mathrm{C_F} \underline{\setminus}\ Y',$$
$$\underline{\neg} Y'' \equiv \mathrm{C_F} \underline{\setminus}\ Y'',$$

It can be remarked that the extended sum $Y' \underline{\cup}\ Y''$ represent bunches of trajectories satisfying Y' in the time-interval I' or Y'' in the time-interval I'' (or satisfying both of them), while the extended intersection $Y' \underline{\cap}\ Y''$ can geometrically be interpreted as a consistent prolongation of Y' by Y''. The intersection of relations defines also the following two sub-relations of Y' and $\mathbf{Y''}$ called their conditional relations:

$$Y'|Y'' = (Y' \underline{\cap}\ Y'')_{F'} \times \mathrm{C}_{F''\setminus F'} =$$
$$= \{[3,2,4,5,5,*,*,*,*,*], [5,3,4,6,5,*,*,*,*,*]\},$$
$$Y''|Y' = \mathrm{C}_{F'\setminus F''} \times (Y' \underline{\cap}\ Y'')_{F''} =$$
$$= \{[*,*,*,5,5,4,3,2,3,1], [*,*,*,6,5,0,3,4,5,5]\},$$

(lower indices at the Cartesian products and relations denote their projections on the given sub-families of sets) read, respectively, as: "Y' assuming that Y'' " and "Y'' assuming that Y' ".

A pair of relations Y' and Y'' is called mutually independent if $Y' \underline{\cap}\ Y'' \equiv Y' \times Y''$; in such case it is $(Y'|Y'')_{F'} \equiv Y'$ and $(Y''|Y')_{F''} \equiv Y''$ •

The conditional relations play a substantial role in process extrapolation. From a formal point of view all algebraic operations illustrated in Example 1 can also be interpreted as super-relations (relations between relations): a/ described on a composite Cartesian product $C' \times C'' \times \mathrm{C}_{F'' \cup F''}$ in the case of extended sum, intersection or differences and b/ on $C' \times \mathrm{C}_{F'' \cup F''}$ or on $C'' \times \mathrm{C}_{F'' \cup F''}$ in the case of complementary relations.

Till now, deterministic relations and their application to deterministic processes description were considered. A notion of parametric relation is a step to non-deterministic relations definition. Let $\mathrm{W}^{(m)}$ be a set of real parameter values. We take into consideration a Cartesian product $\mathrm{C}^{(m)}$ and a relation $\mathrm{R}^{(m)}$ as defined by (1) and (2). A Cartesian product

$$\mathrm{D}^{(m)} = \mathrm{C}^{(m)} \times \mathrm{W}^{(m)} \tag{6}$$

and a relation

$$\mathrm{P}^{(m)} \subseteq \mathrm{D}^{(m)} \tag{7}$$

such that: 1) the projection $\mathrm{P}^{(m)}|_{\mathrm{C}}{}^{(m)}$ of $\mathrm{P}^{(m)}$ on $\mathrm{C}^{(m)}$ is identical to $\mathrm{R}^{(m)}$, 2) to each instance of $\mathrm{R}^{(m)}$ exactly one value w, $\mathrm{w} \in \mathrm{W}^{(m)}$, is assigned. Apparently, if additional parameters are considered as other relations' variables, the nature of the relation is not changed and the extended relations algebra rules hold as well. However, this means that following from this algebra rigid rules of inheritance of parameter values on algebraic combinations of the trajectories are imposed. For the sake of practical utility parametric relation should be defined rather so that parameter transformation rules are defined independently on the algebraic operation rules. Parametric relations are then created by parameterization of some ordinary relations consisting in: 1st choosing the sets of parameters W, 2nd assigning parameter values to the instances of the relations, and 3rd establishing a set Q of functional relations:

$$\mathrm{q}_{\cup} \subseteq \mathrm{W}^{(m)} \times \mathrm{W}^{(n)} \times \mathrm{W}, \tag{8a}$$
$$\mathrm{q}_{\cap} \subseteq \mathrm{W}^{(m)} \times \mathrm{W}^{(n)} \times \mathrm{W}, \tag{8b}$$
$$\mathrm{q}_{\setminus} \subseteq \mathrm{W}^{(m)} \times \mathrm{W}^{(m)} \times \mathrm{W}, \tag{8c}$$

assigning in unique way the values of parameters, respectively, to the instances of extended sums, intersections, and differences of relations. The extended algebraic operations on parametric relations can then be defined as super-relations:

$$P^{(m)}\cup^* P^{(n)} = [(P^{(m)}\ \bar{\cup}\ P^{(n)})\ \bar{\cap}\ q_{\cup}]_{R(m)\times R(n)\times W}, \qquad (9a)$$

$$P^{(m)}\cap^* P^{(n)} = [(P^{(m)}\ \bar{\cap}\ P^{(n)})\ \bar{\cap}\ q_{\cap}]_{R(m)\times R(n)\times W}, \qquad (9b)$$

$$P^{(m)}\setminus^* P^{(n)} = [(P^{(m)}\ \bar{\setminus}\ P^{(n)})\ \bar{\cap}\ q_{\setminus}]_{R(m)\times R(n)\times W}, \qquad (9c)$$

which mean that 1st the algebraic operations should separately be performed on the component relations and on the assigned to them parameters, 2nd their results should be integrated by intersection of relations, and 3rd redundant parameter values from the super-relations should be removed by their projection on reduced sub-families of states. The form of the relations $q_{\cup}$, $q_{\cap}$ and $q_{\setminus}$ is not predetermined, it depends on the application purposes. If a family of parametric relations in the same universe F is considered, a family G_W of parameter sets instead of a single set W should be taken into consideration.

For a given universe F, its Cartesian product C_F, a family G_W of sets of parameters, a family Q of parameters transformations and a family Ω_D of all parametric relations reached by parameterization of the relations of Ω_F an algebra of parametric relations can be defined as an 8-tuple:

$$A_P = [F, C_F, G_W, Q, \Omega_{D}, \cup^*, \cap^*, \setminus^*]. \qquad (10)$$

Example 2

There will be considered the relations ***Y'*** and ***Y"*** described in Example 1. It is established a set of parameters W = [0,…,1] and the parameters are assigned to the trajectories as follows:

P' = {[3,2,4,5,5; 0.2)], [2,3,4,5,4; 0.6), [5,3,4,6,5; 0.3)]},

P"={[3,2,4,5,5,6,4; 0.3], [5,5,4,3,2,3,1; 0.1], [6,5,0,3,4,5,5; 0.5], [1,2,0,3,4,6,7; 0.4]} (parameters being separated from other components by semicolons). It is assumed that the parameters will be assigned to the sum and intersection of the relations in the below-described way.

If w_p, w_q ∈ W are parameter values assigned, respectively, to two given trajectories $\boldsymbol{u'}_p \in \boldsymbol{P'}$, $\boldsymbol{u''}_q \in \boldsymbol{P''}$ then:

1. if $\boldsymbol{u'}_p\ \bar{\cup}\ \boldsymbol{u''}_q$ satisfies ***P'*** only then parameter value w_p is to it assigned;
2. if $\boldsymbol{u'}_p\ \bar{\cup}\ \boldsymbol{u''}_q$ satisfies ***P"*** only then parameter value w_q is to it assigned;
3. if $\boldsymbol{u'}_p\ \bar{\cup}\ \boldsymbol{u''}_q$ satisfies both ***P'*** and ***P"*** then parameter value $\max(w_p,w_q)$ is to it assigned;
4. for $\boldsymbol{u'}_p\ \bar{\cap}\ \boldsymbol{u''}_q$ the parameter value $\min(w_p,w_q)$] is to it assigned;

According to this the following parameter values (weights) to the trajectories will be assigned:

P' ∪* ***P"*** = {[**3,2,4,5,5**,4,5,5,6,4; 0.2],
[**2,3,4,5,4,**4,5,5,6,4; 0.6], [**5,3,4,6,5**,4,5,5,6.4;0.3],
[**3,2,4,5,5,4,3,2,3,1**; 0.2)],
[**2,3,4,5,4,**4,3,2,3,1; 0.6], [**5,3,4,6,5**,4,3,2,3.1;0.3],
[**3,2,4,5,5**,0,3,4,5,5; 0.2)],
[**2,3,4,5,4,**0,3,4,5,5; 0.6],
[**3,2,4,5,5**,0,3,4,6,7; 0.2)],
[**2,3,4,5,4,**0,3,4,6,7; 0.6], [**5,3,4,6,5**,0,3,4,6.7;0.3],
[3,2,4,**3,2,4,5,5,6,4**; 0.3],
[2,3,4,**3,2,4,5,5,6,4**; 0.3], [5,3,4,**3,2,4,5,5,6,4**; 0.3],
[2,3,4,**5,5,4,3,2,3,1**; 0.1], [5,3,4,**5,5,4,3,2,3,1**; 0.1],
[3,2,4,**6,5,0,3,4,5,5**; 0.5],
[2,3,4,**6,5,0,3,4,5,5**; 0.5], [**5,3,4,6,5,0,3,4,5,5**; 0.5],
[3,2,4,**1,2,0,3,4,6,7**; 0.4],
[2,3,4,**1,2,0,3,4,6,7**; 0.4], [5,3,4,**1,2,0,3,4,6,7**; 0.4]};

P' ∩* ***P"*** = {[**3,2,4,5,5,4,3,2,3,1**;0.1],
[**5,3,4,6,5,0,3,4,5,5;** 0.3]};

¬****P'*** = (*C'* \ ***F'***) ×{0.4};

¬****P"*** = (*C"* \ ***F"***) ×{0.5},

where the sub-trajectories which contributed to the resulting parameter values have been indicated in bold.

Let us remark that in the above-given case the parameters are not additive; they may reflect relative “importance”, ”reliability” or other sort of “usefulness” of the trajectories. Moreover, to all trajectories of a negation (¬****P'*** or ¬****P"***) the same parameter values (0.4 or 0.5, respectively) have been assigned •

Example 2 shows a way to blurring (fuzzying) the relations: fuzzy relation is a parametric relation whose parameter values assigned to the instances reflect a level of credibility that the relation is by them satisfied. The expressions (8a-c, 9) hold thus for the fuzzy relations assuming that the sub-relations $q_{\cap}$, $q_{\cup}$, $q_{\neg}$ have been chosen adequately to instances' credibility description purposes. For this purpose they should satisfy some general triangular norms and co-norms conditions [9]. Such conditions are satisfied not only in the above- presented Example 2 but also in some other cases. Among them the following one deserves some attention.

Example 3

Once again, the relations ***Y"*** and ***Y"*** will be taken into consideration. However, instead of exact numerical credibility values their symbolic denotations to their instances will be assigned as follows:

P' = {[3,2,4,5,5; ε_1)], [2,3,4,5,4; ε_5), [5,3,4,6,5; ε_2)]},
P" ={[3,2,4,5,5,6,4; ε_2], [5,5,4,3,2,3,1; ε_0],
[6,5,0,3,4,5,5; ε_4], [1,2,0,3,4,6,7; ε_3]}

under additional assumptions:

$$0 < \varepsilon_0 < \varepsilon_1 < \varepsilon_2 < \varepsilon_3 < \varepsilon_4 < \varepsilon_5 < \varepsilon_6,$$

level ε_0 being assigned to all instances not belonging to ***P'*** or to ***P"***.

Then, according to the formerly presented rules 1 – 4, the following credibility values to the instances of algebraic combinations of relations will be assigned:

P' ∪* ***P"*** = {[**3,2,4,5,5**,4,5,5,6,4; ε_2],
[**2,3,4,5,4**,4,5,5,6,4; ε_6], [**5,3,4,6,5**,4,5,5,6.4; ε_3],
[**3,2,4,5,5,4,3,2,3,1**; ε_2)],
[**2,3,4,5,4**,4,3,2,3,1; ε_6], [**5,3,4,6,5**,4,3,2,3.1; ε_3],

[**3,2,4,5,5**,0,3,4,5,5; ε_2)],
[**2,3,4,5,4,**0,3,4,5,5; ε_6],
[**3,2,4,5,5**,0,3,4,6,7; ε_2)],
[**2,3,4,5,4,**0,3,4,6,7; ε_6], [**5,3,4,6,5**,0,3,4,6.7; ε_3],
[3,2,4,**3,2,4,5,5,6,4**; ε_3],
[2,3,4,**3,2,4,5,5,6,4**; ε_3], [5,3,4,**3,2,4,5,5,6,4**; ε_3],

[2,3,4,**5,5,4,3,2,3,1**; ε_1], [5,3,4,**5,5,4,3,2,3,1**; ε_1],
[3,2,4,**6,5,0,3,4,5,5**; ε_5],
[2,3,4,**6,5,0,3,4,5,5**; ε_5], [**5,3,4,6,5,0,3,4,5,5**; ε_5],
[3,2,4,**1,2,0,3,4,6,7**; ε_4],
[2,3,4,**1,2,0,3,4,6,7**; ε_4], [5,3,4,**1,2,0,3,4,6,7**; ε_4]};
$\boldsymbol{P'} \cap^* \boldsymbol{P''} = \{$[**3,2,4,5,5,4,3,2,3,1**; ε_2],
[**5,3,4,6,5,0,3,4,5,5;** ε_3]};
$\neg^*\boldsymbol{P'} = (C' \setminus \boldsymbol{F'}) \times \{\varepsilon_4\}$;
$\neg^*\boldsymbol{P''} = (C'' \setminus \boldsymbol{F''}) \times \{\varepsilon_5\}$ •

Definition. Fuzzy relations whose credibility levels are given in symbolic form with assumed inequalities instead of their exact numerical values are below called non-deterministic relations.

It is important to remark that in the non-deterministic relation case for finding the most credible algebraic combination of relation instances (e.g. their intersection) no exact numerical credibility values excepting assumed inequalities between them are needed.

III. Inference Rules Based on Non-Determined Relations

According to the definition of relative relations the following identities hold:

$$(\boldsymbol{F'}|\,\boldsymbol{F''})\ \overline{\cap}\ \boldsymbol{F''} \equiv \boldsymbol{F'}\ \overline{\cap}\ \boldsymbol{F''} \equiv (\boldsymbol{F''}|\boldsymbol{F'})\ \overline{\cap}\ \boldsymbol{F'}. \tag{11}$$

Assuming that $\boldsymbol{F'}$ and $\boldsymbol{F''}$ are two processes described, respectively, on discrete time-intervals $I' = [i_1,...,i_2]$, $I'' = [i_2,...,i_3]$ where the time-instants $i_1,\ldots,i_2-1$ belong to the "past", i_2 belongs to the (common for I' and I'') "present time" and $i_2+1,\ldots,i_3$ belong to the "future" it will be considered a problem of extrapolation of the process on I'' under the assumption that its behavior in the time-interval I'' has been observed. No special assumptions about the nature of the instant states of the process are made (the processes are thus not obviously numerical) excepting that the $U^{(i)}$ for all i are some isomorphic finite sets, $|U^{(i)}| = K$, K being a natural number. For credibility levels of the trajectories of $\boldsymbol{F'}$ and $\boldsymbol{F''}$ assessment it will be introduced a set of symbolic parameters $\mathbf{e} = [\varepsilon_0, \varepsilon_1,\ldots, \varepsilon_K]$. The components of $\mathbf{e}$ in K! ways can be linearly semi-ordered so that the component ε_0 remains at the first position. Moreover, for any fixed ordering each symbol (excepting the ε_0 one) can be preceded by = or < which gives 2^K different possibilities. Totally, it follows that there are $2^K\cdot$ K! different ways of possible relative credibility levels establishing in this given case.

Example 4

An example of semi-ordering of credibility levels can be presented in the form of a linear graph as shown in Fig. 2.

a/ $\varepsilon_0 = \varepsilon_4 < \varepsilon_5 < \varepsilon_7 < \varepsilon_6 < \varepsilon_{12} < \varepsilon_1 = \varepsilon_3 < \varepsilon_{10} < \varepsilon_2 = \varepsilon_9 = \varepsilon_{11} < \varepsilon_8$

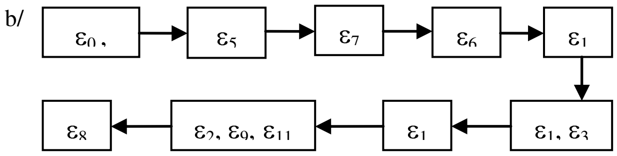

Fig. 2. Example of semi-ordering of credibility levels: a/ algebraic form, b/ graphical form.

For process extrapolation relative credibility levels of longer trajectories should be established [8]. Let us assume that it is given a non-deterministic relation **Y** describing a discrete process in the time-interval $I' \cup I''$. The credibility levels of its instances have been evaluated on the basis of past observation of the process. Therefore, **Y** can play the role of an experimental model of the process, suitable for process prediction decisions making (like training sets used in pattern recognition). For process extrapolation purposes **Y** will be presented in the form of an extended intersection of sub-relations:

$$\mathbf{Y} = \mathbf{Y}_{I'} \cap^* \mathbf{Y}_{I''} \equiv \boldsymbol{Y'} \cup^* \boldsymbol{Y''} \tag{12}$$

where $\boldsymbol{Y'}$ (a sub-process obtained by projection of $\mathbf{Y}$ on I') is considered as a model of the "past" and, similarly, $\boldsymbol{Y''}$ is used as a model of the "future". The credibility levels assigned to the instances of **Y** are without changing assigned to the corresponding instances of $\boldsymbol{Y'}$ and $\boldsymbol{Y''}$.

Similarly, conditional relations $\boldsymbol{Y'}\ |\boldsymbol{Y''}$ and $\boldsymbol{Y''}|\boldsymbol{Y'}$ can be calculated. The relation $\boldsymbol{Y''}|\boldsymbol{Y'}$ describing future trajectories of the process under the assumption that the past trajectories of the process are known is for process extrapolation of particular interest. Let $\mathbf{x} \in C'$ be a new past trajectory. Then, two cases should be considered:

1st it exists in $\boldsymbol{Y'}$ a trajectory $\mathbf{u}^{(\mathbf{x})}$ identical to $\mathbf{x}$:

$$\mathbf{u}^{(\mathbf{x})} \equiv \mathbf{x}; \tag{13}$$

2nd no such trajectory in $\boldsymbol{Y'}$ exists.

Direct one-step extrapolation. In the first case, an intersection:

$$\boldsymbol{Y''}(\mathbf{x}) = \mathbf{u}^{(\mathbf{x})} \cap^* (\boldsymbol{Y''}|\boldsymbol{Y'}) \tag{14}$$

consisting of all sub-trajectories in I'' being prolongations of **x** can be considered. This is illustrated by a graph shown in Fig. 4. The top-row of nodes represent the sub-trajectories belonging to $\boldsymbol{Y'}$ while the bottom-row corresponds to those belonging to their prolongations in the conditional relation $\boldsymbol{Y''}|\boldsymbol{Y'}$. A black node represents the condition $\mathbf{u}^{(\mathbf{x})}$ while grey nodes correspond to its possible prolongations. Moreover, to each sub-trajectory a credibility level is assigned. Therefore, a partial process consisting of the most credible sub-trajectories can be selected according to the rule:

$$\boldsymbol{z}^* = [\boldsymbol{u}^{(x)}, \boldsymbol{v}^{(p)}, u^*] \text{ where } (\boldsymbol{v}^{(p)}: e^{(p)} = max_{(q)}\{e^{(q)}\}, \boldsymbol{v}^{(q)} \in \boldsymbol{Y''}|\boldsymbol{u}^{(x)}, u^* \in \boldsymbol{v}^{(q)}) \tag{15}$$

$e^{(q)}$ being relative credibility levels assigned to the sub-trajectories $\boldsymbol{v}^{(q)}$; u^* denotes a final state of the most credible future sub-trajectory. Bold arrow in Fig. 3 represents the extension of the highest credibility level.

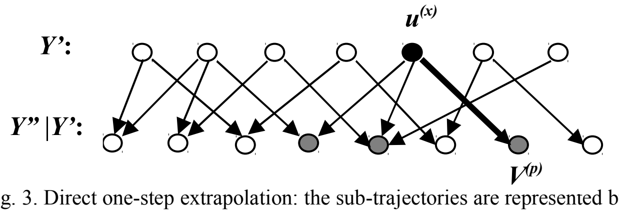

Fig. 3. Direct one-step extrapolation: the sub-trajectories are represented by the nodes.

Indirect one-step extrapolation. The 2nd case of a lack in $\boldsymbol{Y'}$ of an adequate past trajectory needs a more sophisticated approach. Solution of the problem on a general *case-based* approach consisting in finding a closely similar situation is possible. For this purpose a *relative similarity* $\rho(\boldsymbol{u}^{(i)}, \boldsymbol{u}^{(j)})$ of the pairs of elements of the sub-universe C' should be defined. Formally, it can be presented in equivalent form of a parametric relation:

$$\boldsymbol{\rho} \subseteq C' \times C' \times \boldsymbol{e} \tag{16}$$

where $\boldsymbol{e}$ is a finite set of symbols of relative credibility levels on which a semi-ordering relation σ has been imposed. In practice, the semi-ordering σ may be connected with a *similarity measure* of the pairs of sub-trajectories $(\boldsymbol{u}^{(i)}, \boldsymbol{u}^{(j)}) \in C' \times C'$.

Let $\boldsymbol{x} \in C'$ be a given past sub-trajectory. Then it can be defined a partial relation $\boldsymbol{S}_{x^*} \subset \boldsymbol{\rho}$ consisting of all instances containing the pairs $[\boldsymbol{x}, \boldsymbol{u}^{(j)}]$ and their corresponding credibility levels $e_{x,j}$. It will be taken into consideration an intersection:

$$\boldsymbol{Y'}_x = \boldsymbol{S}_{x^*} \cap^* \boldsymbol{Y'} \tag{17}$$

It evaluates the (on similarity measure based) credibility levels of the trajectories $\boldsymbol{u}^{(j)} \in \boldsymbol{Y'}$ used as models approximating the given past sub-trajectory $\boldsymbol{x}$. Then, an extrapolation of $\boldsymbol{x}$ can be reached like in the above described direct one-step extrapolation case when $\boldsymbol{Y'}$ is replaced by $\boldsymbol{Y'}_{\boldsymbol{x}}$. Analytically, the solution is given by the decision rule:

$$\begin{aligned} \boldsymbol{z}^* = [\boldsymbol{x}, \boldsymbol{u}^{(j)}, \boldsymbol{v}^{(p)}, u^*] \text{ where } (\boldsymbol{u}^{(j)}, \boldsymbol{v}^{(p)})&: e^{(j,p)} = \\ = max_{\{j,q\}} min(e_{x,j}, e_{j,q}), (\boldsymbol{x}, \boldsymbol{u}^{(j)}) &\in \boldsymbol{Y'}_{\boldsymbol{x}}, \\ \boldsymbol{v}^{(q)} \in \boldsymbol{Y''}|\boldsymbol{Y'}_x ; u^* \in \boldsymbol{v}^{(p)};\ e_{x,j}, e_{j,q} &\in \boldsymbol{e}. \end{aligned} \tag{18}$$

A scheme of this problem solution is shown in Fig. 4. It is important to remark that the most credible solution of the in-direct extrapolation problem due to the relative, non-numerical credibility levels has been found.

Direct multi-step extrapolation. In the one-step extrapolation an extrapolation range is by the length of sub-trajectories of $\boldsymbol{Y''}$ limited. However, it by a multi-step extrapolation procedure can be extended. For this purpose a sequence of equal-length overlapping time-intervals $I^{(m)}, \ldots, I^{(2)}, I^{(1)}$ will be considered, each time-interval being divided by a "present" time-instant into its "preceding" and "following" sub-interval, as shown in Fig. 5.

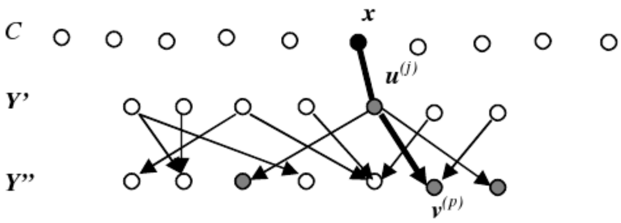

Fig.4. A scheme of in-direct one-step extrapolation problem solution.

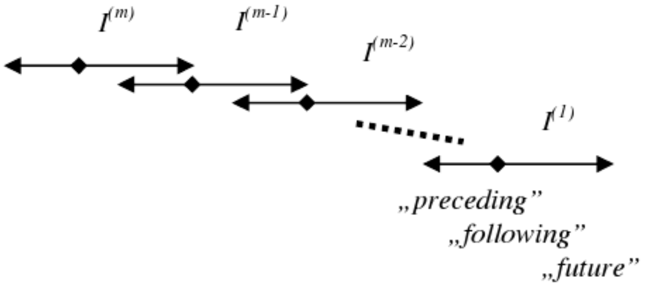

Fig. 5 Extension of process extrapolation intervals.

Let us assume that on the time-intervals the corresponding sub-processes $\boldsymbol{Y}^{(m)}, \boldsymbol{Y}^{(m-1)}, \ldots, \boldsymbol{Y}^{(1)}$ described by isomorphic relations have been defined. In each sub-process $\boldsymbol{Y}^{(\mu)}$ a "preceding" $\boldsymbol{Y}^{(\mu)}$' and "following" $\boldsymbol{Y}^{(\mu)}$'' part so that

$$\boldsymbol{Y}^{(\mu)} = \boldsymbol{Y}^{(\mu)'} \cap^* \boldsymbol{Y}^{(\mu)''} \tag{19}$$

will be distinguished. Then, an intersection:

$$\boldsymbol{Y} = \boldsymbol{Y}^{(m)} \cap^* \boldsymbol{Y}^{(m-1)} \cap^* \ldots \cap^* \boldsymbol{Y}^{(1)} \tag{20}$$

will be taken into consideration. In the process $\boldsymbol{Y}$ a sub-process $\boldsymbol{Y}^{(m)}$' as the "past" and $\boldsymbol{Y}|\boldsymbol{Y}^{(m)}$'as the "future" can be considered. Formally, solution of the multi-step extrapolation problem is similar to this of the one-step extrapolation one excepting that the "future" sub-universe becomes larger as containing more alternating sub-trajectories leading from a "present" to a "final" state. A solution of the direct multi--step extrapolation problem is given by the decision rule:

$$\begin{aligned} \boldsymbol{z}^* = [\boldsymbol{u}^{(x)}, \boldsymbol{v}^{*(p)}, u^*] \text{ where } (\boldsymbol{v}^{*(p)}: e^{(p)} = \\ = max_{(q)}\, min\{e^{(q1)}, e^{(q2)}, \ldots, e^{(qm)}\}, \boldsymbol{v}^{*(q)} \in \boldsymbol{Y''}|\boldsymbol{u}^{(x)}) \end{aligned} \tag{21}$$

Above, $\boldsymbol{v}^{*(q)}$ denotes the q-th path leading from $\boldsymbol{u}^{(x)}$, $\boldsymbol{u}^{(x)} \in \boldsymbol{Y}^{(m)}$', through a chain of connected sub-trajectories $\boldsymbol{v}^{(q1)}$, $\boldsymbol{v}^{(q2)}, \ldots, \boldsymbol{v}^{(qm)}$ to a final future state $u^* \in \boldsymbol{v}^{(qm)}$.

Example 5

Systolic pressures of a patient have been daily recorded for several weeks (a real medical record has been used as a basis of this example). The scale of pressure have been divided into intervals as follows:

D_1: 101 – 105 mmHg
D_2: 106 – 110 mmHg,
D_3: 111 – 115 mmHg,
…
D_{24}: 215 – 220 mmHg.

An observed discrete process trajectory after quantization took the form:

$D_5\ D_4\ D_5\ D_4\ D_4\ D_1\ D_6\ D_2\ D_6 D_6\ D_5\ D_7\ D_4\ D_4\ D_5\ D_6\ D_6\ D_5\ D_3\ D_6$ …

The trajectory has been used as an experimental model of the process. From the above-given sequence of data 16 sub-sequences have been selected as follows:

P_1: $D_5\ D_4\ D_5 \mid D_4\ D_4$,
P_2: $D_4\ D_5\ D_4 \mid D_4\ D_1$,
P_3: $D_5\ D_4\ D_4 \mid D_1\ D_6$,
…
P_{16}: $D_6\ D_6 D_5 \mid D_3 D_6$

where the marks | separate the (arbitrarily chosen) "past" and "future" parts of the sub-sequences. Then, there have been established formally admissible connections between the sub-sequences, like:

P_1: $D_5\ D_4\ D_5\ \mathbf{D_4\ D_4},$
P_4: $\mathbf{D_4\ D_4}\ D_1\ D_6\ D_2$
$P_1 - P_4$: $D_5\ D_4\ D_5\ \mathbf{D_4\ D_4}\ D_1\ D_6\ D_2.$

This led to a list of admissible connections shown below:

$\underline{P_1 - P_4}$, $P_1 - P_{13}$, $\underline{P_2 - P_5}$, $\underline{P_3 - P_6}$, $\underline{P_4 - P_7}$, $\underline{P_5 - P_8}$, $\underline{P_6 - P_9}$, $P_6 - P_{16}$, $\underline{P_7 - P_{10}}$,
$P_7 - P_{17}$, $\underline{P_8 - P_{11}}$, $\underline{P_9 - P_{12}}$, $P_{10} - P_4$, $\underline{P_{10} - P_{13}}$, $P_{11} - P_2$, $\underline{P_{11} - P_{14}}$, $\underline{P_{12} - P_{15}}$,
$P_{13} - P_9$, $\underline{P_{13} - P_{16}}$, $P_{14} - P_{10}$, $\underline{P_{14} - P_{17}}$, $\underline{P_{15} - P_{18}}$, $\underline{P_{16} - P_{19}}$, $\underline{P_{17} - P_{20}}$,
$P_{18} - P_4$, $P_{18} - P_{13}$, $P_{20} - P_{17}$…

To the connection their relative credibility levels e can be assigned according to the number of cases they have been really noticed. A symbolic credibility level e_1 is assigned to the connections that have been noticed and e_0 to those which only formally are possible. It is assumed that $e_0 < e_1$; the connections to which e_1 has been assigned are in the list underlined.

Let us assume that an initial sub-process $\boldsymbol{Y'} = [D_5\ D_4\ D_5\}$ has been observed. The question is: what are the most credible extrapolations of the process? Its extrapolations are:

1st step: $\underline{\boldsymbol{Y'} - P_1}= [D_5\ D_4\ D_5 \mid D_4\ D_4\}$ with credibility level e_1;

2nd step: $\underline{\boldsymbol{Y'} - P_1 - P_4} = [D_5\ D_4\ D_5 \mid D_4\ D_4\ D_1\ D_6\ D_2]$ with credibility level $e = \min(.e_1,e_1) = e_1$;

$$\underline{\boldsymbol{Y'} - P_1}–P_{13} = [D_5\ D_4\ D_5 \mid D_4\ D_4, D_5\ D_6\ \ D_6]$$

with credibility level $e = \min(.e_1,e_0) = e_0$.

In similar way, further process extrapolation can be reached •

IV. Conclusions

Human natural ability to forecast possible future events is based on experience and intuition rather than on formal logical inference. Early computer-aided forecasting systems tried to reach similar goals using formal tools like stochastic processes theory, logical inference methods, etc. However, it occurred that including less rigid, heuristic methods into forecasting procedures may also lead to their improvement. The case-based methods of processes extrapolation as well as relative credibility levels of their future states forecasting presented in this paper belong to this new approach to human thinking imitation. Presentation of a process as a relation makes consideration of not only numerical but also qualitative and multi-aspect processes possible. Credibility levels are considered as comparative, not obviously absolute numerical values. As a consequence, indication of the most credible future states of an extrapolated process is based on a simple comparative analysis instead of rigid numerical calculi. Evidently, some shortcomings with the above-presented approach, like: dependence of the extrapolation effectiveness on the representativeness of the past process observations as models of the future process behavior also exist. The methods of relative credibility levels of process instances assessment need thus deeper investigation which should be a task for future works to be undertaken..

Acknowledgment

The Author would like to thank Prof. Halina Kwasnicka and Dr Urszula Markowska-Kaczmar for their kind inspiration to write this paper as well as to the Reviewers for their substantial critical remarks.

***Abstract*—Both associative networks and RDF model (here we consider especially its graph version) belong to formal systems of knowledge representation based on concept-oriented paradigm. To treat properties of both of them as common properties of the systems is therefore natural. The article shows a possibility to use universal and existential quantified statements introduced prior to associative networks also within RDF graphic system and to define a RDF formal system with extended syntax and semantic that can use inference rules of associative networks. As an example solution, a logical puzzle is presented.**

I. Introduction

ABSTRACT RDF metamodel forms a framework and approach how to express a piece of knowledge by means of a directed, labeled graph that links relevant resources. All entities described by RDF expressions have to be treated as resources that are identified by resource identifiers - URIs. According to the metamodel RDF graph notation RDF statement consists of two labeled nodes (subject and object) linked together by a labeled edge (predicate). All of the labels of subject or predicate are represented by names as URIs, in the case of object it is also possible to use literal value. RDF in its second part RDFS also has an ability to define vocabularies (new terms) for practical use in RDF statements to specify kinds or classes of resources with specific attributes.

The graph view is the easiest possible and easy-to-understand visual explanations of RDF statements.

A similar idea as in the case of RDF occurred several years ago at the beginning of knowledge representation approach by means of association (semantic) networks. The authors of the idea tried to express semantics of knowledge about a concrete topic by a certain context framework represented graphically in the form of a binary labeled network (see for example [1]).

In relation to the first order logic associative networks as well as RDF graphs have been built on atomic vectors - elementary network statements, represented in the first order predicate logic by binary predicates:
⟨ predicate_symbol ⟩ (⟨attribute_1⟩, ⟨attribute_2⟩), or graphically:

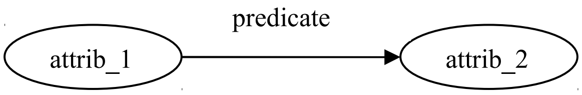

Fig.1 Associative network

In our paper [2], we have treated the RDF modeling as a special case of knowledge representation in associative networks (without functions). This fact brought a possibility to use notification and inference methods of associative networks also in the frame of RDF modelling. Moreover it has given a possibility to see RDF as a formal system.

The formal system of RDF(S) ought to be defined by its language, special axioms used to represent a knowledge base, and inference rules as a ground for creating special theories by means of formal proofs. The system ought to be presented as a formal system corresponding to predicate logic.

II. Extended Language Syntax of the RDF(S) Formal System

Our definition of RDF(S) language corresponds to the document W3C [3]. Authors of the document define names (node labels) as URIs or literals or *blank nodes* expressing the fact that there exists a URI reference making the statement of the triple true.

Graphs without blank nodes are ground RDF graphs.

According to [3], the RDF language does not contain a mechanism to represent universal or existential quantification. However, first order logic formulas can be transformed to special clausal form, where all individual variables (previously bounded to existential quantification) are eliminated by skolemization, and in this form (without quantification symbols) marked with special characters as existential terms. Universally quantified variables are (represented without quantification) conceived as variables of a universal character.

For the sake of expressing inference rules in a manner corresponding to the clausal form of the first order logic we add a metalanguage extention to the original RDF graphic language:

1. We extend the set of node names of the graphic RDF language by:

978-83-60810-27-9/09/$25.00 © 2010 IEEE

a. existential metasymbols (strings with the @ at the beginning) that give a possibility within a statement to express an existence of a name in subject or object label that satisfies the corresponding triple. (The original definition of the RDF language recommendation [3] do not suppose the necessity to distinguish existential symbols in different statements or different nodes and solves the problem universally by means of blank nodes only);

b. universal variable metasymbols (strings with a capital at the beginning) that give a possibility within a graph or its special part to express its universal properties.

2. We introduce a new kinds of RDF graphs that can express conditions "if -then". So we use within knowledge bases similarly as in association networks graphs the following kinds of networks:

   a. Unconditional networks:

   i. *ground* representing facts, containing purely constant node names, without variable or existential metasymbols

   ii. *universal/existential* with an occurrence of a universal/existential metasymbol

   b. *Conditions* (*rules*) - represent rules: q if p_1, p_2 ,...p_n with antecedent p_1, p_2 ,...p_n and consequent q. Edges in an antecedent part of the rule are represented via dash-line, consequent is represented via solid line, as usual. Conditions can have more than one atom in antecedent, but exactly one atom in consequent. Again, they can be divided into:

   i. ground

   ii. universal/existential

Network with a node label containing universal/existential metasymbol is a universal/existential network; otherwise it is taken as a ground network.

III. 3 Semantics of the Extended RDF(S) Language

Name in RDF(S) is a URI-reference or a literal (possibly ordered to a URI-reference). A set of used names of a language defines its vocabulary.

As the RDF graphs are described by RDF syntax triples, we have to consider an interpretation of the RDF language relative to a corresponding vocabulary, it means relative to a set of names (identifiers) - a set of node's and arcs' labels.

Resources corresponding to the URI-reference set of a vocabulary form a *universe of discourse* IR of an interpretation I.

To be able to use interpretation rules of a language, we need to have a *structure* of the interpretation including the universe of discourse IR that orders in the model theoretic semantics of a language:

- an object of the universe of discourse to each of the name in the model,
- a truth value to each of the statement of the model.

To define interpretation of our extended language RDF(S), we follow a two-part process corresponding to that one of syntax definition of the RDF(S) language:

- rdf-interpretation (rdfs-interpretation) concerning interpretation of the rdf vocabulary (rdfs vocabulary) that orders an object of the universe of discourse to each of the names in the model;
- rules of interpretation as methods how to derive truth values of basic statements (event. obtained from universal/existential statements) and consequently a truth value of the whole RDF graph.

Interpretation rules according to [6] (slightly modified and extended):

A simple interpretation ***I*** of a vocabulary **V** is defined by the structure of interpretation ***I*** as follows:

1. A non-empty set IR of resources, called the domain or universe of ***I***.
2. A set IP $\subseteq$ IR - the set of resources of IR corresponding to properties.
3. A mapping IEXT from IP into the powerset of IR x IR i.e. the set of sets of pairs <x,y> with x and y in IR.
4. A mapping IS from URI references in V into IR.
5. A mapping IL from typed literals in V into IR.
6. A distinguished subset LV of IR, called the set of literal values, which contains all the plain literals in V.

Points 4. - 6. concern interpretation of names. In this cases interpretation values are elements of the universe of discourse. The interpretation assigns to each URI reference its corresponding resource, to literals it assigns them.

The mapping of the point 3 concerns interpretation of a property (predicate) of a ground triple E:

If E is a ground triple (⟨subject⟩, ⟨predicate⟩, ⟨object⟩), then ***I***(E) = true if ⟨subject⟩, ⟨predicate⟩ and ⟨object⟩ are in V, ***I***(⟨predicate⟩) is in IP and the pair (***I***(⟨subject⟩), ***I***(⟨object⟩)) is in IEXT(***I***(⟨predicate⟩)), otherwise ***I***(E)= false.

It means in this case an interpretation I denotes a truth-value to a ground triple E: If E is a ground graph then ***I***(E) = false iff ***I***(E′) = false for some triple E′ in E, otherwise ***I***(E) = true.

Interpretation also has to specify the truth-value of a graph containing nodes with existential symbol labels.

If ***I*** is interpretation and ***A*** is a mapping from the set of nodes labeled by existential symbols to the universe IR of ***I*** then the interpretation [***I***+***A***](E) orders to every triple E containing an existential symbol label a ground triple via the mapping ***A*** and orders to the triple or to the whole graph a truth value as stated above.

Triples having universal metasymbols as node names give us a possibility to treat them as universal variables, to make valuations of the variables and then to order a truth value to the resulting ground triple (graph) as stated above.

Conditions representing rules q if p_1, p_2 ,...p_n hold universally.

Example 1 - representation of condition (with quantifiers)

“Cheetah belongs to order the Carnivore if it eats meat.”

We can rewrite the sentence as a universal conditional network. “Every animal belongs to the order of Carnivore if it eats meat.”

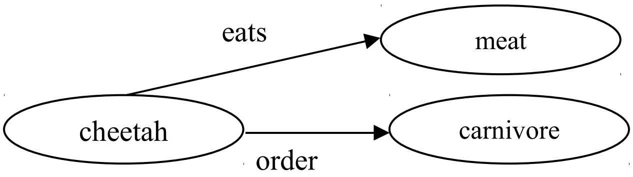

Fig.2 Unconditional network

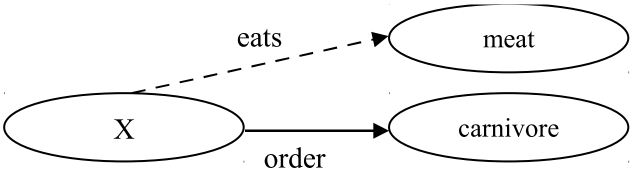

Fig.3 Conditional network

Using existential symbols we can express the sentence “Animal belongs to the order of Carnivore if there exists a meal that is meat and the animal eats it.”

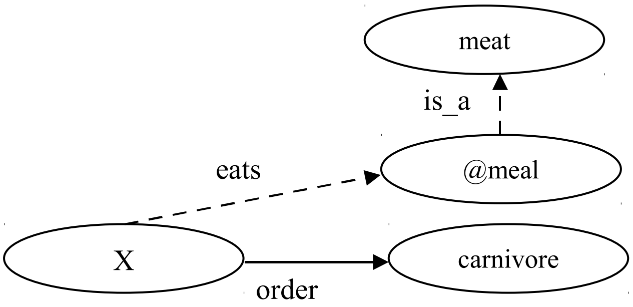

Fig.4 Extended network

IV. Inference in RDF

Deduction in RDF similarly to that in an associative network is a process of filling triples or terms in labels of the nodes from a *particular network* into a *main network* using one of the following rules:

Uniform substitution rule

a) If all the edges of a particular network also appear in the main network containing universal symbols as labels of their connected nodes, then the labels of nodes of the particular network can be substituted uniformly to the corresponding labels of nodes of the main network labeled by universal symbols.

b) If all the edges of a particular network also appear in the main network containing existential symbols as labels of their connected nodes and a maping *A* from the set of nodes labeled by existential symbols to the universe IR of ***I*** has been found then substitute uniformly corresponding elements of IR for existential symbols via the maping ***A***.

Transfer rule

If all dashed edges of the antecedent of a particular network appear (as solid) in the main network, and moreover if the labels of the corresponding nodes are the same then the solid vector of consequent can be added into the main network.

Negation of a triple as a special condition

To negate the triple E of RDF a special statement is used. It stands for the false consequent in the implication with a true antecedent. Due to no existence of a definition for a contradiction triple, a new special symbol of network has been created, called falsum, (notation ⊗), which is false in all interpretations.

Conditions, which consequent is falsum, are called negative facts.

Figure no. 8 represents negative fact „It is not true that dragonfly lives in Iceland. “

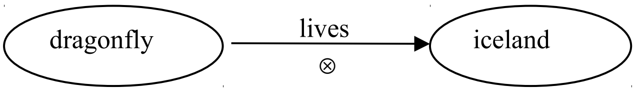

Fig.5 Negated associative network

Example 2 (logical puzzle)

We have 4 animals that live somewhere else and eat something else. Moreover:

1. The cheetah lives in Africa.
2. An animal that eats the flying insect lives in Europe.
3. The falcon doesn’t live in the Atlantic.
4. The dragonfly doesn’t hunt small fish.
5. The cheetah eats the mostly mammals.
6. The swordfish doesn’t live in Europe.
7. The falcon doesn’t eat the flying insects.
8. The dragonfly doesn’t live in the Iceland.
9. An animal that lives in the Atlantic doesn’t eat little birds.

Where does the falcon live and what does it eat?

Universe of discourse IR consists of all the resources used within solving the puzzle. Form of a list of pairs (graph label, URI of corresponding resource) is shown in tab 1.

Tab.1
URIs

mammal	http://dbpedia.org/resource/Mammal
bird	http://dbpedia.org/resource/Bird
fish	http://dbpedia.org/resource/Fish
insect	http://dbpedia.org/resource/Insect
cheetah	http://dbpedia.org/resource/Cheetah
falcon	http://dbpedia.org/resource/Peregrine_Falcon
swordfish	http://dbpedia.org/resource/Swordfish
dragonfly	http://dbpedia.org/resource/Dragonfly
africa	http://dbpedia.org/resource/Africa
iceland	http://dbpedia.org/resource/Iceland
atlantic	http://dbpedia.org/resource/Atlantic_Ocean
europe	http://dbpedia.org/resource/Europe
eat	http://en.wikipedia.org/wiki/Eat
live	http://en.wikipedia.org/wiki/Living

At the beginning we can imagine the main network graph consisting of four connected subgraphs with mutualy different existential node labels (fig. 5).

Next, we can define particular networks representing sentences 1 - 9 (as all the subgraphs are recognizable, the existential labels can be omitted) (fig 6).

Searching a common solution (model) of the main network and all of the nine participating particular networks consists in sequential binding of the label names occurring in particular networks (names of objects of the universe of discourse) to a set of existential nodes symbols (here blank nodes) in the main network until no contradiction is obtained and the proper mapping has been found.

Partially, rules 1. and 5. (similarly the case 4. and 8. and the case 3. and 7.) with the common cheetah label give a possibility to find a mapping within two subgraphs and make a corresponding substitution of labels (fig. 7, 8 and 9).

We can rewrite rules with negation (here for example 11 and 12) by RDF:bag. As an example, for a subgraph "dragonfly" holds a universal (within the puzzle) condition (fig. 10 and 11).

By applying these steps, we come to the conclusion, who lives where and what eats (fig. 12).

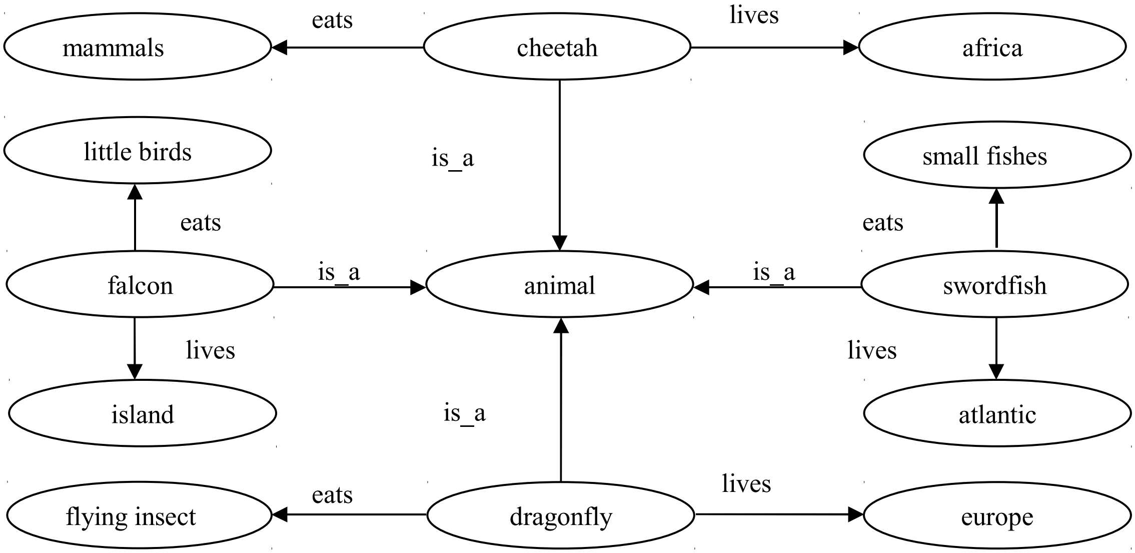

Fig.12 Extended network

V. Conclusion

We can treat the RDF modeling as a special case of knowledge representation in associative networks (without functions). This fact offers us a possibility to use the notification and inference rules of associative networks also in the frame of RDF modeling. Reasoning, possibly supported by the graphical version of representation, then becomes more understandable and easier to use than that of rewriting RDF models by description logic tools (OWL language) because of using their inference mechanisms. However, some issues like how negative and positive vectors are matched together are not fully formalized. Although article presents a mechanism (and an example) how can be semantic network used for inference over RDF models via graphical way affording better understandability, especially for human.

Email: pawel.myszkowski@pwr.wroc.pl

Abstract—**This paper describes our last research results in the field of evolutionary algorithms for rule extraction applied to classification (and image annotation). We focus on the data mining classification task and we propose evolutionary algorithm for rule extraction. Presented approach is based on binary classical genetic algorithm with representation of 'if-then' rules and we propose two specialized genetic operators. We want to show that some search space reduction techniques make possible to get solution comparable to others from literature. To present our method ability of discovering the set of rules with high F-score we tested our approach on four benchmark datasets and ImageCLEF competition dataset.**

Keywords: **data mining, rule extraction, evolutionary algorithms, image annotation**

I. Introduction

The size of datasets is growing constantly and as cannot be analysed it by human being so we use automating process, so-called Knowledge Discovery in Databases (KDD) which is a part of Machine Learning domain. The most interesting, from this paper point of view, is its one stage – data mining (DM). The data mining is an interdisciplinary field and its essence is knowledge acquisition from large amount of data. As our data might contain useful hidden and implicit the knowledge, the extracted knowledge can be successfully used in very important real-world domains such as image annotation.

As Evolutionary Algorithms (EA) are metaheuristics that search the solution space and can be easily applied for data mining tasks, such as clustering, prediction, classification and rule induction (paper [8] is a great survey of EA applications to KDD). Rule discovering (or rule induction) is most studied data mining task and its main goal is to build model of given data that describes it with possible best accuracy. Such model can be based on intuitive 'if-then' rules where: if-part (antecedent) attribute conditions and then-part (consequent) contain predicted class value (label). The classifier quality (accuracy of the gained model) can be tested on unseen data and measured by prediction error value.

EA is group of metaheuristics inspired by nature (Darwinian evolution theory) where the fittest individuals have better chance to survive and EA is widely used in data mining tasks (e.g. [2][3][5][15][20]). EA codes the problem solution as an individual and operates its features with aid of genetic operators (usually by mutation and crossover). Quality of individual is given as fitness function and its better value gives the higher probability of getting an offspring. In rule discovering task, the main motivation is to discover the rules with high predictive accuracy value. In literature we can find some approaches based on natural evolution that extends simple EA (e.g. classical genetic algorithm [9][12]) by some additional elements. For instance, commonly used if-then form of rule can be a single individual (Michigan approach) or included in ruleset form of individual (Pittsburgh approach). Mostly, there is used the Pittsburgh approach as it takes into consideration a rule interaction and is more natural and intuitive.

Interesting EA based method, so-called Genetic Programming (GP) can be found in [3], where individual is represented by logic tree that corresponds to logical expression such as rule: “If attrib$_0$>5 and (attrib$_3$=2,5 or atrrib$_2$<1,3) then class$_3$” to describe attributes' conditions of given class in chest pain diagnosis. The rule is presented as decision tree, where internal nodes are operators and leaf nodes represents attributes and corresponding condition values.

The multipopulation EA is based on the natural phenomena of coevolution (CoEvolutionary Algorithm, CoEA), where fitness function evaluation of few populations runs effectively in parallel way. Such method is proposed in [15], where individuals are selected from a few populations by cooperative selection pressure by choosing the best, previous fitness or classical selection method. There is used a collaboration pool size (from each population a group of the candidate individuals is selected) or a collaboration credit assignment (based on a selection of *n* individuals, where its optimistic, the average or pessimistic version is used). Another CoEA (presented in [20]) operates on populations that correspond to ruleset of *n* rules (where *n* is a parameter) linked by token competition as a form of the niching method. Paper [17] describes approach that takes into consideration distributed genetic algorithm for rule extraction task, where is presented positive influence of dynamic data partitioning distribution model to classifier accuracy.

There is also another strong trend in EA applications in DM – usage of specialized genetic operators. In Pittsburgh approach to classification task it is very important that individual representation consists of a complete classifier where rules cooperate and recombination operator causing its separation may make worse its classification accuracy. In [20] above problem is discussed and there is proposed a symbiotic combination operator which is a kind of heuristic that ana-

This work is partially financed form the Ministry of Science and Higher Education Republic of Poland resources in 2008-2010 years as a Poland-Singapore joint research project 65/N-SINGAPORE/2007/0.

lyzes results of changes in newly created individual. Another type of genetic operator specialization can be the usage of some hill-climbing algorithms to improve individuals (as candidate solution) by making “minor” modifications: if it causes fitter individual, given change is accepted. As a matter of fact, this causes the Baldwin effect [12]. Also, in evolution process ruleset can be modified in pruning procedure (e.g. [5]) - is optimized by removing unused/invalid attribute condition according to information gain measure value and/or examines results by some small changes in the ruleset. Also, we can find hybridization as a quite strong trend, where main motivation of such propositions is to build approach and link advantages of connected methods.

The remainder of this paper is organized as follows. Details of problem definition and our approach for rule discovering task is presented in section 2. Research methodology, used benchmark dataset and results of experiments are presented in section 3. Finally, section 4 presents conclusions and future research directions.

II. CAREX: Coevolutionary Algorithm for Rule EXtraction

Proposed method uses standard EA schema and starts a learning process with initial population (usually created randomly) and next individuals of current population are evaluated: each individual receives a fitness function value that corresponds to quality of proposition of given problem solution. In next step EA checks if stop conditions are not met: usually it is limit of generations and the best individual fitness value is acceptable (success). If stop criteria is not met EA runs the selection procedure that defines a seed of the new generation; next it is a communication between individuals (by crossover operator) and the independent trial (by mutation operator). The whole process repeats until some stopping condition is met. The crucial issue in evolutionary based method is the definition of individual representation schema, genetic operators (mutation and crossover) and evaluation function form, that give information about the individual fitness function value. In this section above elements are described.

A. Representation schema

In CAREX approach we decided to construct individual representation schema as simple as possible to get reduction of solution search space size. This is gained by coding of arguments value in binary representation (usually 2x8 bits per arguments) and only two logical operators: IN and NOT_IN. This methodology makes possible to use simple genetic algorithm, as we wanted to show that there is no need of EA extension to get solution comparable to others based on literature. Also we shown that there is possibility to build a specialized genetic operators.

We considered Michigan and Pittsburgh [12] approaches and finally CAREX system implements both, but in our research we use only the Pittsburgh model to keep all rules interactions in one individual. Therefore individual is represented as the set of rules (*ruleset*) that can assign instance to one class (if the task is to find completely one class description, so-called one-class-model) or to get model of all classes presented in dataset the individual consists of rules connected to class identifiers (all-class-model) as follows:

$$RuleSet := \{Rule_0, \ldots, Rule_n\}$$

Each rule is represented as the set of commonly used if-then type rules IF <*attributes_conditions*> THEN <*class_identifier*> as follows:

$$Rule_i := \ IF\ A_0 \text{ and} \ldots \text{and } A_n\ THEN \text{ class}_j$$

Where *class$_j$* symbol represents given class identifier, and $A_i, i \in \{0, \ldots, n\}$ represents a numeric range for a condition for *i*-th attribute as follows:

$$A_i := attribute_i\ operator\ (a,b)$$

where bellow *operator* can be:

$$\text{IN}(a,b) \rightarrow a < attribute_i < b \quad \text{or}$$

$$\text{NOT\_IN}(a,b) \rightarrow attribute_i < a \text{ or } attribute_i > b$$

where $a<b$ and $a,b \in \mathbb{R}$. Above representation is strictly based on conditions combination for selected attributes. We decided to use only two operators to keep individual representation as simple as possible. For instance, rule is:

$$IF\ attribute_0\ \text{IN}(0.1, 0.5)\ \text{and}$$
$$attribute_2\ \text{NOT\_IN}(1.0, 1.2)\ THEN\ class_2$$

Above rule describes all instances with values from range <0,1; 0,5> for attribute$_0$. Another condition takes into consideration attribute$_2$, where its value cannot be in range <1,0; 1,2>. Data described by conjunction of conditions are proposed to label with class$_2$.

In CAREX we decided to use binary vector representation thus we are allowed to use classical binary genetic operators to manipulate individual's particles. To avoid a drastic change of attribute value we use a Gray code. Also each attribute is extended by one enabled/disabled bit. Before CAREX starts, the dataset is preprocessed: instances are analyzed to recognize domains for all attributes. Then, each attribute domain is mapped into binary vector. That allows to keep each individual valid and there is no need to waste extra CPU time for repairing or removing invalid attribute values.

In proposed representation we use only “AND” logical operator, therefore EA to describe some set of instances as two separate conditions using ruleset as two connected rules. Indeed, the relation between these rules is logical disjunction, and indeed there exist a sort of rules coevolution phenomena.

B. Fitness Function

Generally, in EA, fitness function evaluation is very critical issue. Its definition decides about shape of solution landscape and must be defined very carefully. As rule extraction problem corresponds to data mining and our individual is a ruleset we can use commonly used classifier measure. In classification the main goal is prediction of the value $c_i \in C$ (class) analyzing values of attributes x_i of given instance $x_i = \{x_i^0, \ldots, x_i^n\}$ where $x_i^n \in X$ defines solution landscape. Thus classification task is based on explore set of $(x_1, c_1), \ldots, (x_n, c_m)$ to build model $m(x_i): X \rightarrow C$ that labels unseen instance $x_k \in X$. Evaluation of rule is connected to its quality as classifier. In such context of data mining domain, the terms true positives (*tp*), true negatives (*tn*), false positives (*fp*) and false negatives (*fn*) we can define *recall* :

$$recall = \frac{tp}{tp+fp} \quad (1)$$

and *precison* measure as follows:

$$precision = \frac{tp}{tp+fn} \quad (2)$$

The *recall* value tells only if given rule labels instances in proper way, *precision* informs if rule covers all labeled data by proper class identifier. Above formulas say a lot about rule classification quality but there are two separate values. Although EA should use only one value to evaluate rule in literature (e.g. [3]) we can find some combinations of these values. However, we decided to use measure based on modified van Rijsbergen's effectiveness measure (F*score*) [18], than can be used also in data mining, as it combines *precision* and *recall*:

$$Fscore = \frac{1}{\frac{\alpha}{precision} + \frac{1-\alpha}{recall}} \quad (3)$$

where α can give a predominance of one of two elements, but we established its value on 0,5 to keep two elements equal. If *Fscore* value is near 1 means that evaluated rule has high quality as it corresponds to maximizing problem. Bellow *Fscore* measure is very useful as fitness function form, but for comparison of gained results in literature is used other measure of predictive *accuracy*, as a rule quality measure, defined as follows:

$$accuracy = \frac{tp+tn}{tp+fp+fn+tn} \quad (4)$$

where *tp/tn/fp/fn* correspond respectively to true positive/true negative/false positive/false negative to denote accuracy of classification in given set of instances.

We do not use accuracy formula as fitness function because of more practical features of *Fscore.* As individual is a ruleset the fitness function value is calculated as the average value of *Fscore* of all existing in dataset classes. Such form of fitness function occurs some distortions specially when dataset is dominated by one class and others have small representation. In dominated datasets we can use stratified crossover mechanism to reduce such problem.

C. Genetic operators

Our individual is represented by binary vector which can be operated by classic binary operators in simple way. Random modification of selected bit works as mutation (***SM***, Simple Mutation) and inserts new information into chromosome. To deliver communication in population in CAREX we developed one-point crossover (***OX***) that links two individuals to build the new one as combination of their genes. As all individuals have the same size, there is no situation of invalid individual creation using the random cut position. The high efficiency of basic set of genetic operators (*SM* and *OX*) in CAREX encouraged us to construct some specialized operators. We developed and tested two: Directed Mutation (*DM*) and Best Class Crossover (*BCX*).

Directed Mutation (DM)

This operator is not semi blind as simple mutation *(SM)* and it tries to direct evolution process by increasing the mutation probability if given rule has low quality (fitness function value is low). Given *Rule$_i$* mutation probability is given according to below formula:

$$P'_m = P_m * (2 - Fit^{class_i}(Rule_i)) \quad (5)$$

where P_m is constant mutation probability given to whole *EA.* The $Fit^{class_i}(Rule_i)$ formula part gives a value of fitness value of given *class$_i$* classification accuracy. The motivation is to change rules in class that has worst quality value (near 0,0), but it is almost absent when value is near 1,0 (the best quality). Of course, such directed mutation selects rules to modification but if such direction is too hard it could stuck the whole learning process in local optima. To avoid such situation we establish an increasing parameter as maximal value to double P_m value.

Best Class Crossover (BCX)

The standard crossover operator (such as *OX*) does not take into consideration specific problem knowledge. It just randomly cuts individuals and randomly generates a new individual. Our main motivation was to build a new crossover operator that uses specific domain knowledge and links two individuals more effectively. We inspired slightly the *BCX* operator (presented in [13] which, in its base form, is used for graph coloring problem, we developed the other version of *BCX* (Best Class Crossover), which is presented as pseudo code on Błąd: Nie znaleziono źródła odwołania.

The BCX operator takes two RuleSet P_1 and P_2 as parental individuals and returns the newly generated as result. The offspring is compilation of two parental individuals based on analyse which a parental *RuleSet* has better accuracy of given class description c_i – its rules are included in newly generated offspring individual. Such operation is repeated for each class independently.

The operator is specific form of communication between individuals where each of them gives the best part of selected rules and it is very useful, but its frequent usage is rather

```
function crossover_BCX ( RuleSet $P_1$,
                         RuleSet $P_2$ )
  begin
  RuleSet $Off := \emptyset$
     foreach class $c_i$
       begin
              if $(Fit^{c_i}(P_1^{c_i}) > Fit^{c_i}(P_2^{c_i}))$
                  then $Off := Off \cup P_1^{c_i}$
                  else $Off := Off \cup P_2^{c_i}$
       end
  return $Off$
  end
```

Fig 1. BCX operator pseudocode

risky. As it is determinate, it can cause loss of diversity in population and premature convergence indeed. Such operator we use not more than P_x<0,1.

D. CAREX programming platform speedup

Our experiments needed programming platform and we decided to use Java language. To make experiments less time consuming we developed:

- data buffering, all data are stored in RAM memory not in hard drive – it makes data query more effective and less time consuming,
- data indexing based on binary search that gives us more effectively access to our data,
- data sequence covering based on attributes condition cascade techniques that give evaluation function of each rule less time consuming,
- evaluation cache, that stores in RAM memory rules that were already evaluated and in evolution process are without any changes. Thanks this mechanism time for evaluations is significantly reduced.

Such low level programming techniques (not connected to EA conception directly) make experiments less time consuming. It is worth mentioning because of stochastic character of EA, where experiments must be repeated many times.

III. Computational experiments and results

Evaluation of learning method is important to compare results against other methods. This can be done experimentally. We developed in Java a research environment that supports learning and rule validating process. To evaluate predictive classification ability of developed model we split data into train and test data using commonly used crossvalidation method.

First, there are used train data to generate *RuleSet* by CAREX to get possible high accuracy (*Fscore* is used as fitness function). Learning process based on evolution runs using selection, mutation and crossover operators. For evaluation accuracy of gained rules there is used train dataset, but when evolution process is finished test dataset is used to validate predictive accuracy of generated *RuleSet*. To minimalize a random elements influence on our research we use 5x2 crossvalidation (according to research presented in [7]). Also to reduce influence of stochastic aspect of EA to our research the whole evolution process is repeated 10 times to each crossvalidation fold.

A. Used datasets

To show CAREX application we decided to use benchmark data set from UCI data Repository [21]. From set of 187 datasets we selected four connected to important real-world domains such as biology, medicine, chemical industry, food industry or health care, as follows:

- **iris**: 150 instances, 4 attributes, 3 classes (distribution: 50/50/50),
- (pima indians) **diabetes**: 768 inst., 8 attributes, 2 classes (distrib.: 500/246),
- **glass**: 214 instances, 9 attributes, 6 classes (distribution: 70/17/76/13/9/29)
- **wine**: 178 instances, 13 attributes, 3 classes (distribution: 59/71/48)

First dataset (Fisher's iris flower) is benchmark for each new classification algorithm. The diabetes dataset includes medical records of medical review if the patient shows signs of diabetes according to the World Health Organization criteria. The third dataset consists of glass identification in chemical industry data. The last one (wine) contains results of chemical analysis of wines grown in the same region in Italy.

B. Experimental CAREX

We experimented to establish CAREX algorithm optimal parameters values. The most influential parameter is the probability of mutation (see its influence on average predictive accuracy presented on Fig 1). Our experiments showed that CAREX results are the most stable and the best in P_m=0,01. Probability of crossover P_x=0,2 but our first research result showed that crossover has minor influence on CAREX results.

Another very important CAREX issue is population size and number of generations. We developed several experiments series to establish its optimal values. Results of such experiments are showed in Fig 2, where influence of number of births (as product of population size and number of generations) to average accuracy of developed model in iris dataset is presented. We used population size and generations number from set {10,20,50,100,200 and 1000}. The Fig 3 shows that the optimal value of births is between 10 and 20 thousands, which is connected to population size 100 and 200-400 generations.

The higher values of births make CAREX less effective – it is more time consuming learning process and we do not have the significant increase of accuracy value.

Basically, we tested two types of selection methods: tournament selection and roulette wheel selection. The best results were achieved in tournament selection, where individuals are selected without replacement to the pool size of 2 or 10 individuals. The roulette wheel method causes smaller selection pressure and makes learning process less effective. In our experiments we do not use elitism parameter.

C. *Effectiveness of CAREX*

This part of paper presents experiments connected to population size and genetic operators usage influence on CAREX effectiveness. Evaluation of CAREX approach in the context of four benchmark dataset is given. Used values of EA parameters are presented in Table 1.

Table 1. CAREX parameters used in experiments

parameter name	IRIS	DIABETES	GLASS	WINE
Population size	200	20	200	100
Number of generations	200	200	500	200
Prob. of crossover [OX]	0,2	0,2	0,2	0,2
Prob. of mutation [DM]	0,01	0,01	0,01	0,01
Selection method	10	2	10	10
Number of rules	5	10	30	15

In CAREX an individual is represented by set of rules and this number strictly depends on used dataset: usually we use about 3-5 rules per class. As different datasets have various CAREX parameters requirements are presented in Table 1. The population size in our approach usually equals to 100-500 individuals. Number of generations gives evolution process the "time" to work out a solution but we experimentally tested that there is no need to extend it to not more than 1000 generations. Another important aspect of EA is selection – we experimentally developed a tournament selection of 2 or 10 individuals. A mutation operator (*Pm*) rate is experimentally set to 0,01. Stop condition is met if individual that has *Fsc* equals to 1,0 (success) or number of generation is exceed (fail).

Corresponding to literature we compare results of CAREX with other methods (see Table 2) - we selected EA based methods (e.g. CORE [20], CCE [15], ESIA [11]) and classical C4.5 [16] algorithm. For each dataset we presented results of each selected method (as it is given in literature): the average predictive accuracy, standard deviation value and maximal value of observed accuracy. Unfortunately, not for all dataset the results are given in the literature.

We can observe that CAREX achieves the best accuracy for **iris** dataset. Also comparable results gain CORE method and EMA-AIS. It is worth to mention that difference is very small (near to statistical error value). For **diabetes** dataset we can see that CAREX does not achieve the best accuracy (but comparable to classical C4.5 algorithm). It is outperformed by CORE and EMA-AIS method. It is also worth mentioning that EMA in its basic form gives comparable results to CAREX, while EMA-AIS is the hybrid of EMA with AIS and gives potentially better solution. Comparison of predictive accuracy value in **glass** dataset to other methods shows that CAREX results can successfully compete with other methods. Unfortunately, stochastic element of CAREX causes relatively large value of standard deviations (8,75%). That value is very puzzling, because ESIA approach uses 5-fold cross-validation and standard deviation equals to 0,03%. Dataset **wine** results presented in the above table show that given dataset is no problematic for CAREX. We compared our results with two other approaches, and CAREX outperforms classic C4.5 and gives results comparable to SEA method.

decided to generate rules in photo annotation problem – and we used benchmark dataset from ImageCLEF conquest [14]. Automatic Image/photo annotation problem [4] needs method for multiclass labeling images, as problem concerns a number of classes and large size of datasets. There is many approaches in literature based on decision trees, suport vector machine (SVM) and others (survey can be found in [1]).

The ImageCLEF conquest dataset consists of 8000 images labeled by 93 classes (words). We do not use any segmentation methods and we use 18 global image Tamura [19] features such as coarseness, contrast or directionality. We run CAREX method using 10 individuals to run 100 generations to get one word annotation. The example of such run is presented on Fig 4, where is shown the best *Fscore*, average *Fscore*, worst *Fscore* and best Accuracy in given evolution process. Evolutionary Algorithm searches the whole solution space effectively and even so small population (only 10 individuals) makes possible to get optimal solution.

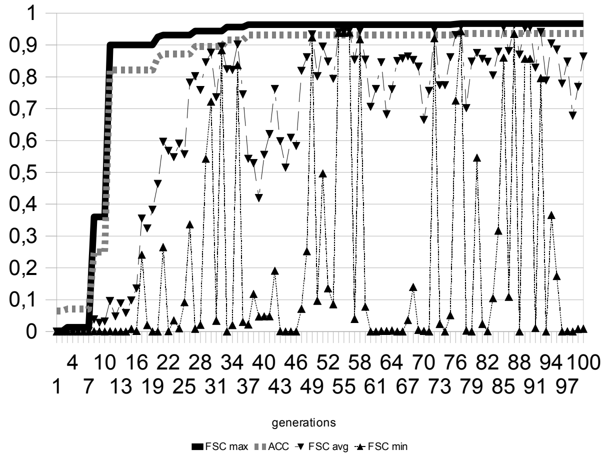

Fig 4. Example of CAREX run of Photo ImageCLEF word 'Neutral_Illumination'. CAREX parameters: 2 Rules, popsize=10, generations=100. P_m=0.01. P_x=0.2

Some initial experiments were done and effectiveness of presented CAREX method is very promising. First results were presented in Table 3, where the best of 10 word were shown. The average *Fscore* for 10 chosen words equals to 74,5%. However, these words are frequent and the average F-score value in dataset equals 26%. Example of 2 rules generated on word 'Neutral_Illumination' with very high value of *Fscore*:

Table 3. CAREX results for 10 best words for ImageCLEF images dataset

	average	0,745			

```
IF      a4 IN<58,128;341,378>
    AND  a7 NOT_IN<170,012;266,089>
    AND  a8 NOT_IN<291,938;312,497>
    AND  a13 NOT_IN<169,923;265,895>
    AND  a14 IN<178,128;345,282>
    AND  a15 IN<19,201;218,386>
THEN class = 'Neutral_Illumination'
  [Rec=0,013 Prec=0,981 Acc=0,077 Fsc=0,027]
IF      a7 NOT_IN<586,874;603,571>
THEN class = 'Neutral_Illumination'
  [Rec=1,000 Prec=0,935 Acc=0,935 Fsc=0,967]
```

The CAREX in the first results is very promising but also needs some extra ImageCLEF experiments connected to specialized genetic operators, another set of features (not only 18 Tamura features), segmentation influence to CAREX effectiveness and time consuming EA run as extra tests. Another positive aspect of CAREX usage is very intuitive rule representation that allows to understand the annotation description by the human.

IV. Conclusions and further work

The presented method CAREX is based on EA and simple binary solution representation. We wanted to show that binary based EA can be effective in searching a large search space in data mining tasks. We presented results of performance based on four benchmark databases. The CAREX results are compared to other methods and show that CAREX is able to compete successfully in rule induction/classification task. Also, in our opinion CAREX has great potential in this area of research. However, experiments results showed some problems, especially connected to stochastic aspects of presented approach – in our opinion the standard deviation value of results is too high to be accepted in real-world applications. We presented first experiment results on real world of image annotation problem using the ImageCLEF dataset. Results of developed experiments encourage to continue work on CAREX.

We plan further research into two main directions. First, fitness function modification by adding some niching methods to make it more competitive. Other way we see in specialization of genetic operators, including some ruleset improving methods such as hill climbing, local search type or simple pruning rules procedure and discovering potential labeling conflicts in the whole ruleset.

***Abstract*—This paper shows an evolutionary algorithm application to generate profitable strategies to trade futures contracts on foreign exchange market (Forex). Strategy model in approach is based on two decision trees, responsible for taking the decisions of opening long or short positions on Euro/US Dollar currency pair. Trees take into consideration only technical analysis indicators, which are connected by logic operators to identify border values of these indicators for taking profitable decision(s). We have tested the efficiency of presented approach on learning and test time-frames of various characteristics.**

***Keywords:* financial data mining, evolutionary algorithm, genetic programming, decision tree induction, trade strategy, Forex**

I. Introduction

IN THE literature we can find many approaches to the automatic trading and many attempts to use artificial intelligence methods to trade on stock markets. A good summation on large part of the work already done in this matter is [2], where the list of surveyed markets, potential input data and modeling methods were shown. On financial markets automatic trade systems are widely used (especially by great investment funds), but the rules of taking the decisions are not publicly known. We don't know how far they are human controlled, and how far autonomic they are in their decisions. There is a lot of artificial neural networks (ANN), evolutionary algorithms (EA) or genetic programming (GP) usages as appropriate methods to search rules and strategies that could use ineffectiveness of the markets to earn money. How far they are well developing on current, not historical data, is an open question.

We have decided to investigate the usability of EA to generate rules, which will trade on foreign exchange market (Forex). Forex is a very interesting market because of its liquidity and open hours. It's closed only on weekends, normally operating 24 hours per day [7]. It means that (sometimes huge) price gaps between trading days, what is a normal behavior in stock markets, are here rarely observed. Thanks to high liquidity we can always sell and buy any amounts of assets at actual price without the risk that we will strongly affect the price or run out of contrary orders (thus being unable to sell or buy at reasonable prices), at least if we are individual investors and not great investment funds. Liquidity means constant movements, which means constant opportunities to make profitable trades. Thanks to high leverage and very small transaction costs it's possible to generate high profits even on very small price movements (such as 0.1% changes). Unfortunately, the leverage means the risk of taking high losses or even losing whole invested capital.

A. Related works

In the literature there are many interesting approaches, which take into consideration an automating profitable trade strategy generation.

In paper [16] is described GP to build decision trees. There are two types of decision trees, based on moving averages values and filters – decision is being taken after stock value rising up over last maximum or falling down below last minimum for specified percent value. Decision trees evaluated by GP can use arithmetical operations, functions, logical operators (incl. negation), conditional operators (IF-THEN), numerical and logical constants. However, its search space is being very big. Also in [16] daily intervals are used, where we used 10 minutes intervals. It means that the transactions have a much longer investment time horizon. Such approach has successfully generated many profitable strategies on various currency pairs, at limited risk. The risk value is calculated with beta indicator[1], which was compared with its value for some benchmark portfolios based on various stock market indicators. What's interesting, rules generated for one currency pair were much worse, when used on others.

GP can be used also for trade strategies generation on Warsaw Stock Exchange were investigated [15]. Based on the decision trees stored in GP individual a portfolio up to 10 stocks is build. The content of the portfolio vary in time. After doing several experiments authors stated that the profits earned by automatically generated strategies exceed those generated by benchmark (WIG stock indicator as buy&hold strategy profit). On decreasing time-frames no tremendous profits were generated, but substantial losses were avoided too and according to decreasing character of used time-frame such results are acceptable.

In work [13] EA is used to optimize values for predefined filters. Authors optimize and test filters on data from Australian Stock Exchange. They find out that EA finds profitable strategies more effectively than greedy algorithm. This conclusion is important if we want to use this solution for real time usage.

Paper [18] shows that there is no direct correlation between the distance from the learning to testing time-frame

[1] measures the correlation between an investment's value and movements in the overall market

and the efficiency of gained strategy. There is another interesting conclusion that no positive results of removing strategies, which behave worse on some validating time-frames, where found. It means that if we will remove strategies, because they are not as good as the others on one validating frame, we probably can lose one of the best strategies for another time-frame.

In work [9] EA usefulness to generation set of rules is investigated, which decides about the moments to buy or sell stocks on the Paris Stock Exchange (France). The individual there is represented not as a tree, but a sequence of bits, where each bit responses for usage of technical analysis indicators. Such representation allows EA to search the solution space very effectively. As there were shown, strategies generated in such way give better results than benchmark buy&hold strategy. What's important, there wasn't found any proof that some stocks are easier in prediction. Also, that constant generating of new rules on current data can improve the results, which is contrary to the conclusion from [18]. Generated rules were profitable only on those stocks on which they were learned, and there weren't found any sign of some indicators being preferred over others.

Another EA usage were shown in [1], where task was to find technical trading rules on Standard and Poor's composite stock index. Rules generated by EA have form of decision trees, where the nodes can be logical operators, functions (avg/max/min), arithmetic operations, comparisons or constants. Training data were given from years 1963-69, and test data from the years 1970-1989 and other periods since 1929. The rules generated excess returns only on the first test period. On periods before 1963, including the transaction costs, they generated losses.

In [12] method searches for similarities in the history of stock value movement to predict its values. EA is used to find as good as possible analogies between some latest intervals and those taken from history of given stock. Such historical data are preprocessed, where outliers are removed to make the predictions more accurate. There was proven that filtering outliers and replacing them with moving average or just average values from the nearest neighbors gives positive results. Prediction results of volume values are much worse, mostly because of some huge random fluctuations.

The stock trading predictions system was build in [17] . As predictions there were used ANN, dynamic time-frames and case based reasoning technique. The ANN was used to predict buy/sell points for interesting stocks, previously chosen by some pre-defined rules, e.g. monthly sales, daily trading volumes, 5 day average volumes. Such method generated significant revenues on test data, even for stocks in downtrend.

In [20] there is another interesting ANN usage, where the task is to predict "next" values of Warsaw Index Futures. Technical analysis techniques – such as channel breakout, Bollinger Bands, Momentum Oscillators, Moving Averages – are used in combination of ANN predictions and without them, as competitive strategies. Technical analysis usage with ANN forecast makes possible to generate profits even for strategies, which normally were not profitable at all.

In [10] consists in Evolution Strategies usage to portfolio optimization problem. The main goal was defined to minimize the risk at fixed level of the expected return. Risk was measured as a semi-variance of returns (similar to variance, but emphasizing the "downside risk" - *actual return - expected return* but only if it's smaller than 0). Artificial "experts" were built by the EA, using some of predefined technical analysis rules (chosen by the EA algorithm). The portfolio of stocks was chosen at the beginning, and artificial "experts" were able to reduce or increase the share of each stock in the portfolio. There is stated, that the results were much better than random portfolio shares (buy&hold strategy), but worse than market index. Worth noticing, that buy&hold is here understood as keeping initial (random) portfolio shares unchanged, and market index is market value weighted (bigger companies has bigger share in the index). They stated that additional research is needed.

Work [8] uses a hybrid approach based on various types of ANN and EA to detect interesting patterns in stock market, where data came from the daily Korea Stock Price index 200. EA were applied to optimization of time delays and network architectural factors. The various types of ANN were connected into a multilayer feed-forward network, where time series were the input. Also there were tested and compared time delay ANN, adaptive time delay ANN, recurrent ANN and stated that their integrated approach gives better results than standard ANN.

Another interesting approach was used in [19]. A data mart was created and data mining techniques applied to predict future stock prices using historical values. A traditional grey prediction[2] model was expanded by fuzzy logic model. Data for each stock were pre-classified in groups using the "time" attribute. On the test data, the average deviation from the predicted highest stock price and the actual price was less than 9%, which authors interpreted as pretty accurate, as "predictions are feasible".

Another interesting approach presents [4], where Genetic Network Programming (GNP) was used for building stock trading model. Build network consists of judgment and processing nodes. Judgment nodes use technical analysis indicators and candlestick chart formations to decide which next node should be processed, and processing nodes take actions such as buying/selling stocks. Training and test data were taken from Tokyo Stock Exchange (Japan). As results are very promising, is suggested that it was achieved due to the representation of solutions as graph structures, which allows memorizing past actions sequences more effectively.

In our work we generate trade strategies as BUY/SELL decision trees, which are responsible for opening long or short positions on the EUR/USD currency pair on Forex market.

This paper is organized as follows. Section II describes details of proposed EA based approach: representation schema, genetic operators, selection method and the form of the fitness function. Research to find as good as possible EA parameters is shown in section III. Experiments are present-

[2] grey system theory requires limited amount of data to estimate the behavior of unknown systems [5]

ed in section IV, where are defined used dataset, research methodology and gained results. Section V shows possible further research and issues that have been skipped in this work. Section VI consists of conclusions and short summary of this work.

II. Proposed Approach

Our approach is based on GP [11] and is slightly inspired by [15]. In our work EA generates trade strategy based on BUY/SELL decision trees that consists in technical analysis indicators that are connected by logical operators. We decided to work with EUR/USD currency pair, because it's the most popular and liquid pair as it generates 27% of the total volume on Forex [3].

A. Individual representation

Each individual is represented as two decision trees, where one is responsible for BUY signals, and one for SELL signals recognition. Each of the decision trees is actually a trading rule. It consists of logical functions binding leafs, which are technical analysis indicators.

Used technical indicators are some variants of Simple Moving Averages (SMA), Weighted Moving Averages (WMA), Displaced Moving Averages (DMA), Relative Strength Index (RSI), Moving Average Convergence-Divergence (MACD), Rate Of Change indicators (ROC), volume value and volatility for specified period values. They are widely described in [14] as very useful tools for the investors to determine trends, reversal points, to identify interesting buy/sell points. They are very popular among investors of any kind, but can be used in sometimes very complex ways, where the same indicator value can be interpreted by various investors in a different way.

In decision tree each node can be logical (and/or) or terminal node in form *(Indicator [<, >] Value).* Example tree can be presented as follows:

```
  ((ISMINOF<11) or ((ROC (5)<0.234) and
(MACD (26,12)<-1.155))) and (VOLUME<833)
```

Example of decision tree is shown in Figure 1.

B. Selection method

We used a combination of tournament and roulette method. We select randomly 5 (value is set experimentally) individuals, whom we rate and sort in descending order. We chose one individual with probabilities 5/15, 4/15, 3/15, 2/15, 1/15. After selection mutation and crossover generates an individual.

C. Genetic operators

In our work mutation and crossover operators are used.

Mutation operator works on one individual and gives some changes in its genome. Mutation is stochastic based, some methods of decision trees:

- leaf mutation, (I) where a random value is chosen from the possible value set for given indicator (60% chance), (II) mutation changes inequality sign from ">" to "<" and in another direction (16% probability) and last one (III) changes the indicator type (24% chance)
- mutation for logical nodes, that changes "and" into "or" and in another direction (50% chance)
- mutation of tree size: (I) that reduces of given tree to left or right child (50% chance), (II) split given leaf into two leaves connected with „or" or „and" node. The second node is generated randomly (40% chance for each child, only if not at maximal height) and (III) switches left and right child (10% chance)

Crossover operator links two individuals and switches their buy/sell decision trees. The probability usage of crossover was experimentally set to 3%.

D. Fitness function

We have chosen a fitness function that is closely related to the real use of strategies in the stock market, which is the possibility of such strategy to generate gains. It must include transaction costs, because ignoring them can result in over reactive strategies, generating losses if transaction costs are taken into consideration.

Fitness =

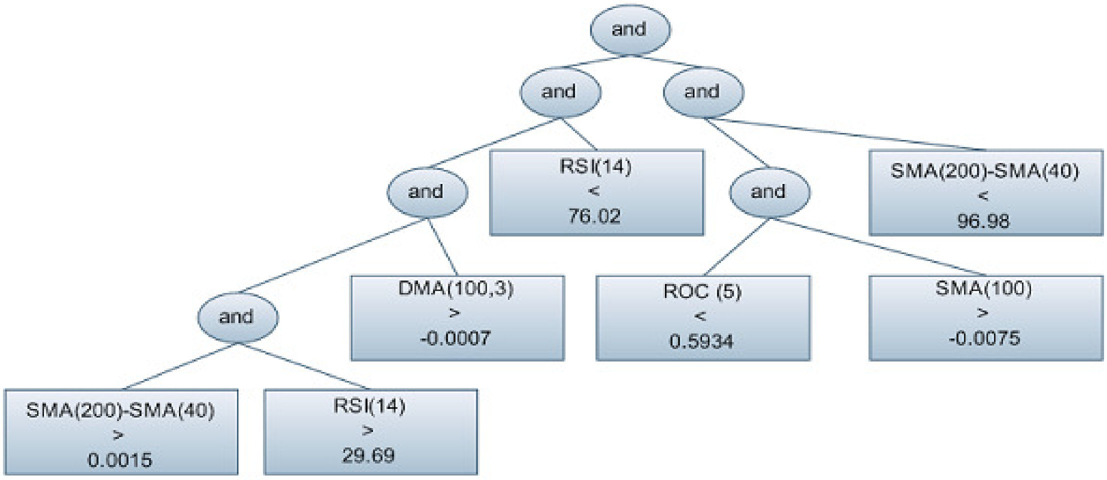

Fig 1: Example of buy decision tree. The presented decision tree as rule: *(*(((SMA(200)-SMA(40)>0.00150) and (RSI(14)>29.69711)) and (DMA(100,3) >-0.00073)) and (RSI(14)<76.02417)) and (((SMA(100)>-0.00757) and (ROC (5)<0.59348)) and (SMA(200)-SMA(40)<96.98830))

```
Sum of all profits/losses
+ Transaction count * Transaction cost
– MAX (0, 4 - Transaction count) * 8
```

Our fitness function form needs stock simulation, playing with the chosen strategy on the learning set data, and taking the result in points (adjusted by transaction costs as provision that equals 4 points). The last component in given function is responsible for faster learning to make more transactions rather than trying to buy/sell and hold. The 4 constant means, that if the strategy has made at least 4 transactions, there will be no punishment. For each transaction less than 4, it gets a punishment of 8 points (which is 2 times greater than transaction costs, which equals 4 points). It means that the punishment for the simplest buy&hold strategy is 24 points as the maximal value.

III. Research on EA parameters

All parameters of EA were tested to find the best values. Searching for EA parameters is a multidimensional problem. Additionally best parameters vary for each of the learning frames, so our results are only some approximation and trade-off between many possibilities. Results were obtained from repeated 200 runs under the same conditions, which generated 200 strategies (1 for each run). Average profit inc. provisions was taken to decide which parameter value is most promising.

Example of such parameter is *maximal tree height.* Some tests (e.g. L1 time-frame, see Table I) have shown, that best results can be obtained with the maximal height equal 5 or 6. Too high trees mean probably too big search space, however too small trees are too simple to represent the complexity of price movements. Maximal height means, that tree can be lower, but never higher as specified height (if mutation could make the tree higher, it will be stopped). Our experiments have shown that the optimal values for transaction provision is 4 points, probability of mutation 72%, and probability of crossover 3%.

In Table II we have shown the averaged profits of strategies in population of *population size* parameter. We can see, that populations greater and smaller than 200 give worse results as the optimal 200, by 300 even much worse.

Strategy profits are measured on test data, not on training data. Stop condition (*generations*) amount in all tests is fixed and equal 150.

IV. Experiments

In our tests we have generated a very well developing strategy (verified on test data), which we will be describe in details in this section.

A. Used datasets

The EA operates on time-frames consisting of about 1400 of 10 minutes intervals, which is about 2 weeks of currency pair historical values [6]. To obtain the fitness of each rule pair (BUY/SELL decision) we virtually play stock with these rules, opening and closing positions on historical data (learning periods in the learning phase, testing periods in testing phase). Example of used datasets (time frames) in learning or validation process (cross-validation was applied for testing):

Falling:
L1 (2009-12-11 10:50, 2009-12-24 15:10) intervals: 1412
L2 (2010-01-12 19:40, 2010-01-26 00:00) intervals: 1412
...
L8 (2007-05-15 19:20, 2007-05-29 00:00) intervals: 1412
Neutral:
N1 (2009-09-24 00:00, 2009-10-07 00:00) intervals: 1386
N2 (2009-11-16 15:50, 2009-11-27 21:50) intervals: 1428
...
N6 (2009-11-02 15:50, 2009-11-13 21:50) intervals: 1428
Rising:
H1 (2009-08-30 23:10, 2009-09-11 00:00) intervals: 1397
H2 (2009-10-07 00:00, 2009-10-20 00:00) intervals: 1386
...
H9 (2009-06-23 04:20, 2009-07-07 00:00) intervals: 1412
Long time-frame:
LONG1 (2008-09-01 15:50, 2008-10-06 02:40) int.: 3593

There were used 24 time-frames for learning and testing process, 3 additional only for testing process. Charts for time-frames of selected L1, L2, L8 and H1 are shown in Fig 2. We can see, that in each of the time-frames a one directional price movement (so-called *trend*) could be noticed,

Table I. Results of testing of 200 strategies produced with various max tree height parameter

Max. tree height	2	3	4	5	6	7	8	9	10
Avg. profit	1028	933	1155,9	**1221,6**	**1290,7**	1073	1094,2	870	985,6

Table II. Results of experiments with various population size parameter

Population size (individuals)	25	50	100	150	200	250	300
Avg. profit	1000	800	1153	778	**1309**	1060	769
Avg. profit (incl. prov)	590	378	678	338	**878**	614	282

with various short term deviations from the trend line. If the time-frame has more such big-enough short term trends, it's more interesting for our algorithm, because it gives an opportunity to learn when to switch from long to short position. We can see, that time-frame L2 gave very few opportunities to earn more than a simple strategy "sell at the beginning and wait" (sell&hold strategy) (if we consider transaction costs). Time-frame L1 was much more interesting, because there were many rapid movements which resulted in corrective movements.

Simulating FOREX stock strategy can meet three types of situations in the market with long, short position or out of the market. We admitted to keep always 1 position open. The profits are measured in points (or so-called *pips*), which are the fourth number after the point, for example value 1,2548 means 8 pips, instead of percent difference. It is standard measure used in future markets, because each investor can use other leverage and so the percent difference varies, even if they open identical transactions.

B. *Example of strategy*

Example of BUY decision tree is presented on Figure 1. It's a decision tree taken from a strategy which was best behaving on the test data. Transactions of this strategy on H5 dataset are shown in Table III. Such rule is easy to analyze, because for example it expects, that RSI indicator (for 14 intervals) has higher value than 30, and lower than 76, which are similar to values mentioned in the literature [14], 30 and 70. It means that the algorithm try to avoid extreme values (peaks). The important part of the rule is that SMA for 200 days must be at least 15 points higher than the SMA for 40 days, so it buys if the prices are relatively low, but at the same time not extremely falling down (already mentioned RSI > 30). Other parts of the rule are either only small optimizations or are of no meaning for the strategy, at least on the test data. Rule describing the SELL decision tree:

```
( (DMA(100,3)>-0.00082) or ((SMA(200)
>0.00238) or (SMA(200)>0.00349)))
and (WMA(200)<-0.00067)
```

To understand how the SELL rule works, we can see, that it sells when either the DMA with parameters 100 and 3 (average on 100 intervals, delayed by 3 intervals) is higher than the actual price minus 8 points or the SMA of 200 intervals is higher than price +23 points and in both situations the WMA is lower that actual price minus 6 points. It's hard to judge if this rule is reasonable, because it's not so obvious. The last part using WMA means, that we will sell only if the price is a bit better that the average price in the past (200 intervals) – it ensures, that we will not sell if the price is too cheap.

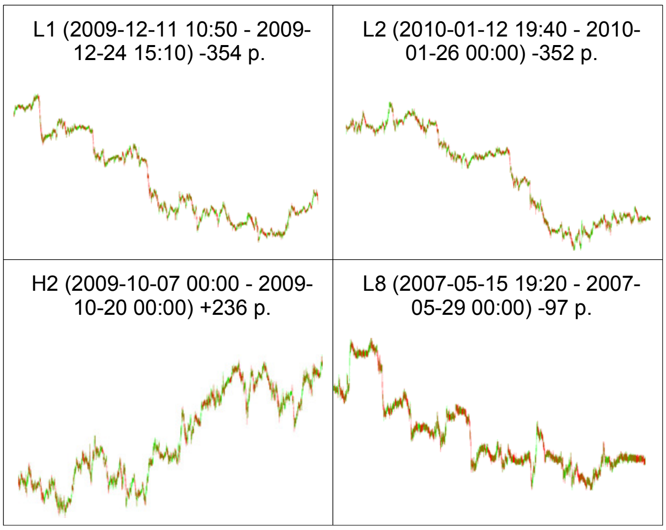

Fig 2. Example charts of the learning sets character. Time frames L1 and L8 are interesting for learning set than L2, which has fewer possibilities for position reversal.

C. *Tests*

In our research test (results are presented in Table IV and Table V) we are running our EA on all learning sets 200 times to get the best strategy for each run. After that we have generated 200 strategies to test their profit on 3 data sets.

To describe its genealogy, strategies learned on a specific time-frame are specified as the name of training time-frame and a name of the test data-set in brackets, for example "L1 (T1)" means strategies learned on time frame *L1* and tested on *T1* data set. Used data sets (*T1*, *T2*, *T3*) of time-frames are specified as follows (in brackets are the results of using *buy&hold* and *sell&hold* strategies, on each time frame from the dataset separately, and then adding the results):

T1: 24 time-frames (*sell&hold* strategy including provisions: 731 points, *buy&hold* strategy: -827 points)

T2: 23 time-frames (*sell&hold* strategy including provisions: -1051 points, *buy&hold* strategy: 959 points)

Table III. Table of transactions on h6 time-frame of the best found strategy (profits are given without provision cost)

Transaction type	Opened	Closed	Opening price	Closing price	Profit [in points]
LONG	2009-05-28 11:50	2009-06-01 00:00	1.3855	1.4101	**246**

LONG	2009-06-05 14:50	2009-06-10 00:00	1.4006	1.4069	**63**

T3: 24 time-frames (*sell&hold* strategy including provisions: -1227 points, *buy&hold* strategy: 1131 points)

For reasons of clarity: we were testing our strategies on data sets, which consist of 23-24 time-frames. Total amount of used time-frames is 27. Time-frames are independent, short time periods (shown in Fig 2), and data sets *T1*, *T2* and *T3* are collections of time-periods of various kind (rising, falling), but adding the price changes, causes rising (*T2*, *T3*) or falling (*T1*) type. We have used 3 data-sets instead of one, to show how the generated strategies behave on rising and falling data-sets. Using only one data-set does not allow us to do this.

In the traditional stock market we can always compare results of our strategy with a simple *buy&hold* strategy, which means simply buying at the beginning and selling at the end, which is the simplest way to invest. Growth of the market is the expected direction, as we all expect that the economy will rise in a long term.

Differently from the stock market on FOREX we have no real benchmark strategy – *buy&hold* strategy is exactly as good as *sell&hold* (sell at the beginning, buy at the end, such strategy is possible when we consider futures market), because the expected market direction isn't known. Such situation occurs because we always consider pair of currencies, for example EUR/USD, which we could as well switch to USD/EUR to get the ideal opposite of all price movements. That's the reason why we are showing the results of both strategies – *buy&hold* and *sell&hold*. Of course, provision costs are included, which arise when we open a transaction at the beginning of each time frame and close it at the end. The transaction costs are 2 point per transaction (1 for opening and 1 for closing), which is reasonable value on EUR/USD pair. We used transaction costs equal 4 only in the learning approach, to get more steady strategies.

In Table IV and Table V are given some experiments results. Benchmark *(buy&hold)* and *(sell&hold)* columns are the same values as those for datasets, adjusted by the learning time frame which is always taken out of the consideration. Positive *buy&hold* means that the prices on the test data was mainly raising, negative means the opposite. It's including provisions. Profits are presented in points rather than percentage, because we always have one position

Table IV. Results of testing of 200 strategies produced on 5 rising time-frames and one long time-frame on 3 data sets

Learned on (tested on)	H1 (T1)	H1 (T3)	H9 (H1)	H2 (T1)	H2 (T3)	LONG1 (H1)	SUM

opened, so earned points mean always the same real profit (10 dollars per point). That means, that consecutive profits add linearly, not exponentially. To get exponential results we have to open variable amount of contracts. It's difficult to give the results in percentage, because we need to know the leverage of the potential investor.

Average profit is the profit earned by 200 strategies generated on present learning set, ignoring transaction costs. *Avg. profit incl. provisions* are average results adjusted by transaction costs (2 points per transaction). *Avg. profit with transaction balancing (incl. provision)* is an average profit per strategy generated by playing with all strategies simultaneously, and balancing together buy and sell transactions opened on the same interval. This value is always between avg. profit and avg. profit including provision. *Combined strategy (incl. provision)* is a result of a strategy being built from all 200 strategies generated by EA. We run all strategies simultaneously, but open a transaction only if at least 60% want to open it and agree for the same direction. We are always playing with maximally 1 opened position. *Standard deviation, max, min* and *median* are some statistical functions run on all profits including provision for all 200 strategies.

We can see that strategies learned on time-frames *L1* and *L8* (see Table V) give extraordinary profits on both rising as falling data sets. For example if one has been very bullish on all time frames from second data set he would have earned 959 points, but average strategy (learned on *L1*) has gained 1295 points. The median of all strategies is high: 1362 points. Results on first data set are even better – bearish *sell&hold* strategy would have earned 444 points, where average generated (on *L1*) strategy would have earned 1381 points. Each point is valued as 10 dollars gain for the investor with one position opened, so it means $13.810 gain per one standard contract (so called *lot*), which is a very good result.

Other interesting result is the value of avg. profit with transaction balancing vs. without balancing. If we run all strategies simultaneously and balance trades which are contrary to each other we can spare 12-13% on transactional costs. It means for example that instead of earning 752 points we can earn 847 points (see Table V, it would be 1547 points without transactional costs) on one data set using strategies generated on *L8*. Unfortunately we must be ready to have so many opened contracts as many strategies we use, which limits the use of this strategy to either a limited choice of strategies or investors with great amounts of cash allowing opening 100-200 contracts.

The ultimate solution to the already mentioned problem is a combined strategy. We take our 200 EA generated strategies and build one strategy from it. The rule is easy, if 60% of all strategies show buy signal, we buy. If 60% of all strategies generate sell signal, we sell. In this case uncertain strategies (what happens pretty often) act against opening transactions. Interesting results can be obtained too, if we decide to leave the market if the uncertainty rate is higher than 90-98%.

Such combined strategies have one main advantage: they are single strategies. We can open just one contract, and still get the knowledge from all strategies and get the same or even better results as the average of all these strategies. In fact the results of such combined strategy are nearly always better as avg. profit for all strategies (for *L1* tested on second dataset the result was a little bit worse – 1125 vs. 1295 points, but still comparable, the same for *LONG1* (see Table IV), only on *H1* (*T1*) the results for combined strategy were much worse than average, -960 vs. -67 points).

In the Figure 3 we can see a schematic representation of our combined strategy mechanism. In the lower part we can see how many strategies were bullish (light bars) and bearish (dark bars). They are placed on each other. If the amount of bullish/bearish transactions crosses the decision line, a new position is opened or the old one closed. We can move this line higher or lower, so we can possibly ignore some signals or not. Studies have shown that optimal values depend on the learning set and vary between 42-62%.

We can see that strategies generated on *L2*, and *H2* (*T1*) were behaving worse, than even a wrong direction of buy/sell and hold strategy. It’s alarming, because it means that if we choose wrong learning set, the results can be really bad, although not much worse than keeping a wrong position opened. We cannot forget that it’s an expected result. There are some time-frames which give a great opportunity for our EA algorithm to extract some reasonable rules and some that are not. We have to choose interesting time-frames by hand and by using some additional testing.

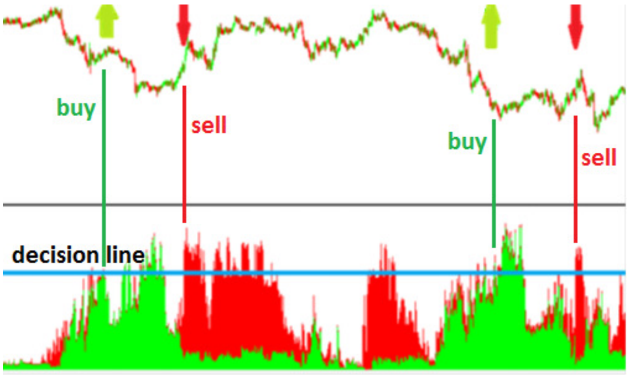

Fig 3: Combined strategy as an additional indicator. Chart below the actual price chart shows the distribution of bullish and bearish strategies (at each interval of time).

Such interesting time-frames are definitely *L1* and *L8* (shown in Table 2). Frames, that are generating some strategies which are very neutral are, not surprisingly, “neutral” time-frames *N1*, *N2*, *N6*. They would be profitable if we would ignore transactional costs. Interesting time-frame is *H2* – it produces profitable strategies but only for growing market. Obviously we wouldn’t use such strategies because of heavy (but a bit lower than wrong *buy&hold* strategy) losses generated by those on falling market.

We have run a “long term” test on a 05-01-2007 - 01-05-2007 time-frame. Results for *buy&hold* on this time-frame would be 549 points, and for *sell&hold* gives -553 points.

Results for a strategy learned on *L8* are: the average profit equals 324 points (including provision: 178 points). The profit gained by transaction balancing equals 191 points and combined strategy gained 280.

Results are not as good as one could expect, but there are some important things to mention - we have learned our EA on a falling time-frame, and it’s a rising one. If we would just sell at the beginning and buy at the end, we would lose 553 points and we have earned 280 points which is over a half of 549 points earned by a *buy&hold* strategy.

Also, we have tested *H2* combined strategy on the same time-frame. *H2* has gained 650 points, which is better than *buy&hold*. It’s not surprising, it’s a rising time-frame and it was thought on a rising time-frame too. What’s interesting it’s the fact, that it has made some profitable short trades (3 out of 4). It has proven to detect some local heights.

To summarize the results, our approach allows generating profitable strategies if we consider profits from more than 20 test time-frames. It was impossible to obtain a strategy, that was always gaining money independent of the actual time-frame, but when adding profits and losses from many time-frames, the results are definitely positive. It's important to choose a right learning time-frame – not each of them contains enough information to learn. Choosing combined strategy is nearly always a good idea, allowing us to open just one contract and still profit as an average strategy, without the risk connected with arbitrarily chosen strategy from all generated, which could possibly result in a very poor behavior (see *Min* column in Table IV or Table V). The most important – it's possible to trade with our strategies without human intervention and generate gains.

V. Further work

The matter of risk of our automatically generated strategies was ignored in this work, so as the capital management. In further studies they need additional research, because without those it cannot be used in any long term trading system, were not only random, high capital losses are not allowed, but also the amount of opened positions must vary in a way that uses the invested capital optimally. In future market such as Forex without proper capital management a so called “margin call” can happen, which means that in case of losses an additional deposit of cash must be made, or the position will be closed and (nearly) all the money lost.

Another case that needs more attention is so called “take-profit” (*tp*) and “stop-loss” (*sl*) orders. They were ignored in this work, but they are widely used by most of the investors, especially on Forex market. They allow us to profit from very short moments of euphoria on the market, where the price peaks only for seconds (*tp*) or to save our capital if we want to limit our losses on single transaction (*sl*). We could possibly allow the genetic algorithm to set this orders to either fixed values (for example 100 points from the transaction price) or values constantly adjusted by decision trees.

VI. Conclusion

We think that although our automating generated strategies are still too unstable and unreliable to use them in real trading systems, they can be used as an additional help for an experienced investor. Especially in the form of additional indicator, which shows in real time how many strategies are for and how many against our decisions. If we combine strategies from rising and falling learning time-frames our indicator is even more interesting, revealing us the knowledge of hundreds of automatically generated strategies in a very accessible form (which needs some practice though). However, reliability of such an indicator still needs further studies. We are planing to verify our method results comparing with another methods on the same data.

***Abstract*—Human emotions can provide an essential clue in searching images in an image database. The paper presents our approach to content based image retrieval systems which takes into account its emotional content. The goal of the research presented in this paper is to examine possibilities of use of an artificial neural network for labeling images with emotional keywords based on visual features only and examine an influence of used emotion filter on process of similar images retrieval. The performed experiments have shown that use of the emotion filter increases performance of the system for around 10 percent. points**

***Index Terms*—Artificial neural network, feature selection, similarity measures, emotion recognition, image retrieval, relevance feedback.**

I. Introduction

IN RECENT years an increase of computer storage capacity and Internet resources can be observed. Fast development of new image and video technologies and easy access to sophisticated forms of information demand constantly improving searching and processing tools. Existing methods of text documents retrieval give satisfying results, so now research is focused on images retrieval. Finding the right set of images in a base containing thousands of them is still a challenging task. Few working methods were created and developed to solve the issue. The first category of approaches is based on textual annotations. It assumes that every image in the database has a label describing its content. Systems, which use only annotations, are nothing more than text-based searchers.

Another way of dealing with the same problem is based on observation that textual labels are not always available. Content based image retrieval (CBIR) systems assume that many features useful during searching process can be extracted from the image itself. In the approach looking for similar images may be reduced to measuring a visual distance between them. Many of the systems use color information; as an example we can point the paper [1], where authors created images retrieval system based on color-spatial information. The main difference between both approaches is the type of similarity they can find. Textual searchers are capable to find semantic similarity, also named similarity of ideas (for example tiger in summer and tiger in winter) and content based searchers return visually similar images, even if they present different ideas.

CBIR systems look for similar images, but criteria of similarity are not explicitly defined. They can take into account image coloring, objects included in it, its category (for instance *outside* or *inside*) or its emotion (also called mood or feeling). The last one, depending on interpretation, can be seen as emotional content of a picture itself or an impression it makes on a human. In the paper we consider both definitions as equivalent. These systems are called EBIR (Emotion Based Image Retrieval) and they are a subcategory of CBIR ones. The term EBIR was introduced in the paper [2].

The most of research in the area is focused on assigning image mood on the basis of of eyes and lips arrangement, because the studies concentrate on images containing faces. In the current version of our research we assumed that emotional content is characterized by image coloristic, texture and objects represented by edges, and the information can be used in similar images retrieval process. An extension of this list can contain faces or other objects and symbols which can have an influence on the image affect.

When talking about emotions, we can not skip two important topics: subjectivity and the emotion classification. As stated in the paper [3], different emotions can appear in a subject while looking at the same picture, depending on a person and its current emotional state. But what we are looking for is not a system perfectly matching images and emotions. Our far reaching aim is to build a system, which can in an effective way support a searching process and increase a number of relevant pictures returned by any given query. The goal of the research presented in this paper is to examine possibilities of use of an artificial neural network for labeling images with emotional keywords based on visual features only and examine an influence of used emotion filter on process of similar images retrieval. Advantages of such approach is easiness adjustment to any kind of pictures and emotional preferences. Neural networks are machine learning techniques well known because of their noise resistance, which is very desirable feature in this application.

The paper is organized as follows: in the section II various approaches to image emotional content recognition described in a domain literature are presented. In the section III a general overview of the system is presented, together with a description of used visual descriptors and measurement of the image similarity. The constructed neural network is presented and a note about image databases used for learning and testing is added. In the section IV results of performed experiments are presented and an analysis of the results is given. Finally, in the section V, a conclusion and further work directions are proposed.

II. Related works

Broadly speaking there are three main methods of acquiring emotional information from pictures: labels' analysis, face expression's analysis and visual content analysis. The first method is based on textual descriptions of pictures and dictionaries of emotional terms. An example of such approach is presented in the paper [4]. The second method is used only to find emotions in pictures of human face and further applied for example in human-robot interactions. Analysis of faces are presented in the paper [5]. The last method assumes no information about pictures. Extraction of visual features is based only on properties like color and texture. The method was implemented in some systems, for example in the one presented in the paper [6].

A problem connected with EBIR systems is connected to sets of emotions considered by their authors. Many classifications of emotions exist; that is why it is difficult to compare them. The simplest set, presented in the paper [7], contains positive-negative categories. In [4] the basic emotion set is as follows: happiness, sadness, anger, fear and disgust. In the paper [5] surprise has been added to the above set. Authors of the paper [8] removed disgust from the set, but added neutral emotion and hate.

Another way of classification of images is based on adjectives describing more objective attributes of a picture, like a warm-cold, static-dynamic, heavy-light set, presented in [6]. Authors of the paper [9] developed the concept and created the following set: exhilarated-depressive, warm-cool, happy-sad, light-heavy, hard-soft, brilliant-gloomy, lively-tedious, magnificent-modest, vibrant-desolate, showy-elegant, clear-fuzzy, fanciful-realistic. Some other proposals are: Kobayashi's words (used for example in the paper [2]) and space of valence-arousal-control describing emotions, presented in the paper [3].

Let us recall that for learning rules of matching visual features to emotions some solutions were also developed. The most common are: regression [9], neural networks [5] [8] [10] and genetic algorithms [10]. Our system does not use any rules for classification; it is not a hybrid system also.

III. NECR – Neural-based Emotional Content Retrieval system

As we have mentioned above, the research investigates the feasibility of use of visual features for the retrieval of emotional content of images and tests feasibility of training ANN to accomplish classification task. To achieve this goal, a prototype system has been designed and implemented. The next subsection presents an idea of our approach.

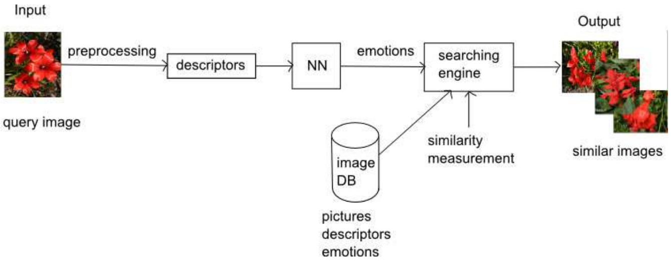

Fig. 1. Schema of the system

A. Idea

A general idea of the system is presented in Fig. 1. The system consists of a database of images, neural network, searching engine and interface to communicate with a user. All images in the database need to be preprocessed in order to find their visual feature descriptors, which refer to coloristic, texture and edges in pictures. We assume that the system is able to recognize an emotional content of images on the basis of classification method. Classification is performed by a supervised trained neural network. A learning set for the network was prepared manually, by assigning class labels to images from the database.

In our system in order to test an influence of the visual feature descriptors on an ability to recognize the emotional content of images and to find similar images, we have considered three various groups of emotion classification:

- positive-negative with neutral option,
- groups of adjectives:
  - warm, cold, neutral,
  - dynamic, static, neutral,
  - heavy, light, neutral,
  - artificial, natural; to distinguish between photos and hand-made pictures,
- 5 basic emotions (happiness, sadness, anger, disgust and fear).

After the training process the neural network is ready to assign emotions to pictures; one emotion from each category, what makes 6 labels for each picture. However, before any classification can take place, images need to be preprocessed. As a result of this step, visual descriptors are calculated and stored in the database, together with pictures. The network uses values of descriptors in classification process, and assigned labels are also stored in the database. The first stage of system's work is presented in Fig. 2.

Searching engine takes information about the pictures from the database and about the query image, calculated on an ongoing basis. As a result of the engine's work, 12 the most similar images are returned. The user can accept results or run the program again, with a modified query. The new query contains of an original picture and these of returned 12, which the user has marked as appropriate. The process can

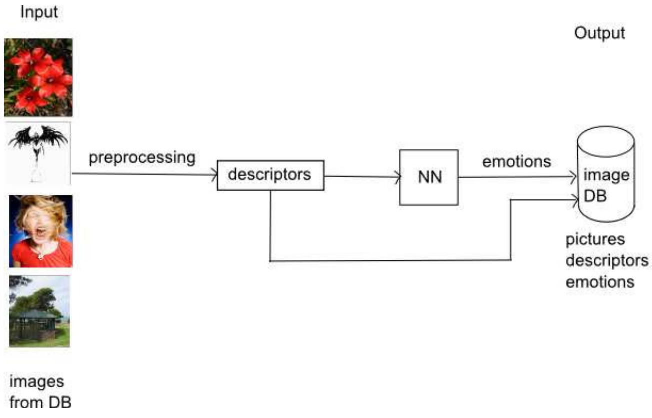

Fig. 2. Preparation of data

be repeated many times if needed. In a multi-images query, for each query image the most similar pictures are found and then a common list is built, as an average of distances between query images and images from the database.

Visual descriptors are calculated and emotional classification is made only once for each database; it means that if a user does not change the database, the program will run much faster. Because a query image can be of any kind, descriptors for it are always calculated, even if the picture belongs to the database. There is no option of retraining the network in the program.

B. Visual descriptors

Extracting information from a picture is a challenging task. Descriptors need to meet performance, reliability and accuracy criteria. Standard MPEG-7 defines some descriptors, which can be used for similar images retrieval (from the Internet article [11]). Some of the proposed there descriptors were used already in image retrieval systems [6]. They allow acquiring information about colors, edges and textures. In the system, three of them are used: Edge Histogram, Scalable Color Descriptor and Color Layout Descriptor. We base on implementations published in [12]. Additionally, two commonly available custom descriptors are used: CEDD and FCTH (described in [13] [14] [15]). They combine information about colors and edges or textures respectively.

Edge Histogram returns 80 numbers representing quantity of edges: 16 regions x 5 directions of edges (vertical, horizontal, 2 diagonals and without direction). We added global number of edges for each category to let the network to easily label pictures with dominating edges direction. Scalable Color Descriptor divides color space into 256 colors and calculates percentage of a picture covered with that color. Color Layout Descriptor divides picture into 64 regions and chooses a dominant color for each region. It allows us to obtain spatial-color information. CEDD (Color and Edge Directivity Descriptor) divides a picture into 1600 regions. 144 numbers are obtained as count of regions for each combination of 24 colors and 6 types of edges. FCTH (Fuzzy Color and Texture Histogram) works similar as CEDD, but in place of 6 categories of edges, it uses 8 categories of textures, what gives 192 numbers representing each picture.

The purpose of using so many descriptors is to acquire as much information about a picture as possible and as a result - to train the network efficiently. Of course, balance between amount of information collected by the system and processing time has to be found.

C. Neural network

The multi-layered perceptron neural network is used for emotional image classification on the basis of its visual descriptors, because it is universal, easy to construct and it performs well. Neural networks can distinguish between very similar input vectors and are immune to redundant or noisy information. We wanted to make classification of input images as consistent as possible, but it is not possible to judge few thousands of pictures in the same way. There is no theoretical model matching visual content of a picture to its emotional content. Neural networks have the ability to find schemas and rules even in such extreme environment.

After the preprocessing stage every image from the base is represented by its visual features vector **v**. The first elements of the vector **v** refer to SCD, the next to CLD, EH and the last two to CEDD and FCTH. In other words, for *i*-th image in database vector $\mathbf{v}^i$ is composed of 5 component vectors (eq.1)

$$\mathbf{v}^i = [\mathbf{v}_{SCD}, \mathbf{v}_{CLD}, \mathbf{v}_{EH}, \mathbf{v}_{CEDD}, \mathbf{v}_{FCTH}] \tag{1}$$

The query image is processed in the same way and is also described by its visual features vector $\mathbf{v}^q$.

Vector **v** is an input for the neural network. Its length is equal 869, so the number of inputs of neural network is also equal 869. It is worth pointing out that values of each element in vector **v** are scaled in the range (0-1). In the output layer we have 19 neurons. They encode 18 different emotions belonging to 6 categories. An answer of the output neuron equals to 1 indicates presence of a particular emotion. Only one emotion from each of 6 sets given in the section III-A can be present, so from all output neurons representing a category the one with the highest activation is chosen and its value is set to 1. For all others within the same category 0 is set.

The network contains three layers: input, hidden and output. All output neurons are connected with all hidden ones; 128 hidden neurons are connected with input ones in a way allowing better feature and pattern recognition. It means that hidden neurons are responsible for discovering only one feature. The schema of the network is presented in Fig. 3. For clarity reasons, only one set of connections between hidden and output neurons is shown.

It is visible that hidden neurons have their unique role in the classification process and are responsible for detecting only one kind of feature. Such specialized structure of the network was inspired by authors of the paper [16]. Because of limited set of connections between input and hidden layers (the network is not fully connected), learning process takes considerably less time. More complex structures with two hidden layers or more hidden neurons in already existing layer

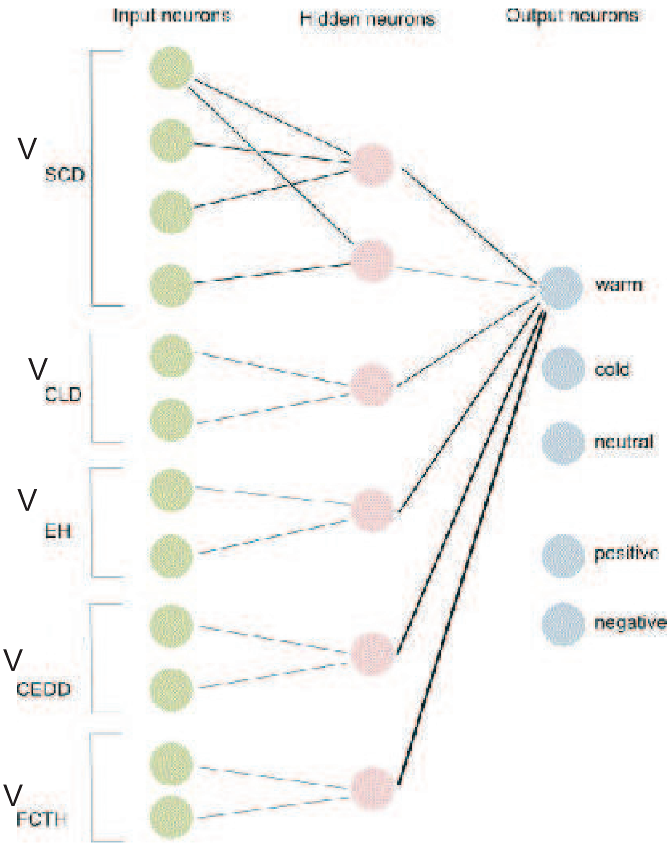

Fig. 3. Schema of the network. Only one set of connections between hidden and output neurons is shown

were considered as well. But, with concern about speed of images' classification and retrieval processes, we decided to use a simpler model.

After processing by the neural network each i-th image is represented by two vectors: vector of visual descriptors $\mathbf{v}^i$ and vector of emotions $\mathbf{e}^i$.

D. Similarity of images

To measure similarity between a query image and i-th image in the database, the distance between them is calculated. In some experiments we take only visual similarity, in other experiments we take both visual and emotional similarities (both vectors $\mathbf{v}$ and $\mathbf{e}$ were considered in this case). Let us focus on vector $\mathbf{v}$ first. The distance is separately assigned for each component vector $\mathbf{v}_{SCD}$, $\mathbf{v}_{CLD}$, $\mathbf{v}_{EH}$, $\mathbf{v}_{CEDD}$ and $\mathbf{v}_{FCTH}$. It is weighted and summed as in eq. 2.

$$d' = w_{SCD} \cdot d_{SCD} + w_{CLD} \cdot d_{CLD} + w_{EH} \cdot d_{EH} + \\ + w_{CEDD} \cdot d_{CEDD} + w_{FCTH} \cdot d_{FCTH} \quad (2)$$

Where w with an index denotes a weight of a given part of a distance component. The final distance d between query image and i-th image in the base is a weighted average. It is expressed by eq. 3.

$$d = \frac{d'}{w_{SCD} + w_{EH} + w_{CLD} + w_{CEDD} + w_{FCTH}} \quad (3)$$

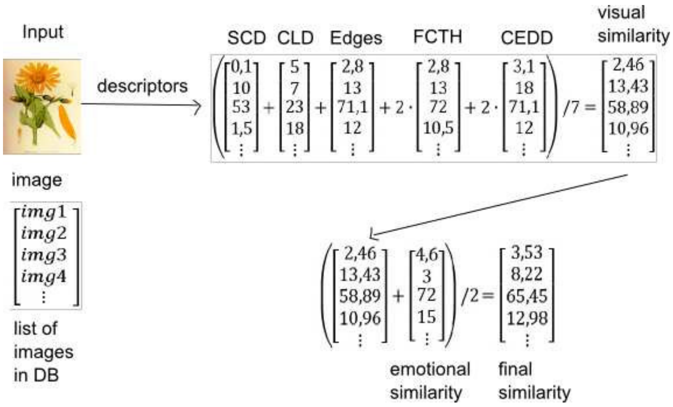

Fig. 4. An example of calculation of distance between a query images and images from the database

The way of distance computation was inspired by the paper [15], where the detailed description of the method can be found. To measure the distance on the basis of the part $\mathbf{v}_{CLD}$ the method was modified to deal with the three values referring to the three components of a color. The distance is transformed into the range (0-100). In particular 0 means the same image. Fig. 4 shows an example of visual distance calculation between a query image and each of images in the database. For the query image the similarity vector to each image in the base is obtained.

In the performed experiments weights w_{FCTH} and w_{CEDD} were set to 2, because these descriptors have the best individual retrieval scores. Remaining weights were equal to 1.

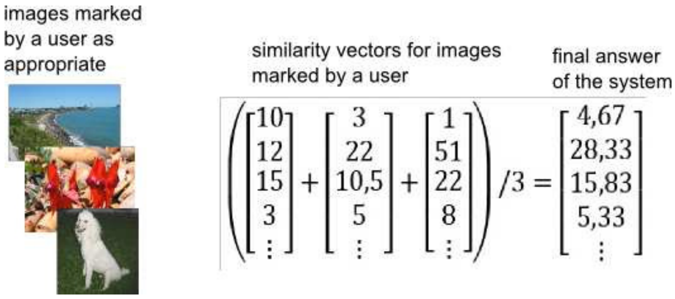
The second component in evaluation of images similarity takes into account emotional aspect and is based on the vector $\mathbf{e}$. For every matching label, 1 is added to a temporal result and then the final number is casted on the range 0-100, with 0 denoting maximal similarity. The query image is described by a vector of emotional similarities to each database image. Finally, both results (visual and emotional) are added and divided by 2. This is the final answer of the system. Whole method is illustrated by Fig. 4.

In a case with multiple query images, an average from all rankings is taken. Twelve images from the database with the smallest values are presented to the user. A case with multiple query images is presented in Fig. 5.

IV. Experimental study

To evaluate performance of our system and effectiveness of the similar images retrieval method, we performed some experiments. We assessed performance of the neural network (correct emotions assignment) and accuracy of retrieval results independently, with concern about various factors which can influence the performance.

The testing set in these experiments consists of 42 images, labeled manually and checked for consistency with labels given by the network. We tested the network trained on two different learning sets and we compared results. Details are



images marked by a user as appropriate
similarity vectors for images marked by a user
final answer of the system
$\left(\begin{bmatrix}10\\12\\15\\3\\\vdots\end{bmatrix}+\begin{bmatrix}3\\22\\10,5\\5\\\vdots\end{bmatrix}+\begin{bmatrix}1\\51\\22\\8\\\vdots\end{bmatrix}\right)/3=\begin{bmatrix}4,67\\28,33\\15,83\\5,33\\\vdots\end{bmatrix}$

Fig. 5. An example of finding similar images to a multiple query

TABLE I
CROSS-VALIDATION TESTS FOR THE NEURAL NETWORK

Subject	Accuracy	Deviation
Percent of correctly assigned (CA) labels	64.4	2.15
Percent of CA labels for warm-cold	80	2.32
Percent of CA labels for light-heavy	62.4	4.03
Percent of CA labels for dynamic-static	67.6	6.15
Percent of CA labels for artificial-natural	82	3.6
Percent of CA labels for positive-negative	55	4.1
Percent of CA labels for basic emotions	52	4.26

presented in subsection IV-A. We also did cross-validation tests.

The second part of these tests, dedicated to overall system performance analysis is more complex. We tested the system against many factors: various query images, image databases, learning sets and finally we evaluated difference in performance given by an emotions recognition module. Details are presented in the following subsections.

A. Datasets

Few image sets were created for learning and testing purposes. Because the system is supposed to support emotion based image retrieval, construction of sets was made with high consideration of an emotional content of pictures, especially for learning sets creation. The images in learning set were selected in a way which provides a fair representation of variously labeled pictures (the learning set consists of pictures labeled by every emotion from the set of 18 emotions). Fig. 6 presents the number of representative images in LS3 belonging to the particular emotions' categories.

First learning set (LS1) was intended to support good distinction between warm-cold, heavy-light and positive-negative categories and it consists of 893 pictures. It contains mainly landscape pictures, so expressing dynamism or anger is not possible there. Second learning set (LS2) was intended to support these categories, which are not supported in the first one: basic emotions, dynamic-static and artificial-natural and is built from 636 images. It contains images returned by searching engine like Flickr and Google for emotional keywords queries. But, the neural network trained on this set can not classify correctly any general images (for example landscapes), so third one (LS3) was made from 1456 pictures. It contains pictures from previous two sets, to support all classifications.

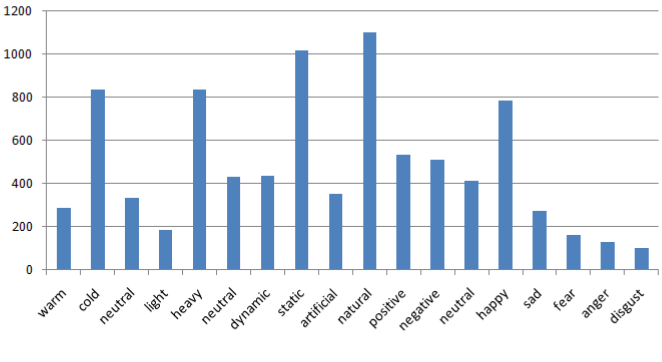


Fig. 6. Number of representatives of emotions in LS3

Three image sets are used in experiments, to evaluate performance of the system. All of them contain various pictures, belonging to different categories. We tried to balance quantity of representatives of every category. The first set (DB1) contains 2096 images, mostly landscapes. The second set (DB2) contains 1456 images, mostly emotionally rich and artificial ones. The third set (DB3) contains 1612 images, mostly natural ones and photos of people.

B. Evaluation of neural network performance

The network was trained with back-propagation method. The following values of parameters were set: learning rate 0.1, number of epochs 500, momentum 0.6, sigmoid unipolar activation function and error tolerance 0.1. For every learning set the network is trained only once and after that it is used in experiments.

Performance of the neural network was checked in two independent tests: by 5-cross-validation method and on a testing set of images different from learning sets. Cross-validation was performed with use of LS3 data set. The results are presented in Table I.

It is visible that performance of the network depends heavily on subsets chosen for learning and testing (the standard deviation can be as high as 6.15). But high classification score for one category has its drawback - lower scores for other categories: the network trained on the 3rd subset classified correctly 78% of pictures according to dynamic-static category had lower classification score for all other categories.

To determine performance of the network in an unknown environment, 42 different from learning sets pictures were chosen and classified by the network. Then, an automatic classification was compared with a manual one and results are shown in Table II.

In the test the learning sets LS1 and LS3 were used. The learning set LS2 was build only from pictures returned as results for emotional keywords queries and a network trained on it would not be able to determine a category of emotion properly 1-4 (rows 4-7 in Table II).

TABLE II
COMPARISON OF PERFORMANCE OF THE NEURAL NETWORK TRAINED WITH USE OF 2 TRAINING SETS

	Subject	Set LS1	Set LS3
1	Percent of correctly classified images	8	17
2	Percent of images with 1 wrong label	22	37
3	*Percent of correctly assigned (CA) labels*	*64*	*73*
4	Percent of CA labels for warm-cold	78	87
5	Percent of CA labels for light-heavy	62	74
6	Percent of CA labels for dynamic-static	70	69
7	Percent of CA labels for artificial-natural	70	83
8	Percent of CA labels for positive-negative	51	64
9	Percent of CA labels for basic emotions	49	60

Percentage of correctly assigned labels is used as measurement of system's efficiency because more common measures like recall and precision can not be used here. The system has to return 12 pictures in every run, so there is no possibility to define a set of false positives (even if some pictures score less than others, they are still present in results as complement to true positives). Moreover, if more than 12 images in the database are similar to the query image, the system has no possibility to show them all as a result.

As it can be seen in Table II, the network trained on a more general learning set (LS3) performs better than the one trained on less general one (LS1). The most problematic categories are basic emotions and positive-negative. It proves that emotional content of pictures can not be fully expressed only with chosen by us visual descriptors.

The network was trained two times on learning set LS3 (starting from random values of weights) and answers of the network from both trials were compared. Only in 17% of cases both networks were wrong and most of these mistakes were connected to basic emotions, which were not possible to be discovered without semantic knowledge about the picture. In 20% of cases one of the networks was wrong.

In most cases a network trained on the whole set LS3 performed better than the one trained on 80% of the set, even though test pictures here differed more than in the previous experiment. For dynamic-static, artificial-natural and positive-negative categories some subsets from the previous experiments scored higher than the network in the current one (trained on the whole set LS3). It can be explained in two ways: test images in the second experiment were more difficult to be classified and random division of the 3rd set favored different categories in different subsets.

C. Different image sets

Three different sets of pictures (DB1, DB2 and DB3) were created in order to test retrieval performance of the system. Results of experiments are presented in Table III. We are interested in number of runs (queries) needed to find all similar images from the sets. Three numbers, separated by commas, in every cell denote three sets. The network trained on the third learning set was used in the section.

TABLE III
PERFORMANCE OF THE SYSTEM AGAINST DIFFERENT QUERIES AND SETS. THREE NUMBERS, SEPARATED BY COMMAS, IN EVERY CELL DENOTE RESULTS REFERRING TO THREE SETS

Picture	N_{sr}	N_{pr}	N_{Runs}
black-white	2, 2, 3	2, 2, 1	1, 1, 1
red flower	10, 4, 10	5, 1, 5	5, 2, 4
lagoon, mountain	4, 4, 5	4, 4, 1	1, 2, 1
tropical forest	9, 11, 6	3, 4, 3	1, 3, 2
iceberg	8, 8, 2	6, 7, 0	2, 2, 0
sunset	12, 15, 5	10, 12, 4	4, 7, 1
red, shouting man	1, 6, 1	1, 6, 1	1, 1, 1
grey-scale	2, 7,-	1, 2, -	1, 1, -
worm	-, 6, -	-, 3, -	-, 2, -
boxing fight	-, 7, -	-, 6, -	-, 2, -

In Table III N_{sr} refers to the number of pictures in the set, which are similar to the query image. N_{pr} refers to the number of relevant pictures returned by the system and N_{Runs} refers to the number of searching trials the system had to perform to retrieve such results. Three numbers separated by commas in every cell denote results for every set: the first number refers to DB1, the second to DB2 and the third to DB3.

Some problems are shown here: color quantization and difficulty in finding precisely described set in hundreds of very similar pictures. Still, characteristic images are easy to find and overall results are very good. In many cases one query is enough to find the whole set, in others rerunning the program allows to receive better results. Images containing worms and boxing fights were present only in one set, so for others "-" is placed in Table III. The set DB3 contains pictures similar semantically to query images, but not visually, that is why retrieval results are worse than for the other two sets.

D. Emotions' filter

Emotion filter is a tool which uses vector **e** to produce final similarity score between two pictures as shown in Fig. 4. Without it, only vector **v** is used. To evaluate an input of an emotion filter to the final result, the same tests as in the subsection IV-B were run, but without calculating the vector of emotional distance between pictures. Results are presented in Table IV.

It is clear that emotions are important in the image retrieval process and improve results of traditional CBIR systems. In the EBIR system, more adequate pictures are found and it is done faster. Moreover, it can be noticed that the number of not relevant images (for example green building returned for tropical forest query) decreases when emotions' filter was used. Quality of results is higher for the system with the filter, what supports our theory.

To evaluate influence of the emotional filter, we created a metrics of efficiency E, expressed by eq. 4.

$$E = \frac{\frac{N_{pr}}{N_{sr}}}{1 + 0.05 \cdot (N_{Runs} - 1)} \cdot 100\% \tag{4}$$

TABLE IV
PERFORMANCE OF THE SYSTEM WITHOUT EMOTIONS' FILTER. THREE NUMBERS, SEPARATED BY COMMAS, IN EVERY CELL DENOTE RESULTS REFERRING TO THREE SETS

Picture	N_{sr}	N_{pr}	N_{Runs}
black-white	2, 2, 3	2, 2, 0	1, 1, 0
red flower	10, 4, 10	4, 0, 6	8, 0, 6
lagoon, mountain	4, 4, 5	4, 4, 4	3, 2, 5
tropical forest	9, 11, 6	3, 4, 0	1, 3, 0
iceberg	8, 8, 2	6, 7, 0	2, 2, 0
sunset	12, 15, 5	6, 6, 4	3, 3, 1
red, shouting man	1, 6, 1	1, 6, 1	1, 1, 1
grey-scale	2, 7, -	0, 2, -	0, 2, -
worm	-, 6, -	-, 1, -	-, 1, -
boxing fight	-, 7, -	-, 5, -	-, 2, -

where:
N_{pr} – number of pictures returned,
N_{sr} – number of pictures that should be returned,
N_{Runs}– number of runs. This metrics describes accuracy in relation to the number of runs. In the case with use of emotion filter E equals to 71%, 67% and 47% for sets DB1, DB2 and DB3 respectively. In the case without emotions filter E is equal to 59%, 57% and 42% for the same sets. Average decrease in performance is 9 percent points. The biggest differences in performance for various pictures are 31 percent points for a worm, 27 percent points for a grey-scale image and 19 percent points for a sunset. A lagoon picture scored 12 percent points better without emotions filter, but it is the only exception.

Detailed comparison between the results presented in two tables is illustrated in Fig. 7. Further conclusions are given in the subsection IV-E. Comparison between Tables III and IV shows that decrease in quality of results for the case without emotions filter is 17% and speed decrease is equal to 17%. Additionally, in a case with use of emotions filter, only in two situations no similar images were retrieved, but in the case without the filter – five times.

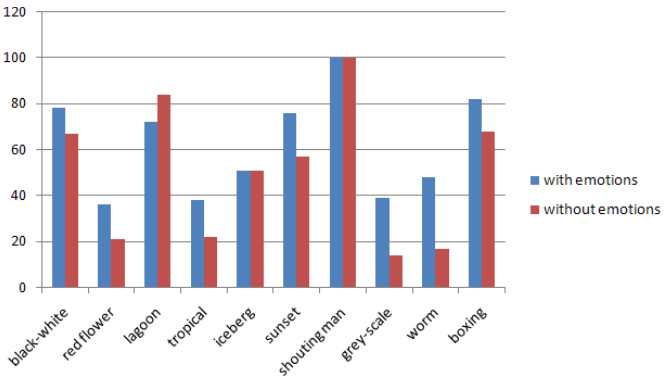

Fig. 7. Value of metrics E for different sets and pictures

TABLE V
PERFORMANCE OF THE SYSTEM AGAINST DIFFERENT LEARNING SETS

Picture	N_{sr}	N_{pr}	N_{Runs}
black-white	2	2, 2	1, 2
red flower	4	1, 0	2, 0
lagoon, mountain	4	4, 4	2, 1
tropical forest	11	4, 4	3, 3
iceberg	8	7, 7	2, 1
sunset	15	12, 7	7, 3
red, shouting man	6	6, 6	1, 2
grey-scale	7	2, 2	1, 1
worm	6	3, 1	2, 1
boxing fight	7	6, 6	2, 3

E. *Different learning sets*

Two learning sets were tested here: LS1 and LS3. Retrieval performance was checked in the same way as in previous sections (but only the DB2 set was used). Here numbers in cells denotes two learning sets. The first number belongs to the third set and the second one to the first set. Results can be found in Table V.

It can be seen that learning set influences retrieval results, so it should be chosen with high consideration about databases with which it will work or, in case when a working environment of the system is not known, learning set should be universal and should contain all kinds of pictures. Still, learning sets influence less overall system performance than lack of the emotion filter.

V. CONCLUSION

Our system is capable of finding similar images in a database with relatively high accuracy. Use of the emotion filter increases performance of the system for around 10 percent points. Experiments showed that average retrieval rate depends on many factors: a database, a query image, number of similar images in the database and a training set of the neural network. Although a user not always receives satisfying results during the first run of the searching engine, in most cases, after few runs they are satisfying.

Interface of the application and results returned by the system for a query image (boxing fight) are presented in Fig. 8.

Further improvements to the system are considered. To increase accuracy of the results, a module for face detection and analyzing face expression can be added. More work is needed to develop the system in a way allowing it to analyze existing textual descriptions of images and other meta-data. More accurate and informative descriptors can be also created. Another idea is to build a system containing two or more neural networks and use them as an ensemble classifier.

To fully evaluate the results obtained with the neural network in future we plan to apply another classifier instead. Bayesian models, linear models, decision trees and K-NN methods are concerned.

***Abstract*—Low–level vision approaches, such as local image features, are an important component of bottom–up machine vision solutions. They are able to effectively identify local visual similarities between fragments of underlying physical objects. Such vision approaches are used to build a learning system capable to form meaningful visual objects out of unlabelled collections of images. By capturing similar fragments of images, the underlying physical objects are extracted and their visual appearances are generalized. This leads to formation of visual objects, which (typically) represent specific underlying physical objects in a form of automatically extracted multiple template images.**

I. Introduction

Image understanding, although generally considered the highest level of machine vision applications, provides useful information for low–level image processing tasks. For example, noise removal, image segmentation, etc. can be performed more effectively if the presence of certain contents is known or assumed in the processed images. On the other hand, the results of low–level operations are usually indispensable to detect such contents in unknown images. This contradiction is apparently one of the most challenging issues in advanced applications of machine vision.

A similar, and equally challenging, problem exists in *content-based visual information retrieval* (CBVIR). Two operations can be relatively easily done for a given image, namely (1) image annotation (manually performed by a human) and (2) low–level feature extraction (performed automatically by dedicated algorithms). However, a *semantic gap* [1] exists between these two operations, i.e. it is usually very difficult to relate image features to semantically meaningful image tags.

The paper proposes a technique that handles the above contradictions from the low–level perspective. In general, we attempt to automatically build image semantics using purely visual characteristics of the images. The content of images is assumed unknown and random (although they may be collected from a certain "world"). The first step of the proposed approach, i.e. the automatic formation of *visual objects* [2] (which typically correspond to physical objects depicted in the images) is discussed in the paper in detail. Such *visual objects* are built as groups (clusters) of *prototypes* [2] containing multiple similar fragments identified in the available collection (database) of images. If the database is a representative description of the "world", we identify typical components and, thus, provide a certain level of understanding of that "world". The presented results are development of preliminary ideas highlighted in [3].

The similarity between image fragments is determined using sets of locally computed feature vectors, i.e. the proposed method falls into the *local* category. Each feature vector describes a small fragment of the image (usually an elliptical or circular *keypoint*). To calculate the keypoints, we use popular, widely discussed approaches such as *Harris-Affine* [4] and *SIFT* [5], [6].

Detection and clusterization of similar fragments in the image database is executed in four steps: (1) image pre-retrieval, (2) image fragment matching, (3) formation of *prototypes* from similar fragments, (4) formation of *visual objects* from prototypes. The first two steps are responsible for localization of similar image fragments within the database. Image pre–retrieval is introduced solely for a higher efficiency of the method, while image fragment matching is the key operation in finding similar image fragments.

In the remaining two steps, relations are established between similar image fragments identified in the first two steps. *Prototypes* are formed based on intersections of image fragments located within the same image. These multiple intersecting fragments come from matching of the same image with other images. The last step merges prototypes found in different images into *visual objects*.

The general idea of the proposed method is illustrated in Fig. 1 and detailed explanations of the underlying algorithms are provided in Section II.

Altogether, the automatic visual object formation is a grouping algorithm. Its input is a collection (database) of unlabelled images. The output is a set of groups (visual objects), where each group consists of image fragments that have been found mutually similar. The number of output visual objects is determined fully automatically based on the visual properties of database images.

II. Visual object formation

A. *Efficient image pre–retrieval (step A)*

Given a collection $\{\mathcal{I}_1, \mathcal{I}_2, ..., \mathcal{I}_n\}$ of n unlabelled images, our objective is to identify the presence of similar fragments within these images. Therefore, for a collection of n images we have to match up to n^2 image pairs. This can be a time–consuming operation even for a small database. Given a pair of images $\mathcal{I}$ and $\mathcal{J}$, similar fragments are identified using an *image fragment matching* method (described in Section II-B). The results of such a matching are accurate, but the operation is computationally intensive. Therefore, we have introduced an efficient image pre–retrieval scheme so that the system can be applied to image collections of relatively large sizes. The proposed pre–retrieval mechanism is one of the novelties presented in this paper.

For a query image $\mathcal{I}_x : x \in \{1, ..., n\}$, we attempt to identify the most relevant (candidate) images $\{\mathcal{I}_x^1, \mathcal{I}_x^2, ..., \mathcal{I}_x^m\} : m \ll n$ from the whole database $\{\mathcal{I}_1, \mathcal{I}_2, ..., \mathcal{I}_n\}$. Detection of fragments similar to unspecified fragments of $\mathcal{I}_x$ query is attempted within those candidate images only.

The candidate images are identified using a specialized *similarity function* $s(\mathcal{I}, \mathcal{J})$ defined for a pair of images $\mathcal{I}$ and $\mathcal{J}$. The similarity function is called *image topology similarity*. The function can be converted (if necessary) into an image–distance function using a variety of approaches. Unlike many classic image similarity measures, the proposed similarity function is able to identify images that are very different but contain similar fragments. The idea of the proposed function is conceptually similar to the previously proposed topological image fragment matching algorithm [7], i.e. it is based on pairs of matched keypoints. The main difference is that in here we use *weaker topological constrains*.

The proposed similarity function is defined as follows: First, we obtain matched pairs of keypoints $P(\mathcal{I}, \mathcal{J})$ between the input images (details to be discussed later). Having a non-empty set of such pairs P, we check the topological constrains for each keypoint pair $(p_I, p_J) \in P$. The topological constrains are verified within spatial neighbourhoods $\mathcal{N}(p_I)$ and $\mathcal{N}(p_J)$ of both keypoints from the pair. The spatial neighbourhood is defined as a set of r keypoints being the nearest neighbours in terms of image coordinates (Euclidean distance d) of a given keypoint. The neighbourhoods are found off–line and the nearest neighbours can be cached for each keypoint (and quickly retrieved on demand). Formally, the spatial neighbourhood $\mathcal{N}(p_X)$ for a keypoint p_X from an image (set of keypoints) $\mathcal{X}$ is equal to:

$$\mathcal{N}(p_X) = \arg\min_{N \in \mathcal{X}} \sum_{n \in N} d(n, p_X), \quad |N| = r. \tag{1}$$

Given $\mathcal{N}(p_I)$ and $\mathcal{N}(p_J)$ neighbourhoods of p_I and p_J keypoints, we check *how many* pairs of matched keypoints $P(\mathcal{I}, \mathcal{J})$ can be found within these neighbourhoods. The larger number of found keypoint pairs, the more credible (topologically) is the selected keypoint pair $(p_I, p_J) \in P$. We can now define a *topological verification function* $t(\mathcal{I}, \mathcal{J}, p_I, p_J)$ for a pair of keypoints $(p_I, p_J) \in P$ as the normalized number (r is the neighbourhood size) of matched pairs found in the neighbourhoods ($\times$ stands for Cartesian product):

$$t(\mathcal{I},\mathcal{J},p_I,p_J) = \frac{1}{r}\Big|\big[\mathcal{N}(p_I)\times\mathcal{N}(p_J)\big]\cap P(\mathcal{I},\mathcal{J})\Big|. \quad (2)$$

An illustrative example is shown in Fig. 2.

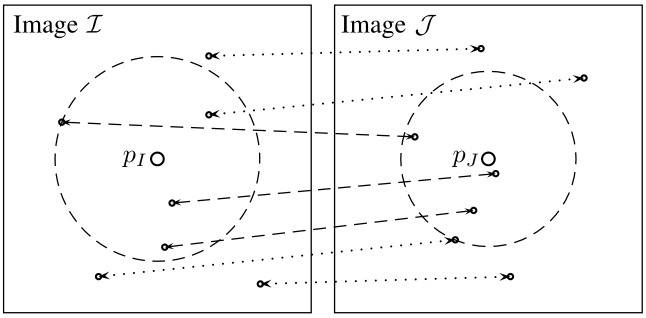

Fig. 2. Illustration of the topological constrains. Only three (dashed lines) out of $r = 4$ neighbours are matched keypoint pairs, $t(\mathcal{I},\mathcal{J},p_I,p_J) = \frac{3}{4}$.

The *similarity function* $s(\mathcal{I},\mathcal{J})$ between two images $\mathcal{I}$ and $\mathcal{J}$ is defined using the *topological verification function* $t(\mathcal{I},\mathcal{J},p_I,p_J)$ for all matched keypoint pairs $P(\mathcal{I},\mathcal{J})$ of both images (Eq. 3). The normalization factor $P^{max}(\mathcal{I},\mathcal{J})$ is the maximum possible number of matched keypoint pairs generated by the matching routine, given images $\mathcal{I}$ and $\mathcal{J}$.

$$s(\mathcal{I},\mathcal{J}) = \sum_{(p_I,p_J)\in P(\mathcal{I},\mathcal{J})} \frac{t(\mathcal{I},\mathcal{J},p_I,p_J)}{P^{max}(\mathcal{I},\mathcal{J})}. \quad (3)$$

An important property of the proposed *similarity function* is that it can detect the presence of similar fragments (even very small ones) in images with very complex and diversified backgrounds. The function is also computationally effective; it requires only $O(pr)$ operations, where p is the number of keypoint pairs $P(\mathcal{I},\mathcal{J})$ and r is the size of the neighbourhood (the costs of keypoint matching are not included into the complexity of the function). Additionally, it is not sensitive to a certain level of inaccuracies in keypoint matching.

Efficiency of keypoint matching is, obviously, another important aspect of the algorithm. The classic approach (e.g. *coherent pairs* method, i.e. *one-to-one* matching) is extremely slow and takes as much as $O(fp^2)$, where f is the length of keypoint descriptor vectors. This makes the classic (exact) approach not applicable to the pre–retrieval step, and we need to search for an approximate keypoint matching approach. There is a variety of approximate nearest neighbour algorithms e.g. [8], [9]. We have implemented a method which has been experimentally found time–efficient (although we did not compare its performances against the available alternatives). Exemplary pre–retrieval results are shown in Fig. 3.

B. Image fragment matching (step B)

The key factor in automatic visual object formation is a reliable detection of multiple similar fragments in a collection images (without any prior knowledge about the image contents). The assumption regarding the complete lack of prior knowledge is very important, because the system has to explore and learn unknown environments.

(j) 4-th result (k) 5-th result (l) 6-th result

Fig. 3. Examples of pre–retrieval based on *image topology similarity* function $s(\mathcal{I},\mathcal{J})$. The proposed similarity function is able to detect a presence of small similar fragments in images with very complex and diversified backgrounds.

Let us now formalize the similar fragments detection routine. Given a set of images $\mathcal{I} = \{\mathcal{I}_1, \mathcal{I}_2, ..., \mathcal{I}_n\}$ we would like to detect all existing similarities within the set. To make the process more efficient, for each image $\mathcal{I}_x : x \in \{1, ..., n\}$, we filter out only a subset of most similar images $\{\mathcal{I}_x^1, \mathcal{I}_x^2, ..., \mathcal{I}_x^m\} : m \ll n$ (see Section II-A). Thus, there are nm possible image pairs to be checked. For a single pair of images, a reliable detection of similar fragments can be solved by a *image fragment matching* method. The fragment matching method generates a set of image fragment pairs, first element of each pair represents a fragment on the first image, second element of the pair represents the similar fragment on the second image. When all similar images in the database are matched, the resulting set (union of sets from all pairs) contains all similarities found within the database.

Image fragment matching the most important and the most time consuming operation of the whole approach. We use two such methods, namely: *geometric* and *topological* keypoint matching. We will shortly present both of them, now.

1) The geometrical method with triangles: The objective of geometric image fragment matching is to reconstruct a set of *affine* transformations relating similar planar surfaces present on both input images. The transformations are reconstructed from triangle pairs built over both images using pairs of matched keypoints. Affine transformations are decomposed into elementary transformations (rotations, translations and scales). A six–dimensional histogram (affine transformations have six degrees of freedom) of all transformations is built for a pair of images. A 2D subspace (two elementary rotations) of an exemplary histogram for a selected pair of images is visualized in Fig. 4. A non–parametric approach is used to find peaks of the histogram, which represent dominant affine transformations relating both images (i.e. relating similar fragments in the images). Sets of triangle pairs which contribute to these peaks form the outlines (convex hulls) of similar fragments shared by both images. Further details can be found in [10], [11].

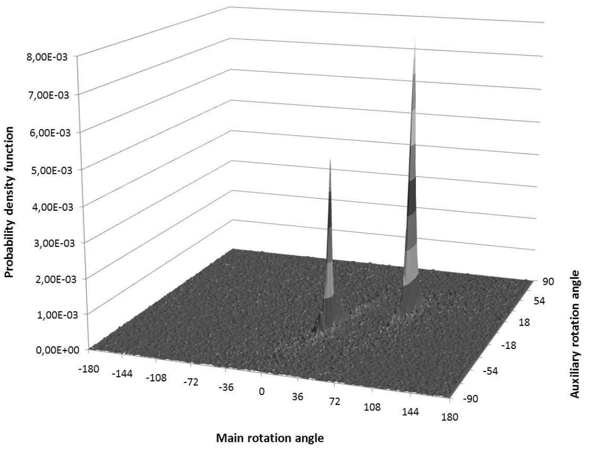

Fig. 4. Histogram of two rotations extracted from affine transformations [11]. Two peaks are visible, they represent two similar fragments.

2) The topological method: An alternative approach is the topological image fragment matching. Instead of recreating exact geometrical transformations between fragments of two images, this method focuses only on image topology. A *topological constrain* is introduced which, in general, reliably represents shape distortions of physical objects. We assume that neighbouring keypoints have to obey this constrain to be considered a similar fragment. Locally similar fragments are, therefore, extracted according to the results of topological constrain verification. The proposed topological constrain is the *matching order of vector orientations connecting keypoints from a selected pair to the neighbouring keypoints*. The constrain for a given keypoint pair is illustrated in Fig. 5. The topological method is more flexible than the geometric one; it is able to detect non-planar and deformed fragments of similar objects. However, the detection is less accurate in terms of generated fragment outlines (also represented as convex hulls). Further details on the topological method can be found in [7].

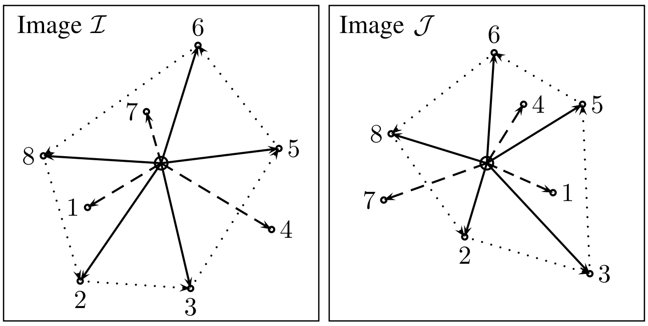

Fig. 5. Topological image matching concept. For each pair of matched keypoints, the largest subset of orientation-ordered neighbors is found. An exemplary subset of size 5 is shown.

3) Performances of image fragment matching: Reliable visual object formation is possible only if image fragment matching is performed with a high quality. In fact, any *false positive* matching error is very problematic for the future processing based on graph analysis. Such errors result in false connections within the graph and may result in incorrect contents of visual objects. The proposed routines are somewhat resistant to such errors, but this resistance is rather weak. On the other hand, *false negative* fragment matching errors are much less problematic. In case of missing graph connections, some visual objects may not be formed correctly. To solve this problem, it is usually enough to pre–retrieve more images or to deliver more images which would contain the corresponding physical objects. However, both of these solutions increase the computational costs of the method.

The achieved matching results (the geometric and topological approaches) on the processed database are shown in Table I. Two measurement modes are used: in the first one (object-wise) we check if the similar fragments are matched, in the second one (area-wise) we measure how accurately the shapes of matched fragments are outlined. The geometric method is more precise in terms of area measurement, due to very strict mathematical foundations. The topological method is less precise, but it is able to find more matching fragments.

In Fig. 6 we show two exemplary cases of similar fragment matching using the geometric approach.

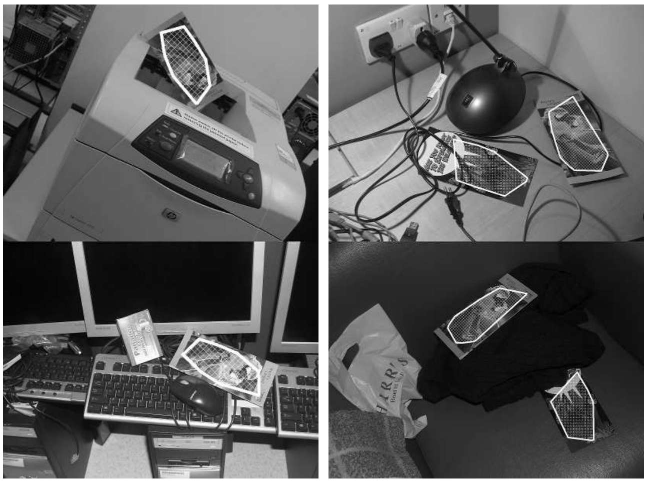

Fig. 6. Examples of image fragment matching using geometrical method

C. Automatic formation of prototypes (step C)

Image fragment matching provides us with a set of image fragment pairs. While image fragments within a pair are related (similar) there is not direct visual relation between fragments belonging to different pairs (even if detected in the same image). We need, nevertheless, to establish such relations because some of those fragments may represent the same physical object; the first step is to build relations between fragments extracted within the same image.

As shown in Fig. 1 a single image $\mathcal{I}_x : x \in \{1, ..., n\}$ is matched (i.e. it shares similar fragments) with a subset of images from the database. These fragments depicts physical objects present in the corresponding pairs of images. If we consider physical objects located in a single image $\mathcal{I}_x$, there might be several image fragments depicting each of these objects (they come from different matching processes against the same fragments of image $\mathcal{I}_x$). Such fragments should be very similar in shape, size and location (they are on the same image and approximate the same underlying physical object). Therefore, we assume that similar fragments represent the same physical object of image $\mathcal{I}_x$ and, thus, such groups of similar fragments are called *prototypes*; this is an important concept in the proposed approach. In fact, *prototypes* are intermediate structures required for form **visual objects**.

The process of prototypes construction is a grouping problem. To extract prototypes in a single image $\mathcal{I}_x$ we analyse intersections of image fragments. The larger is the relative size of the intersection, the higher chance that both fragments represent the same physical object. Two fragments are merged (to form a prototype) if: (1) both have similar sizes (areas), (2) the intersection of fragments is relatively large, i.e.

$$\min\left(\frac{c_1}{c_2}, \frac{c_2}{c_1}\right) > t_R, \quad \frac{c_I}{\min(c_1, c_2)} > t_I, \qquad (4)$$

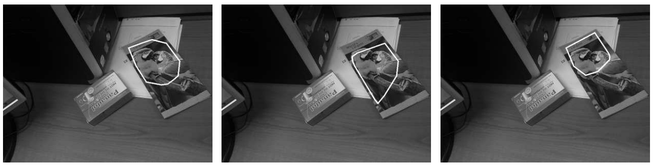

Fig. 7. Different image fragments (convex hulls) belonging to the same *prototype*. They come from matching of a single image with other images from the collection.

where: c_1 – area of the first fragment, c_2 – area of the second fragment, c_I – area of fragment intersection, t_R – area ratio threshold, t_T – intersection area ratio threshold.

Prototypes are formed from multiple fragments using a graph analysis technique. Each fragment is represented by a single graph node. Two graph nodes are connected by an edge if the underlying fragments satisfy the above merging criterion (Eq. 4). At least two fragments are necessary to form a prototype. Given the graph representation, prototype construction can be simply solved using graph connected component search. Various fragments of the same prototype formed in an exemplary image are given in Fig. 7.

D. Automatic formation of visual objects (step D)

Each prototype depicts (usually) a physical object located within a single image. Our ultimate objective is, however, to establish relations between prototypes form all database images, i.e. to form groups of prototypes that are referred to as *visual objects*.

Fortunately, the connections between images are already established in a form of similar fragment pairs (see Section II-B and Fig. 1). Since similar fragments are matched using a high–precision matching process (see Table I) the generated inter–image connections are mostly correct (this is a fundamental requirement for the visual object formation).

Formally, the formation of visual object is another graph–based grouping problem. We simply build a graph representing the above–mentioned connections between images. Each prototype $O_y \in y = \{1, ..., q\}$ is represented by a single graph node (note that prototypes are groups of image fragments from the same image). Each image fragment is matched with a similar fragment in another database image. Therefore, graph edges are created between nodes (prototypes) according to the matches between image fragments. Each prototype has a number multiple outgoing edges, equal to the number of similar fragments within this prototype. However, because the precision of similar fragment matching is still below 100%, a verification mechanism has to be put in place. The proposed verification mechanism is based on the analysis of graph *k-edge-connectivity*. A graph is *k-edge-connected* if it remains connected when less than k edges are deleted from the graph. In other words, a new prototype can be added to an existing visual object *if and only if* it is connected with at least k prototypes from the visual object. Such an approach is effective in eliminating random matching errors, because they usually form only a single connection to another

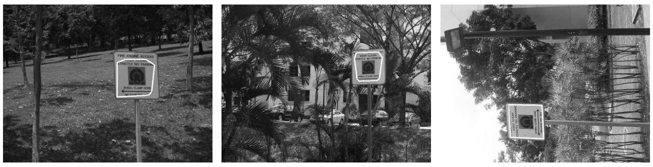

Fig. 8. Visual objects are formed out of many prototypes present on different images.

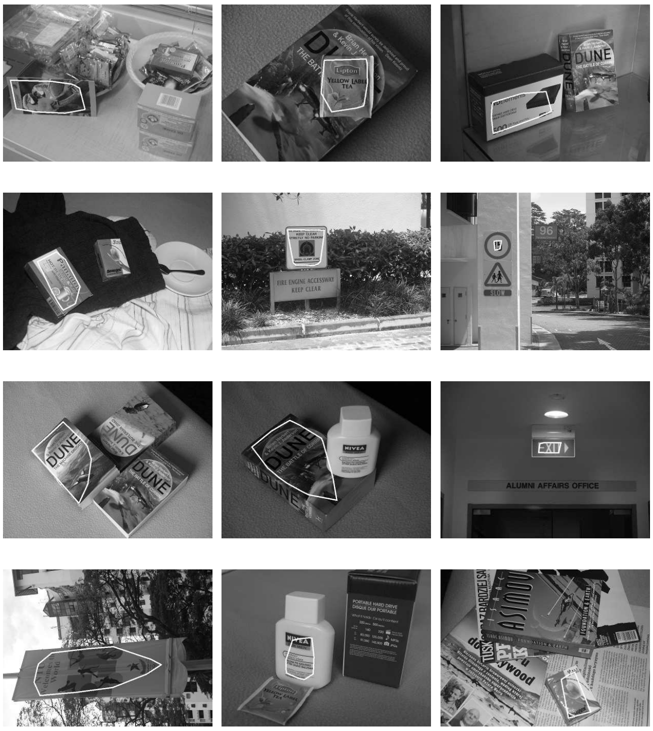

Fig. 9. Exemplary image fragments (instances of prototypes) representing visually formed objects.

prototypes. The resulting grouping algorithm is, therefore, a *k-edge-connected* subgraph search routine.

Exemplary image fragments belonging to different prototypes (but within the same visual object), found in various images are presented in Fig. 8.

In Fig. 9 we show a subset of visual objects automatically formed in the analysed collection of images (due to size limitations, each object is represented just by a single image fragment from one of the prototypes belonging to the object). Although no semantics is used during the object formation process, one my find that the created visual objects represent the actual physical objects appearing in multiple images within the database.

III. Discussion

Before presenting the experimental results we would like to discuss the applicability of the method and note its limitations. As stated above, the key requirement for successful object formation is very high precision of matching. Nowadays, precision near 100% may only be reached for image (fragment) matching problem, i.e. localization of image fragments containing identical objects. State-of-the-art approaches applicable for similarity based retrieval and grouping could not be used for the stated object formation problem, because their precision is still too low. Thus, the proposed method applies only for image collections depicting the same objects. Popular image databases such as *Caltech 101/256* may not be processed by the method, because they mostly contain similar (but *not identical*) underlying physical objects. For such databases *nothing would be found*.

Due to the mentioned, specific requirements, we have tested the method on a dataset containing images depicting a set of physically identical objects. For the reference and test purposes, the dataset may be downloaded from a web site[1]. First, we will discuss this dataset, later on we will show how to set up method's parameters. In the last part of this section we will summarize the achieved results.

A. The dataset and the objective of experiments

The dataset consists of 100 diversified images, captured both indoors and outdoors, containing a variety of objects. Most images in the database contains more than one object of interest, appearing in different configurations with diversified backgrounds. Camera settings and lighting conditions also differ between images.

Some of the physical objects repeat in several database images and thus, they are the candidates for visual objects. We have identified a set of physical objects present on at least three different images. These objects are: four different books, a notepad, a leaflet, two different medicine boxes, tissue pack, three different bottles, tea bag, two road signs, an exit sign and a street advertising poster. There are also other physical objects repeating only twice in the database (we consider them irrelevant because the assumed minimum number of prototypes in a visual object is $k = 3$, see Section III-B).

Our objective is to find all those repeating objects in the database and form visual object out of them. We expect that there will be no errors in the created objects, i.e. each visual object may represent *only one* underlying physical object. If a single physical object is represented by more than one visual object, we consider it a problem of lesser grade, because it is easily solvable in the proposed framework (see Section II-B3). Of course, the more correctly formed objects (without errors and object duplications) the better.

B. Method parameters

The proposed method has five parameters, related to (1) image pre–retrieval, (2) prototype formation and (3) visual object formation. All parameters, their short description and suggested values are listed in Table II.

The parameter m defines the size of the subset of most similar pre–retrieved images. The larger value of the parameter, the higher chance to capture important visual connections

[1] Image fragment matching dataset: http://www.ii.pwr.wroc.pl/∼visible

TABLE II
DEFAULT VALUES OF THE METHOD'S MAIN PARAMETERS.

Param.	*Meaning*	*Value*
m	Number of pre–retrieved images (% of n)	0.25n
r	Size of topological neighbourhood	60
t_A	Minimum ratio of image fragments area size	0.75
t_I	Minimum ratio of image fragments intersection size	0.75
k	Visual objects graph edge connectivity	3

between images from the database. However, larger values of the parameter significantly slows down the method. The maximum value of this parameter is n; this represents a disabled pre–retrieval, i.e. all image pairs are matched. The parameter r defines the size of the topological neighbourhood (see Eq. 2). To choose the proper value of the parameter, we need to consider two issues. The topological neighbourhood has to be large enough to be informative and it has to be small enough due to memory requirements (to speed up the method all neighbourhoods are pre–computed off–line).

Another two parameters are related to prototypes. They are used in the image fragment merging routine. As mentioned in Section II-C, merging should happen only if two image fragments (they are on the same image) represent the same physical object. Both parameter values t_A and t_I have been experimentally set to 0.75.

The last parameter is related to the visual object formation. To eliminate potential error matches, we want each prototype to be linked to at least k other prototypes (i.e. each prototype should contain at least k image fragments). In the presented approach, we have assumed $k = 3$, which is the minimum possible value. Due to high precision of image fragment matching, it is fully sufficient. However, if matching errors are more frequent (lower precision of image fragment matching) especially on larger databases, one should consider a larger value of the parameter. As a result, it would be more difficult to form visual objects but they would be more credible.

C. Discussion on created visual objects

The minimum requirement to form a visual object is having a physical object *correctly matched* on at least three different images ($k = 3$, see Section III-B). The quality of matching (i.e. precision of matched area) is in fact the most important element of successful object formation. To measure how well the visual objects are formed, we use the ground truth information as discussed in Section III-A. In fact, we want to capture as much of underlying physical objects as possible.

Given the processed database and the proposed parameter set up, there are *no errors* in the generated visual objects, i.e. each formed visual object represents only one physical object. In some cases, a physical object is represented by more than one visual object, but such objects are merged together when more data is provided (the pre-retrieval size is increased). Also, larger amount of matching data leads to larger number of formed objects. Given the pre–retrieval mechanism, we can easily set up how many images will be given to image fragment matching and subsequently how many similar fragments may be found. Comparison of results for different pre–retrieval scenarios are given in Tab. III. We note that not all objects have been found (see Section III-A), non–planar ones were the most problematic. Low number of pre–retrieved images causes only a few objects to be created. The more pre–retrieved images, the more formed objects and the quality increases, but the computational cost also increases.

Having the geometrical method employed for the matching task, we may expect very high area precision (see Tab. I). The number of pixel–level false positive errors in generated image fragments is minimal. But there is also a cost, non–planar objects will be only partially captured and they will most probably not constitute correct prototypes. The topological fragment matching overcomes the problem of non–planar objects, but has much lower precision in terms of matched area. Statistics demonstrating the ability to recreate meaningful objects are shown in Tab. III. Due to high precision the geometrical method is a more suitable candidate for object formation than the topological one. The main problem with the topological approach is much smaller number of prototypes successfully used in object formation. Large differences in image fragments (the main criterion for successful prototype formation) prevent capturing identical parts on the same image. Even though the number of matched fragments (mostly correct) is higher for the topological method, the overall number of formed objects is lower. Statistics for the numbers of created prototypes and visual objects are given in Tab. IV.

m [%]	Matched fragments	Formed prototypes	Prototypes in objects	Formed objects	True objects
	Geometrical fragment matching				
3	203	106	39	11	9
4	291	131	64	12	11
5	357	138	72	11	11
10	589	162	95	14	13

TABLE IV
CREATED PROTOTYPES AND VISUAL OBJECTS FOR VARIOUS SETTINGS OF PRE-RETRIEVAL (m).

An interesting case is present for geometrical matching, $m = 15$ and $m = 20$. The number of prototypes successfully used in object formation is in fact *decreasing*. Surprisingly, this is a correct behaviour. Some image fragments, which should create a single prototype, were not merged together for $m = 15$. Instead, multiple different prototypes are created. If the number of pre–retrieved images is increased to $m = 20$, missing links between these prototypes are found. Image fragments are properly merged and a single prototype is formed. Thus, we can also see a decrease (by 1) of the number of visual objects. In fact, similar behaviour happens quite often (see "±" in Tab. III), but in this case it is well captured.

We may also observe a much lower number of formed visual objects for the topological fragment matching. It is related to the already mentioned problem of lower area precision. Decreasing the values area related merging thresholds (t_A and t_I) results in creating of *false objects* and thus is not an acceptable approach. This confirms one of the initial statements, that successful visual object formation requires image fragment matching working with very high precision.

Apart of the listed features of the proposed method, there are also weak points. In some cases one detected prototype is a part of another prototype. Prototype formation criterion based on fixed merging thresholds (t_A and t_I) can not capture it correctly. Such prototypes (and later on visual objects) will not be joined, even though they represent the same underlying physical object (or a part of it). Therefore, we should consider building a *hierarchy* of prototypes and visual objects, instead of a plain structure.

IV. SUMMARY

A method for automatic formation of visual objects has been presented. The method is able to find meaningful image fragments from an unlabelled set of images. Visual objects are formed out of repeating, similar image fragments within the dataset. The proposed method employs *image fragment matching* techniques to extract such similar fragments of images. Two matching techniques are used, namely: the geometric and the topological ones. Apart from the visual object formation solution, we have also presented a novel image pre–retrieval method that effectively identifies images prospectively containing similar fragments. The method uses a topology–based similarity function. It is an important component of the system, because it significantly shortens the matching process.

The proposed solution creates a set of visual objects, without any kind of structure or hierarchy. This might be its weak point, because some similar fragments may indeed be structured (e.g. one object represents a visual fragment of another object). Our further research will focus on building such a hierarchy of visual objects.

ACKNOWLEDGEMENT

***Abstract*—This paper presents a methodology for learning taxonomic relations from a set of documents that each explain one of the concepts. Three different feature extraction approaches with varying degree of language independence are compared in this study. The first feature extraction scheme is a language-independent approach based on statistical keyphrase extraction, and the second one is based on a combination of rule-based stemming and fuzzy logic-based feature weighting and selection. The third approach is the traditional *tf-idf* weighting scheme with commonly used rule-based stemming. The concept hierarchy is obtained by combining *Self-Organizing Map* clustering with agglomerative hierarchical clustering. Experiments are conducted for both English and Finnish. The results show that concept hierarchies can be constructed automatically also by using statistical methods without heavy language-specific preprocessing.**

I. Introduction

An ontology is a directed graph consisting of concepts as nodes and relations as the edges between the nodes. A well-defined ontology has names for the concepts and specify what kind of relation there is between the concepts. The ontology is represented using a formal language, such as DARPA Agent Markup Language (DAML) or Web Ontology Language (OWL). With the use of the formal language, axioms can be specified to determine validity and to define constraints in ontologies. Ontologies are used widely in different Natural Language Processing (NLP) applications: examples are word sense disambiguation [1], annotating images [2], assessing text difficulty [3], and monitoring disease epidemics by analysing textual reports from the Web [4].

Creation of ontologies has obvious benefits, since it appears ideal that all systems within some domain would use similar terminologies and shared ontologies. The continuous change of conceptual systems through innovations and other activities requires that also ontologies need to be updated. The costs related to ontologies stem from two main sources: the development of a shared conceptual system and the use of it [5]. The development of an ontology typically consists of defining the concepts and the relationships between the concepts. The typical stages of an ontology building process are the following [6]: (1) domain analysis resulting into the requirements specification, (2) conceptualization resulting into the conceptual model, (3) implementation that leads into the specification of the conceptual model in the selected representation language, and (4) the ontology population i.e. the generation of instances and their alignment to the model that results into the instantiated ontology. Ontology maintenance includes getting familiar with and modifying the ontology. Reuse involves costs for the discovery and reuse of existing ontologies in order to generate a new ontology [6]. Simperl et al. [7] present a cost estimation model for ontology engineering. They estimate the person months associated to building, maintaining and reusing ontologies calculated as the product of the size of the ontology.

Ontologies have been mainly created manually but since the cost of manual creation is huge, also automated ways have been studied, often using methods developed originally for other fields of science. Ontology learning is the process of identifying terms, concepts, taxonomic and non-taxonomic relations and optionally axioms from natural language text and using them to construct and maintain an ontology.

In this paper, we assume that we have a set of text documents, each describing a concept in natural language. We extract taxonomic relations between the described concepts by using a selection of feature extraction methods and clustering the resulting feature vectors. This approach is automatic and easily portable to other domains and languages since it needs just a set of dictionary-like pages or documents as resources. One of our approaches is language-independent while the others use some language-dependent preprocessing steps.

A. Related work

Learning or extracting taxonomic relations means finding hypernymies between concepts with the goal of constructing a concept hierarchy. On the other hand, non-taxonomic relations are other than hyponymic relations between concepts in an ontology including e.g., synonymy and antonymy.

Taxonomic relations have been extracted automatically for a long time: Amsler created automatically a taxonomy for English nouns and verbs using dictionary definitions [8]. Hearst introduced lexico-syntactic patterns that indicate hyponymy relations [9]. Those have been further used for taxonomy learning e.g. in [10], [11]. Taxonomies have been learned also from Wikipedia by using the Wikipedia categories as concepts in a semantic network, connectivity of the network and on applying lexico-syntactic patterns [12]. Statistical methods for extraction of taxonomic relations have been covered in [13] including hierarchical and non-hierarchical clustering,

978-83-60810-27-9/09/$25.00 © 2010 IEEE

similarity measures and different linking schemes. [14] introduced their guided agglomerative hierarchical clustering algorithm that create concept hierarchies from text collections exploiting a hypernym oracle. The oracle exploits hypernyms from WordNet and using the Hearst lexico-syntacic patterns matched in a corpus or Internet. [15] proposed a clustering approach for taxonomy learning that incorporates evidence from multiple classifiers to optimize the entire structure of the taxonomy.

Also a combination of natural language processing tools have been used in extracting relations from text. A massive approach uses lemmatiser, syntactic parser, part-of-speech tagger, pattern-based classification and word sense disambiguation models together with resources such as domain ontology, knowledge base, and lexical databases [16]. Another approach is an unsupervised model for learning arbitrary relations between concepts of an ontology [17]. The approach uses corpus of manually tagged named entities, corresponding to ontology concepts and syntactic patterns.

In a recent work [18] the variety of ontology and concept hierarchy learning have been explained comprehensively. The work also introduces the Tree-traversing Ants (TTA) clustering technique for learning taxonomic relations. TTA is based on dynamic tree structures and it adopts a two-pass approach for term clustering. During the first pass, nodes are recursively broken into sub-nodes using Normalized Google Distance (NGD). The second pass is a refinement phase where terms are relocated according to n-degree of Wikipedia (noW) measure that uses Wikipedia Categories information.

The problem of the current methods is that they use of a wide range of language-specific tools, dictionaries or ontologies and thus exporting to new languages or domains is difficult or in some cases even impossible due to the lack of resources. The work by Wong seems to be more independent of the used language but instead needs access to Google and Wikipedia.

B. *Our contribution*

Our methodology can use any encyclopedia entries or other topic-related documents as definitions of concepts and creates taxonomic relations based on this data alone. No access to online sources is needed after the collection of the document set. Our methodology uses a very small amount of language-specific information and is thus easily portable to other languages. Other works that use Wikipedia use mostly the category information as concepts for taxonomy learning. Instead, we use the Wikipedia articles as concepts. Wikipedia articles have been used as concepts also in [19] but they do not create taxonomies but only measure relatedness between words or documents. In the existing work, term extraction methods are usually used for extraction of labels for concepts in the ontology, but we use keyphrase extraction for selection of a relatively small amount of terms for document representation.

II. Methods

We propose a methodology to generate taxonomic relations or concept hierarchies automatically from a set of encyclopedia documents. Each document is a description of a concept (the same assumption is made e.g. in [19]). These concepts are on the lowest level of the ontology and we aim to cluster the documents hierarchically to obtain an ontological structure of the concepts. Our methodology for generation of taxonomic relations consists of two basic steps: 1) feature extraction and 2) hierarchical clustering of the feature vectors. The result is a hierarchical structure generated according to the contents of the text documents.

In this study, generation of taxonomic relations is carried out for both English and Finnish languages. Finnish is a highly agglutinative language and as such relatively different from English. By using this language pair in our experiments we want to show that our methodology is further exploitable for several other languages.

A. *Feature extraction*

Feature extraction aims to reduce input data dimensionality, extracting the relevant information and removing redundancies. Traditional document representations are built over the *Vector Space Model (VSM)* [20], using term weighting functions based on term and document frequencies. The weighting is supposed to reflect the importance of each word to represent a particular document in the context of a document collection or corpus.

We propose three different approaches for document representation. One of them is a combination of heuristic criteria exploiting document structure by means of fuzzy logic. The second approach utilizes a statistical keyphrase extraction method to automatically extract features for document representation. The third method is the traditional *tf-idf* term weighting function that is also used as a baseline for our study. These representations are selected to compare how purely statistical method performs compared to a more heuristic method that gathers extra knowledge from the documents' meta information.

1) Fuzzy combination of criteria: When a human reader tries to understand the contents of a document, his or her attention is focused on some particular elements. Title or emphasized words are usually considered more important than the rest of the document. Moreover, the first and the last parts of a document usually contain overviews, summaries or conclusions with important keywords.

A fuzzy logic-based representation called *Extended Fuzzy Combination of Criteria* (*efcc*) [21] aims to exploit the semantics reflected by the use of a specific subset of HTML tags. The main idea is to define the importance of each word by combining several heuristic criteria. These criteria are related to word frequencies in the whole document, in titles, in emphasized text segments, or in first or last parts of a document. If similar information is available, the *efcc* approach can be used with any kind of document, not only with HTML-encoded documents.

The fuzzy system is built over the concept of linguistic variable, which value can be defined using natural language words and fuzzy sets. Each variable describes the membership degree of an object to a particular class. In the *efcc* approach, they are defined from human expert knowledge based on word frequencies mentioned above. Then, the knowledge base is defined by a set of IF-THEN rules combining these variables, in order to describe system behaviour as much precisely as possible. The aim of these rules is to combine one or more input fuzzy sets (antecedents), associating them with another output fuzzy set (consequent). Once the consequents of each rule have been calculated, and after an aggregation stage, the final set is obtained.

In this way, the knowledge used to build the rules is based on the following simple ideas: (1) A word appearing in the title or emphasized should appear in any other criterion to be considered important; (2) Words appearing in the first or last part of a document could be more important than others, because documents usually contain summaries or relevant ideas to attract reader's interest; (3) A non-emphasized word could mean that no words are emphasized in the web page; (4) A word not appearing in the title may indicate that the page has no title or the title has no meaning, i.e. it does not enclose relevant words; (5) High frequency of a word in a page could be important when the previous criteria are not enough to choose the most relevant words.

Some samples of these rules are (the rest can be found in [21]):

TABLE I
SAMPLE RULES

IF Title == High AND emph == High
THEN relevance = Very relevant
IF Title == High AND emph == Medium AND Position == Preferential
THEN relevance = High relevance
IF Title == High AND emph == Medium AND Position == Standard
THEN relevance = Medium relevance
...
IF Frequency == Medium
THEN relevance = Medium relevance

The inference engine is based on a center of mass algorithm (COM) that weights the output of each fired rule taking into account the truth degree of its antecedent. The output is a linguistic label with an associated number related to the relevance of a specific word in the page. A more detailed explanation of the fuzzy system can be found in ([21], [22] and [23]).

In addition to the *efcc* term weighting function, also inverse document frequency *idf* is used (equation 1).

$$\mathrm{idf_i} = \log \frac{|D|}{|\{d : t_i \in d\}|} \tag{1}$$

Where D is the total number of documents, and the denominator represents the number of documents containing the term i in the collection.

This modification of *efcc* aims to penalize those words appearing in a high number of documents due to the fact that Wikipedia pages are template-based and, therefore, there are terms appearing in each and every page (equation 2).

$$(\mathrm{efcc\text{-}idf})_{\mathrm{i,j}} = \mathrm{efcc_{i,j}} \times \mathrm{idf_i} \tag{2}$$

Where $\mathrm{efcc_{i,j}}$ is the relevance value obtained by means of the fuzzy system for a term i in a document j.

Moreover, discarding terms appearing in less documents than a particular percentage of the whole collection size can alleviate the effect of *idf* over too discriminative terms. If a concrete term appears in less than 4 documents, it is removed. This approach is called *df-efcc-idf*. Other intermediate variants were tested, like using just *efcc* values and the one shown in equation 2, but the results were uniformly worse.

To reduce the dimensionality of document vectors by selecting the most important features, we use the *Most Frequent Terms until n level* (*mft*) reduction method. This method consists of ranking the terms document by document based on the term weighting function values. A separate ranking is created for each document. In the first step, we will take terms appearing in the first position of each document ranking, ordering them first based on how many times a term has been found in different document rankings, and then, if two or more terms appear the same number of times in different rankings, based on the maximum weight found for each term. If we do not have terms enough, then we will take the terms appearing in second position in each ranking, and so forth.The process stops when the desired number of terms has been reached.

2) Statistical keyphrase extraction: The second feature extraction approach *Likey* [24] comes from the tradition of statistical machine learning. It extracts keyphrases of a document based on phrase frequencies. *Likey* does not use any language-dependent preprocessing tools or vocabularies and the only language-specific component needed is a reference corpus in each language. The basic idea in the method is to see whether the relative frequency of term candidates in the document collection is larger than their frequency in the reference corpus.

The *Likey ratio* [24] for each phrase is defined as

$$L(p, d) = \frac{rank_d(p)}{rank_r(p)}, \tag{3}$$

where $rank_d(p)$ is the rank value of phrase p in document d and $rank_r(p)$ is the rank value of phrase p in the reference corpus. Phrases are all the n-grams of the document up to a phrase length n. The rank values are the ordered frequencies of the phrases of the same length; the phrase having the largest frequency gets the rank of 1. In case of the same frequency value the rank value also stays the same. If the phrase p does not exist in the reference corpus the value of the maximum rank for phrases of length n is used: $rank_r(p) = max\_rank_r(n) + 1$. The *Likey ratio* is used to order the phrases existing in each document with those phrases having the smallest ratio being the best candidates for being a keyphrase.

As a post processing step, the phrases of length $n > 1$ face an extra removal process. If the reference rank value $rank_r$ of any of the single words constituting the phrase is smaller than the rank of the whole phrase, that means, the word is more common than the phrase, the phrase is removed. This uses the assumption that the maximum rank value is usually smaller for longer phrases than for unigrams since the frequencies of longer phrases are lower. In addition, lower rated subphrases of the existing keyphrase are also pruned.

The *Likey ratio* cannot be used directly as keyphrase weights since the best keyphrases get the smallest *Likey ratio* values. We thus scale the ratio to values between [0, 1], where values closer to 1 are the best keyphrases. The scaled weights are calculated with

$$w_2(p) = \begin{cases} (\frac{1}{t} - L(p,d)) * t & \text{if } L(p,d) < \frac{1}{t} \\ 0 & \text{otherwise} \end{cases} \quad (4)$$

where $1/t$ is the maximum *Likey ratio* taken into account.

3) Tf-idf *term weighting:* As our third feature extraction method and also the baseline, we use the traditional *tf-idf* term weighting scheme (equation 5).

$$(\text{tf-idf})_{\text{i,j}} = \text{tf}_{\text{i,j}} \times \text{idf}_{\text{i}} \quad (5)$$

Where $\text{tf}_{\text{i,j}}$ is the number of times a given term i appears in document j.

We weight the unigrams of each document with the other documents as a reference. To reduce vector size, terms with high and low document frequencies are discarded.

This is selected as the baseline method because it is a very well known representation used nowadays in many fields like clustering, classification, information retrieval, etc. *Tf-idf* has also been used as a baseline in several unsupervised learning and clustering works that combine VSM with Self-Organizing Maps, e.g. [25], [26], and [27].

B. Hierarchical clustering

To learn the taxonomic relations between concepts, we assume that each concept has a hypernym, i.e. a parent node. Moreover, we assume that there is a maximum number of distinct hypernyms among the concepts. The concepts are represented by term feature vectors, and *Self-Organizing Map (SOM)* [28] is used to create an ordered space of the concept vectors. The *SOM* is an artificial neural network that orders data using unsupervised learning. Even though the *SOM* is a good method for reducing dimensionality and finding a topological order of data, it does not perform the explicit classification task. Because of this, hierarchical clustering of the prototype vectors of the *SOM* is applied on the top of the *SOM* map to define the borders of clusters. We use agglomerative hierarchical binary clustering to produce up to m clusters for the *SOM* map. The next levels are obtained by training a new *SOM* separately for the feature vectors in each cluster and using agglomerative hierarchical clustering for the new *SOM* maps.

A K-level concept hierarchy is built by first assuming that the zero-level data (concepts, i.e. term vectors) constitute the zero-level cluster, i.e., the root node. The zero-level data are then clustered into first-level clusters. The feature vectors in each of the level k clusters are further clustered to get the $k + 1$-level clusters and thus a more fine-grained clustering until $k = K$. The level K concepts are then the original concepts represented by the feature vectors. Somewhat similar approach is the *growing Self-Organizing Map* [29] and further the *growing hierarchical Self-Organizing Map* [30]. The growing of the map in that case is based on variations of Average Quantization Error, expanding single neurons instead of clusters.

Another possibility in this study would have been to use hierarchical clustering algorithm directly to the feature vectors but that would have needed another method that reduces the resulting binary tree into a small number of hierarchy levels.

C. Evaluation methodology

The evaluation of automatically generated ontologies may concentrate on different levels: evaluation of the lexical layer, hierarchy, or context level [31]. Four approaches for evaluating ontologies have been considered in the literature: comparison to a gold standard (which may itself be an ontology), evaluation as a part of an application, comparison to a source data about the domain, and evaluation by humans [31]. We follow the first approach and compare the generated conceptual hierarchies to a manually constructed reference ontology.

To be able to compare the hierarchical structure to an ontology, we label the concepts of the generated hierarchical structure with the terms (concept names) in the reference ontology. First, the topic of each text document is extracted from the incorporated meta data of the documents. The topics are used to label concepts on the lowest-level in the generated concept hierarchy. Also the parents for each topic are extracted from the reference ontology. The clusters on the generated hierarchy act as the hypernyms (parent concepts) and they are labeled according to the concepts forming the cluster. The majority of the parents is selected as the label for the cluster, i.e., the hypernym. In a case of two parent candidates of equal sizes the hypernym is selected randomly.

Each label can exist only once in the hierarchy in evaluation. Therefore, for labeling purposes, clusters having both the same label and the same parent are merged. In a case where the clusters with the same label have different parents, the cluster having less concepts assigned with that label is considered as unclassified. In a case of equal size, the unclassified cluster is selected randomly. In this way, we penalize similar clusters when they are far away, avoiding penalizing the errors due to too fine-grained clustering.

We use the TP_{csc} evaluation metrics [32] for evaluation of the automatically generated ontologies. Also Wilks and Brewster [33] and Brewster et al. [34] have performed their evaluation by a gold standard using these metrics, but not using reference labels. The experiments are focused on finding single concepts and their relations, and not the whole hierarchy as is our case.

Dellshcaft and Staab [32] introduce TP_{csc}, TR_{csc} and TF_{csc} values for the evaluation of a concept hierarchy of an ontology. The TP_{csc} metric is a global taxonomic precision TP, which uses the common semantic cotopy csc. The common semantic cotopy csc is defined as a set of concept identifiers, which are sub concepts $c <_{\mathcal{C}_1} c_1$ and super concepts $c >_{\mathcal{C}_1} c_1$ of the concept identifier c_1 in concept a hierarchy $\mathcal{C}_1$ and which are also concept identifiers in the ontology $\mathcal{O}_2$

$$csc(c, \mathcal{O}_1, \mathcal{O}_2) = \{c_i | c_i \in \mathcal{C}_1 \cap \mathcal{C}_2 \wedge (c_i <_{\mathcal{C}_1} c \vee c <_{\mathcal{C}_1} c_i)\}. \tag{6}$$

Local taxonomic precision tp_{csc} compares common semantic cotopies of concepts of $c_1 \in \mathcal{C}_1$ and $c_2 \in \mathcal{C}_2$

$$tp_{csc}(c_1, c_2, \mathcal{O}_1, \mathcal{O}_2) = \frac{|csc(c_1, \mathcal{O}_1, \mathcal{O}_2) \cap csc(c_2, \mathcal{O}_1, \mathcal{O}_2)|}{|csc(c_1, \mathcal{O}_1, \mathcal{O}_2)|}. \tag{7}$$

The global taxonomic precision TP_{csc} metric is based on local taxonomic precision of the common concepts of a learned ontology $\mathcal{O}_C$ and the reference ontology. The value of TP_{csc} tells how many of the semantic relations of the learned ontology can be found in the reference ontology

$$TP_{csc}(\mathcal{O}_C, \mathcal{O}_R) = \frac{1}{|\mathcal{C}_C \cap \mathcal{C}_R|} \sum_{c \in \mathcal{C}_C \cap \mathcal{C}_R} tp_{csc}(c, c, \mathcal{O}_C, \mathcal{O}_R). \tag{8}$$

The global taxonomic recall TR_{csc} metric is calcuated using global taxonomic precision TP_{csc}

$$TR_{csc}(\mathcal{O}_C, \mathcal{O}_R) = TP_{csc}(\mathcal{O}_R, \mathcal{O}_C). \tag{9}$$

The taxonomic F-measure TF_{csc} is the harmonic mean of the global taxonomic precision and recall.

$$TF_{csc}(\mathcal{O}_C, \mathcal{O}_R) = \frac{2 \cdot TP_{csc}(\mathcal{O}_C, \mathcal{O}_R) \cdot TR_{csc}(\mathcal{O}_C, \mathcal{O}_R)}{TP_{csc}(\mathcal{O}_C, \mathcal{O}_R) + TR_{csc}(\mathcal{O}_C, \mathcal{O}_R)} \tag{10}$$

III. Data

The data used in this study consists of a document collection from Wikipedia that is used in learning of taxonomic relations, evaluation data that is a manually constructed ontological structure of the text documents, and a reference corpus for the *Likey* keyphrase extraction method.

A. Wikipedia articles

The data for concept representation are collected as HTML pages from the English[1] and Finnish Wikipedia[2]. The Wikipedia data are articles about animals (mammals and birds) in both English and Finnish. The data are collected manually using the meta information from both categories and information boxes. The data were collected originally for Finnish such that the length of each article exceeds 200 words to be able to extract keyphrases of sufficient quality, resulting 119 articles. The English articles are the Wikipedia-provided translations of the Finnish articles, resulting 113 articles due to five too short articles and one article that is linked from two Finnish articles. These data sets are available on our web pages.

B. Reference ontology

The evaluation data are collected from the Wikipedia articles. Most of the Wikipedia articles about animals contain a separate meta information box explaining the scientific classification of the animal. This meta information is collected to construct the reference ontology manually. In our evaluation, we use a simplified version of the scientific classification: just three levels of hierarchy are taken into account besides the actual articles. The three levels were inherent in the document collection and it is also the first non-trivial number of levels.

The Wikipedia articles are situated as the leaf nodes, located on the third level of the reference ontology. Their topics are about different Families, Subfamilies or Species, e.g. Black Grouse, Galapagos Hawk and Jaguar. In the English reference ontology there are 113 third-level concepts and in the Finnish ontology 119 concepts. Each third-level concept has a super concept on the second level, which consists of nine different animal Orders (according to the scientific classification) in both languages, e.g. the parent of Black Grouse is Order *Galliformes*, Galapagos Hawk is of Order *Accipitriformes* and Jaguar is of Order *Carnivora* (see Figure 1). There are two concepts on the first level in both languages: the Classes *Mammalia* (parent of e.g. *Carnivora*) and *Aves* (parent of e.g. *Accipitriformes* and *Galliformes*). The root concept of both of the reference ontologies is Kingdom *Animalia*. Both ontologies have 5 subclasses (*Orders*) for *Mammalia* and 4 subclasses for *Aves*. In the Finnish ontology, 84 concepts on the third level (79 in English) belong to Class *Mammalia* and 35 (34) to Class *Aves*.

C. Europarl corpus

The statistical keyphrase extraction method *Likey* requires a reference corpus that is a sample of the general language. We use English and Finnish parts of Europarl, European Parliament plenary speeches [35] as the reference corpus. Our preprocessing excludes all XML tags containing some meta data and results in the sizes of 35 758 149 word tokens in English and 22 676 344 word tokens in Finnish.

IV. Experiments

Our concept hierarchy generation process is based on unsupervised learning. As ontologies are structured by default, in this first approach we decided to select manually the maximum number of clusters on each hierarchy level to simplify the process of comparison to the reference ontology. In our experiments, the maximum was two clusters on the first level and ten clusters (5 + 5) on the second level. If the hierarchical

[1] http://en.wikipedia.org, accessed on 12th January 2010

[2] http://fi.wikipedia.org, accessed on 13th August 2009

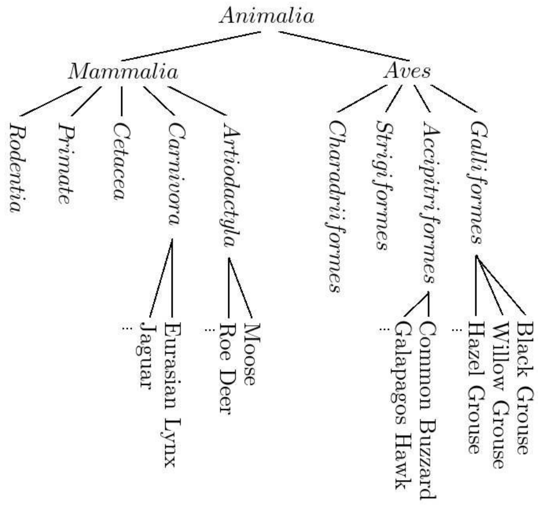

Fig. 1. Part of the reference ontology.

clustering was not able to find the total number of classes, a smaller amount was accepted.

On the first level, we trained a 3x3-cell (5x5 cells in a larger map) *SOM* with normalization of the variance and batch training using SOM Toolbox[3]. On the second level, the map size was slightly larger, 5x5 cells (7x7 cells). These sizes were selected according to our preliminary tests where we found that larger maps (up to 20x20 cells) do not perform very well. Hierarchical clustering was carried out with correlation distance using complete linking scheme. In the preliminary tests, we also used other distance measures (e.g. cosine and spearman) and linking schemes (single and average). Correlation and cosine distance performed very similarly but spearman distance usually slightly worse. Overall, the differences were very small. Single and average linking had the problem that with our implementation in Matlab there were cases where the clustering could not be found.

A. Fuzzy-based representation

In the *efcc* feature extraction approach, the data was preprocessed in the following way. A set of stop words for each language was used to remove common words. The HTML-specific entities were converted to their corresponding characters or discarded, depending on the case. The punctuation marks were also removed. Finally, suffixes were removed using a language dependent stemmer: a standard implementation of Porter's algorithm for English and Snowball Finnish stemmer[4].

The number of features per document vector was chosen to be 100 since that had been enough in our preliminary tests. A second representation for both languages is selected to be approximately the sizes used by the keyphrase extraction method. The second vector size is 913 for English and 1157 for Finnish.

B. Keyphrase extraction

The keyphrase extraction method uses only the plain text portion of the Wikipedia HTML pages without any meta data and is thus a language-independent approach. The Wikipedia preprocessing produces plain text by removing HTML and Wikipedia markup-specific tags, figures, tables, lists, links, and references. Preprocessing for both Wikipedia articles and Europarl reference corpora in Finnish and English removes punctuation and changes numbers to a <NUM> tag. Note that no stemming nor other linguistic filtering takes place in this approach.

We selected the first 15 keyphrases from each article and weighted them with a scaled Likey weight (Eq. 4) that might decrease to zero. We used a threshold value $1/t = 0.01$ since in most of the documents the *Likey ratio* for the first 15 keyphrases is less than that. The resulting feature vectors have 934 features in English, and 1211 features in Finnish.

C. Tf-idf *baseline*

For *tf-idf* the same preprocessing as for *efcc* representation was carried out. The number of features per document vector were selected in the same manner than *efcc* representation, described in section IV-A.

D. Results

The results of the experiments for English Wikipedia documents are given in Table II. The global taxonomic precision (TP), recall (TR) and F-measure (TF) results for the three feature extraction approaches are presented. For *df-efcc-idf* and similarly for *tf-idf*, results for vectors with 100 features (df-efcc-idf 100 and tfidf 100, respectively) and 913 features (df-efcc-idf 913 and tfidf 913, respectively) are shown. Also the results for *Likey* are presented. The results are calculated as averages of the two different map sizes.

TABLE II
RESULTS FOR ENGLISH FOR DIFFERENT REPRESENTATIONS. TP, TR, AND TF STAND FOR GLOBAL TAXONOMIC PRECISION, RECALL AND F-MEASURE, RESPECTIVELY.

Representation	TP	TR	TF
df-efcc-idf 100	0.782	0.900	0.836
df-efcc-idf 913	0.725	0.956	0.825
Likey	0.764	0.886	0.820
tf-idf 100	0.707	0.853	0.772
tf-idf 913	0.698	0.869	0.774

The second experiment is for the Finnish language with the same parameters and representatons than for English, except for the vector size of the second representation of *df-efcc-idf* and *tf-idf* is 1157. The results are presented in Table III.

These results show that for both English and Finnish languages a level of about 80% in Taxonomic F-measure can be achieved within the task of generating hierarchical structures. For the Finnish language, the language-independent feature extraction approach *Likey* does not perform as well as the other approaches. Anyway, the stemming preprocessing step is missing from the *Likey* results and that might explain the poorer performance at least partly.

[3] http://www.cis.hut.fi/somtoolbox/

[4] http://snowball.tartarus.org/algorithms/finnish/stemmer.html

TABLE III
RESULTS FOR FINNISH FOR DIFFERENT REPRESENTATIONS. TP, TR, AND TF STAND FOR GLOBAL TAXONOMIC PRECISION, RECALL AND F-MEASURE, RESPECTIVELY.

Representation	TP	TR	TF
df-efcc-idf 100	0.734	0.872	0.796
df-efcc-idf 1157	0.722	0.852	0.781
Likey	0.685	0.841	0.755
tf-idf 100	0.779	0.847	0.812
tf-idf 1157	0.837	0.865	0.851

For the English language, the heuristic fuzzy logic-based *df-efcc-idf* performs better than the statistical approaches. This is of course a natural result since *df-efcc-idf* exploits more knowledge by using the semantic information of the HTML structure.

The results seem to be not very consistent. This may be due to the fact that a small difference in the *SOM* clustering may have large effect in the resulting ontology. If *SOM* were initialized randomly instead of using the default setting of linear initialization along the two greatest eigenvectors, different results could be obtained on different runs and more precise results reached.

V. Conclusions and discussion

In this paper, we have presented an automated methodology for concept hierarchy generation from a set of text documents. We used three different representations of the documents: 1) a combination of rule-based stemming and fuzzy logic-based feature weighting and selection, 2) automatic keyphrase extraction and 3) the traditional *tf-idf* measure with rule-based stemming. The hierarchy generation has been run by a hierarchical approach of the Self-Organizing Map (*SOM*) together with agglomerative hierarchical clustering. The experiments have been conducted for English and Finnish to show the applicability to different kinds of languages.

We used more than 100 Wikipedia articles about *Animalia* as our data for both English and Finnish. We also created reference ontologies out of the Wikipedia articles for both languages. In the future work, a much larger collection of Wikipedia articles could be used to obtain larger number of levels in the ontology. We also want to exclude the information about the amount of clusters needed for building the hierarchy. Another future improvement consist of extracting concept identifiers from the corpus instead of generating just the taxonomy. Any of our representations could be utilized also here.

Metric properties of populations in artificial immune systems using Hadamard representation

Zbigniew Pliszka and Olgierd Unold,

***Abstract*—A Hadamard representation, which is an alternative towards the binary representation, is considered in this study. It operates on numbers $+1$ and -1. Several properties of such defined representation were pointed out and properties of the immune system were expressed based on this representation.**

***Index Terms*—Genetic algorithm, binary coding, Hadamard representation, artificial immune system.**

I. Introduction

DESPITE the continuous development since the 1960s, the discipline of genetic algorithms [5], [11], [1] is still focused more on the empirical aspects of algorithms than theoretical studies. Methods, which are currently in use in theoretical studies of these algorithms, could be classified into one of the following groups: schema theory [7], markov chains theory [10], dimensional analysis [12], order statistics [4], quantitative genetics [8], orthogonal functions analysis [3], quadratical dynamical systems QDS [14], statistical physics [2].

Despite the fact that sophisticated and complex mathematical models were implemented, neither results were obtained which could have broader field of application (e.g. the schema theory or the Markov chains theory) nor were these methods subject for a vivid discussion. Simplistic assumptions adopted frequently in the theoretical analyses deform the analyzed algorithms in such a way that they question the real connection between the obtained results and the investigated algorithms.

This study undertakes rather unfertile topic of representation of binary chromosomes. In place of the classic, zero-one binary representation, other representation {-1, 1} has been proposed for which the metrics in the binary chromosomes space was determined. This representation, called later the Hadamard representation, allows for an effective proof of the dependence between the whole groups of chromosomes. In the Hadamard representation all chromosomes are equal to the length in a defined metric, and there is no chromosome "'zero"', which often had to be separately discussed in the binary representation due to its distinct properties. Note that in the zero-one binary representation each chromosome can be normalized, and each chromosome has a clearly defined direction except chromosome "'zero"'.

The Hadamard representation was applied for defining properties of the artificial immune systems.

II. Hadamard representation

In 1893, French mathematician Jacques Hadamard in his study *Résolution d'une question relative aux déterminants* [6] presented the properties of a matrix, whose only elements were +1 or -1. In this study, we used this representation as a substitute of a binary representation, omitting the requirement of orthogonal columns pairs. Subject of our deliberation was the following series:

TABLE I
Indexing and representation of points in A_n space.

Element's symbol	Decimal representation	Binary representation	Hadamard representation
h_1	0	(0,0,. . . ,0,0,0)	(1, 1,. . . , 1, 1, 1)
h_2	1	(0,0,. . . ,0,0,1)	(1, 1,. . . , 1, 1,-1)
h_3	2	(0,0,. . . ,0,1,0)	(1, 1,. . . , 1,-1, 1)
$\vdots$	$\vdots$	$\vdots$	$\vdots$
h_{2^n-2}	$2^n - 3$	(1,1,. . . ,1, 0, 1)	(-1,-1,. . . ,-1, 1,-1)
h_{2^n-1}	$2^n - 2$	(1,1,. . . ,1, 1, 0)	(-1,-1,. . . ,-1,-1, 1)
h_{2^n}	$2^n - 1$	(1,1,. . . ,1, 1, 1)	(-1,-1,. . . ,-1,-1,-1)

$$A_n = \{(h_n, h_{n-1}, \ldots, h_2, h_1) : \forall i \in \{1, 2, \ldots, n\} \quad h_i \in \{-1, 1\}\} \tag{1}$$

Its elements represent all possible binary chromosomes of equal length n. We will be considering in our work that n is a natural number higher than 1. The proposed representation has one, apparently insignificant property, which distinguishes it from the binary representation: a square of each coordinates is equaled 1. This fact draws two subsequent conclusions: the sum of the squares of coordinates of each element of the A_n space is constant and equals this space dimension, and there is no element with zero coordinates. The collection of these simple facts allows for the formulation of rules for phenotypes (indices) and development of automate methods of moving frame A_n, as well as determination of the distance (level of differentiation) between the elements of this space.

At the beginning, we determined the order of the indexing of points in A_n and their four representations, which we will use alternating (see Table I).

The number of points included in A_n

$$|A_n \,| = 2^n \tag{2}$$

For each element in the binary representation there are numerous functions transforming the elements of this representation to the elements of the Hadamard representation and inversely. The same can be said about the Hadamard representation in relation to the binary representation. Three pairs of such functions are presented in Table II.

The distance of points in A_n

The distance of two points $a = (a_n, \ldots, a_2, a_1)$ and $b =$

978-83-60810-27-9/09/$25.00 © 2010 IEEE

TABLE II

EXEMPLARY FUNCTIONS TRANSFORMING THE HADAMARD REPRESENTATION INTO THE BINARY REPRESENTATION AND INVERSELY.

For binary representation	For Hadamard representation
$B_1(h_{j,i}) = \begin{cases} 0 & for \quad h_{j,i} = 1 \\ 1 & for \quad h_{j,i} = -1 \end{cases}$	$H_1(b_{j,i}) = \begin{cases} 1 & for \quad b_{j,i} = 0 \\ -1 & for \quad b_{j,i} = 1 \end{cases}$
$B_2(h_{j,i}) = \frac{1-h_{j,i}}{2}$ where $h_{j,i} \in \{-1,1\}$	$H_2(b_{j,i}) = 1 - 2b_{j,i}$ where $b_{j,i} \in \{0,1\}$
$B_3(h_{j,i}) = \log_{-1} h_{j,i}$ where $h_{j,i} \in \{-1,1\}$	$H_3(b_{j,i}) = (-1)^{b_{j,i}}$ where $b_{j,i} \in \{0,1\}$

$(b_n, \ldots, b_2, b_1)$ in A_n space is measured according to the following equation:

$$\forall a, b \in A_n \qquad w(a,b) = n - \frac{1}{4}\sum_{i=1}^{n}(a_i + b_i)^2 \tag{3}$$

The distance defined in that way will always be a positive integer, which will tell us on what coordinates in Hadamard representation the values differ (exactly as in the binary representation) (see Table I). In addition, A_n space with the w distance determined in this way is metric.

Proof:

1. (identity of indiscernibles)

$$w(a,a) = n - \frac{1}{4}\sum_{i=1}^{n}(a_i + a_i)^2 = n - \frac{1}{4}\sum_{i=1}^{n}4(a_i)^2 = n - n = 0$$

and at the same time

$w(a,b) = 0 \Rightarrow n = \frac{1}{4}\sum_{i=1}^{n}(a_i + b_i)^2$. Therefore, for $a_i, b_i \in \{-1,1\}$, $\forall i \in \{1,2,...,n\} \quad a_i = b_i$, we finally arrive at the equation $a = b$.

2. (symmetry)

$$w(a,b) = n - \frac{1}{4}\sum_{i=1}^{n}(a_i + b_i)^2 = n - \frac{1}{4}\sum_{i=1}^{n}(b_i + a_i)^2 = w(b,a).$$

3. (triangle inequality)

$$w(a,b) + w(b,c) =$$

$$= n - \frac{1}{4}\sum_{i=1}^{n}(a_i + b_i)^2 + n - \frac{1}{4}\sum_{i=1}^{n}(b_i + c_i)^2 =$$

$$= 2n - \frac{1}{4}(\sum_{i=1}^{n}(a_i + b_i)^2 + \sum_{i=1}^{n}(b_i + c_i)^2) =$$

$$= 2n - \frac{1}{4}\sum_{i=1}^{n}\left(a_i^2 + 2b_i\left(a_i + b_i + c_i\right) + c_i^2\right)$$

Due to $a_i, b_i, c_i \in \{-1,1\}$, we obtain the weak inequality $b_i\left(a_i + b_i + c_i\right) \leq a_i c_i + 2$. Therefore,

$$\geq 2n - \frac{1}{4}\sum_{i=1}^{n}\left(a_i^2 + 2\left(a_i c_i + 2\right) + c_i^2\right) =$$

$$= 2n - \frac{1}{4}\sum_{i=1}^{n}\left(a_i^2 + 2a_i c_i + c_i^2\right) - n =$$

$$= n - \frac{1}{4}\sum_{i=1}^{n}\left(a_i^2 + 2a_i c_i + c_i^2\right) = w(a,c).$$

Hence, we have $w(a,b) + w(b,c) \geq w(a,c)$.

■

Remark R1

For any point established in A_n space, there are $\begin{pmatrix} n \\ n-z \end{pmatrix} = \begin{pmatrix} n \\ z \end{pmatrix}$ different points at exactly z distance.

A set of points in A_n with w metrics constitute the limited metric space of diameter n, it can be easily observed that for any two points $h_t, h_k \in A_n$ there is an inequality

$$w(h_t, h_k) \leq n, \tag{4}$$

and the equality occurs only for $k = 2^n - t + 1$, which is presented in Theorem **T1**.

Lemma L1

$$\forall h_t, h_k \in A_n \qquad w(h_t, h_k) = n \Leftrightarrow$$
$$\forall i \in \{1,2,...,n\} \qquad h_{t,i} = -h_{k,i}$$

Proof:

$$w(h_t, h_k) = n$$

$$\Updownarrow$$

$$n - \frac{1}{4}\sum_{i=1}^{n}(h_{t,i} + h_{k,i})^2 = n$$

$$\Updownarrow$$

$$\sum_{i=1}^{n}(h_{t,i} + h_{k,i})^2 = 0$$

The last equation is true if and only if all the elements of the sum are equal to 0. A single element of the sum $(h_{t,i} + h_{k,i})^2$ is equal to 0 if and only if $h_{t,i} = -h_{k,i}$. ■

Theorem T1

$$\forall t \in \{1,...,n\} \qquad w(h_t, h_k) = n \Leftrightarrow$$
$$ID(h_k) = k = 2^n - t + 1 = 2^n - ID(h_t) + 1$$

where $ID(h_i)$ returns index of h_i.

Proof:

$$\Rightarrow$$

From the Lemma L1, we have $h_{t,i} = -h_{k,i}$. As $h_{j,i} \in \{-1, 1\}$, we conclude that at i-th position one of the element has 1, and the second one -1. Transforming h_t and h_k to a binary representation, we obtain two numbers having the feature, that at i-th position one of the number has 0, and the second one 1. The value of the sum of such elements is equal to $2^n - 1$. At the same time, in a decimal representation h_t and h_k represent $t-1$ and $k-1$, respectively. Therefore,

$$(t-1) + (k-1) = 2^n - 1,$$

which is equivalent to

$$k = 2^n - t + 1.$$

$$\Leftarrow$$

Note that the sum of h_t and h_k in a decimal representation is given by

$$(t-1) + (k-1) = (t-1) + (2^n - t) = 2^n - 1$$

Hence, the sum in a binary representation has n-digits 1. Therefore, the components of this sum are the two binary numbers with the property, that at each i-th position one of the components has 1, and the second one 0. Transforming the components into Hadamard representation, we obtain two numbers with the property, that at each i-th position one of the components has -1, and the second one -1. Therefore,

$$h_{t,i} + h_{k,i} = 0$$

$$\frac{1}{4}\sum_{i=1}^{n}(h_{t,i} + h_{k,i})^2 = 0$$

$$w(h_t, h_k) = n$$

■

The points which comply with the above theorem will be called *polar points* and designated as a and $\overline{a}$ pairs. Thus, following equations for the polar points are received:

$$\forall a \in A_n \quad w(a, \overline{a}) = n \tag{5}$$

$$\forall a \in A_n \quad \overline{\overline{a}} = a \tag{6}$$

We can assume:

$$\overline{a} = (\overline{a_n}, \ldots, \overline{a_1}) \tag{7}$$

Lemma **L1** can be presented as follows:

Lemma L2

$$\forall h_k \in A_n \quad \forall i \in \{1, 2, ..., n\} \quad h_{k,i} = -\overline{h_{k,i}}$$

Based on the **R1** remark and **T1** Theorem, it could be concluded that for each point h_t in A_n space, exactly one point h_k occurs in this space, different from h_t, which gives a pair of polar points. Polar points have the following extra two properties

$$\forall c \in A_n \quad \forall a \in A_n \quad w(a, c) + w(c, \overline{a}) = n$$

$$\forall a, b \in A_n \quad w(a, b) = w(\overline{a}, \overline{b})$$

Proof:

$$\forall c \in A_n \quad \forall a \in A_n \quad w(a, c) + w(c, \overline{a}) = n$$

Note that

$$w(a, c) + w(c, \overline{a}) = n$$

$$\Updownarrow$$

$$n - w(a, c) + n - w(c, \overline{a}) = n$$

$$n - w(a, c) + n - w(c, \overline{a}) = \frac{1}{4}\sum_{i=1}^{n}(a_i + c_i)^2 + \frac{1}{4}\sum_{i=1}^{n}(c_i + \overline{a_i})^2 =$$

$$= \frac{1}{4}\sum_{i=1}^{n}(a_i^2 + 2(a_i + c_i + \overline{a}_i)c_i + (\overline{a}_i)^2) =$$

from the Lemma L2, for each $i \in \{1, \ldots, n\}$ we have $a_i + \overline{a_i} = 0$, and $a_i^2 = (\overline{a_i})^2 = c_i^2 = 1$. Hence,

$$= \frac{1}{4}\sum_{i=1}^{n} 4 = n.$$

■

Proof:

$$\forall a, b \in A_n \quad w(a, b) = w(\overline{a}, \overline{b})$$

From Theorem T2 we have

$$w(a, b) + (b, \overline{a}) = n$$

$$w(b, \overline{a}) + w(\overline{a}, \overline{b}) = n$$

From the equality of the right sides, follows the equality of the left sides:

$$w(a, b) + w(b, \overline{a}) = w(b, \overline{a}) + w(\overline{a}, \overline{b})$$

Hence,

$$w(a, b) = w(\overline{a}, \overline{b}).$$

■

After translation to the indices of points of the A_n space, the equation demonstrates another symmetry, besides the one, which results from the second condition of the metric space:

$$w(h_k, h_t) = w(h_{2^n - t + 1}, h_{2^n - k + 1}) \tag{8}$$

The distance $w(h_k, h_t)$ between two points, h_k i h_t, can be estimated according to the **Pod_Od** algorithm. We reduce indices k and t by 1 and divide n times by 2, saving the remainders. The number of differences between the remainders will constitute the sought distance.

Pod_Od Algorithm

```
Input data:
n - number of positions in representation of point from $A_n$
k, t - indices of points $h_k$ and $h_t$
  begin
    od:=0;
    k:=k-1; t:=t-1;
    i:=0;
    while i < n do
    begin
      od:=od+((k mod 2)-(t mod 2))$^2$;
      i:=i+1;
      k:=k div 2;
      t:=t div 2;
    end;
    return od;
  end.
```

During estimation of the distance between two points belonging to the A_n space, the following theorem can be useful.

Theorem T2

$\forall s \in \{0, 1, \ldots, n-1\}$ and $\forall k, t \in \{1, 2, \ldots, 2^s\}$ with $h_k, h_t \in A_n$

$$w(h_k, h_{t+2^s}) = w(h_k, h_t) + 1 \tag{9}$$

$$w(h_{k+2^s}, h_{t+2^s}) = w(h_k, h_t) \tag{10}$$

$$w(h_{k+2^s}, h_{t+2^s}) = w(h_{t+2^s}, h_k) - 1 \tag{11}$$

Proof:

For each $s \in \{0, 1, ..., n-1\}$, if $j = ID(h_j)$ satisfies the inequality $2^{s-1} < j \leq 2^s$ (or equivalent $2^s < j + 2^s \leq 2^{s+1}$), the elements h_j and h_z, where $z = j + 2^s$, differs only at the position $s + 1$. The element h_j at this position has the value 1 ($h_{j,s+1} = 1$), and the element h_z -1 ($h_{z,s+1} = -1$). Therefore, two elements h_t and h_z, where $z = t + 2^s$ while meeting the assumptions of Theorem T2 about s and t, differ at exactly one position only. Hence, if h_k is remote from the element h_t with $w(h_k, h_t)$, then the distance from h_k to the element h_z will be greater by one (according to the Equation (3)), what proves Equation (9). In case of Equation (10), a difference in the value of the coordinate s occurs at the same time in both pairs, i.e., with the k indexes, as well as with t indexes. The simultaneous change in a value on the same coordinate, according to the Equation (3), does not change the value $w(h_k, h_t)$, what proves Equation (10). Equation (11) is to be obtained by using the Equations (10) and (9) and the symmetry rule

$$w(h_{k+2^s}, h_{t+2^s}) = w(h_k, h_t) =$$

$$= w(h_k, h_{t+2^s}) - 1 = w(h_{t+2^s}, h_k) - 1$$

■

Theorem **T2** allows for the construction of an algorithm, which produces the table of distances between any elements from the A_n space. In the **Tab_Od** algorithm, a table was built mechanically (without the estimation of the distances between particular elements). The number situated on the cross of the k-row with the t-column corresponds to the $w(h_k, h_t)$ distance. Therefore, a table of dimension $2n$ could be obtained from the table of dimension n according to the following symbolic equation:

$$\langle W_n \rangle \overset{\mapsto}{\longrightarrow} \left\langle \begin{array}{cc} W_n & \langle W_n + 1 \rangle \\ \langle W_n + 1 \rangle^T & W_n \end{array} \right\rangle$$

where +1 means addition to each element of the table a value of 1.

Tab_Od Algorithm

```
Input data: Enter_size_of_gene  $m$;
  begin
    n:=1;
    T[n,n]:=0;
    while n<2$^m$ do
    begin
      n:=2*n; {enlarging the table twice}
      {extending all rows, copying the already existing one
      and adding 1 to each expression}
      for i:=1 to (n div 2) do
        for j:=(n div 2)+1 to n do
          T[i,j]:=T[i,j-(n div 2)]+1;

      {copying the new part symmetrically, below the first part}
      for i:= n/2+1 to n do
        for j:=1 to n/2 do T[i,j]:=T[j,i];

      {Pasting a copy of the original square under the calculated
      in the beginning of the loop, as the last part of a new,
      twice as large square}
      for i:= n/2+1 to n do
        for j:=(n div 2)+1 to n do T[i,j]:=T[i-(n div 2),j-(n div 2)];
    end;
  end.
```

The conditions for the distance alignment for $n = 4$ are presented in Table III. The elements were placed according to the order of indices increase. It is worth to mention that the sum of k and $2^n - (k-1)$ indices is constant and equals $2^n + 1$ (with accordance to the **T1** Theorem). Thus, elements calculated in this way constitute a pair of polar points (the distance between polar points in our example is $n = 4$, which lies along the diagonal starting in the right upper corner).

III. Definitions Describing States of Artificial Immune Systems

Artificial immune systems constitute currently a significant trend in the studies on biologically inspired calculations [13]. Idealized states of the artificial immune system are determined in the study and subsequently defined using Hadamard representation. Properties determined in such a way are illustrated by the examples based on the content of Table III.

Radius of tolerance R

A radius of tolerance is understood as the border value enabling a mutual recognition of elements in A_n space.

Two elements $x, y \in A_n$ recognize or do not tolerate each other if the distance between them is higher than the radius of tolerance.

$$w(x, y) > R \tag{12}$$

where R complies with the inequality: $0 \leq R \leq n$.

Elements $x, y \in A_n$ complying the weak inequality

$$w(x, y) \leq R \tag{13}$$

will be described as not recognizing or tolerating each other.

Example 0

In the examples considered here we use the A_n space, whose

TABLE III
TABLE OF DISTANCES BETWEEN ANY ELEMENTS IN A_n SPACE $(n = 4)$.

	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**	**13**	**14**	**15**	**16**

16	4	3	3	2	3	2	2	1	3	2	2	1	2	1	1	0

distance tables are presented in Table III. Moreover, for all the demonstrated examples we assume the value of the radius of tolerance $R = 2$.

Self-aggression

System $B_k \subseteq A_n$ undergoes self-aggression if elements x, y occur, which recognize each other and belong to this system.

$$\exists x, y \in B_k \ : \quad w(x, y) > R$$

Example 1

In A_4 , the systems undergoing self-aggression are for example:
$B_8 = \{h_1, h_2, h_3, h_5, h_9, h_4, h_6, h_7\}$ where $w(h_2, h_7) = 3$
$B_4 = \{h_4, h_6, h_7, h_{10}\}$ where $w(h_7, h_{10}) = 4$

System $B_k \subseteq A_n$ is free of self-aggression if any two elements belonging to this system do not recognize themselves.

$$\forall x, y \in B_k \qquad w(x, y) \leq R$$

Example 2

Free systems of self-aggression, when $R = 2$:
$B_5 = \{h_1, h_2, h_3, h_5, h_9\}$
$B_3 = \{h_4, h_6, h_7\}$
$B_2 = \{h_1, h_2\}$

Let us notice that system B_2 is free of self-aggression also when $R = 1$.

Striking distance

A striking distance of a system $B_k \subseteq A_n$ is a series of points of A_n recognized by any point of B_k .

$$P(B_k) = \{z \in A_n : \quad \exists x \in B_k \ \wedge \ w(x, z) > R\}$$

Example 3

For $B_3 = \{h_4, h_6, h_7\}$ from the **Example 2** the striking distance is:

$$P(B_3) = \{h_2, h_3, h_5, h_9, h_{11}, h_{12}, h_{13}, h_{14}, h_{15}\}$$

If B_k undergoes self-aggression then some points belonging to B_k simultaneously belong to $P(B_k)$, which means that

$$B_k \cap P(B_k) \neq \emptyset$$

Example 4

In such state occurs system $B_4 = \{h_4, h_6, h_7, h_{10}\}$ from the **Example 1**:

$$P(B_4) = \{h_2, h_3, h_5, h_7, h_8, h_9, h_{10}, h_{11}, h_{12}, h_{13}, h_{14}, h_{15}\}$$

thus:

$$B_4 \cap P(B_4) = \{h_7, h_{10}\} \neq \emptyset$$

Otherwise, if B_k is free of self-aggression, then B_k and $P(B_k)$ are disjunctive series, which can be presented as follows:

$$B_k \cap P(B_k) = \emptyset$$

Example 5

Free system of self-aggression is B_3, described in **Example 2** and **3**, for which identity occurs:

$$B_3 \cap P(B_3) = \emptyset$$

Complete system

System B_k is complete if its striking distance contains its whole completion $\overline{B_k} = A_n \backslash B_k$.

$$\overline{B_k} \subseteq P(B_k)$$

Example 6

The conditions of the complete system are fulfilled by $B_5 = \{h_1, h_2, h_3, h_4, h_5\}$, for which following identities occur:

$$P(B_5) = \{h_4, h_5, h_6, h_7, h_8, h_9, h_{10}, h_{11}, h_{12}, h_{13}, h_{14}, h_{15}\}$$

$$\overline{B_5} = \{h_6, h_7, h_8, h_9, h_{10}, h_{11}, h_{12}, h_{13}, h_{14}, h_{15}\},$$

Thus, a relation occurs:

$$\overline{B_5} \subseteq P(B_5)$$

Balanced system

System B_k is balanced if at the same time it is a system free of self-aggression, and complete.

$$\overline{B_k} = P(B_k)$$

Example 7
This time let us assume that $B_5 = \{h_1, h_2, h_3, h_5, h_9\}$. For such a system the following identities are fulfilled:

$$P(B_5) = \{h_4, h_6, h_7, h_8, h_{10}, h_{11}, h_{12}, h_{13}, h_{14}, h_{15}\}$$

$$\overline{B_5} = \{h_4, h_6, h_7, h_8, h_{10}, h_{11}, h_{12}, h_{13}, h_{14}, h_{15}\}$$

and

$$\overline{B_5} = P(B_5)$$

Extensive system
We call $B_k \subseteq A_n$ an extensive system if any crossing of its elements results in offspring, which also belongs to this system.

$$\forall x, y \in B_k \subseteq A_n \quad \forall c \in \{0, 1, \ldots, n\} \quad K(\{x, y\}, c) \subseteq B_k$$

where $K(\{x, y\}, c)$ denotes the crossing operation of the two elements x, y from the A_n space in the point c, and is defined as follows:

Let $r_t, r_k \in A_n$, where $r_t = (r_{t,n}, r_{t,n-1}, \ldots, r_{t,2}, r_{t,1})$, $r_k = (r_{k,n}, r_{k,n-1}, \ldots, r_{k,2}, r_{k,1})$.

For $0 \leq c \leq n$,

$$K(\{r_t, r_k\}, c) \mapsto \{(r_{t,n}, r_{t,n-1}, \ldots, r_{t,c+1}, r_{k,c}, r_{k,c-1}, \ldots, r_{k,1}), (r_{k,n}, r_{k,n-1}, \ldots, r_{k,c+1}, r_{t,c}, r_{t,c-1}, \ldots, r_{t,1})\} \quad (14)$$

Example 8
The examples of the extensive systems are presented below:

$$B_2 = \{h_1, h_2\}$$

$$B_4 = \{h_1, h_2, h_3, h_4\}$$

To check the extensibility of B_2 and B_4 systems, equations given by [9] can be used. It can be noticed that both the singleton system and any A_n space, as a whole, are extensive systems.

Expansive system
A system is expansive if it possesses elements (not necessary different), which after a peculiar crossing produce elements out of the system.

$$\exists x, y \in B_k \subseteq A_n \quad \exists c \in \{0, 1, \ldots, n\} : \quad K(\{x, y\}, c) \not\subseteq B_k$$

Example 9
Let us assume $B_3 = \{h_1, h_2, h_3\} \subseteq A_4$. After crossing on chromosomes h_2 and h_3, performing cuts between the first and the second allele, we obtain chromosomes h_1 and h_4. Chromosome $h_4 \notin B_3$ represents an expansive character. In the study [9], equations allowing calculation of crossings' results directly on chromosomes indices, without the need to recreate their internal structure, could be found. The conclusion of those equations is:

$$K(\{h_2, h_3\}, 1) \mapsto \{h_1, h_4\} \not\subseteq B_3$$

IV. Summary

In this study a so called Hadamard representation was implemented. It allows to prove the dependence between subsequent generations of binary chromosomes. Some properties of this representation were pointed out, which allows for quick and simple operations on chromosomes indices, instead of processing the binary sequences.

Hadamard representation was applied in a brief definition of some properties of the artificial immune systems. This representation will also allow employing natural numbers in calculating the results of such operations like crossing, mutation, or genetic inversion, as well as determining the influence of these operations on the whole concerned population.

Introduced concepts allow a distinction and classification of different populations, which allows us to ponder the future potential directions of their evolution (states reachable, unreachable, etc.) regardless of the crossing algorithm. Further, it should allow us to compare the genetic algorithms in terms of effectiveness and optimization! Comparing the two algorithms, we must ensure comparability of the populations in which we conduct experiments. It is obvious that the same algorithm for example in the population of the class of expansive systems, has a chance of finding new solutions in subsequent generations, but populations with extensive class, after reviewing the current population, better solutions will no longer find. Self-aggression systems have dispersed chromosomes in the space, as opposed to the free systems of self-aggression, which are concentrated in the vicinity of a chromosome. For such systems we can have a suspicion that for the purpose of continuous functions we have to deal with a local extremum. In the case of complete systems, we can be sure that we control the entire space under consideration, although we use only a separate part of the chromosomes of that space. It is important in many cases to set minimum-complete systems for the space in question.

The presentation of the majority of the basic genetic operators known in the literature as Hadamard representation is planned, as well as studies on the analytical demonstration of temporal properties of the genetic operators and the artificial immune system expressed an {+1, -1} notation will be carried out.

***Abstract*—Nowadays personal identification is a very important issue. There is a wide range of applications in different spheres, such as video surveillance security systems, control of documents, forensics systems and etc. We consider a range of most significant aspects of face identification system based on support vector machines in this paper. At first we propose improved face detector to get the region of interest for next face recognition. In paper the technique of face detection jointly image normalization is introduced. We compare three algorithms of feature extraction in application on face identification (PCA NIPALS, NNPCA, kernel PCA). The presented system is intended for process the image with low quality, the photo with the different facial expressions. Our goal is to develop face recognition techniques and create the system for face identification.**

I. Introduction

THE PERSON identification systems are increasingly becoming popular in modern society. The producers of security systems are interested in the new technologies for the automation of the person identification process. This fact is due to rise the level of these systems reliability because of depreciation of the components of used hardware in the designing and the construction of ones.

The range of the biometric systems identification is wide enough, there're the identification on the fingerprints, the iris identification, the face recognition methods and etc. All these technologies are different by the algorithms, methods and techniques that used for the system development. The considerable quantity of solutions are proposed in the field of face recognition and in the sphere of the person identification by photo. Nowadays the development of the automatic personal identification system is a very important issue because of the wide range of applications in different spheres, such as video surveillance security systems, control of documents, forensics systems and etc.

It should be noted that the process of pattern recognition in the field of image processing consists of several required stages before getting final result. There are the preprocessing of the source patterns (the image data processing such as the readjustment of light conditions, the detection of region of interest, the image resizing), the dimension reduction of source data space by data transformation (to remove the noise and to approximate the data), the selection and the implementation of techniques for the data classification.

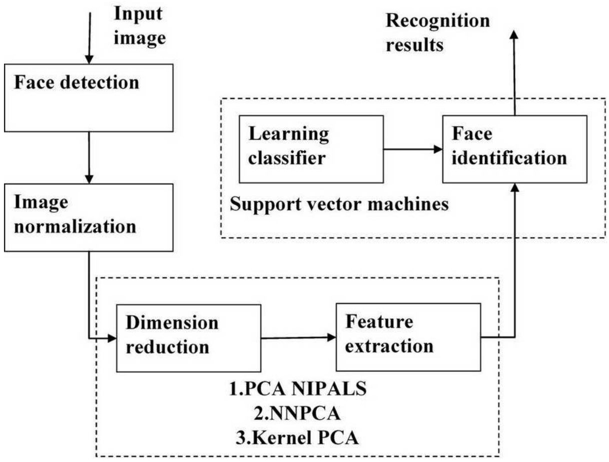

Fig. 1. The structure of face identification system

In this paper we describe the experimental face identification system based on support vector machines (SVM) [1] and we consider some more interesting aspects with designing and constructing of the person system identification by photo. Our system consists of several typical modules (see fig. 1) that are important for the systems of this type such as block of the region of interest (face) detection, block of the image normalization (with the functions of enhancement of brightness and contrast characteristics), the features' extraction block for the dimension reduction of source data space, the module of face recognition (identification) with the functions for the training SVM-classifier and the functions of classification of the processed pattern by the definition of the test image to the certain class.

We researched automated biometric identification systems that were tested on data of the National Institute of Standards and Technology (USA) in particular FERET database. So we propose you to read the results of testing several systems that were developed by different companies (see fig. 2). There are automated portrait identification system "Portrait 2005", developed by specialists LLC "Bars International", LLC "Portland" (Russian Federation) and LLC "ASPI-Soft" (Belarus); automated portrait identification system "Crime Face", developed by RPLLC "Todes" (Belarus); hardware-software complex "Image++"(or"SOVA"), developed by LLP

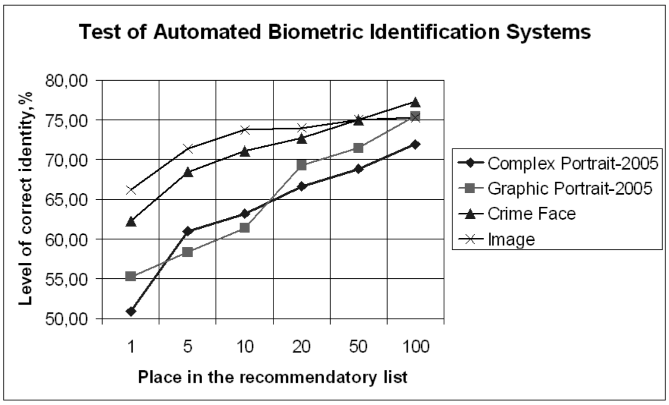

Fig. 2. Test of Automated Biometric Identification Systems

"DANA" (Kazakhstan). Information with test results of automated biometric identification systems that were tested on data of the National Institute of Standards and Technology (USA) is presented at figure 2. In February-July 2006 the State Expert Forensic Center of Ministry of Internal Affairs of Belarus carried out a test of these automated biometric identification systems based on technology of face recognition. The source of this research is [2].

This paper is organized as follows. In the next section the methods of face detection are described. In section III the approaches of the preparation and normalization of the images are introduced. In section IV the neural network approaches as tool for reducing source space of data is considered. The section V contains the description of classifier for pattern recognition based on support vector machines. Finally, the section VI collect some experimental results and brief conclusions.

II. Face detection approaches

A precise detection of face at image strongly simplifies the process of classification. At stage of system development we have realized some experiments and established that at first face detection procedure must be executed due to its importance. The module of image normalization should work at second stage. The results of performance of these procedures in determinate order like this are displayed in a fig. 3 and fig. 4. Presence of background and of facial parts (ears, hair) have effect on obtained results of these experiments. We apply the image enhancement unit in detected region of interest (face in particular) to get more contrasting images that are more suitable for a consequent procedure of reduction of original data space and pattern recognition process. At the beginning the unit of face detection performs detection of facial region using the famous algorithm of Viola-Jones [3]. This method uses an image representation called the "Integral Image" which allows the features used by detector to be computed very quickly [4]. A simple and efficient classifier is built using the AdaBoost learning algorithm [5] to select a small number of critical visual features from a very large set of potential features. Viola-Jones proposed a method for combining classifiers in a "cascade" which allows background regions of the image to be quickly discarded while spending more computation on promising face-like regions. However, the results of initial algorithm are not acceptable to further process of face recognition. We can observe a lot of noised data such as background, hair, clothes (see fig. 5).

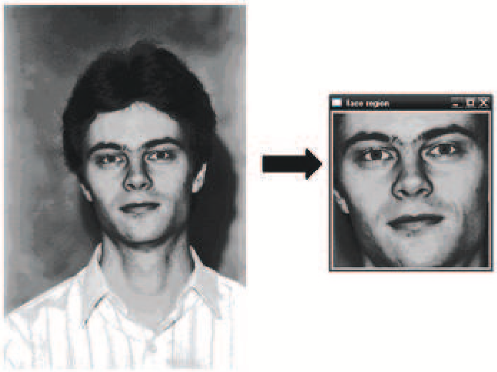

Fig. 3. Image enhancement by "normalization-detect"

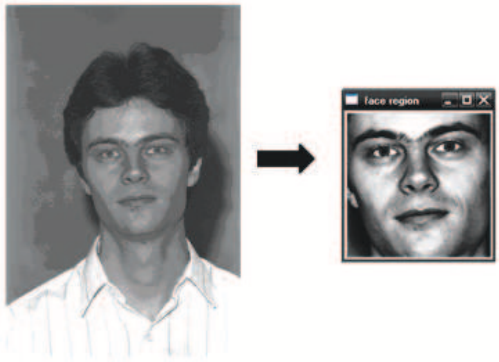

Fig. 4. Image enhancement by "detect-normalization"

These elements of image are not interested for process of pattern recognition. To achieve a higher level of authenticity in face recognition it is necessary to select a more narrow region of interest. We have developed the technique to detect region of face only. Our method intends for extracting facial features only without any noised data. It is based on applying of information about human anthropometric measurements. The results of application of presented algorithm are shown in fig. 7. Our approach is based on discrete adaboost ap-

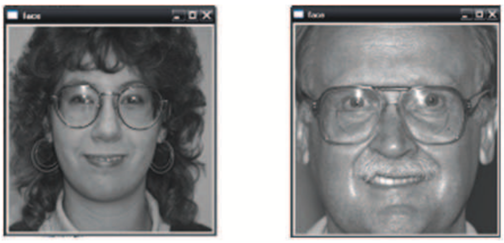

Fig. 5. The face region with the noised data

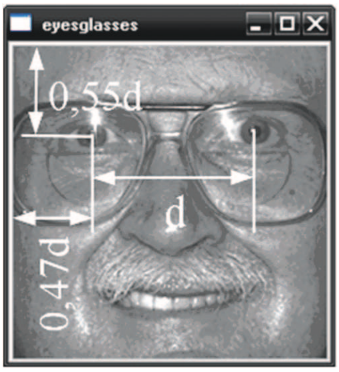

Fig. 6. Facial anthropometric Measurements

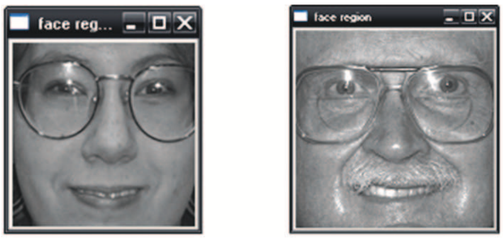

Fig. 7. The region of interest

plication [6] to select simple classifiers based on individual features drawn from a large and over-complete feature set in order to build strong stage classifiers of the cascade. This technique executes the iris area only, not whole face as the previous method. The input image for iris detection procedure is image obtained at the previous stage of image processing that contains parts of clothes, hair etc.

At first we perform the search of left-hand eye area only. The procedure of search of right-hand eye starts if the previous stage was finished successfully. When we get a beneficial effect the distance between pupils in pixels is calculated. At the next step we compute coordinates of left upper point of region of interest. The facial region is presented as squared area with left-upper point calculated at previous stage.

To compute the coordinates of each of four points we use the distance between pupils and some of facial anthropometric data. A length from left iris to upper boundary is calculated as $0,55 \cdot D$ and length from the left iris to the left boundary of the region of interest is equal $0,47 \cdot D$, where D is the distance between pupils in pixels. Thus the length of the side of square of face region is calculated as $2 \cdot 0,47 \cdot D + D = 1,94 \cdot D$. All of these estimated coefficients were obtained experimentally(see fig. 6).

Our approach allows of finding the specified face region on the majority tested images. Failing of iris detection we use additional techniques to solve this problem and to find the region of interest. This technique is enhancement of basic detector and it is designed to find eyeglasses. The current detector was trained to find each part of eyeglasses and after that to detect the iris area. The results of search of eyeglasses are represented in fig. 8(a). The search of region of pair eyes starts after unsuccessful attempt of search of eyeglasses (see fig. 8(b) with results). Our algorithm has found the face regions of interest on all tested images. However, when nothing found at work image we provide the original entry image in the capacity of region of interest.

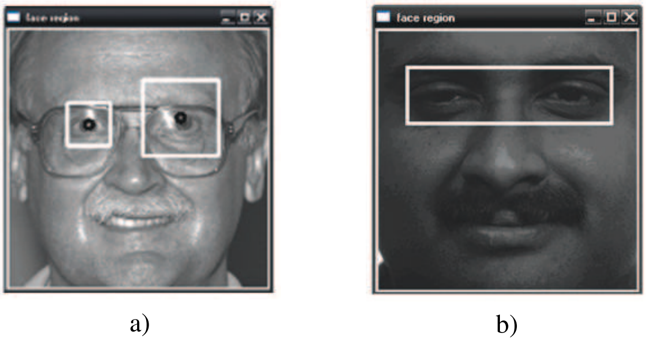

Fig. 8. Face detect with: a)- eyeglasses, b)- pair eyes

The region of interest is presented as squared area which contains necessary data (features of face) with minimal noise level to face recognition process. The initial size of facial region has arbitrary size but then we scale it to size of 169×169 pixels. Square side is chosen subject to several important factors. The most important restriction imposed on the procedure of identification is the quality of processed images, primarily due to the resolution image and due to conditions of exposure. The minimum distance between eyes of frontal images that are used at face identification is determined by international standards as "ISO 19794-5:2005" [7], "ANSI/INCITS 385-2004 (Information technology - Face Recognition Format for Data Interchange)" [8]. This parameter is equal 90 pixels. If we keep constraint about minimal distance between eyes then the square side of region of interest is equal about 170×170 pixels for our system face identification. We have chosen the square side size equal 169 pixels subject to some details of image processing with artificial neural networks PCA.

III. Image enhancement techniques

At next stage our system performs the procedures of image normalization. We perform an expansion of pixels values to the whole intensity range and the equalization of histogram. The first approach maps the values in intensity image to new values such that values between low and high values in current image map to values between 0 and 1. Thus new pixel values allocate to whole intensity range. After that we perform the histogram equalization which enhances the contrast of images by transforming the values in an intensity image so that the histogram of the output image approximately matches a specified histogram. After use these methods image contains some distortions as sharp face lines. That's why we apply the median filter to dither face features. This method performs median filtering of the input image in two dimensions. Each output pixel contains the median value in the 3×3 neighborhood around the corresponding pixel in the input image. This part of image processing removes significantly the illumination

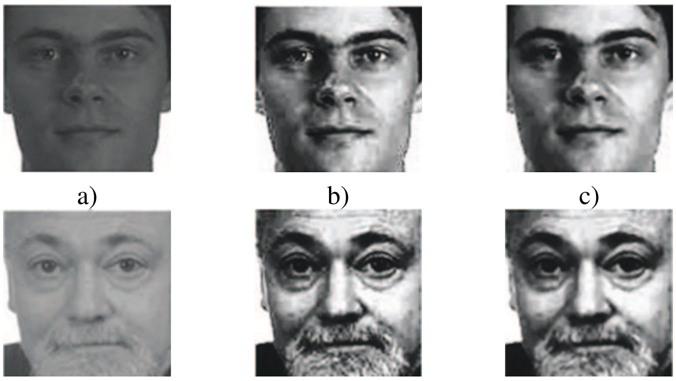

Fig. 9. Examples of normalized images: a - input images, b - after application adjusting image intensity values and histogram equalization, c - after using median filter

changes among the images. The fig. 9 illustrates the results of introduction the image pre-processing methods described above. We use these methods in the following sequence: expansion of pixels values to the whole intensity range - the equalization of histogram - median filtering.

IV. Dimension reduction and feature extraction

Some classification-based methods use the intensity values of window images as input features of classifier. However, direct use of intensity values of image pixels are dramatically increases the computation time. On the other hand the huge capacity of data contains many waste data being overfull. In our system we extract features via method of principal component analysis. We use three techniques for implementation of this approach. There are the algorithm NIPALS (non-linear iterative partial least squares) [9] for compute the principal components, the neural network PCA (NNPCA) [13], [16], and the kernel principal component analysis [17]. These methods have different computational cost and various confidence levels at recognition stage. The user of system can choose the method to work by oneself.

Principal Component Analysis (PCA) - is a useful statistical technique that has found application in fields such as face recognition and image compression, and is a common technique for finding patterns in data of high dimension. PCA involves a mathematical procedure that transforms a number of possibly correlated variables into a smaller number of uncorrelated variables called principal components. The first principal component accounts for as much of the variability in the data as possible, and each succeeding component accounts for as much of the remaining variability as possible. PCA is mathematically defined as an orthogonal linear transformation that transforms the data to a new coordinate system such that the greatest variance by any projection of the data comes to lie on the first coordinate (called the first principal component), the second greatest variance on the second coordinate, and so on.

The NIPALS ("Nonlinear Iterative Partial Least Square") algorithm is one of the many methods that exist for finding the eigenvectors (another example is SVD [10]). It was originally made for PCA, but it has been used in other methods as well. Algorithm is used in principal component analysis to decompose a data matrix into score vectors and eigenvectors (loading vectors) plus a residual matrix. This is an overview of the algorithm:

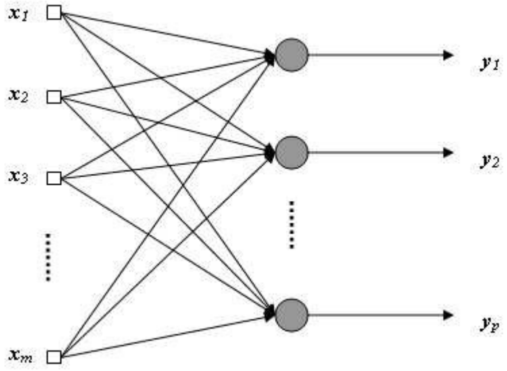

Fig. 10. A single-layered feedforward neural network for extracting p principal components

X is a mean centered data matrix, $E_{(0)} = X$. The E-matrix for the zero-th PC (PC_0) is mean centered X, t vector is set to a column in X, t will be the scores for PC_i, p will be the loadings for PC_i, $threshold = 0,00001$, just a low value, to do the convergence check.

Iterations ($i = 1$ to number-of-PCs):

1.Project X onto t to find the corresponding loading p

$$p = (E_{i-1}^T / t^T t) \tag{1}$$

2.Normalise loading vector p to length 1

$$p = p \cdot p(p^T p)^{-0.5} \tag{2}$$

3.Project X onto p to find corresponding score vector t

$$t = (E_{(i-1)} p / (p^T p)) \tag{3}$$

4.Check for convergence. If difference between eigenvalues $\tau_{new} = (t^T t)$ and τ_{old} (from last iteration) is larger than $threshold \cdot \tau_{new}$ return to step 1.

5.Remove the estimated PC component from $E_{(i-1)}$

$$E_{(i)} = E_{(i-1)} - (tp^T) \tag{4}$$

Principal components can be extracted using single-layer feed-forward neural networks [11]. These networks learn unsupervised by using variants of the Hebbian rule. The Generalized Hebbian Algorithm (GHA) [12], also known in the literature as Sanger's rule, is a linear feedforward neural network model for unsupervised learning with applications primarily in principal components analysis. It is similar to Oja's rule in its formulation and stability, except it can be applied to networks with multiple outputs.

$$y_j(n) = \sum_{i=1}^{p} w_{ij} x_i(n), \qquad j = 1, 2, ..., m. \tag{5}$$

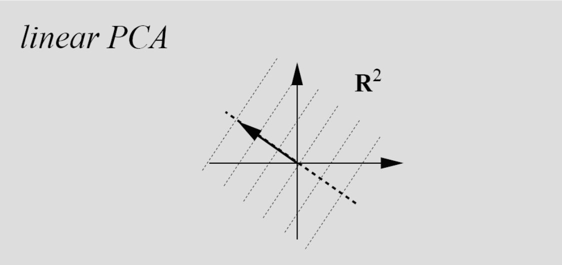

Fig. 11. Linear PCA

$$\Delta w_{ij}(k) = \eta[y_j(n)x_i(n) - y_j(n)\sum_{k=1}^{j} w_{ki}(n)y_k(n)] \qquad (6)$$

The neural network PCA (NNPCA) is used in our work. The Generalized Hebbian Algorithm by Sanger [6] is one among the best known learning algorithms that allow a neural network (see fig. 10) to extract a selected number of principal components from a multivariate random process. It applies to a single-layered feedforward neural network that may be described by equation(5) with the rule for updating weights (see equation 6).

The weight of first eigenvector has been estimated and its value lies within the range from 75 to 84%. Therefore, to decrease the computation expenses we used only one eigenvector for calculation one principal component.

Kernel principal component analysis (kernel PCA) [14] is an extension of principal component analysis using techniques of kernel methods. Instead of directly doing a PCA, the original data points are mapped into a higher-dimensional (possibly infinite-dimensional) feature space defined by a (usually non-linear) function Φ through a mathematical process called the "kernel trick":

$$\Phi : \mathbf{R}^N \to F,\ x \to \mathbf{X} \qquad (7)$$

The kernel trick [15] transforms any algorithm that solely depends on the dot product between two vectors. Wherever a dot product is used, it is replaced with the kernel function. Thus, a linear algorithm can easily be transformed into a non-linear algorithm. This non-linear algorithm is equivalent to the linear algorithm operating in the range space of Φ. However, because kernels are used, the Φ function is never explicitly computed. This is desirable, because the high-dimensional space may be infinite-dimensional (as is the case when the kernel is a Gaussian).

Like in PCA, the overall idea is to perform a transformation that will maximize the variance of the captured variables while minimizing the overall covariance between those variables. Using the kernel trick, the covariance matrix is substituted by the Kernel matrix and the analysis is carried analogously in feature space. An Eigen value decomposition is performed and the eigenvectors are sorted in ascending order of Eigen values, so those vectors may form a basis in feature space that explain most of the variance in the data on its first dimensions.

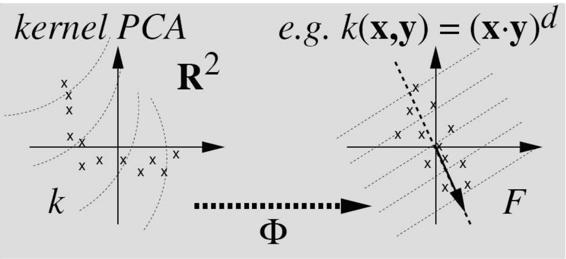

Fig. 12. The basic idea of kernel PCA. In some high dimensional feature space F (see fig. 12 right), we are performing linear PCA, just as a PCA in input space(figure 11). Since F is nonlinearly related to input space (via Φ), the contour lines of constant projections onto the principal Eigenvector (drawn as an arrow) become nonlinear in input space. Note that we cannot draw a pre-image of the Eigenvector in input space, as it may not even exist. Crucial to kernel PCA is the fact that we do not actually perform the map into F, but instead perform all necessary computations by the use of a kernel function k in input space (here: R^2).

However, because the principal components are in feature space, we will not be directly performing dimensionality reduction. Suppose that the number of observations m exceeds the input dimensionality n. In linear PCA, we can find at most n nonzero Eigen values. On the other hand, using Kernel PCA we can find up to m nonzero Eigen values because we will be operating on a $m \times m$ kernel matrix.

Each time the features extracted vector is presented as the sequence of more significant coefficients of the principal components. In our work the size of face region extracted in face detection block is 169×169 pixels. Thus the original dimension of data space counts 28.561 points. We form sequence with 169 features only by use of most important coefficients from process of feature extraction. The second part of data (less significant coefficients) is rejected. Thus we use three different approaches to extract the vector of features from original data set (region of interest that contains a facial image).

V. Face identification with SVMs

The Support Vector Machines (SVMs) [1] present one of kernel-based techniques. SVMs based classifiers [18] can be successfully apply for text categorization, face identification. A special property of SVMs is that they simultaneously minimize the empirical classification error and maximize the geometric margin; hence they are also known as maximum margin classifiers. SVMs are used for classification of both linearly separable (see fig. 13) and unseparable data. SVMs based classifiers can be successfully apply for text categorization, face identification.

Linear classifiers are not complex enough sometimes. SVM solution: map data into a richer feature space including non-linear features, then construct a hyperplane in that space so all other equations are the same. Basic idea of SVMs is creating the optimal hyperplane and calculating the decision function for linearly separable patterns. This approach can be extended to patterns that are not linearly separable by transformations of

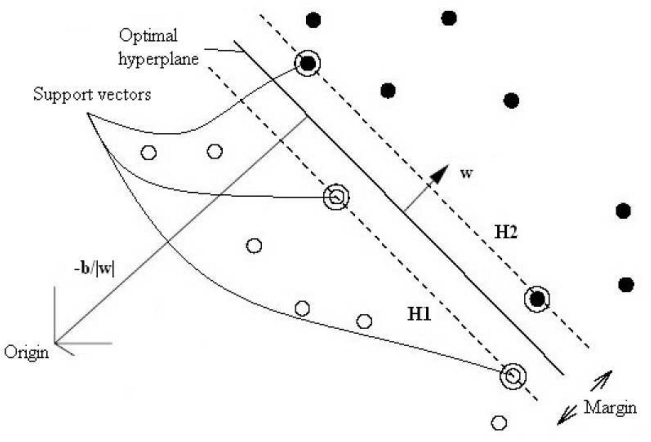

Fig. 13. Linear separating hyperplanes for the separable case.

original data to map into new space due to using "kernel trick". In the context of the Fig. 13, illustrated for 2-class linearly separable data, the design of the conventional classifier would be just to identify the decision boundary w between the two classes. However, SVMs identify support vectors (SVs) $H1$ and $H2$ that will create a margin between the two classes, thus ensuring that the data is "more separable" than in the case of the conventional classifier.

Suppose we have N training data points $(x1, y1), (x2, y2), \ldots, (x_N, y_N)$ where $x_i \in \Re^d$ and $y_i \in \pm 1$. We would like to learn a linear separating classifier:

$$f(x) = sgn(w \cdot x - b) \tag{8}$$

Furthemore, we want this hyperplane to have the maximum separating margin with respect to two classes. Specifically, we wish to find this hyperplane $H : y = w \cdot x - b$ and two hyperplanes parallel to it and with equal distances to it:

$$H_1 : y = w \cdot x - b = +1 \tag{9}$$

$$H_2 : y = w \cdot x - b = -1 \tag{10}$$

with the condition that there are no data points between H_1 and H_2, and the distance between H_1 and H_2 is maximized.

For any separating plane H the corresponding H_1 and H_2 we can always "normalize" the coefficients vector w so that H_1 will be $y = w \cdot x - b = +1$, and H_2 will be $y = w \cdot x - b = -1$ as shown [1].

We want to maximize the distance between H_1 and H_2. So there will be some positive examples on H_1 and some negative examples on H_2. These examples are called support vectors because only they participate in the definition of the separating hyperplane, and other examples can be removed and moved around as long as they do not cross the planes H_1 and H_2.

In the space the distance from a point on H_1 to $H : w \cdot x - b = 0$ is $|w \cdot x - b|/||w|| = 1/||w||$, and the distance between H_1 and H_2 is $2/||w||$. Thus, to maximize the distance we should minimize $||w|| = w^T w$ with the condition that there are no data points between H_1 and H_2:

$$w \cdot x - b \geq +1, \text{ for positive example } y_i = +1 \tag{11}$$

$$w \cdot x - b \leq -1, \text{ for negative example } y_i = -1 \tag{12}$$

These two conditions can be combined into

$$y_i \cdot (w \cdot x_i - b) \geq 1 \tag{13}$$

So, this problem can be formulated as

$$\min_{w,b} \frac{1}{2} w^T w \text{ subject to } y_i \cdot (w \cdot x_i - b) \geq 1 \tag{14}$$

This is a convex quadratic programming problem (in w, b) in convex set.

Introducing Lagrange multipliers $\alpha_1, \alpha_2, \ldots, \alpha_N \geq 0$, we have the following Lagrangian:

$$L(w, b, \alpha) \equiv \frac{1}{2} w^T w - \sum_{i=1}^{N} \alpha_i y_i (w \cdot x_i - b) + \sum_{i=1}^{N} \alpha_i \tag{15}$$

We can solve the wolfe dual insread: maximize $L(w, b, \alpha)$ with respect to α subject to constrains that the gradient of $L(w, b, \alpha)$ with respect to the primal variables w and b vanish:

$$\frac{\partial l}{\partial w} = 0 \tag{16}$$

$$\frac{\partial l}{\partial b} = 0 \tag{17}$$

and that $\alpha \leq 0$

From equations (16) and (17) we have

$$w = \sum_{i=1}^{N} \alpha_i y_i x_i \tag{18}$$

$$\sum_{i=1}^{N} \alpha_i y_i = 0 \tag{19}$$

Substitute them (18), (19) into $L(w, b, \alpha)$ we have

$$L_D \equiv \sum_{i=1}^{N} \alpha_i - \frac{1}{2} \sum_{i=1}^{N} \alpha_i \alpha_j y_i y_j x_i x_j \tag{20}$$

in which the primal variables are eliminated.

When we solve α_i, we can get $w = \sum_{i=1}^{N} \alpha_i y_i x_i$ and we can classify a new object x with:

$$\begin{aligned} f(x) &= sgn(w \cdot x + b) \\ &= sgn((\sum_{i=1}^{N} \alpha_i y_i x_i) \cdot x + b) \\ &= sgn(\sum_{i=1}^{N} \alpha_i y_i (x_i \cdot x) + b) \end{aligned} \tag{21}$$

Note that in the objective function and solution, the training vector x_i is occurred only in the form of dot product.

If the surface separating the two classes are not linear we can transform the data points to another high dimensional space such that the data points will be linearly separable [19]. Let the transformation be $\Phi(\cdot)$. In the high dimensional space, we solve

$$L_D \equiv \sum_{i=1}^{N} \alpha_i - \frac{1}{2} \sum_{i=1}^{N} \alpha_i \alpha_j y_i y_j \Phi(x_i) \cdot \Phi(x_j) \tag{22}$$

Suppose, in addition, $\Phi(x_i) \cdot \Phi(x_j) = k(x_i \cdot x_j)$. That is, the dot product in that high dimensional space is equivalent to a kernel function of the input space. So we need not be explicit about the transformation $\Phi(\cdot)$ as long as we know that the kernel function $k(x_i \cdot x_j)$ is equivalent to the dot product of some other high dimensional space. There are many kernel functions that can be used this way, for example, the radial basis function (Gaussian kernel):

$$K(x_i, x_j) = e^{-||x_i - x_j||^2/2\sigma^2} \tag{23}$$

Formally, preprocess the data with $\Phi : \Re^N \rightarrow F$, then a data set that is not linearly separable in the input data space (as in the left hand side of fig. 14) is separable in the nonlinear feature space (right hand side of fig. 14) defined implicitly by the non-linear kernel function.

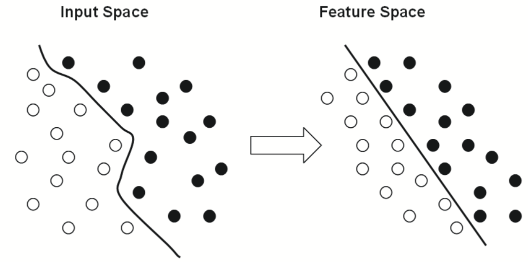

Fig. 14. Kernel trick for the unseparable case

For multi-class classification we use the "one-against-one" approach in which $k \cdot (k-1)/2$ classifiers are constructed and each one trains data from two different classes. In classiffication we use a voting strategy: each binary classiffcation is considered to be a voting where votes can be cast for all data points x - in the end point is designated to be in a class with maximum number of votes. We implemented probabilistic approach to identify the processed pattern by calculating the confidence level for this face. And we construct a list of 6 samples by descending to make a final decision.

Basic idea of SVMs relative to the Nearest Neighbor [20] approach is creating the optimal hyperplane and calculating the decision function for linearly separable patterns. This approach can be extended to patterns that are not linearly separable by transformations of original data to map into new space due to using kernel trick.

To train the SVM, we search trough the feasible region of the dual problem and maximize the objective function. The optimal solution can be checked using the Karush-Kuhn-Tucker (KKT) conditions [1].

The KKT optimality conditions of the primal problem are

$$\alpha_i[y_i(w^T x_i - b) + \xi_i - 1] = 0 \tag{24}$$

$$\sum_{i=1}^{N} \mu_i \xi_i = 0 \tag{25}$$

To solve this quadratic programming problem we used the sequential minimal optimization (SMO)-type decomposition method[21] for support vector machines [22].

The SMO algorithm searches through the feasible region of the dual problem and maximizes the objective function

$$L_D \equiv \sum_{i=1}^{N} \alpha_i - \frac{1}{2} \sum_{i,j} \alpha_i \alpha_j y_i y_j x_i x_j \tag{26}$$

$$0 \leq \alpha_i \leq C, \quad \forall i$$

It works by optimizing two α_i's at time (with the other α_i's fixed) and uses heuristics to choose the two α_i's for optimization [22].

The decision function is

$$sgn(\sum_{i=1}^{l} y_i \alpha_i K(x_i, x) + b). \tag{27}$$

VI. Experiment results

Our system contains two basic blocks. There are training SVM-classifier module and face identification unit developed on SVM-classifier. At first we have to create the model for following pattern recognition. At this stage we train our SVM-classifier by the algorithm proposed Jones C.Platt [22]. In our system we used the libsvm implementation [23] of this algorithm. The one-type input feature vector containing the significant coefficients from PCA is used both for train and classification.

Scaling data before applying SVM is very important. [24] explains why we scale data while using Neural Networks, and most of considerations also apply to SVM. The main advantage is to avoid attributes in greater numeric ranges dominate those in smaller numeric ranges. Another advantage is to avoid numerical difficulties during the calculation. Because kernel values usually depend on the inner products of feature vectors, e.g. the linear kernel and the polynomial kernel, large attribute values might cause numerical problems. We linearly scale each attribute to the range $[0; 1]$. Of course we use the same method to scale testing data before testing.

To increase the level of correct identity we applied choose the parameters of C-support vector classification with cross validation via parallel grid search. There are two parameters while using RBF kernels: C and γ. It is not known beforehand which C and γ are the best for one problem; consequently some kind of model selection (parameter search) must be done. Therefore, a common way is to separate training data into two parts of which one is considered unknown in training the classifier. Then the prediction accuracy on this set can more precisely reflect the performance on classifying unknown data. An improved version of this procedure is cross-validation.

In v-fold cross-validation, we first divide the training set into v subsets of equal size. Sequentially one subset is tested using the classifier trained on the remaining $v - 1$ subsets. Thus, each instance of the whole training set is predicted once so the cross-validation accuracy is the percentage of data which are correctly classified.

We used the sample collection of images with size $512 - by - 768$ pixels from database FERET [25] containing 100 classes (unique persons) to test our face recognition system

TABLE I
RESULTS OF TESTING PERSON IDENTIFICATION SYSTEM

	Recognition rate, percent	Feature extraction time for each vector, s	Training time, s
PCA NIPALS	80	0,6	28,4
NNPCA	84	12	28,8
Kernel PCA	81	0,8	28,3

based on support vector machines. This collection counts 300 photos. Each class was presented by 3 images. So, to train SVM-classifier we used 200 images where 2 photos introduced each class. 100 images were used to test our system. Note, that any image for testing doesn't use in training process. The results of realized experiments are shown in the table I. In this paper we proposed an efficient face identification system based on support vector machines. This system performs several algorithms to ensure the full process of pattern recognition. Thus, our system is intended for face identification by processing the image even low quality. The face detection region procedure without any noise is a very important stage of the person identification process. The angle of inclination and the rotation angle of head influence on the level of validity of recognition. These factors are the most significant in person identification system.

***Abstract*—We present a novel segmentation technique that effectively segments natural images. The method is designed for the purpose of image retrieval and follows the principle of clustering the regions visible in the image. The concept is based on the multiscale approach where the image undergoes a number of diffusions. The algorithm has been visually compared with a reference segmentation.**

I. Introduction

KNOWLEDGE-BASED society is taking advantage of communication services and IT-tools that manage, store and retrieve the information more and more often. There is a continuing demand to enhance the services that are based on visual information such as movies or images.

The problem of content-based image retrieval in large databases has been a research topic for many years. There exist semi-automatic tools to accomplish this task but still there is no standard method of general applicability. The difficulty lies in understanding what actually the image presents (image understanding) and how the contents can be described (image annotation problem). Additional limitations arise when the goal is to search for similar images in large databases. Since the analysis will require enormous demand for computer resources, the framework allowing for automated analysis will be of great use. In this paper we present a novel segmentation method based on the multiscale approach that was designed especially for image retrieval.

The concept treats the image as a set of disjoint regions that can be described by a set of features such as color, texture or shape:

$$\textbf{Image} \rightarrow \textbf{Image regions} \rightarrow \textbf{Region features} \rightarrow \\ \rightarrow \textbf{Distance between feature vectors} \quad (1)$$

With this assumption an image can be represented in multidimensional feature space as a set of points which number is consistent with the number of significant regions identified during segmentation. Regions characterized by a set of features are located in different locations in the feature space and the position depends on their visual properties. Following the Leibniz's principle called *Identity of indiscernibles* ”two things are identical if and only if they share the same and only the same properties” we assumed that similar images share objects/regions of similar properties. Which means that for a subset of images containing objects from the same category, we will observe a set of closely located points, as the regions in that subset will be similar.

Such an approach has the following consequences. Images of little complexity, for example with a few objects and an uniform background will contain only a small number of clusters separated in the feature space [1]. For more complex scenes the number of clusters will be higher and their separation will be probably difficult.

In image understanding it is difficult to find a compromise between interpretation of all image details and the interpretation where certain details could be omitted. Without *a priori* knowledge there is no automated way to determine which details can be disregarded and which objects are large enough to be treated as significant. Therefore, a scale should be considered as a parameter that changes dynamically and generates images with different level of details. With changing scale the degree of precision also changes. Generated images form a so-called multiscale representation.

The concept of multiscale representation was first introduced by Rosenfeld and Thurston [2]. They observed the influence of linear operators of different scale on edge detection. Also, Klinger [3], [4] and Tanimoto [5] used the multiscale approach to describe an image, similarly to Burt and Adelson [6] who proposed a popular, pyramidal representation of an image.

An important aspect in all these attempts is that the images at a larger scale are simplified version of images at smaller scales. Therefore, increasing the scale is equivalent with eliminating the details from images at lower scales. Following such a definition, the scale-space filtering was firstly introduced by Witkin [7] and then further developed by Koenderink [8].

Our concept to image retrieval differs from methods named *Query By Image Content* that tries to extract the information from the whole image [9]. In contrary, the method considers the image as a set of regions represented by a cluster of points in the feature space where the similarity between images is equivalent to a degree of similarity between feature vectors. Therefore, correct segmentation of the regions is a prerequisite

978-83-60810-27-9/09/$25.00 © 2010 IEEE

in image retrieval and machine vision tasks where objects play the necessary role. Determination of the criterion for object homogeneity is equally important. Mostly features based on color are used but also other features are often employed, i.e. low-level features such as SIFT, visual descriptors in MPEG-7 standard [10]–[12].

Multiscale approach to segmentation has been already proposed. Wang used a multiscale approach based on high frequency wavelet coefficients and their statistics to perform context-dependent classification of individual blocks of the image. Unlike other edge-based approaches, his algorithm does not rely on the process of connecting object boundaries [13], [14].

The next section describes the segmentation method. The method takes into account the color as the most discriminating feature. Since it is based on concepts such as mean-shift clustering and multiscale approach based on anisotropic diffusion, also these concepts are presented. The last section presents the results and conclusions.

II. Segmentation method

The aim of segmentation is to partition the image into non-overlapping regions that share common features. In case of images of human nature the significant information are derived by color, therefore the features of interest are taken from color model and position. We have decided to take the multiscale approach because such a concept is natural for human perception. When we see the picture, first, we focus on the core objects and analyze regions of strong contrast and different color, next we analyze their details, such as texture. By running a number of diffusions on the image, such concept can be imitated, as with the number of diffusions the details in the image get blurred and only the objects with highest contrast remain. The information on the image is, therefore, simplified.

The segmentation method is depicted in Fig. 1 and can be described as follows. Original image (1) undergoes the multiscale operation and a set of images with different degree of diffusion is generated (2). Next, mean-shift segmentation is produced for each of the image. The results are accumulated in special storage system called accumulator (4). The mode-shift clustering together with a certain metric (6) and a threshold value assigned to it (7) is used in order to label disjoint region of interest and partition them into two layers. The principle layer stores labeled objects that are clearly visible at all the scales and the vague layer contain the regions less distinguishable (8).

A. Anistropic diffusion in multiscale approach

This is the initial step of the algorithm. Here, a number of images are generated in the process of convolving the original image I_0 with the Gaussian kernel with the t variance:

$$I(x, y, t) = I_0(x, y) * G(x, y; t) \tag{2}$$

The variance controls the degree of details visible in the image. Higher values correspond to the image with fewer details that can be clearly distinguishable. The set of derivative images $I(x, y, t)$ is equivalent to concurrent solutions of the heat transport problem or diffusion on the plane [8], namely:

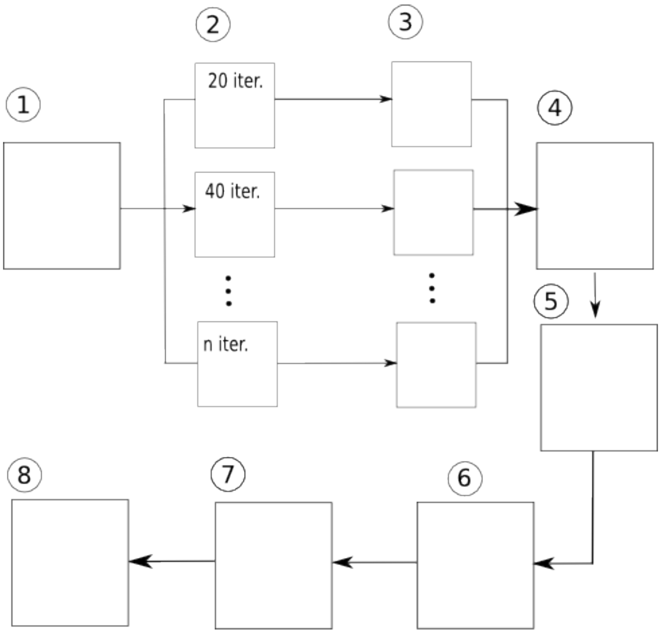

Fig. 1. Segmentation Algorithm. 1. Input image. 2. Multiscale approach, anisotropic diffusion. 3. Meanshift Segmentation. 4.Accumulator. 5. ”Modeshift” clustering. 6. Calculation of the metric. 7. Adaptive thresholding. 8. Output image.

$$I_t = \nabla^2 I = I_{xx} + I_{yy} \tag{3}$$

with initial conditions defined as $I(x, y, 0) = I_0(x, y)$.

Since, the convolution operation smoothes the whole image together with boundaries between objects, we decided to use edge-preserving anisotropic diffusion. The importance of this approach lies in the fact that the diffusion coefficient is not the same for all the pixels. The method is define as follows [15]:

$$I_t = div(c(x, y, t) \cdot \nabla I) = c(x, y, t)\nabla^2 I + \nabla c \cdot I \tag{4}$$

where $c(x, y, t) = g(||\nabla I(x, y, t)||)$ is monotonically decreasing so that within homogeneous regions the diffusion is stronger than in the vicinity of region edges.

In the case of approximation of ∇I with 4-directional neighbourhood we can describe this process as

$$\begin{aligned} I^{(t+1)}_{x,y} = I^{(t)}_{x,y} + \lambda[D_N \cdot \Delta_N I + D_S \cdot \Delta_S I + \\ D_E \cdot \Delta_E I + D_W \cdot \Delta_W I]^{(t)}_{x,y} \end{aligned} \tag{5}$$

where $\lambda = 1/4$, symbols N, S, E, W correspond to directions North, South, West, East, respectively, and Δ is the difference between pixel values in the directions for each iteration t:

$$\begin{aligned} \Delta_N I \equiv I_{x,y-1} - I_{x,y},\ \Delta_S I \equiv I_{x,y+1} - I_{x,y}, \\ \Delta_W I \equiv I_{x-1,y} - I_{x,y},\ \Delta_E I \equiv I_{x+1,y} - I_{x,y}, \end{aligned} \tag{6}$$

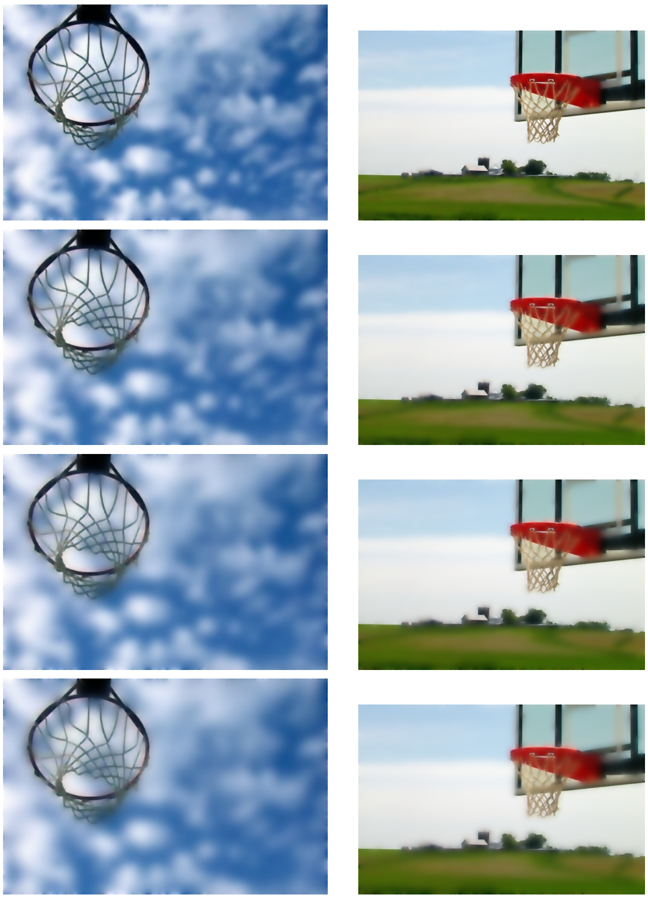

Fig. 2. Filtration results with anisotropic diffusion for $t = 50, 100, 150, 200$ iterations and . $K = 25$.

Similarly, diffusion coefficients are modified for each iteration t as follows:

$$\begin{aligned} D_N &= g\left(||(\nabla I)_{x,y-\frac{1}{2}}||\right)\ D_S \\ &= g\left(||(\nabla I)_{x,y+\frac{1}{2}}||\right) \\ D_W &= g\left(||(\nabla I)_{x-\frac{1}{2},y}||\right)\ D_N \\ &= g\left(||(\nabla I)_{x+\frac{1}{2},y}||\right) \end{aligned} \quad (7)$$

Gradient values $||(\nabla I)||$ were calculated by the Canny filtering [16] that guarantees that the edges are one pixel thick. Similarly to [17] the $g(\cdot)$ was defined as :

$$g\left(||(\nabla I)||\right) = 1 - \exp(-\frac{\tau}{[\Psi(||\nabla I||)/K]^m}). \quad (8)$$

where $m = 4$, $\tau = 3.31488$ a K is a diffusion parameter.

Fig. II-A describes the results of anisotropic diffusion for $K = 25$ and $t = 50, 100, 150, 200$ iterations.

B. Mean Shift Segmentation

During this step, each of the image at different scale goes through so called meanshift segmentation. In contrary to low-level segmentation methods that depend on parameters or apriori knowledge about image contents, clustering methods have ability to be independent on these limitations. The ”mean-shift” algorithm is a non-parametric clustering method widely used for segmentation of images of human nature. The method does not require to know the number and the shape of clusters. For each pixel of an image, the set of adjacent pixels is established according to a certain kernel function. For these adjacent pixels the new spatial and color mean values are calculated and used the new center for the next iteration. These steps are repeated until the means do not change. At the end of the iteration, the final mean color will be stored.

The method can be described as follows. Let us define an image as a set of n points $x_i, i = 1, \cdot, n$ in d-dimensional space R^d, and estimator for the density kernel $K(x)$ with radius h defined as

$$f(x) = \frac{1}{nh^d}\sum_{i=1}^{n} K\left(\frac{x - x_i}{h}\right) \quad (9)$$

For radially symmetric kernels it is sufficient that $K(x)$ follows

$$K(x) = c_{k,d}k(||x||^2) \quad (10)$$

where $c_{k,d}$ is normalization constant for which $\int_x K(x) = 1$. Modal values of density function are located in intercepts of the $\nabla f(x) = 0$. Density gradient is defined as follows:

$$\nabla f(x) = \frac{2c_{k,d}}{nh^{d+2}}\sum_{i=1}^{n}(x_i - x)g\left(||\frac{x - x_i}{h}||^2\right) =$$
$$\frac{2c_{k,d}}{nh^{d+2}}\left[\sum_{i=1}^{n} g\left(||\frac{x - x_i}{h}||^2\right)\right]\left[\frac{\sum_{i=1}^{n} x_i g\left(||\frac{x-x_i}{h}||^2\right)}{\sum_{i=1}^{n} g\left(||\frac{x-x_i}{h}||^2\right)} - x\right]. \quad (11)$$

where $g(s) = -k'(s)$. The first term is propotional to the estimator of the density kernel of x vector calculated with the the kernel function $G(x) = c_{g,d}g(||x||^2)$ and the second term is defined as

$$\frac{\sum_{i=1}^{n} x_i g\left(||\frac{x-x_i}{h}||^2\right)}{\sum_{i=1}^{n} g\left(||\frac{x-x_i}{h}||^2\right)} - x \quad (12)$$

as is called a ”mean shift” vector. This vector is responsible for traversals between the given point to the prototype of a given cluster (attractor). Direction of the vector is oriented to the highest ascend of density. The range of the kernel h is described by two components: a planar one h_s and the feature-driven one h_r that describes the range of features. This procedure is an iterative process made of two steps:

- calculation of the mean-shift vector

$$m_h(x^{(t)}) \quad (13)$$

- translation within the window with the vector

$$x^{(t+1)} = x^{(t)} + m_h(x^{(t)}) \quad (14)$$

and converges to the point where the density gradient is equal to zero. The more detailed description of the method can be found in [18].

C. Definition of Accumulator

Here all the segmentation results at various scale t_q are accumulated and the final segmentation is derived. This procedure has the following steps:

Step 1 Define L-dimensional matrix A which we will call *accumulator*, where L corresponds to the dimension of the feature space that describe the regions. A will store regions defined by a prototype $v_i(t_q)$ composed of features $v_i^{(\cdot)}(t_q)$. In the current stage the features will be defined in the following LAB color model. Obviously, each feature space will determine different prototype distributions in the feature set $v_i(t_q)$. Let us assume, that a single prototype will be described by a $L+2$–dimensional vector:

$$v_i(t_q) = [v_i^{(x)}(t_q), v_i^{(y)}(t_q), v_i^{(1)}(t_q), \ldots, v_i^{(L)}(t_q)]^T \tag{15}$$

where T is a symbol of transposition. In the accumulator space the features $v_i^{(1)}(t_q), \ldots, v_i^{(L)}(t_q)$, will be added without planar features of the prototypes. Matrix A is initialized with zeros.

Step 2 Scan the pixels of $I(x,y,t_q)$ image for each scales t_q and define the feature vector for corresponding prototypes $[v_i^{(1)}(t_q), \ldots, v_i^{(L)}(t_q)]$. Store the mapping:

$$\begin{aligned} I(x,y,t_q) &\to [v_i^{(x)}(t_q), v_i^{(y)}(t_q), v_i^{(1)}(t_q), \ldots, \\ &\ldots v_i^{(L)}(t_q)] \to [v_i^{(1)}(t_q), \ldots, v_i^{(L)}(t_q)] \end{aligned} \tag{16}$$

Step 3 For each pixel in each scale increment the accumulator:

$$\begin{aligned} &A[v_i^{(1)}(t_q), \ldots, v_i^{(L)}(t_q)] = \\ &\qquad A[v_i^{(1)}(t_q), \ldots, v_i^{(L)}(t_q)] + 1 \end{aligned} \tag{17}$$

D. Mode Shift clustering

This procedure aims at finding significant *modal values* in the accumulator space (4-dimensions: three color values and one corresponding to the accumulator range) where each region is represented by a single point. Mode shift clustering groups points in the vicinity of modal values. The resulting clusters are restrained by spatial and range limit values: σ_S and σ_R. The first parameter defines the searching window of the cubic shape, the latter one compares the accumulator range with local extrema. During this searching procedure, each point in the accumulator moves along the direction of the closest modal value with some finite number of steps.

The points that are grouped form a cluster and define the next mapping:

$$\begin{aligned} &[v_i^{(1)}(t_q), \ldots, v_i^{(L)}(t_q)] \to \\ &\qquad [V_j^{(1)}, \ldots, V_j^{(L)}];\ j = 1, 2, \ldots, C \end{aligned} \tag{18}$$

where C is the number of detected modal values. Note, that the mapping (18) does not have to be defined for all prototypes from the set $v_i(t_q)$.

E. Calculation of the metric

The clusters formed in the previous step are restrained according to a certain metric that defines the *type of distance*. Different metrics (for the sake of simplicity we named them Epsilon) were considered to calculate the distance and number of steps between a given point in the accumulator and the modal value (the cluster prototype) established during ”mode-shift” clustering. They are defined as follows:

- Epsilon type 0—Sum of consecutive steps between a given point and the modal value
- Epsilon type 1—Manhattan distance
- Epsilon type 2—Euclidean distance
- Epsilon type 3—Sum of consecutive steps in a given time
- Epsilon type 4—Euclidean distance weighted by the number of steps needed to achieve a cluster prototype
- Epsilon type 5—Sum of consecutive steps in a given time weighted by the number of steps needed to achieve a cluster prototype

F. Adaptive threshold

With each metric a certain threshold value is associated. This value controls whether the point belongs to the *principle layer* or to the *vague layer*. The regions of higher contrast that survived diffusions and have higher values in the accumulator constitute the principle layer. Objects with lower contrast have smaller values in accumulator and, therefore, belong to the vague layer.

During this step the labeling of the pixels in the image with the mappings: (18) and (16) is performed according to the mentioned threshold. Pixels with undefined mapping (16) are labeled as -1.

The output image contains disjoint regions and the algorithm is terminated. The image will contain two subsets with pixels:

- with a label equal to -1, which form the vague layer.
- with a label different than -1, which will create the principle layer.

III. Results

The algorithm has been tested for different parameter settings on Segmented and Annotated Benchmark set [19]. Especially metric Epsilon has been thoroughly tested and the segmentation results were compared visually with a reference segmentation done by the expert. The analysis of results indicated that the best results were achieved for Epsilon type 4 and 5. Example images 3 were analyzed with two different threshold values and presented in consecutive rows in Figs. 4–5. As one can see, the results are comparable to each other, alas, more work is needed to perform a detailed analysis of parameter influence.

Nevertheless, it may be easily noticed that the segmented regions correspond to the reference segmentation with a satisfactory accuracy, i.e. the significant objects on principle layer are detected (the right column) and their periphery are close to the boundaries defined by the expert. Such region

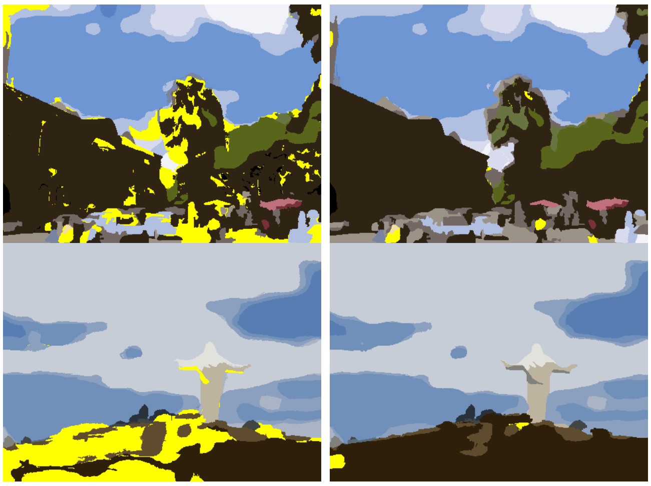

Fig. 5. Example results for epsilon type 5 and different threshold values. The vague layer is indicated by yellow pixels.

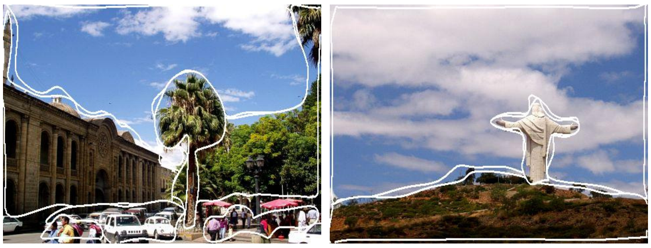

Fig. 3. Original images.

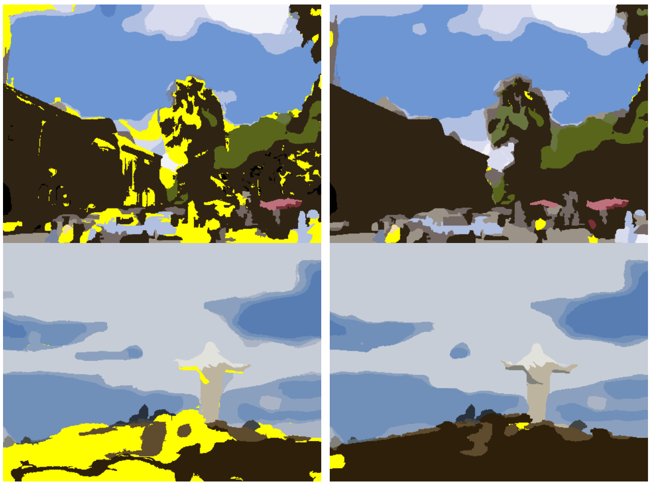

Fig. 4. Example results for epsilon type 4 and different threshold values. The vague layer is defined by yellow pixels.

representation as a feature set are a requirement for image retrieval based on clustering principle.

IV. Conclusions

The paper presents the segmentation method based on multiscale approach and mean-shift clustering. A novel algorithm partitions the image into disjoint sections that form the layers with significant (principal layer) and insubstantial regions (vague layer). Detected regions The results were assessed visually for a number of image classes method. Although, the results were satisfactory for a number of image classes and the method can serve as a potential tool in image retrieval task, more work is needed to fully customise the method.

Relational database as a source of ontology creation

Abstract—**The article headed “Relational database as a source of an ontology creation” deals with mapping relational data into ontology, or filling ontology with data from relational databases. It describes the issue of mapping database schemas (particularly relational models) for common data models expressed in the form of ontology. Generous room is given to methods of acquiring ontology from relational databases, where rules are specified and simple example are used to demonstrate their use, mapping of individual concepts of a relational data model into ontology concepts.**

I. Methods of Creating Ontology from Database

AN ontology provides shared and repeatedly usable knowledge about a specific domain. Existing relational databases, which contain enormous amounts of data, can be used to fill ontology with knowledge. There are numerous methods how to use existing databases to fill ontology using rules or using the so-called middle model. Many works deal with the issue of adding semantic to database schemas, e.g. [2]. Also, object-oriented data models are closely linked to ontological theory, nevertheless, even these do not offer sufficient semantic properties, such as hierarchies, for example. Methods of using relational databases for acquiring ontology can be divided minimally into the following four areas.

Area 1: Creation of a new database schema based on an analysis of the current relational schemas and mapping of this schema onto an ontology using reverse engineering. The new data model is designated as a so-called middle model, which is a common model above partial relational models [3].

Area 2: A method based on filling ontology instances using external relational sources. It uses a declarative interface between the ontology and data sources in XML.

Area 3: A method which creates ontology from a conceptual database schema, in the process the aim of this method is to create a RDF(S) ontology. However, this method has an unclear semantic and does not offer an inference model which is necessary for automatic derivation.

Area 4: A method which creates ontology from a conceptual database schema, whereas the aim of this method is to create an OWL ontology.

Further, we shall deal with only the last of the above said methods.

II. Ontology over the Relational Schema

The following definitions are necessary for describing the method of mapping relational data to an OWL ontology [9].

Definition I. (ontology with relation)

The ontological structure consists of five concepts
$O = \{C, R, H^C, rel, A^0\}$, where
C is a finite set of concepts
R is a finite set of relations

H^C is a concept hierarchy or taxonomy, $H^C \subseteq C \times C$, e.g. $H^C (C_1, C_2)$ expresses that C_1 is a sub-concept of C_2

rel is a set of non-taxonomic relations, e.g. $rel(R)=(C_1, C_2)$ expresses that concepts C_1, C_2 enter into relation R.

A^0 is a set of axioms expressed in the respective logical language, e.g. first-order logic.

The ontological structure includes as its extension a set of instances which suit this structure. Most OWL ontology elements involve classes, properties and instances. Most concepts of a specified domain correspond with classes which are the roots of various taxonomic trees. Properties are used to express general facts about class members and specific facts about instances. A property is a binary relation with a specified domain and scope. OWL distinguishes two types of properties. There are property between an instance and data type and property between instances of two classes. Both properties and classes may be classified in a hierarchy.

Definition II. (relational model)

In a relational model the R_i relation corresponds to a table where columns are called attributes and are designated A. The $attr(R_i)$ function returns attributes connected with a specific R_i relation. The dom (A_i) function determines the value range of attribute A_i, $A_i \in A$. The $pkey(R_i)$ function returns the primary key of the given R_i relation, whereas it must apply that $pkey(R_i) \subseteq attr(R_i)$. The $fkey(R_i)$ function returns a foreign key of the given relation R_i, again, it must apply that $fkey(R_i) \subseteq attr(R_i)$. Relations in a relational schema may be interdependent inclusively or equivalently.

Definition III. (inclusive dependence of relations)

Let R_i and R_j be relations and it is presumed that $A_i \subseteq attr(R_i)$ and $A_j \subseteq attr(R_j)$. Let $t_i(A_i)$ be value of t_i with attributes A_i and $t_j(A_j)$ value of t_j with attributes A_j. If for each $t_i(A_i)$ in R_i exists a $t_j(A_j)$ in R_j, for which it applies that $t_i(A_i) = t_j(A_j)$, then A_i and A_j are inclusively dependent, $R_i(A_i) \subseteq R_j(A_j)$ is recorded.

Definition IV. (equivalent dependence of relations)

Let R_i and R_j be relations and it is presumed that $A_i \subseteq attr(R_i)$ and $A_j \subseteq attr(R_j)$. If exists $R_i(A_i) \subseteq R_j(A_j)$ and $R_j(A_j)$

$\subseteq R_i(A_i)$, then A_i and A_j are equivalently dependent, $R_i(A_i) = R_j(A_j)$ is recorded.

III. Acquiring Ontology from a Relational Database

The task of acquiring ontology from a relational database can be divided according to which constructs, characteristics respectively, are acquired. Further, only the following constructs and characteristics of the created ontology shall be considered: classes, properties, hierarchy, cardinality, instances.

The principle of building ontology from a relational database, as is described by the set of rules in the following chapters, presents the reverse procedure to the procedure of transforming the conceptual model to a relational model. This transformation is based on the definition of a relational data model and transforms constructs designed in the conceptual model to constructs which permit a relational data model. This involves primarily decomposition of relations in the N:M cardinality and a conceptual model using multi-value and group attributes. Further, the issue of compulsory or optional participation of entities in relation to a conceptual model entity is discussed. The building of ontology is then based on the revealing of the original conceptualization, which the transformation process rendered unnoticed and thus the original semantic of modelled reality was lost (hidden). We propose following set of rules that allows inverse process to the process of transforming conceptual model into relational model. These rules transform relational model into conceptual model or ontology.

A. Rules for creating classes

The creation of ontology concepts as "classes" is based on two rules.

Rule I:

If we have database relations R_1, R_2, …, R_i, where P_1= pkey(R_1), P_2=pkey(R_2), …P_i=pkey(R_i), for which $R_1(P_1) = R_2(P_2) = … = R_i(P_i)$ apply, then information from these database relations can be integrated into one ontological class C_i. These relations form one entity on a conceptual abstract level.

Rule II:

Ontological class C_i can be created from relation R_i, if no other relation exists which could be integrated with relation R_i according to Rule I. and, at the same time, one of the following conditions applies:

|pkey(R_i)| = 1

|pkey(R_i)| > 1 and, at the same time, it applies that A_i exists, where $A_i \in$ pkey(R_i) and also $A_i \notin$ fkey(R_i).

This rule expresses that if relation R_i is used to describe an identification independent entity, then it may be mapped into one ontological class. The following example shows a practical case of mapping relations into an ontological class.

Example I.

A relational database schema consists of relations, their attributes, primary and foreign keys, as is shown in the following table.

Table I.
Relational Database Schema

Relation	Primary key	Foreign key
Student(Pers_number, Name,...., Town_residence)	Pers_number	Town_residence refers to relation Town Id_town
PhDStudent(Pers_numb er, …, Trainer)	Pers_number	Pers_number refers to relation Student Pers_number
Town(Id_town, Name_town, …..)	Id_town	-
Department(Id_departme n, Name_department, …)	Id_department	-
Studies(Pers_number, Id_department, ….)	Pers_number, Id_department	Pers_number refers to relation Student Pers_number
Employee(Id_employee , ….)	Id_employee	Id_department refers to relation Department Id_department

Example II.

According to Rule I. it is possible to create ontological class `Student`, which shall integrate relations `Student` and `PhDStudent` because `Student(Pers_number) = PhD Student(Pers_number)`. In OWL this class can be created as

```
<owl:Class rdf:ID = "Student" />.
```

According to Rule II. it is possible to create ontological classes `Town`, `Department` and `Employee` (condition 1 of this rule is fulfilled, |pkey(R_i)| = 1, i.e. number of attributes of primary key is one. In OWL classes can be created:

```
<owl:Class rdf:ID = "Town" />
<owl:Class rdf:ID = "Department" />
<owl:Class rdf:ID = "Employee" />.
```

B. Rules for creating properties

In OWL there are two types of properties – object properties and data type properties. The following rule must be defined for capturing properties arising from the relation schema into ontology.

Rule III:

If R_i and R_j are relations, where $R_i(A_i) \subseteq R_j(A_j)$ and, at the same time, $A_i \not\subset$ pkey(R_i), object property of ontology P can be created, based on attributes A_i of relation R_i. Assuming that relation R_i was mapped into class C_i and relation R_j was mapped into class C_j the domain of P is C_i and range of P is C_j.

Rule IV:

If R_i and R_j are two relations, then it is possible to create two object properties “has_part” and “is_part_of”, if the following two conditions are fulfilled:

$|pkey(R_i)| > 1$

$fkey(R_i) \subset pkey(R_i)$, where $fkey(R_i)$ refers to R_j

Provided that R_i is mapped on C_i and R_j on C_j, the domain, or range respectively, of the “is_part_of” C_i, C_j respectively, and the domain, or range respectively, of the “has_part” is C_j, C_i respectively.

Rule V:

Let R_i, R_j and R_k be relations and let it apply: A_i=pkey(R_i), A_j= pkey(R_j), $A_i \cup A_j$ = fkey(R_k) and $A_i \cap A_j = \emptyset$, the two ontology object properties can be created P_j‘ and P_j‘‘ based on R_k. Provided that R_i is mapped on C_i and R_j on C_j, domain and range of P_j‘ is C_i and C_j and domain and range of P_j‘‘ is C_j and C_i. Pj‘ and P_j‘‘ are two inverse object ontology properties.

Example III.

According to Rule III. `Town_residence` can be created as an ontology object property. The domain of this concept is `Student`, range is `Town`. In OWL the creating of a concept can be written as:

```
 <owl:Object Property
rdf:ID=‶Town_residence‶ />
 <rdfs:domain rdfs:source=‶#Student ‶ />
 <rdfs:range rdfs:source=‶#Town ‶ />
 <owl:ObjectProperty />.
```

Example IV.

According to Rule V., two object properties can be created based on the `Studies` relational relation. We’ll call these properties `pertains_to` and `has_student`, which shall be associated with classes of ontology `Student` and `Department`. The corresponding record in OWL is as follows:

```
 <owl:Object Property rdf:ID = ‶
pertains_to ‶ />
 <rdfs:domain rdfs:source = ‶#Student
‶ />
 <rdfs:range rdfs:source = ‶#Department
‶ />
 <owl:ObjectProperty />
 <owl:Object Property rdf:ID =
‶has_student ‶ />
 <rdfs:domain rdfs:resource =
‶#Department ‶ />
 <rdfs:range rdfs:resource =
‶#Student‶ />
 <owl:inverseOf rdf:resource=‶
pertains_to ‶ />
 <owl:ObjectProperty />.
```

RuleVI:

Rule VI. defines the method of creating data type properties and specifies that each attribute of all relations of the relational schema, which cannot be transferred to an object property, can be transferred to a data type property.

For ontology class C_i and a set of data type designated as DP(C_i), if C_i correspond to database relations R_1, R_2, …R_i, then for each attribute in R_1, R_2, …R_i, for which an object property cannot be created subject to Rule III., a data type property can be created. The domain of each property P_i is C_i and the range of each property is dom(A_i) for each $P_i \in$ DP(C_i) and $A_i \in$ attr(R_i).

Example V.

According to Rule VI. it is possible to create data type properties corresponding to ontology classes from attributes of relational schemas `Pers_number`, `Name`, `Trainer`, `Id_town`, `Name_town`, `Id_department`, `Name_department`, `Id_employee`. The segment in OWL could be as follows:

```
 <owl:Datatype Property rdf:ID =
‶Pers_number‶ />
 <rdfs:domain >
   <owl:Class >
 <owl:unionOf rdf:parseType =
‶Collection ‶ />
 <owl:Class rdf:about = ‶ #Student ‶ />
 <owl:Class rdf:about = ‶ #PhDStudent
‶ />
 <owl:Class rdf:about = ‶ # Pers_number
‶ />
 </owl:unionOf >
 </owl:Class >
 </owl:domain >
 <rdfs:range rdfs:source = ‶&xsd;int
‶ />
 <owl:DatatypeProperty />
 …
```

C. Rules for creating hierarchies

As is well known, the conceptual model uses the so-called Isa hierarchy, which enables the application of heritability in the object model. This Isa hierarchy does not permit the relational data model and therefore this Isa hierarchy must be decomposed during transformation of the conceptual model to a relational data model. Usually the identification dependence of relations is used, i.e. the identification key of the super-type becomes the identification key of the sub-type and also its foreign key. Conversely it can be deduced that if a relation has a foreign key as a part of its primary key, then it is a relation which was created by an Isa hierarchy transformation.

RuleVII:

If R_i and R_j are relations and it applies that P_i=pkey(R_i) and P_j=pkey(R_j), then if Rule I. cannot be applied and $R_i(P_i) \subseteq Rj(P_j)$ is fulfilled, then class/property of the corresponding R_i is a sub-class/sub-property of the corresponding R_j.

Example VI.

According to Rule VII., ontological class `PhDStudent` is a sub-class of ontological class `Student` and can be recorded in OWL as follows:

```
  <owl:Class rdf:ID = ‟PhDStudent‟ />
  <rdfs:subClassOf     rdf:resource     =
‟#Student ‟ />
  </owl:Class >
```

D. Rule for creating cardinalities

Attributes of relations according to the domain integral limitation designed above individual attributes of relations may acquire no, only one, at least one, maximum of one or more values. Based on a specified domain integral limitation in the relational schema the property cardinalities can be defined in the ontology.

Rule VIII:

If R_i is a relation with attributes $A_i \in$ attr(R_i), where A_i = pkey(R_i), then the minimum and, at the same time, maximum cardinality corresponding to property P_i is equal to 1.

Rule IX:

If R_i is a relation with attributes $A_i \in$ attr(R_i), where A_i is declared as NOT NULL, then the minimum cardinality corresponding to property P_i is equal to 1.

Rule X:

If R_i is a relation with attributes $A_i \in$ attr(R_i), where A_i is declared as UNIQUE, then the maximum cardinality corresponding to property P_i is equal to 1.

Example VII.

According to Rule VIII. the minimum and, at the same time, maximum cardinality of attributes `Pers_number`, `Id_town`, `Id_department` is equal to 1. In OWL it is recorded as:

```
  <owl:Restriction />
  <owl:onProperty rdf:resource =
‟#Pers_number ‟ />
  <owl:minCardinality>1</owl:minCardinali
ty>
  <owl:maxCardinality>1</owl:maxCardinali
ty>
  </owl:Restriction >
  <owl:Restriction />
  <owl:onProperty     rdf:resource     =
‟#Id_town ‟ />
  <owl:minCardinality>1</owl:minCardinali
ty>
  <owl:maxCardinality>1</owl:maxCardinali
ty>
  </owl:Restriction >
  <owl:Restriction />
  <owl:onProperty  rdf:resource  =  ‟#Id_
‟ />
  <owl:minCardinality>1</owl:minCardinali
ty>
  <owl:maxCardinality>1</owl:maxCardinali
ty>
  </owl:Restriction >
```

E. Rule for creating instance

The following rule can be used for automatic creation of ontology instances from data stored in relational databases.

Rule XI:

If C_i is an ontological class of the corresponding to database relations R_1, R_2, …R_i, then each n-tuple of t_i, for which $t_i \in R_1$ x R_2 x … x R_i applies, can become an instance C_i.

Note: x designates the Cartesian sum of relations.

Fig 1. Graph shows the fragment of the ontology created by describing examples using Altova SemanticWorks software.

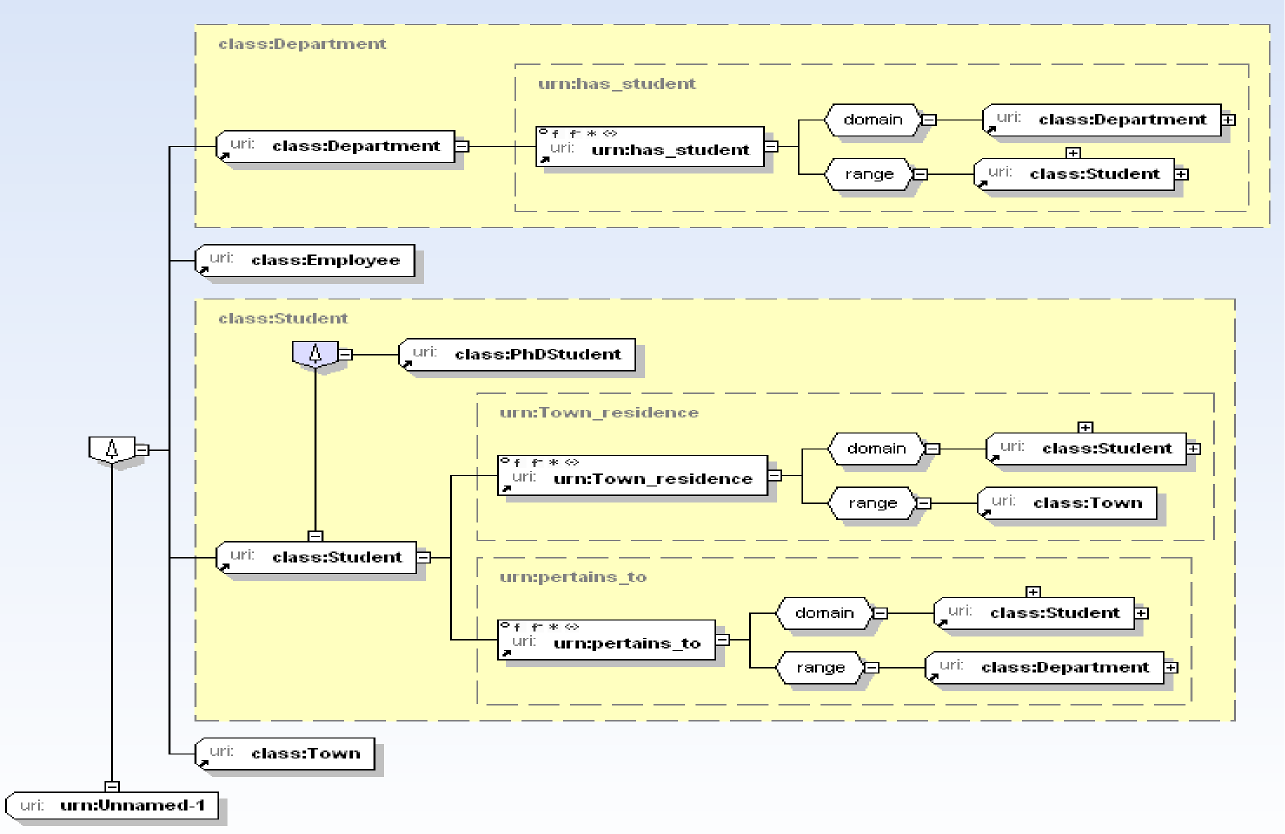

Fig. 1 Graph

IV. Conclusion

Mapping relational data into ontology, or filling ontology with data from relational databases respectively, plays an important role during the creation and updating of ontology. If we consider the quantity of data found in relational databases and the potential of their joint use across various applications, the question of finding a method for their use becomes obvious. The heterogeneity of data complicates use and therefore methods of their integration are being sought. The method based on a common semantic model – ontology is one way of efficient integration. The question is how to correctly map relational database data into ontology instances. The quantity of manual work during creation of ontology poses a serious problem; therefore, automation based on mapping subject according to the rules is a god solution. This article focuses on the principles of automatic conversion of constructs of the relational data model to constructs of OWL ontology and transfer of relational data to ontology instances. Mainly, rules are defined which map the basic concepts of the relational data model onto ontology. Individual rules are complemented by specific examples. Examples utilize a common simple data model.

***Abstract*—In the present text, we deal with the problem of classification of speech emotion. Problems of speech processing are addressed through the use of artificial neural networks (ANN). The results can be use for two research projects - for prosody modelling and for analysis of disordered speech. The first ANN topology discussed is the multilayer neural network (MLNN) with the BPG learning algorithm, while the supervised SOM (SSOM) are the second ANN topology. Our aim is to verify the various of knowledge from phonetics and ANN but also to try to classify speech signals which are described by musical theory. Finally, one solution is given for this problem which is supplemented with a proof.**

I. Introduction

MANY problems in technology, medicine, and the natural and social sciences still remain unsolved: the complexity of solutions, the importance of time, and the considerable quantity of data required for processing form the real cause of the situation. Seeking help through new information technology is highly appropriate; and one such method is through the development of artificial neural networks (ANN). Success in the application of ANN depends on thorough knowledge of their function, which cuts across a wide range of academic disciplines – mathematics, numerous technical fields, physiology, medicine, phonetics, phonology, linguistics and social sciences. Initially, the ANN paradigm was regarded as a cure-all for many problems, yet simultaneously was often disparaged by its detractors for its inability to solve increasingly high requirements through the use of simple principles. The robustness of the solution for real methods by ANN is a great advantage, for example, in the area of noise signal processing. In this case, ANN should be a highly useful source of help, and the results thus acquired could be of a higher quality than those found with standard methods. The research goal described in this contribution was to verify an ability to classify optional speech through the use of ANN. We use three approaches for comparison of results. First, a frequency dependence and statistical parameters are created from input data, while the second approach is based on music theory (see [8]) and the final approach is a combination of both cases.

The contribution has two parts. A brief notice about some publications from international researchers which concerns emotional speech, basic information about emotions, and the specific ANN applied to the experiments create the first part of the text. The second part is dedicated to the results of the experiments themselves.

A. Classification of emotions in publications of international researchers

Much research around the world is engaged in the processing of emotional speech. Specific projects differ in the number and type of classified emotions, acoustic characteristics, the type of classifiers, and precision. Classification of three emotions (sadness, anger and neutral state) for human-computer communication are described in [13]. Fundamental frequency F_0, voice intensity and cepstral coefficients were the input characteristics. Classification success was 64 % with the classification of the five classes (for anger, pleasure, sadness, surprose, and neutral state) described in [14] and [15]. Data from Danish Emotional Speech were tested by the Bayes classifier and classification success was 54 % (for both gender), 61.1 % for males and 57.1 % for females respectively. Also the five emotions are classified in [12] (fear, pleasure, sadness, anger, and neutrale state). A Gausse SVM (Support Vector Machine) algorithm was applied with a 55 % success rate. A comparison of the SVM, RBF (Radial Basis Function), kNN (k-Nearest Neighbours), Naive Bayes and MLNN (two hidden layers with 15 neurons) is described in [9]. The success for the five classes was 81 %. A description of the five emotional states (pleasure, sadness, fear, anger, and neutral state) is undertaken in [11]. An algorithm is based on relationship of a height note versus the 12 half tones of the melodic scale. The latest publication is closest to our methods described in this contribution.

II. Solving the problems and an applied methods

Automatic speech synthesis is an interdisciplinary part of artificial intelligence, drawing upon knowledge from acoustics, phonetics, phonology, linguistics, physiology, psychology, signal processing and informatics for a successful solution. Many research teams around the world are engaged in the modelling of the prosody of synthetic speech. This problem

This research was supported by grant GACR No. 102/09/0989.

must be solved with relation to the specific attributes of different languages: e.g. [4] for English, [5] for German, [1] for French, [3] for Japanese for example. A majority of prosody control systems are based on the implementation of grammatical rules e.g. realised by decision trees, but some researchers (Sejnowski, Traber), including the authors of this study, use neural networks for prosody modelling. Different input parameters with a significant impact on speech prosody have to be used for neural network training in different languages. As a result, it is very difficult, indeed nearly impossible, to compare the results of prosody controllers for different languages. The most complex evaluation is the listening test, but it is very subjective and cannot be described by an objective metric. A reason for this difficulty is that prosody is deeply affected by the speaker's individual physiologies and mental states, as well as by the uttered speech segments and the universal phonetic properties. The influence of the phonological and phonetic properties of the Czech language, the influence of the quality, size of the speech database, and the influence of the synthesizer type all need to be explored. Furthermore, it is not possible to make complete use of all the information extracted from natural speech signals in automatic input data creation. Our research has taken as its central focus the question of prosody modelling for Text-to-Speech (TTS) Synthesis. A text and its speech signal will be used for the training process of ANN, and only the text and the trained ANN will be used for prosody modelling, allowing it to be as natural as possible. Previously, processing speech had a neutral character, yet in recent months research has concentrated its attention on emotional speech.

A. Basic information about speech emotions

Emotion is a mental state of a living organism accompanied by motive and glandular activities. Emotions are classified according to their psychological aspect. As a result, the term "emotion" represents physiologic disturbance, shock or attack. The second category – attitude – represents a behaviour and a chronic state. Feigned and active emotions have different manners of their division. A physiological reaction (change of cardiac rate and blood pressure, whiteness or redness) is linked to opposite emotions (anger, fear, pleasure, and sadness). Hence it is impossible use this physiological reaction as ANN input features separately. However, it is possible to use prosody characteristics, such as timbre, intensity and rhythm. These is a change of a fundamental frequency f_0, range of fundamental frequency, change of a formant location etc.

The melody, i.e. change of a haight of voice in a sentence, is very important from the point of view of a communication. Expressive changes of melody are important indicators for an emotional and voluntary attitude of a speaker (more in [17]).

B. Classification of emotions by ANN

ANN was used for classification of emotions. A multilayer neural network with one hidden layer was one of the methods applied for the classification of speech emotions. The number of neurons in the input layer is given by the key linguistic parameters which are needed for characterization of the Czech language. The ANN outputs are the various classes of emotions. The target values of prosodic parameters were extracted from the natural speech signal. Many learning algorithms for feed-forward neural networks are based on the gradient descent algorithm. Usually, they have a poor convergence rate and depend on input parameters which characterize specific problems. No theoretical basis for choosing optimal parameters for ANN training exists, but the values of these parameters are often crucial for the success of the training. Therefore we decided to use a Scaled Conjugate Gradient (SCG) algorithm with superlinear convergence rate. SCG belongs to the class of Conjugate Gradient Methods, which shows superlinear convergence for most problems; further description is offered in [19].

Kohonen's Self-Organizing Features Map (KSOM) was the second ANN which was applied for the solution of emotion classification. KSOM is a form of ANN that is trained by unsupervised learning rules, i.e. without target (required) values. It is an iterative process based on the clustering method; cluster analysis methods searching for interdependences and joint properties in a set of submitted patterns. A new SOM variant has been used for emotion classification, namely the supervised Self-Organizing Map (SSOM), which combines aspects of the vector quantization method with the topology-preserving ordering of the quantization vectors. The algorithm of the SSOM represents a very effective method of classification, but only for well-known input data or for well-known classes of input data.

C. Corpus creation

For testing and refining the ANN, it is necessary to create a speech corpus of sentences and, through pre-processing of the corpus, to prepare input data for the network's training and testing. In general, corpuses of natural speech have been created through careful choice from among a wide variety of different neutral sentences. Currently, no emotional speech database is available. As a result, an emotional speech corpus and database for ANN training had to be created for our research. The sentences was read by professional actors, two female and one male. Speech recording was materialized in a recording studio with a professional equipment (format "wav," sampling frequence $44.1kHz$, $24bit$).

The speech corpus is composed of a written text and its corresponding speech signal, both of which will be used for the training of ANN. The compound corpus was divided into two parts, the first set used for training and the second part serving as a testing set, also used for the monitoring of the training process.

Utterances were realised for four types of emotions: anger, boredom, pleasure and sadness – see Table I and Table II.

D. Input data creation

The success of prosody control is clearly dependent on the labelling of the natural speech signal in the database. The labelling (determination of boundaries between speech

units) and phonetic transcription of sentences from the speech corpus is done in the phase of pre-processing. The changes of fundamental frequency F_0, formant frequency F_i, $i = 1, \dots, 4$ and duration Du of phonemes during the voicing of sentences create the melody of the sentence (its intonation). Intonation is also related to the meaning of the sentence and its emotional timbre.

Recorded emotion speech was subjectively evaluated by four persons. The final database contained 720 patterns (360 patterns for one-word sentences and 360 patterns for multi-word sentences).

III. Experiments

All analyses and experiments described in this contribution were performed through use of the computational system MATLAB with NN-toolbox [16] and SOM Toolbox. SOM Toolbox was developed in the Laboratory of Information and Computer Science (CIS) in the Helsinki University of Technology and it is built using the MATLAB script language. The SOM Toolbox contains functions for creation, visualization and analysis of the Self-Organizing Maps. The Toolbox is available free of charge under the General Public License from ([7]). For the projects from the domain of the speech processing by ANN (which are being addressed by our university's department of Circuits Theory), new special M-files, which should be a part of the supporting program package, were created.

MLNN and SOM were applied particularly to the utterances from Table I and Table II. The results from MLNN training are concentrated into the so-called matrix of replacement, where "class 1" is specified as anger, "class 2" is specified as boredom, "class 3" is specified as pleasure and "class 4" is specified as sadness. The database for ANN training obtained 216 patterns, for validation 72 patterns and for testing as many as 72 patterns.

The unified distance matrix or U-matrix is a representation of the KSOM that visualizes the distance between the neurons and their neighbors. The KSOM neurons are represented by hexagonal cells (in our experiment). The distance between the adjacent neurons is calculated and presented in different colors. Darker colors between neurons correspond to a larger distance and thus represent a difference between the values in the input space. Light colors between the neurons mean that the vectors are close to each other in the input space. Light areas represent clusters (classes) and dark areas represent cluster boundaries (more in [2]). The size of the map was 15x15, while quantization (QE) and topographic (TE) errors of the map were also computed.

A. Method I: The patterns based on time and frequency characteristics

Nine patterns for MLNN training are created through the characteristics of the time and frequency domains (see Table III). The hidden layer was 20 neurons, while the output layer was 4 neurons. The number of training epoch was 56 resp. 53 for one-word sentences resp. multiword sentences.

B. Method II: The patterns based on musical theory.

The second presented method is based on the idea of the musical interval: the frequency difference between a specific n-tone and reference tone. E.g. quint is ratio of the fifth tone divided by the first tone, with a numerical value of 1.498. The ratios of the musical intervals are shown in Table IV.

TABLE IV
FREQUENCY RATIOS OF THE MUSICAL INTERVALS

Interval	Variant	Frequency ratios
first		1,000
second	minor	1,059
	major	1,122
third	minor	1,189
	major	1,260
fourth		1,335
fifth		1,498
sixth	minor	1,587
	major	1,682
seventh	minor	1,782
	major	1,888
octave		2,000

TABLE V
COMPARISON OF THE RESULTS

Method	one-word sentences		multiword sentences	
	MLNN [%]	SOM [QE/TE]	MLNN [%]	SOM [QE/TE]
I	88.7	0.185 / 0.02	77.8	0.184 / 0.017
II	70.4	0.274 / 0.014	65.3	0.275 / 0.017
III	85.9	0.431 / 0.011	84.7	0.439 / 0.006

This method of the parametrization of the utterances consists in the description of the signal patterns based on the musical intervals or more precisely on their frequency ratios. The reference frequency, i.e. the fundamental frequency in our case, is given by the choices in each utterance feature. We use autocorrelation function. The frequency ratios are compared with the music intervals and input vector for MLNN training with 20 values is computed. The hidden layer was 35 neurons, the output layer was 4 neurons. The number of the training epoch was 75 for one-word sentences resp. 84 for multiword sentences.

C. Method III: Combination of both previous approaches

The third method was the combination of both previous methods. 29 patterns for MLNN training are created by 20 values containing the ratios respective to the music intervals and 9 values describing the acoustic qualities of the utterance feature. The hidden layer was 55 neurons, while the output layer was 4 neurons. The number of the training epoch was 57 for one-word sentences resp. 106 for multiword sentences.

IV. RESULTS OF EXPERIMENTS

The results of experiments are shown in the following table and figures.

This table summarizes the success rate of emotional classification for all three described methods. For the MLNN approach the first method (based on acoustic parameters) was best for the one-word utterances, but difference between one-word and multiword utterances are the greatest (9.9 %). Success for the second method (based on music theory) is worse for both type of utterances, but the difference between them is smaller (5.1 %). The third method (combination) is the best of them for the multiword utteraces, while additionally the differences between one-word and multiword utterances are absolutely smallest (1.2 %). With the SOM approach, the determining of SOM quality is complicated. We were monitoring the quality of learning by topographic and quantization errors for the comparison of methods. The topographic error (TE) predicates the conservation of data topology between input and output space. The quantization error (QE) reflects the accuracy of the mapping (it relates to the number of the input matrix elements and the size of the map).

The success of the SOM training decreases when the number of map units is larger than the number of training samples, which may be the main problem in our SOM approach. In our experimets we made use of the uniform size of maps for the comparison of all three methods. Our results show progressive values of the quantization errors in dependence to number of training data features, whereas a decreasing value for topographic error shows a very good ability of the classification.

Fig. 2. Method I: Matrix of changes for multiword sentences – time and frequency domain parameters

We can see the matrix of changes for the MLNN classifier in Figure 1, 2. These figures summarize the first described method. We can observe the replacement of the emotion classification between active emotions, i.e. pleasure – anger, and between passive emotions, i.e. sadness – tedium. The results from the second method are shown in Figure 3, 4, the results from the third method are demonstrated in Figure 5, 6. Just as in the Method I, the worst score is for passive emotions (Method II and Method III).

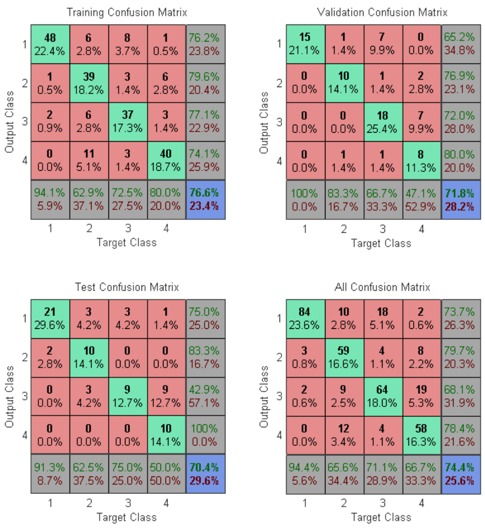

Fig. 3. Method II: Matrix of changes for one-word sentences – time and frequency domain parameters

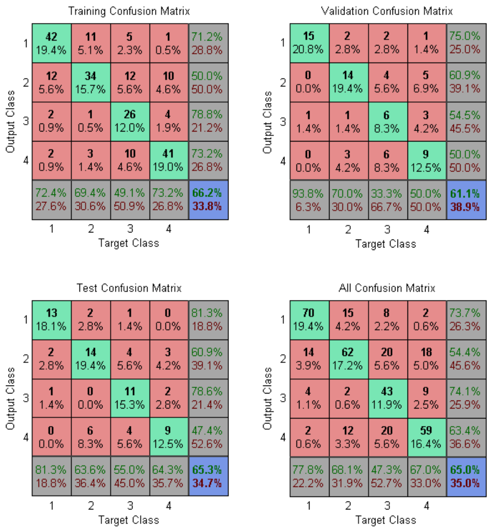

Fig. 4. Method II: Matrix of changes for multiword sentences – time and frequency domain parameters

The unified distance matrix or U-matrix is a representation of the KSOM that visualizes the distance between the neurons and their neighbors. The KSOM neurons are represented by hexagonal cells (in our experiment) marked by 'H' for anger, 'N' for tedium, 'R' for pleasure and 'S' for sadness. Each cell is marked also by a character for class, by real classified font and number registered pattterns.

The distance between the adjacent neurons is calculated and presented with different colors. Dark colors between neurons correspond to a larger distance and thus represent a difference between the values in the input space. Light colors between the neurons means that the vectors are close to each other in the input space. Light areas represent clusters and dark areas represent cluster boundaries.

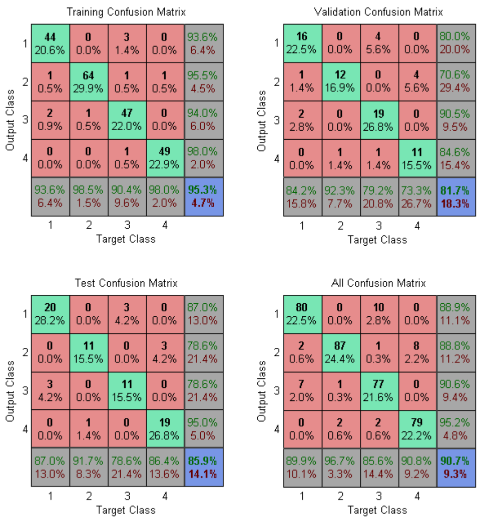

Fig. 5. Method III: Matrix of changes for one-word sentences – time and frequency domain parameters

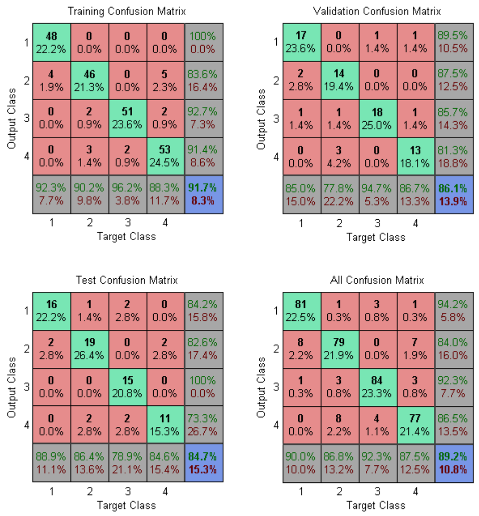

Fig. 6. Method III: Matrix of changes for multiword sentences – time and frequency domain parameters

The U-matrix represents emotion classes based on the parametrization by Method I are visualize in Figure 7, resp. 8, by Method II in Figure 9, resp. 10 and by Method III in Figure 11 and 12. The matrix is divided into four parts respective particular emotions. The topographic error for both type of utterances (one-word and multiwords) is lowest from all three methods (see on the Table V). This result documents the availability to apply the method based on the combination standard and music theory.

V. Conclusion and Future Work

We have established differentiation between the mathematical results and the listening tests. It is necessary to judge recording of emotional speech which is determined for database creation and the resulting synthetic sentences

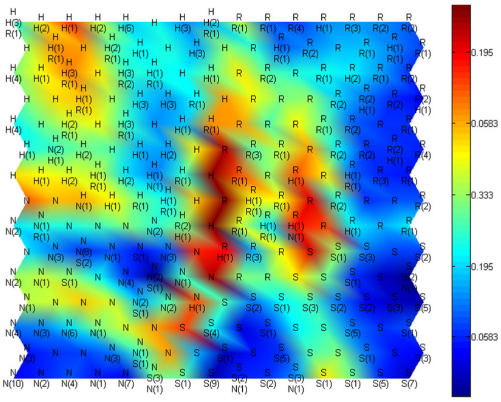

Fig. 7. Method I: U-matrix for one-word sentences

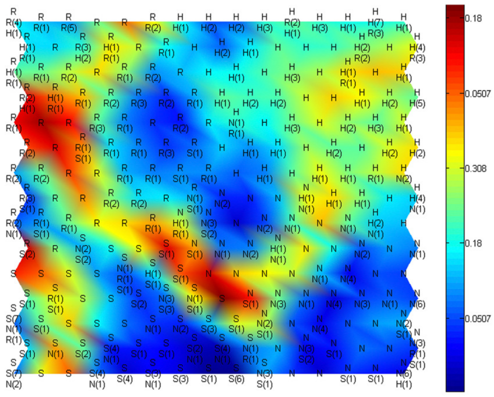

Fig. 8. Method I: U-matrix for multi-word sentences

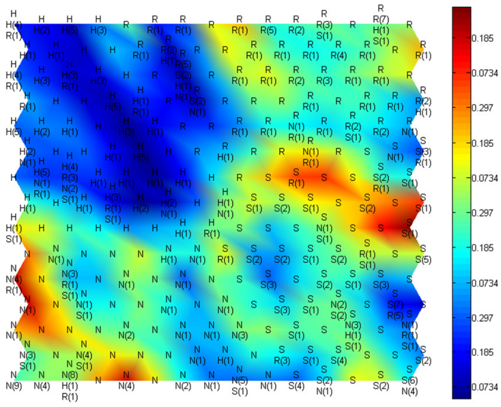

Fig. 9. Method II: U-matrix for one-word sentences

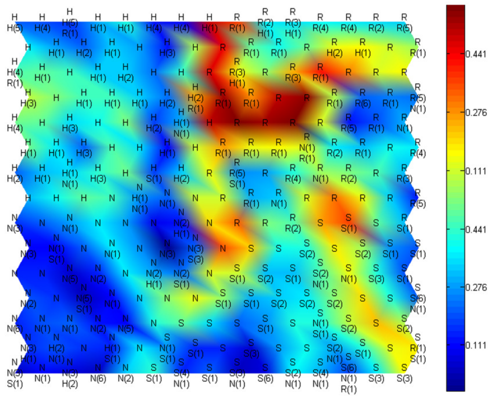

Fig. 12. Method III: U-matrix for multi-word sentences

by listening. The physical properties of the acoustic wave, which are perceived as sounds, are transformed several times: first in the organ of hearing, later at the emergence of neural excitement, and last in the cerebral analysis. Therefore, the sounds perceived in listening tests do not correlate completely with the objective properties of the acoustic patterns. The listening tests must consequently form a part of experiments. We want to conclude by establishing when to use MLNN or SSOM on the base of acquired events and on the base of augmentation, of the number of experiments.

Our effort in future work will focus on our lack of knowledge regarding the possibilities of ANN application in prosody modelling and children's disordered speech analysis. These different domain of the application influence the database creation. Long sentences (called multiword sentences in this contribution) are more acceptable for prosody modelling, yet the database created by one-word sentences is suitable for the analysis of children's disordered speech (often a speech malfunction is manifested in an inability to pronounce whole sentences). We are going to apply results from the described experiments with emotional speech to the improvement of synthetic speech naturalness, but also to the domain of neurodevelopmental disturbances (above all, developmental dysphasia).

***Abstract*—This document describes how information generated by integrated development environment (namely Visual Studio 2008) can be used to generate and usage of knowledge base. The main aim is to explain, how the approach of extension of currently implemented software project can achieve knowledge representation, and how already created and implemented data types can be used to create knowledge bases using modern language's development environment and behavior. The article is aimed to the Description Logic formal system, but can be applied to any formal deduction mechanism.**

I. Introduction

Today, lot of information systems are built in non-research area and most of them use for data or knowledge storage standard relational databases, object databases or other storage places, like XML files.

This, often very large structures, contain a lot of information about company (or any targeted subject), which can be manipulated as knowledge and shared. Information systems or applications from design development phase through fully implementations contains well considered, well organized, and well described and documented schemas (like database models, class models), which are not taken and mentioned as knowledge base and does not contains any kind of inference mechanism. Nevertheless a lot of that information can be taken as concepts/roles/instances and used to create full knowledge base with inference mechanism. Moreover, this process can be done automatically due to source format – implemented diagrams, classes in object oriented programming, etc. However, only minor part use some kind of inference or deduction mechanism, like expert system, or some kind of formal deduction based over knowledge bases.

Although the main reason is not sufficient spread of knowledge mechanism approaches (like expert systems are mostly oriented in technological industry or medicine), one of the another reasons is inability to check, test, or prove those systems on created project, that will simply show the advantages (and disadvantages) of those approaches. If aimed on knowledge bases, and one of the most today's formal system, description logic, the existing implementations often requires to install third party runtime environment (e.g. Java Virtual Machine for .NET users), or are integrated as server applications listening on special ports with special syntax requested for input and output for test. True is, that most of those systems are supported by today's standard for knowledge base/ontology editor and designer Protégé [6], there is again a load on a developer to 1. Find, install and open knowledge base system, 2. Install and execute Protégé system, 3. Learn how to insert data from existing information system and 4. Learn how to profit from those combinations against the classical approaches mentioned above. A lot of other approaches are built on client-server principles, where information system as client has to send its requests to the server realizing inference over knowledge base. Those approaches again includes requirement to create and use any implementation of format of communication protocol(s) between client and server.

This approach is for "common" developer almost impassable, so there are open doors for other approaches, which brings those formal systems into the existing system of developers. The main idea is to extend developer's existing project. The added part will consist of a solution, which can (partially) automatically analyze existing project, generate knowledge base and offer a mechanism to inheritance or deduction over gained data.

Lot of integrated development environments (like Microsoft Visual Studio) offers mechanism providing automatic generating of the content into some universal format (like XML files), moreover, modern programming languages contains mechanism allowing runtime analysis of any compiled code, called "Reflection". Those two built stones open a way how can (and should) knowledge system use those data to offer a developer a ways to use knowledge representational approach in application development.

Here presented solution – XReasoner system – manages three main parts of operation with data presented: a) creation of the knowledge base – T-Box and A-Box, b) managing knowledge base, c) sharing information with other sources based on other modern phenomenon, web services. This article describes first part of this behavior. (System is built over description logic DL1 [1][3] and uses semantic tableau algorithm for inference. Idea of approach presented in this article is mainly commonly applicable over other systems; at least, for description logic (above common constructors) is required constructor of negation (to implement exclusiveness of derived classes), value restriction (for properties and relations) and sometimes quantified number restriction (for "property" behavior in .NET languages) –$\mathcal{ALCQ}$).

One more condition is important. Developer should not (at least in testing phase) adapt or rewrite the existing code. Therefore, the introduced solution, where able, presents two

978-83-60810-27-9/09/$25.00 © 2010 IEEE

approaches: first one with changes to origin source code; second one which remains origin source code intact.

II. Description logic

At the beginning of this contribution, only the short introduction of the formal system of description logic will be mentioned. This formal system is very popular today, for its simplicity, expressivity. Moreover, we prefer it due to its close approach to the object oriented paradigm of programming.

Description logic (presented according to [7]) is a formalism which arises from concept languages. Concept languages are built on description of abstract objects of real world – called concepts, and roles, representing relations between those concepts. In description logic, the concepts are ordered into hierarchical structures. Knowledge base of description logic consists of definition of concepts and their roles (both those items represent intensional knowledge) and instances of the concepts (instances represents extensional knowledge about concrete object of the real world).

From the viewpoint of formal systems for knowledge representation is description logic built on formalism supporting frames, associative networks and object oriented knowledge representation.

Knowledge base of description logic is formally divided into two parts. First part is called T-Box (terminological box) and contains terminological intensional knowledge in the form of concepts and definition of relations between those concepts. Second part is called A-Box (assertional box) and consists of facts about instances – individuals – where each instance is related to the concrete concept or role. Each instance's domain is one or more concepts in T-Box.

Moreover, as mentioned before, concepts in T-Box are automatically ordered into hierarchical structure according to theirs definition. They are classified and placed (subsumed) into taxonomy – this behavior is called *subsumption*.

III. IDE, Reflection and Automatization

As mentioned before, the main aim is to utilize the behavior of modern programming languages and modern integrated development environment. The contribution is aimed on Microsoft's .NET technology (and examples will be presented in C# programming language), because it is in close development with the XReasoner tool – that is description logic implementation over the .NET platform, created to support this behavior. The two main tools of the modern software development in .NET bring opportunity to automatic knowledge base generation from existing application or information system.

The first construct is automatization. The modern IDE (like mentioned Visual Studio) offer tools to generate some universal data (like xml files) from existing classes into structures also called *DataSets*. IDE is able to capture classes, relation between classes (with occurrences count), inheritance, interface implementations into the xml files. This information is not only generated from classes, but databases or source XML files can be used too. So, IDE offers easy way how to extract terminological part of software's "knowledge base" into the xml file, which can be later analyzed.

The second construct is more powerful. It does not rely on development environment, but is part of programming language, and is called *reflection*.

Reflection [5] is ability of modern programming language (including languages used to development over the Microsoft .NET platform) to achieve, process and invoke compiled source code dynamically during application run. Simple said, for example, during application run can a programmer choose library, load a type from it, create an instance and invoke type members over this instance. In both most used programming languages, C# (.NET) and Java uses in compilation mechanism, which includes all information about data types, its members and relations in the compiled file (e.g. .dll assembly file in .NET platform). Due to this behavior reflection does not need any additional information from other files (like C++, where the .h files are required). This part of information are saved in the *manifest* of the assembly (assembly is .NET compiled file). In .NET, assembly is simply loaded (on request by programmer), its manifest is analyzed and the runtime environment "knows" which types can be found in the library, which members can be called and with which parameters. When the object oriented programming is taken into account, there must be mentioned that reflection can access not only public types and members, but also protected, private and internal (means visible only in current assembly) ones are visible and accessible with this mechanism.

When aimed to the behavior of modern programming, one more very powerful and important feature (accessible during reflection) should be mentioned. It is called *attributes*.

Attributes allows a developer to add some special kind of declaration (!) information to a class definition. This information can be later used by compiler or other executing code to adjust its behavior against marked class. For example, class declared this way:

```
[Serializable()]
public class X
{
   public int A;
   [NonSerialized()]
   public int B;
   …
}
```

Class X will be during serialization process successfully stored to a target location; moreover, the field B will be skipped and will not be saved.

Attributes are not built-in part of the language, it the view of language they are special cases of classes. So, the developer can create its own attributes and use them with classes. Other developers can then use those attributes to mark their classes.

This mechanism is now used in coordination with persistence into relational database systems (RDBS); each class has specified into which table, with which properties and which data-types, is stored/loaded. The same way can be used to specify which classes and which its properties can be used to knowledge base generating.

IV. Creation of Knowledge Base

Generally, the mechanism uses set of assemblies containing XReasoner system used to manage description logic knowledge base and set of assemblies containing attributes and classes used to generate knowledge base by adjusted properties. As mentioned in the introduction, two approaches can be used: external, which does not affect code of the existing code, and internal, which affects this code. External approach uses xml file to define requested behavior, however, sometimes internal behavior can be more readable and understandable. Both approaches can be used together, in case of conflict internal approach has higher priority and will be used.

Physically, implementation requires adding references to assemblies of XReasoner into current project (or creating new project and adding references to both, analysed project and XReasoner). If external approach is used, moreover xml file needs to be created and passed as parameter for XReasoner system.

The mechanism of generating knowledge base including concepts, roles and also instances will be divided and introduced in two parts: a) creation of T-Box, b) adding instances into A-Box.

A. T-Box - introduction

The main contribution of reflection technology is its "knowledge" of project classes and relations between them. This information can be presented by reflection simply by analysis of existing data types, their fields, properties and type inference hierarchy.

T-Box creation request to answer three questions: a) what data are available through reflection, b) which data are relevant and public and should be included, c) how to identity and identify different definitions representing the same object.

The first step is to retrieve all defined data types in selected assembly or assemblies. As mentioned before, reflection can provide (and provides) mechanism that returns simple listing of all data types defined in assembly. In .NET, there are a lot of data types, but only classes (reference types) and structures (value types) will be taken into account (that is important, i.a. interfaces are also omitted).

Next step is to analyze inference hierarchy between those data types. .NET languages are strictly object oriented; and therefore inheritance usage is very common. Information about data type also contains references to all its predecessors. With this information tree of hierarchy can be created.

Last part of T-Box analysis aims to properties and fields of the data types. Fields are not very often used to present some information value directly, because it in contrast with encapsulation principle of object oriented paradigm. Therefore properties are used instead. Properties contain information about their data-type and define strictly binary relations between two data types.

All those information can be used to define concepts and roles between them in T-Box. Basically, data-types will represent concepts in description logic knowledge base. Subsumption of concepts will be equal to data-type inheritance hierarchy. This creates only "simple subsumption" in meaning that there is only "Concept A is subsumption of concept B" relation, without any additional conditions. Programming language and object oriented paradigm ensure there will be no cyclic dependencies in definition.

As mentioned before, properties or fields define binary relations between two concepts. Those relations represent roles between concepts. First data type (the one containing the property or field) defines concept which is domain of the created role. Second data type (the one which is property or field data type) represents range of created role. Domain and range can be the same type; the behavior of properties or fields ensures that only binary roles are created.

B. T-Box - implementation

Before implementation description, one more behavior must be explained. Previous paragraph explains that roles always create relation between two objects. In C# language, this is correct. But in knowledge base a slightly different behavior should be required. Let's state an example. We have class "Person" and it has property representing a set of e-mail addresses. Data type of this set will be some collection (in C# language probably a list of strings (List<string>)). The relation is that person has its own list of strings, which contains his e-mail addresses. But the aim of knowledge base is aim to capture the knowledge "person and his e-mails", not "person and his list, containing emails". Therefore this decomposition can be made into multiple roles realizing relation between concrete person and one of its e-mail addresses. But, in this behavior the exact mapping between origin C# code and created knowledge base is lost. Therefore, developer can choose which one of those behavior he will prefer.

As same as in object oriented paradigm not all data types are public and visible to everybody, developer can make decision which of the source data-types will be used to create concept added into knowledge base. Some types can be omitted due to their irrelevance; some may be too complex and will make the knowledge base unnecessarily difficult. Therefore, developer has to mark which types he would like to include in the knowledge base.

As mentioned in the introduction, one of the aims is to have the source code intact. Therefore there are two ways how to achieve that. First one, external, uses xml file to define requested behavior, second one inserts requested info directly into source code. Internal approach is more intuitive and will be explained as first.

This approach uses predefined attributes to define which classes and how will be transformed into concepts; and also, which of its properties will be used. XReasoner defines two attributes:

- EKnowledgeClassAttribute – only classes with this attribute will be converted into concepts. This attributes also defines three properties: a) name – which defines name of the created concept (default name created from class name will be created if not specified); b) IdentityProperties – string defining which properties uniquely define the instances of the concept (s.t. like primary key in databases) – it is used later, in A-Box instantialization; c) URIs – string defining the unique resource identifier(s) for the project – it will be used in knowledge base sharing and is expected if two different concepts (from different sources) have the same URI, then they represents the same object in the real world.

- EKnowledgePropertyAttribute – only properties marked with this attribute will be used to represents roles of the parent class/concept. Again, it has two properties: a) IsIdentity – with the same meaning as above, but is specified for property directly; b) URIs with the same meaning as above, but for role.

Simple example of this approach follows (irrelevant parts of file are dotted):

```
using ENG.XReasoner.AssemblyAnalyser.Attributes;

namespace Solution
{
  [EKnowledgeClass(
    Name="Person",
    IdentityProperties="BornNumber",
    URIs="http://.../Person")]
  public class Person
  {
    [EKnowledgeProperty(IsIdentity=true)]
    public string BornNumber { get; set; }
    [EKnowledgeProperty()]
    public string Name { get; set; }
  }
}
```

This, intensional, approach is more difficult, because all required classes/concepts have to be marked with the attribute, but a developer has exact control over the process.

Extensional approach uses xml file to define requested behavior. Upper file can be created accordingly to DTD file (supplied with XReasoner solution), and (briefly) may looks like this (irrelevant parts of file are dotted):

```
<?xml version="1.0" encoding="utf-8" ?>
<!DOCTYPE …>
<EKnowledge>
  <TBox>
    <Assembly nameRgx=".+">
      <Behavior
        conceptNaming="fullClassName"
        includePropertiesRgx=".*"
        expandEnumerations="false" />
      <Concepts>
        <Concept
          typeName="Person" explicitName="Person" >
          <Property name="BornNumber"
          isIdentity="true" />
          <Property name="Name" isIdentity="false" />
          <Property name="Addresses" isIdentity="false" />
        </Concept>
        <ConceptRgx typeNameRgx=".*" >
        </ConceptRgx>
      </Concepts>
      <Others></Others>
    </Assembly>
  </TBox>
…
</EKnowledge>
```

Simple explanation of presented elements follows.

EKnowledge element covers the whole behavior of the XReasoner system, including not only how the knowledge base is defined, but also how is shared via web services (if any).

TBox element defines how the T-Box is created. This element contains of definition for one or more assembly.

Assembly element defines how the assembly will be treated. The “nameRgx” attribute defines which assemblies will be processed with this element’s setting. It is regular expression, which is matched against full assembly name. If assembly name matches more than one definition, first suitable is taken.

In the assembly, default behavior can be set. This element specifies, how the concepts will be named (is used only for classes/concepts without explicit name specification). Options are to use class name without namespace (here can arise problem with two classes with the same names, which cannot be later treated anyway!), or full class name used, including preceding namespaces. Second attribute, “includePropertiesRgx”, defines which properties will be included as roles of concept (if there is no explicit definition for concept). Again, this is regular expression which will be matched against property name (those names are distinct within class). Last parameter refers to the first paragraph of this chapter and defines, if enumerations (or collections) are expanded into special concept instance, or if multiple roles are created for each element of enumeration (collection). This dilemma has been explained above.

Next part contains definition for concept and conceptRgx elements, both nested under Concepts element.

Concept element describes behavior of one exact class/concept. It defines name of type (obligatory), explicit name for created concept (if any, default will be used), may contains behavior specification (same as explained before) and set of elements “Properties”. Those elements explicitly define which properties will be used to define role.

ConceptRgx element is definition which will be applied on all concepts matching “typeNameRgx” regural expression. Again, expression is matched against full type name. Moreover, ConceptRgx element can contain behavior specification (in the same format as mentioned for assembly element), which is expected to be more specific than any upper one.

There is implementation in the XReasoner solution, the classes “Analyser” and “Converter”. First one takes into its public static function “Analyse” two parameters: 1) name of assembly/list of names of the assemblies, which will be proceeded; 2) name of the xml file containing the definition mentioned in explicit approach explanation. The second one can be omitted (can be “null”). The result of the process will be set of some intermediate info defines which classes and how will be transformed. Second class, “Converter”, contains static function “Convert”, which accepts one argument in the input. It is the result of the “Analyse” function. This transformation produces a set of formulas (in the set of datatypes of XReasoner solution), which can be directly added into XReasoner knowledge base instance.

C. A-Box introduction

A-Box creation is the process where the instances of classes of the project are taken and transformed into instances of concepts and relations between those instances. From the previous part of transformation, there are defined concepts and roles in the terminological box of the knowledge base.

Obtaining instances of classes is a lot tricky, because it may include many different sources (database, xml files, multiple collections in the memory), in which may be the same instances (that means, instances representing the same real object) multiple, sometimes with changed properties, or may contain a lot of unnecessary individuals. Therefore it is required to involve the developer in this process. He has to specify how the instances are achieved and passes for the XReasoner. Its task is to achieve the instances only, analysis and parsing of the instances is made by XReasoner’s classes and is done according to created concepts and roles in the previous part of process.

Physically, the task for the developer is to create a class containing two static methods. They have a simple purpose, but, of course, implementation can be difficult.

First method is used to return names for all instances of current concept. The input for the method is name of the concept (this name must match with the created concept name in the previous part, obviously). The reason for this method is really only to return instance names (that means identifiers) only, it is not necessary to load those objects fully with their properties. This method is used to create list of all instances of current concept.

Second one is used to return all roles for the current instance. It accepts one parameter, defining the name of the instance, and returns a fully loaded object, which will be converted into the instances and roles for the knowledge base.

There is one major issue which is very important and must be taken into account. The presented mechanism, created by the developer, has to always assign the same identifier to the same object, regardless of the state or time of the program. That means, if e.g. person “Michal” changes its name (between calling those two methods) to “Marek”, it have to return still the same identifier. There are two intuitive ways how to assure this: a) create identifier by combination of identity properties (or primary keys). This can assure that instance can have recognizable identifier, bud brings more work for the developer, because he needs implement this for every class/concept in the project. Second approach profits (in the Microsoft .NET technology) from the method derived from highest abstract class “Object” to all its descendants (that are all classes). Every class has method “GetHashCode()”, which should be unique for every instance and therefore can be used to return the unique identifier. However, hash codes are quite long and absolutely unreadable for humans, so person analyzing the knowledge base will not see what every instance is on the first sight.

D. A-Box implementation

The main principle was already explained in previous part of the article.

The implementation of the developer (the created class) has not to implement any specific interface or derive from any class. Therefore, this class can be included in original project. However, developer can inherit from interface presented in XReasoner solution to ensure he uses correct parameters and return types.

As the implementation suggests, XReasoner mechanism again uses reflection to invoke defined methods with requested parameters and achieve requested information. It is done by class named “InstanceExtractor“. This class offers some methods to create knowledge base. According to invoked method and passed parameter it is able to return instances’ names only, as well full instance definition with all roles. The result of this methods are again processed by the “Converter” class, which creates set of formulas (defining instances in the set of data-types of XReasoner solution), which can be directly added into XReasoner knowledge base.

V. Conclusion

There are a lot of information systems, or at least programs, which does not use any of knowledge representation approaches. There can be a motivation for developers to extend already implemented systems, or include this approach to currently developed systems. This article brings simple way how the existing solution can be extended to offer knowledge representation without any penetrative changes in the origin source code. What is not covered by this article, this extension can later be used to next deduction over created knowledge base, and also for sharing partial or full knowledge base using web services and definitions of URIs for selected concepts.

***Abstract*—We extend our previous works of deriving linguistic summaries of time series using a fuzzy logic approach to linguistic summarization. We proceed towards a multicriteria analysis of summaries by assuming as a quality criterion Yager's measure of informativeness of classic and temporal protoforms that combines in a natural way the measures of truth, focus and specificity, to obtain a more advanced evaluation of summaries. The use of the informativeness measure for the purpose of a multicriteria evaluation of linguistic summaries of time series seems to be an effective and efficient approach, yet simple enough for practical applications. Results on the summarization of quotations of an investment (mutual) fund are very encouraging.**

I. Introduction

WITH this paper we continue our previous works (cf. Kacprzyk, Wilbik, Zadrożny [1], [2], [3] or Kacprzyk, Wilbik [4], [5], [6]) which deal with the problem of how to effectively and efficiently support humans in making decisions concerning investments in some financial, notably in investment (mutual) funds. Decision makers are here mainly interested in future gains/losses. However, we follow the decision support paradigm, that is, we assume that the users are autonomous and we only support, not replace, him/her. We do not intend to forecast the future daily prices.

The available information concerns the history, or past, and this implies some problems. Basically in all investment decisions the future is the most important, and the past is irrelevant. But, we know only the the past, and the future is completely unknown. Behavior of the human being is to a large extent driven by his/her (already known) past experience. People usually tend to assume that what has happened in the past will also happen (to some, maybe large extent) in the future. By the way, this is the underlying assumption behind the statistical methods too! That attitude clearly implies that the past can be employed to help the human decision maker find a good solution. We follow here this path, i.e. we present a method to subsume the past, to be more specific the past performance of an investment (mutual) fund, by presenting results in a very human consistent way, using natural language statements.

This line of reasoning has often been articulated by many well known investment practitioners, and one can quote here some more relevant opinions. In any information leaflets of investment funds, one may always notice a disclaimer stating that "Past performance is no indication of future returns" which is true. However, on the other hand, for instance, in a well known posting "Past Performance Does Not Predict Future Performance" [7], they state something that may look strange in this context, namely: "…according to an Investment Company Institute study, about 75% of all mutual fund investors mistakenly use short-term past performance as their primary reason for buying a specific fund". But, in an equally well known posting "Past performance is not everything" [8], they state: "…disclaimers apart, as a practice investors continue to make investments based on a schemes past performance. To make matters worse, fund houses are only too pleased to toe the line by actively advertising the past performance of their schemes leading investors to conclude that it is the single-most important parameter (if not the most important one) to be considered while investing in a mutual fund scheme".

As strange as this may be, we may ask ourselves why it is so. Again, in a well known posting "New Year's Eve: Past performance is no indication of future return" [9], they say "…if there is no correlation between past performance and future return, why are we so drawn to looking at charts and looking at past performance? I believe it is because it is in our nature as human beings …because we don't know what the future holds, we look toward the past …".

And, continuing along this line of reasoning, we can find many other examples of similar statements supporting our position. For instance, Myers [10] says: "…Does this mean you should ignore past performance data in selecting a mutual fund? No. But it does mean that you should be wary of how you use that information …*Lousy performance in the past is indicative of lousy performance in the future…*". And, further: Bogle [11] states: "... there is an important role that past performance can play in helping you to make your fund selections. While you should disregard a single aggregate number showing a fund's past long-term return, you can learn a great deal by studying the *nature of its past returns*. Above all, look for consistency.". In [12], we find: "While

978-83-60810-27-9/09/$25.00 © 2010 IEEE

past performance does not necessarily predict future returns, it can tell you how volatile a fund has been". In the popular "A 10-step guide to evaluating mutual funds" [13], they say in the last, tenth, advise: "Evaluate the funds performance. Every fund is benchmarked against an index like the S&P500, BSE 200, etc. Investors should compare fund performance over varying time frames vis-a-vis both the benchmark index and peers. Carefully evaluate the funds performance across market cycles particularly the downturns".

We can quote more, and basically all of them stress the importance of looking at the past to help make future decisions, and also generally advocate a more comprehensive look not focused on single values but a very essence of past behavior and returns.

We have followed this line of reasoning in our past papers (cf. Kacprzyk, Wilbik, Zadrożny [1], [2], [3] or Kacprzyk, Wilbik [4], [5], [6]), i.e. to try to find a human consistent, fuzzy quantifier based scheme for a linguistic summarization of the past in terms of various aspects of how the time series representing daily quotations of the investment fund(s) behave. However, we have mainly concentrated on a sheer absolute performance, i.e. the time evolution of the quotations themselves. This may be relevant, and sometimes attractive to the users who can see a summary of their gains/loses and their temporal evolution. One can also use a maybe more realistic approach to take into account benchmarks of the particular funds as points of departure which does not change the essence.

Though the use of linguistic data summaries of past performance of the time series representing mutual fund quotations does take into account the importance (or "value") of time, in this paper we will go deeper into this issue by using some results from psychology, cognitive sciences and human decision making. Basically, we will employ some results by Ariely and Zakay [14] who consider the role of time in decision making.

In our case, those psychological analyses served the purpose of suggesting, and/or justifying a new types of protoforms of linguistic summaries of time series. Basically, in most of our works (cf. Kacprzyk, Wilbik, Zadrożny [1], [2], [3] or Kacprzyk, Wilbik [4], [5], [6]) we have used the following protoforms of the linguistic summaries of times series: "Among all y's, Q are P", exemplified by "among all segments (of the time series) most are slowly increasing", and "Among all R segments, Q are P", exemplified by "among all short segments almost all are quickly decreasing". Notice that we took into account, and so to say assign the same weights, the entire time series, i.e. all the segment.

Since in our case the analysis of time series is a highly human focused activity because its very purpose is to provide a human decision maker with some support for making (future) decision, we should take into account some inherent characteristics of time series and their evaluations that are consistent with the human perception of their relevance for the decision making process. One of the crucial aspects in this respect, which will be considered here is the importance of time in the sense that means and ends, like decisions and outcomes, have a carrying relevance and impact depending on the time moment when they occur. Basically, in virtually all cases what occurs in a more immediate past is more relevant and meaningful that what has occurred earlier. This temporal relationships change both the decisions and their evaluation as has been shown in psychology (cf. Ariely and Zakay [14] or Rachlin [15]). Among many approaches one can mention, for instance, a so called *temporal construal theory* by Liberman and Trope [16] who have shown that options are evaluated differently depending on time instants they come into question. They introduce the two main characteristics of options: desirability, which refers to long time wishes or intentions that are far away of their implementation of a decision option, and feasibility, which refers to a short term, close to the implementation characteristics. One can mention other works concerned with similar issues. It should be noted that this fact has already been reflected in (dynamic, or multistage) decision making and control models in which discounting is widely used.

In our context, we proposed(cf. Kacprzyk, Wilbik [17]) to take into account some of those psychological findings related to the importance of time by using different protoforms of linguistic summaries of times series, called *temporal linguistic summaries*. We consider two types of temporal protoforms: "E_T among all y's Q are P", exemplified by "Recently, among all segments, most are slowly increasing", and "E_T among all Ry's Q are P", exemplified by "Initially, among all short segments, most are quickly decreasing"; they both go beyond the classic Zadeh's protoforms.

The analysis of time series data involves different elements but we concentrate on the specifics of our approach. First, we have to to identify the consecutive parts of time series within which the data exhibit some uniformity as to their variability. Some variability must here be neglected, under an assumed granularity. Here, these consecutive parts of a time series are called trends (or segments), and described by straight line segments. That is, we perform first a piece-wise linear approximation of a time series and present time series data as a sequence of trends. The (linguistic) summaries of time series refer to the (linguistic) summaries of (partial) trends as meant above. For the construction of a piecewise linear approximation, we use a modified version of the Sklansky and Gonzalez algorithm (cf. [18]) though many other methods can be used cf. Keogh et al. [19], [20].

The next step is an aggregation of the (characteristic features of) consecutive trends over an entire time span (horizon) assumed. We follow the idea initiated by Yager [21], [22] and then shown more profoundly and in an implementable way in Kacprzyk and Yager [23], and Kacprzyk, Yager and Zadrożny [24], [25], that the most comprehensive and meaningful will be a linguistic quantifier driven aggregation resulting in linguistic summaries of classic protoform exemplified by "Most trends are short" or "Most long trends are increasing" and temporal protoform "Recently most trends are increasing" or "Recently most short trends are increasing".

These summaries are easily derived and interpreted using Zadehs fuzzy logic based calculus of linguistically quantified propositions. A new quality, and an increased generality was obtained by using Zadehs [26] protoforms as proposed by Kacprzyk and Zadrożny [27].

Here we employ the classic Zadehs fuzzy logic based calculus of linguistically quantified propositions in which the degree of truth (validity) is the most obvious and important quality criterion. Some other quality criteria like a degree of specificity, focus, fuzziness, etc. have also been proposed by Kacprzyk and Wilbik [28], [6], [5], [29]. The results obtain clearly indicate that multiple quality criteria of linguistic summaries of time series should be taken into account, and this makes the analysis obviously much more difficult.

As the first step towards an intended comprehensive multi-criteria assessment of linguistic summaries of time series, we propose here a very simple, effective and efficient approach, namely to use quite an old, maybe classic Yagers [30] proposal on an informativeness measure of a linguistic summary which combines, via an appropriate aggregation operator, the degree of truth, focus and specificity.

We illustrate our analysis on a linguistic summarization of daily quotations over an 8 year period of an investment (mutual) fund. We present the characteristic features of trends derived under some reasonable granulations, variability, trend duration, etc.

The paper is in line with some other modern approaches to linguistic summarization of time series. First, one should refer to the *SumTime* project coordinated by the University of Aberdeen, an EPSRC Funded Project for Generating Summaries of Time Series Data[1] in which English summary descriptions of a time series data set are sought by using advanced time series and NLG (natural language generation) technologies [31]. However, the linguistic descriptions obtained do not reflect an inherent imprecision (fuzziness) as in our approach. A relation between linguistic data summaries and NLG is discussed by Kacprzyk and Zadrożny [32], [33].

II. Linguistic Data Summaries

As a *linguistic summary of data (base)* we understand a (usually short) sentence (or a few sentences) that captures the very essence of the set of data, that is numeric, large, and because of its size is not comprehensible for human being.

We use Yager's basic approach [21]. A linguistic summary includes: (1) a summarizer P (e.g. *low* for attribute *salary*), (2) a quantity in agreement Q, i.e. a linguistic quantifier (e.g. *most*), (3) truth (validity) $\mathcal{T}$ of the summary and optionally, (4) a qualifier R (e.g. *young* for attribute *age*).

Thus, a linguistic summary may be exemplified by

$$\mathcal{T}(most \text{ of employees earn } low \text{ salary}) = 0.7 \qquad (1)$$

or in richer (extended) form, including a qualifier (e.g. *young*), by

$$\mathcal{T}(most \text{ of } young \text{ employees earn } low \text{ salary}) = 0.82 \quad (2)$$

Thus, basically the core of a linguistic summary is a linguistically quantified proposition in the sense of Zadeh [26] which may be written, respectively as

$$Qy's \text{ are } P \qquad\qquad QRy's \text{ are } P \qquad (3)$$

III. Linguistic Summaries of Trends

In our first approach we summarize the trends (segments) extracted from time series. Therefore as the first step we need to extract the segments. We assume that segment is represented by a fragment of straight line, because such segments are easy for interpretation.

There are many algorithms for the piecewise linear segmentation of time series data, including e.g. on-line (sliding window) algorithms, bottom-up or top-down strategies (cf. Keogh [19], [20]).

We consider the following three features of (global) trends in time series: (1) dynamics of change, (2) duration, and (3) variability. By *dynamics of change* we understand the speed of change of the consecutive values of time series. It may be described by the slope of a line representing the trend, represented by a linguistic variable. *Duration* is the length of a single trend, and is also represented by a linguistic variable. *Variability* describes how "spread out" a group of data is. We compute it as a weighted average of values taken by some measures used in statistics: (1) the range, (2) the interquartile range (IQR), (3) the variance, (4) the standard deviation, and (5) the mean absolute deviation (MAD). This is also treated as a linguistic variable.

For practical reasons for all we use a fuzzy granulation (cf. Bathyrshin at al. [34], [35]) to represent the values by a small set of linguistic labels as, e.g.: increasing, slowly increasing, constant, slowly decreasing, decreasing. These values are equated with fuzzy sets.

For clarity and convenience we employ Zadeh's [36] protoforms for dealing with linguistic summaries [27]. A protoform is defined as a more or less abstract prototype (template) of a linguistically quantified proposition. We have two types of protoforms of linguistic summaries of trends:
– a short form:

$$\text{Among all segments, } Q \text{ are } P \qquad (4)$$

e.g.: "Among all segments, *most* are *slowly increasing*".
– an extended form:

$$\text{Among all } R \text{ segments, } Q \text{ are } P \qquad (5)$$

e.g.: "Among all *short* segments, *most* are *slowly increasing*".

We can extend our protoforms given in (4) and (5) by adding a temporal expression, E_T, like: "recently", "in the very beginning" or "in May 2010", "initially", etc. (cf. Kacprzyk, Wilbik [17]). The temporal protoforms can have the following forms:

- a simple (short) protoform:

$$E_T \text{ among all segments, } Q \text{ are } P \qquad (6)$$

[1] cf. www.csd.abdn.ac.uk/research/sumtime/

e.g.: "*Recently*, among all segments, *most* are *slowly increasing*".

- an extended protoform:

$$E_T \text{ among all } R \text{ segments, } Q \text{ are } P \tag{7}$$

e.g.: "*Initially*, among all *short* segments, *most* are *slowly increasing*".

The quality of linguistic summaries can be evaluated in many different ways, eg. using the degree of truth, specificity, appropriateness or others.

Yager [30] proposed measure of informativeness, a measure that evaluates the amount of information hidden in the summary. This measure is interesting as it aggregates some of previously mentioned quality criteria, namely the truth value, degree of specificity and degree of focus in the case of extended form summaries. Now we will present shortly those 3 measures.

A. Truth Value

The truth value (a degree of truth or validity), introduced by Yager in [21], is the basic criterion describing the degree of truth (from $[0, 1]$) to which a linguistically quantified proposition equated with a linguistic summary is true.

Using Zadeh's calculus of linguistically quantified propositions [26] it is calculated in dynamic context using the same formulas as in the static case. Thus, the truth value is calculated for the simple and extended form as, respectively:

$$\mathcal{T}(\text{Among all } y\text{'s, } Q \text{ are } P) = \mu_Q\left(\frac{1}{n}\sum_{i=1}^{n}\mu_P(y_i)\right) \tag{8}$$

$$\begin{aligned}&\mathcal{T}(\text{Among all } Ry\text{'s, } Q \text{ are } P) =\\ &= \mu_Q\left(\frac{\sum_{i=1}^{n}\mu_R(y_i)\wedge\mu_P(y_i)}{\sum_{i=1}^{n}\mu_R(y_i)}\right)\end{aligned} \tag{9}$$

where μ_P, μ_R and μ_Q are membership functions of fuzzy set representing summarizer, qualifier and linguistic quantifier, respectively. $\wedge$ is the minimum operation (more generally it can be another appropriate operator, notably a t-norm). In Kacprzyk, Wilbik and Zadrożny [37] results obtained by using different t-norms were compared. Various t-norms can be in principle used in Zadeh's calculus but clearly their use may result in different results of the linguistic quantifier driven aggregation. It seems that the minimum operation is a good choice since it can be easily interpreted and the numerical values correspond to the intuition.

The computation of truth values of temporal summaries is very similar to the previous case. We only need to consider a temporal expression as an additional external qualifier, as the temporal expression limits the universe of interest to those trends (segments) only that occur on the time axis described by a fuzzy set modeling the expression E_T. We compute the proportion of segments in which "trend is P" and occurs in E_T to those that occur in E_T. Next, we compute the degree to which this proportion is Q.

The truth value of the simple temporal protoform (6) is computed as:

$$\begin{aligned}&\mathcal{T}(E_T \text{ among all } y\text{'s, } Q \text{ are } P) =\\ &= \mu_Q\left(\frac{\sum_{i=1}^{n}\mu_{E_T}(y_i)\wedge\mu_P(y_i)}{\sum_{i=1}^{n}\mu_{E_T}(y_i)}\right)\end{aligned} \tag{10}$$

where $\mu_{E_T}(y_i)$ is the degree to which a trend (segment) occurs during the time span described by E_T.

Similarly we compute the truth of the extended temporal protoform (7) as:

$$\begin{aligned}&\mathcal{T}(E_T\text{Among all } Ry\text{'s, } Q \text{ are } P) =\\ &= \mu_Q\left(\frac{\sum_{i=1}^{n}\mu_{E_T}(y_i)\wedge\mu_R(y_i)\wedge\mu_P(y_i)}{\sum_{i=1}^{n}\mu_{E_T}(y_i)\wedge\mu_R(y_i)}\right)\end{aligned} \tag{11}$$

A natural question emerges of how to compute $\mu_{E_T}(y_i)$. Let $\mu_{E_T}(t)$ be a membership function of a fuzzy set representing a linguistic variable E_T. We assume that the time span considered is normalized, i.e. $t \in [0, 1]$, the first observation is made for $t = 0$ and the last for $t = 1$. Let us consider a segment y_i, starting at time a and terminating at time b, $0 \leq a < b \leq 1$. Then

$$\mu_{E_T}(y_i) = \frac{1}{b-a}\int_a^b \mu_{E_T}(t)dt \tag{12}$$

and we can interpret this value as the average membership degree of E_T in $[a, b]$. Graphically it can be represented as the gray stripped area divided by the stripped area in Figure 1.

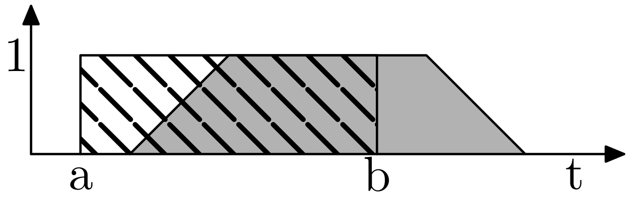

Fig. 1. Graphical presentation of $\mu_{E_T}(y_i)$

B. Degree of Specificity

The concept of specificity provides a measure of the amount of information contained in a fuzzy subset or possibility distribution. The specificity measure evaluates the degree to which a fuzzy subset points to one and only one element as its member [38].

We will consider the original Yagers proposal [38], in which specificity measures the degree to which a fuzzy subset contains one and only one element. The measure of specificity is a measure $Sp : I^X \longrightarrow I$, $I \in [0, 1]$ if it has the following properties: (1) $Sp(A) = 1$ if and only if $A = \{x\}$, (is a singleton set), (2) $Sp(\varnothing) = 0$, and (3) $\frac{\partial Sp(A)}{\partial a_1} > 0$ and $\frac{\partial Sp(A)}{\partial a_j} \leq 0$ for all $j \geq 2$.

In [39] Yager proposed a measure of specificity as

$$Sp(A) = \int_0^{\alpha_{max}} \frac{1}{card(A_\alpha)}d\alpha \tag{13}$$

where α_{max} is the largest membership grade in A, A_α is the α-level set of A, (i.e. $A_\alpha = \{x : \mu_A(x) \geq \alpha\}$) and $card(A_\alpha)$ is the number of elements in A_α.

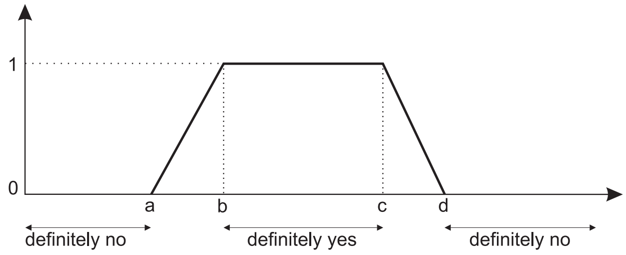

Fig. 2. A trapezoidal membership function of a set

In our summaries to define the membership functions of the linguistic values we use trapezoidal functions, as they are sufficient in most applications [40]. Moreover, they can be very easily interpreted and defined by a user not familiar with fuzzy sets and logic, as in Figure 2. To represent a fuzzy set with a trapezoidal membership function we need to store only four numbers, a, b, c and d. Usage such a definition of a fuzzy set is a compromise between cointension and computational complexity. In such a case measure of specificity of a fuzzy set A

$$Sp(A) = 1 - \frac{c + d - (a + b)}{2} \tag{14}$$

C. Degree of Focus

The very purpose of a degree of focus is to limit the search for the best linguistic summaries by taking into account some additional information in addition to truth values. The extended protoform linguistic summaries (5) does limit by itself the search space as the search is performed in a limited subspace of all (most) trends that fulfill an additional condition specified by qualifier R. The very essence of the degree of focus introduced in this paper is to give the proportion of trends satisfying property R to all trends extracted from the time series. It provides a measure that, in addition to the basic truth value, can help control the process of discarding non-promising linguistic summaries.

The *degree of focus* is similar in spirit to a degree of covering, described above, but it measures how many trends fulfill property R. The degree of focus makes obviously sense for the extended protoform summaries only, and is calculated as (cf. Kacprzyk and Wilbik [29]):

$$d_{foc}(\text{Among all } Ry\text{'s, } Q \text{ are } P) = \frac{1}{n}\sum_{i=1}^{n} \mu_R(y_i) \tag{15}$$

In our context, the degree of focus describes how many trends extracted from a given time series fulfill qualifier R in comparison to all extracted trends. If the degree of focus is high, then we can be sure that such a summary concerns many trends, so that it is more general. However, if the degree of focus is low, we may be sure that such a summary describes a (local) pattern seldom occurring.

The formula for the degree of focus for the extended temporal protoform requires small changes. The temporal expression may be treated as the external qualifier, and we can compute the proportion of trends satisfying property R in the E_T time span to all trends occurring in that time span. So the degree of focus of extended temporal protoform summaries (7) is computed as:

$$\begin{aligned} & d_{foc}(E_T \text{ among all } Ry\text{'s, } Q \text{ are } P) = \\ & = \frac{\sum_{i=1}^{n} \mu_{E_T}(y_i) \wedge \mu_R(y_i)}{\sum_{i=1}^{n} \mu_{E_T}(y_i)} \end{aligned} \tag{16}$$

Here also the degree of focus help us distinguish more general summaries from those describing a (local) pattern seldom occurring.

As we wish to discover a more general, global relationship, we can eliminate the linguistic summaries that concern a small number of trends only. The degree of focus may be used to eliminate the whole groups of extended form summaries for which qualifier R limits the set of possible trends to, for instance, 5%. Such summaries, although they may be very true, will not be representative.

We could think also about an additional measure similar to the degree of focus for the temporal protoforms – a degree of focus of temporal expression. This degree could measure how many trends extracted from a given time series occurs in the time span described by E_T in comparison to all extracted trends. Hence, for the simple and extended temporal protoform summaries we have:

$$d_{E_T}(E_T \text{ among all } Ry\text{'s, } Q \text{ are } P) = \frac{1}{n}\sum_{i=1}^{n} \mu_{E_T}(y_i) \tag{17}$$

D. Measure of Informativeness

The idea of a measure of informativeness (cf. Yager, Ford and Canas [30]) may be summarized as follows. Suppose we have a data set, whose elements are from measurement space X. One can say that the data set itself is its own most informative description, and any other summary implies a loss of information. So, a natural question is whether a particular summary is informative, and to what extent.

Yager et. al [30] proposed the following *measure of informativeness* of a simple protoform summary

$$\begin{aligned} & I(\text{Among all } y\text{'s } Q \text{ are } P) = \\ & = (\mathcal{T} \cdot Sp(Q) \cdot Sp(P)) \vee ((1 - \mathcal{T}) \cdot Sp(Q^c) \cdot Sp(P^c)) \end{aligned} \tag{18}$$

where P^c is the negation of P, i.e. $\mu_{P^c}(\cdot) = 1 - \mu_P(\cdot)$ and Q^c is the negation of Q, i.e. $\mu_{Q^c}(\cdot) = 1 - \mu_Q(\cdot)$. $Sp(Q)$ is specificity of Q, similarly it is calculated for Q^c, P and P^c.

For the extended protoform summary we propose the following measure (cf. Kacprzyk and Wilbik [41]):

$$\begin{aligned} I(\text{Among all } Ry\text{'s } Q \text{ are } P) &= \\ = \; & (\mathcal{T} \cdot Sp(Q) \cdot Sp(P) \cdot Sp(R) \cdot d_{foc}) \\ & \vee ((1 - \mathcal{T}) \cdot Sp(Q^c) \cdot Sp(P^c) \cdot Sp(R) \cdot d_{foc}) \end{aligned} \tag{19}$$

where d_{foc} is the degree of focus of the summary, $Sp(R)$ is specificity of qualifier R and the rest is defined as previously.

The measure of informativeness of the simple temporal protoform summary is calculated as:

$$\begin{aligned} &I(E_T \text{ among all } y\text{'s } Q \text{ are } P) = \\ &= \ (\mathcal{T} \cdot Sp(Q) \cdot Sp(P) \cdot Sp(E_T) \cdot d_{E_T}) \\ &\quad \vee ((1-\mathcal{T}) \cdot Sp(Q^c) \cdot Sp(P^c) \cdot Sp(E_T) \cdot d_{E_T}) \end{aligned} \quad (20)$$

where $Sp(E_T)$ is the specificity of the temporal expression and d_{E_T} is the degree of focus of temporal expression defined as in Eq. (17).

The measure of informativeness of the extended temporal protoform summary is calculated as:

$$\begin{aligned} &I(E_T \text{ among all } Ry\text{'s } Q \text{ are } P) = \\ &= \ (\mathcal{T} \cdot Sp(Q) \cdot Sp(P) \cdot Sp(E_T) \cdot Sp(R) \cdot d_{foc} \cdot d_{E_T}) \\ &\quad \vee ((1-\mathcal{T}) \cdot Sp(Q^c) \cdot Sp(P^c) \cdot Sp(E_T) \cdot Sp(R) \cdot \\ &\qquad \cdot d_{foc} \cdot d_{E_T}) \end{aligned} \quad (21)$$

Here in those formulas different values are aggregated by the product. We could think of using instead of the product other t-norms. However, for example, the minimum would ignore all values that are smaller than the largest one, and the Łukasiewicz t-norm tends to be very small if we aggregate many numbers. Moreover, the product may be a natural choice taking into account many results from, for instance, decision analysis and mathematical economics.

IV. Numerical Results

The method proposed was tested on data on quotations of an investment (mutual) fund that invests at least 50% of assets in shares listed at the Warsaw Stock Exchange.

Data shown in Figure 3 were collected from January 2002 until the December 2009 with the value of one share equal to PLN 12.06 in the beginning of the period to PLN 35.82 at the end of the time span considered (PLN stands for the Polish Zloty). The minimal value recorded was PLN 9.35 while the maximal one during this period was PLN 57.85. The biggest daily increase was equal to PLN 2.32, while the biggest daily decrease was equal to PLN 3.46. We illustrate the method proposed by analyzing the absolute performance of a given investment fund, and not against benchmarks, for illustrativeness.

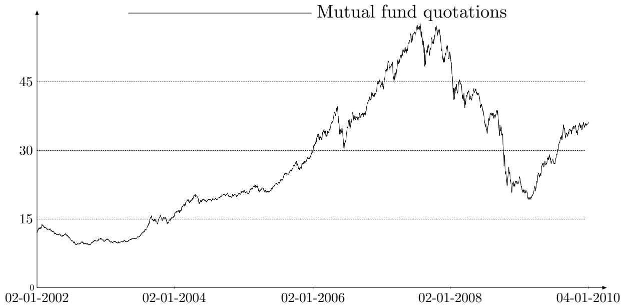

Fig. 3. Daily quotations of an investment fund in question

We obtain 362 extracted trends, with the shortest of 1 time unit only, and the longest – 71 time units. We assume 3 labels only for each attribute: short, medium and long for duration, increasing, constant and decreasing for dynamics and low, moderate and high for variability. The use of linguistic values in the summaries is clearly a reflection of a natural information granulation.

In Table I there are presented the most valid summaries of the classic protoforms. They are ordered according to the degree of truth and then the degree of focus.

TABLE I
Summaries of the classic protoform

linguistic summary	$\mathcal{T}$	d_{foc}	I
Among all y, most are short	1.0000	1.0000	0.4675
Among all moderate y, most are short	1.0000	0.3453	0.0969
Among all decreasing y, most are short	1.0000	0.2267	0.0604
Among all increasing y, most are short	1.0000	0.1688	0.0450
Among all medium y, most are constant	1.0000	0.1394	0.0429
Among all medium y, most are constant and high	1.0000	0.1394	0.0778
Among all medium y, most are high	1.0000	0.1394	0.0349
Among all medium and constant y, most are high	1.0000	0.1366	0.0794
Among all medium and high y, most are constant	1.0000	0.1222	0.0780
Among all high y, most are short	0.8453	0.5789	0.1601
Among all constant y, most are short	0.8341	0.6045	0.2027
Among all high y, most are constant	0.8164	0.5789	0.1565
Among all constant y, most are high	0.7564	0.6045	0.1514

We may notice that the first summary has a very big value of the measure of the informativeness, and this summary is of a simple protoform. It is very informative. Also the last four summaries presented in Table I are interesting, as their values of this measure are quite high. Those summaries do not have the truth value equal to 1, but nevertheless they are also true, moreover they have very high values of degree of focus, indicating that these summaries describe pattern which are quite often occuring.

In Table II we may see the temporal summaries decribing that time series. Me may notice the summaries of the first few years after the the fund wa established (initially), then the middle time (in the middle), and the last two summaries describe more or less ime qotations from autumn 2007, when the finantial crisis started.

The obtained summaries are divide into 2 groups, each describing separate period. The first group describes what was happening initially. First 4 summaries have high values of the measure of informativeness. Especially interesting is the summary "initially among all y, most are constant and very high", it has the value of this measure higher than a summary with only one of the linguistic values used in the summary.

In the second group, only one summary stand out –"middle among all y, most are constant", with a value of the measure of informativeness over twice as big than the other values. We may notice that this value is also the biggest for all summaries presented in Table II. It is partially so, because the temporal expression "in the middle" describes the longest period.

In the last group describing the last 2 years – the time of financial crisis, we obtained just 2 summaries, from which the

TABLE II
SUMMARIES OF THE TEMPORAL PROTOFORM

linguistic summary	$\mathcal{T}$	d_{foc}	I
initially among all constant y, most are very high	1.0000	1.0000	0.0329
initially among all y, most are constant	1.0000	1.0000	0.0387
initially among all y, most are constant and very high	1.0000	1.0000	0.0770
initially among all y, most are very high	1.0000	1.0000	0.0383
initially among all very high y, most are constant	1.0000	0.8089	0.0266
initially among all long and constant y, most are very high	1.0000	0.3566	0.0213
initially among all long y, most are constant	1.0000	0.3566	0.0097
initially among all long y, most are constant and very high	1.0000	0.3566	0.0192
initially among all long y, most are very high	1.0000	0.3566	0.0096
initially among all medium and constant y, most are very high	1.0000	0.3292	0.0214
initially among all medium and very high y, most are constant	1.0000	0.3292	0.0215
initially among all medium y, most are constant	1.0000	0.3292	0.0107
initially among all medium y, most are constant and very high	1.0000	0.3292	0.0212
initially among all medium y, most are very high	1.0000	0.3292	0.0106
initially among all very long y, most are constant	1.0000	0.3230	0.0069
initially among all long and very high y, most are constant	1.0000	0.2947	0.0177
initially among all very long and very high y, most are constant	1.0000	0.1939	0.0105
initially among all high y, most are constant	1.0000	0.1911	0.0059
initially among all very long and high y, most are constant	1.0000	0.1291	0.0068
initially among all high y, most are very long	0.7518	0.1911	0.0028
initially among all high y, most are very long and constant	0.7518	0.1911	0.0073
middle among all very high y, most are constant	1.0000	0.4860	0.0481
middle among all medium y, most are constant	1.0000	0.3205	0.0312
middle among all high y, most are short	1.0000	0.2436	0.0249
middle among all medium and very high y, most are constant	1.0000	0.2422	0.0476
middle among all short and very high y, most are constant	1.0000	0.1094	0.0228
middle among all y, most are constant	0.9659	1.0	0.1124
middle among all medium y, most are very high	0.9113	0.3205	0.0281
middle among all short y, most are constant	0.8506	0.4794	0.0447
middle among all medium and constant y, most are very high	0.8484	0.2840	0.0470
middle among all moderate y, most are short	0.8188	0.2741	0.0200
middle among all short and moderate y, most are constant	0.8084	0.1945	0.0301
middle among all moderate y, most are constant	0.8010	0.2741	0.0179
from the crisis begin among all medium y, most are constant	1.0000	0.2273	0.0513
from the crisis begin among all decreasing y, most are very short	0.9887	0.1438	0.0294

first one is more informative than the other, nevertheless both seems to be interesting for the experts.

V. CONCLUDING REMARKS

We extended our approach to the linguistic summarization of time series towards a multicriteria analysis of classic and temporal summaries by assuming as a quality criterion Yager's measure of informativeness that combines in a natural way the measures of truth, focus and specificity. Results on the summarization of quotations of an investment (mutual) fund are very encouraging.

Workshop on Agent Based Computing: from Model to Implementation VII

The field of agent technology is rapidly maturing. One of key factors that influence this process is the gathered body of knowledge that allows in-depth reflection on the very nature of designing and implementing agent systems. As a result, we know better how to design and implement them. We also understand the most important issues to be addressed in the process. Therefore, on the top-most level we see progress in development of methodologies for design of agent-based systems. Furthermore, these methodologies are usually supported by tools that allow not only top level conceptualization but guide the process towards implementation (e.g. by generating at least some code). Next, we can see that new languages for agent based systems are created, e.g. AML or API Calculus. Separately, tools/platforms/environments that can be used for design and implementation of agent systems have been through a number of releases, eliminating problems and adding new, important features. Resulting products are becoming truly robust and flexible. Furthermore, open source products (e.g. JADE) are surrounded by user communities, which often generate powerful ad-on components, further increasing value of existing solutions.

During the Workshop we are primarily interested in all aspects of the process that leads from the model of the problem domain to the actual agent-based solution. These aspects will cover both principled approaches and established practices of software engineering aimed at producing high quality software. In this context, research into the application of agent-based solutions to key challenges faced by software engineering (e.g. reduction of costs and delivery times, coping with a larger diversity of problems) will be of primary importance.

ABC:MI Workshop welcomes submissions of original papers concerning all aspects of software agent engineering.

Topics include but are not limited to:

- Methodologies for design of agent systems
- Multi-agent systems product lines
- Modeling agent systems
- Agent architectures
- Agent-based simulations
- Simulating and verifying agent systems
- Agent benchmarking and performance measurement
- Agent communication, coordination and cooperation
- Agent languages
- Agent learning and planning
- Agent mobility
- Agent modeling, calculi, and logics
- Agent security
- Agents and Service Oriented Computing
- Agents in the Semantic Web
- Applications and Experiences

***Abstract*—This paper proposes an overview and comparison of mobile agent platforms for the development of wireless sensor network applications. In particular, the architecture, programming model and basic performance of two Java-based agent platforms, Mobile Agent Platform for Sun SPOT (MAPS) and Agent Factory Micro Edition (AFME), are discussed and evaluated. Finally, a simple yet effective case study concerning a mobile agent-based monitoring system for remote sensing and aggregation is proposed. The proposed case study is developed both in MAPS and AFME so allowing to analyze the differences of their programming models.**

***Keywords*: Mobile agent platforms, wireless sensor networks, Java Sun SPOT, finite state machines, intentional agents.**

I. Introduction

Due to recent advances in electronics and communication technologies, Wireless Sensor Networks (WSNs) are currently emerging as one of the most disruptive technologies enabling and supporting next generation ubiquitous and pervasive computing scenarios. A WSN is a network of RF transceivers, sensors, machine controllers, microcontrollers, and user interface devices with at least two nodes communicating by means of wireless transmissions. WSNs have a high potential to support a variety of high-impact applications such as disaster/crime prevention and military applications, environmental applications, health care applications, and smart spaces. However programming WSNs is a complex task due to the limited capabilities (processing, memory and transmission range) and energy resources of each sensor node as well as the lack of reliability of the radio channel. Moreover, WSN programming is usually application-specific (or more generally domain-specific) and requires tradeoffs in terms of task complexity, resource usage, and communication patterns. Therefore the developed software which usually integrates routing mechanisms, time synchronization, node localization and data aggregation is tightly dependent on the specific application and scarcely reusable. Thus to support rapid development and deployment of WSN applications flexible, WSN-aware programming paradigms are needed which directly provide proactive and on-demand code deployment at run-time as well as ease software programming at application, middleware and network layer. Among the programming paradigms proposed for the development of WSN applications [1], the mobile agent-based paradigm [2], which has already demonstrated its effectiveness in conventional distributed systems as well as in highly dynamic distributed environments, can effectively deal with the programming issues that WSNs have posed. In particular, a mobile agent is a software entity encapsulating dynamic behavior and able to migrate from one computing node to another to fulfill distributed tasks. We believe that mobile agents can provide more benefits in the context of WSNs than in conventional distributed environments. In particular, mobile agents can support the programming of WSNs at application, middleware and network levels.

In this paper we present the currently available mobile agent platforms for WSNs which are based either on TinyOS [3] or on Java Sun SPOT [4]. In particular, we focus on MAPS and AFME, the only two available Java-based platforms, by analyzing their architecture, programming model and core performances. Finally they are also exemplified through an effective case study showing the different programming mechanisms of the two platforms.

The rest of this paper is organized as follows. Section II introduces mobile agents, presenting their characteristics and benefits by focusing on the WSN context; moreover, work related to currently available mobile agent systems for WSNs is discussed. Section III describes two Java-based agent platforms (MAPS and AFME) which are also compared with respect to their architecture, programming model and performance. Section IV presents an example application for showing how differently agent behavior can be defined through MAPS and AFME. Finally, conclusions are drawn and on-going research efforts delineated.

II. Mobile Agents for Wireless Sensor Networks

In the context of distributed computing systems and highly dynamic distributed environments, mobile agents are a suitable and effective computing paradigm for supporting the development of distributed applications, services, and protocols [1]. Mobile agents are software processes able to migrate among computing nodes by retaining their execution state (strong mobility). In their seminal paper [2], Lange and Oshima advertised at least seven good reasons for using mobile agents in generic distributed systems. In the following we discuss them by focusing on the WSN context.

1. Network load reduction. Mobile agents are able to access remote resources, as well as communicate with any remote entity, by directly moving to their physical locations and interacting to them locally so that to save bandwidth resources. A mobile agent incorporating data processing capabilities can migrate to a sensor node, perform the needed operations on the sensed data and transmit the results to a sink

[*] Corresponding author

node. This is more desirable, rather than a periodic transmission of raw sensed data from the sensor node to the sink node and the computation of data processing on the latter.

2. Network latency overcoming. An agent provided with proper control logic may move to a sensor/actuator node to locally perform the required control tasks. This overcomes the network latency which will not affect the real-time control operations also in case of lack of network connectivity with the base station.

3. Protocol encapsulation. Suppose that a specific routing protocol supporting multi-hop paths should be deployed in a given zone of a WSN. A set of cooperating mobile agents encapsulating the routing protocol can be dynamically created and distributed into the proper sensor nodes without any regard for standardization matter. Also in case of protocol upgrading, a new set of mobile agents can easily replace the old one at run-time.

4. Asynchronous and autonomous execution. These are distinctive properties of mobile agents and very important in dynamic environments like WSNs where connections may not be stable and network topology may change rapidly. A mobile agent, upon a request, can autonomously travel across the network to gather needed information "node by node" or to carry out the programmed tasks and, finally, can asynchronously report the results to the requester.

5. Dynamic adaptation. Mobile agents can perceive their execution environment and react autonomously to changes. This behavioral dynamic adaptation is well suited for operating on long-running systems like WSNs where environment conditions are very likely to change over time.

6. Orientation to heterogeneity. Mobile agents can act as wrappers among systems based on different hardware and software. This ability can well fit the need for integrating heterogeneous WSNs supporting different sensor platforms or connecting WSN and other networks (like IP-based networks). An agent may be able to translate requests coming from a system into specific suitable requests to submit to another different system.

7. Robustness and fault-tolerance. The ability of mobile agents to dynamically react to unfavorable situations and events (e.g. low battery level) can lead to a better robust and fault tolerant distributed systems (e.g. by migrating all executing agents to an equivalent sensor node so that to continue their operations).

Mobile agents are supported by mobile agent systems (MASs) which basically provide an API for developing agent-based applications, and an agent server able to execute agents by providing them with basic services such as migration, communication, and node resource access. Developing flexible and efficient MASs for WSNs is a challenging and very complex task due to the currently available resource-constrained sensor nodes and related operating systems. Very few MASs for WSNs have been to date proposed and actually implemented. In the following, we discuss Agilla and actorNet, the most significant available research prototypes based on TinyOS

Agilla [5] is an agent-based middleware developed on TinyOS [3] and supporting multiple agents on each node. As shown by its software architecture (see Fig. 1), Agilla provides two fundamental resources on each node: a tuplespace and a neighbors list. The tuplespace represents a shared memory space where structured data (tuples) can be stored and retrieved, allowing agents to exchange information in a decoupling way. A tuplespace can be also accessed remotely. The neighbors list contains the address of all one-hop nodes, needed when an agent has to migrate.

Agents can migrate carrying their code and state, but do not carry their tuples locally stored on a tuplespace. Packets used for nodes communication (e.g. for agent migration/cloning, remote tuples accessing) are very small to minimize messages loss, whereas retransmission techniques are also adopted.

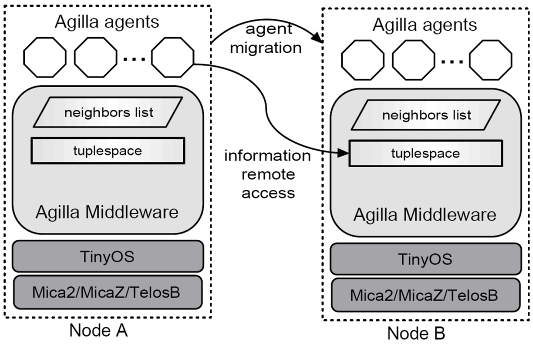

Fig. 1 Agilla software architecture

ActorNet [6] is an agent-based platform specifically designed for Mica2/TinyOS sensor nodes. To overcome the difficulties in allowing code migration and interoperability due to the strict coupling between applications and sensor node architectures, actorNet exposes services like virtual memory, context switching, and multi-tasking. Thanks to these features, it effectively supports agents programming by providing a uniform computing environment for all agents, regardless of hardware or operating system differences. The actorNet architecture is depicted in Fig. 2. The actorNet language used for high-level agent programming, has a syntax and a semantic similar to those of Scheme [7] with proper instructions extension.

Both Agilla and actorNet are designed for TinyOS which is based on the nesC language that is not an object-oriented language but an event- and component-based extension of C. The Java language, through which Sun SPOT [4] and Sentilla JCreate [18] sensors can be programmed, due to its object-oriented features, could provide more flexibility and extendibility for an effective implementation of agent-based platforms. The most significant available Java-based agent platforms for WSNs are MAPS [8, 9, 10] and AFME [11, 12, 13], which are discussed in Section III.

In Table 1, a comparison among the aforementioned agent platform with respect to 7 characteristics (migration, multitasking, communication model, programming language, remote configuration, intentional agents, and sensor platforms) is reported.

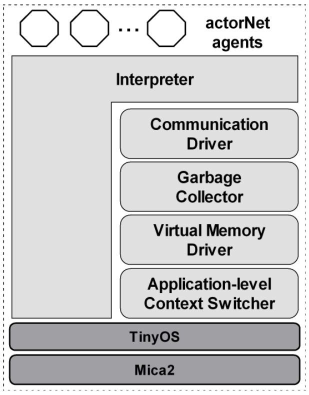

Fig. 2 ActorNet software architecture

TABLE 1
COMPARISON AMONG DIFFERENT WSN MASS

	Agilla	*actorNet*	*MAPS*	*AFME*
Migration	Y	Y	Y	Y
Multitasking	Y	Y	Y	Y
Communication Model	tuple space	messages	messages	messages
Programming Language	proprietary ISA	Scheme-like	Java	Java
Agent Model	Assembler-like	Functional	Finite State Machine	BDI
Intentional Agents	N	N	N	Y
Sensor Platforms	Mica2, MicaZ, TelosB	Mica2	Sun SPOT	Sun SPOT

Agent migration and multitasking, which allows for the execution of multiple agents on the same node, is supported by all the systems. The communication model of Agilla is centered on local tuplespace where agent can asynchronously insert tuples and take tuples left by other agents. Conversely the communication model of the other systems is based on (unicast and broadcast) message-passing. The programming language and model is different among the systems. Agilla is based on a proprietary low-level language composed of an assembler-like instruction set which makes programming of complex agents very difficult. ActorNet is based on a functional Scheme-like language whereas MAPS and AFME on the Java language. Indeed, MAPS uses a finite state machine model to define agent behaviour whereas AFME employs a more complex BDI-like model. Intentional agents are therefore only offered by AFME. Agilla and actorNet run on motes; in particular Agilla on Mica2, MicaZ, and TelosB, whereas actorNet currently only on Mica2. On the contrary MAPS and AFME are based on Sun SPOTs.

III. JAVA-BASED MOBILE AGENT PLATFORMS FOR WSNS

A great variety of Java-based agent platforms have been to date developed for the standard Java virtual machine atop conventional distributed systems. However, in the context of wireless sensor networks, only two Java-based platforms are currently available: MAPS (Mobile Agent Platform for Sun SPOT) and AFME (Agent Factory Micro Edition). While MAPS was specifically conceived for Sun SPOTs, AFME was developed for J2ME enabled PDAs and then ported onto Sun SPOTs. In the following we describe and compare MAPS and AFME with respect to their architecture, programming model and performance.

A. Mobile Agent Platform for Sun SPOTs

MAPS [8, 9, 10] is an innovative Java-based framework expressly developed on Sun SPOT technology for enabling agent-oriented programming of WSN applications. It has been defined according to the following requirement:

- Component-based lightweight agent server architecture to avoid heavy concurrency and agents cooperation models.
- Lightweight agent architecture to efficiently execute and migrate agents.
- Minimal core services involving agent migration, agent naming, agent communication, timing and sensor node resources access (sensors, actuators, flash memory, and radio).
- Plug-in-based architecture extensions through which any other service can be defined in terms of one or more dynamically installable components implemented as single or cooperating (mobile) agent/s.
- Use of Java language for defining the mobile agent behavior.

MAPS architecture (see Fig. 3) is based on components which interact through events and offer a set of services to mobile agents, including message transmission, agent creation, agent cloning, agent migration, timer handling, and easy access to the sensor node resources. In particular, the main components are:

- *Mobile Agent (MA)*. MAs are the basic high-level component defined by user for constituting agent-based applications.
- *Mobile Agent Execution Engine (MAEE)*. It manages the execution of MAs by means of an event-based scheduler enabling lightweight concurrency. MAEE also interacts with the other services-provider components to fulfill service requests (message transmission, sensor reading, timer setting, etc) issued by MAs.
- *Mobile Agent Migration Manager (MAMM)*. This component supports agents migration through the Isolate (de)hibernation feature provided by the Sun SPOT environment [4]. The MAs hibernation and serialization involve data and execution state whereas the code should already reside at the destination node (this is a current limitation of the Sun SPOTs which do not support dynamic class loading and code migration).
- *Mobile Agent Communication Channel (MACC)*. It enables inter-agent communications based on asynchronous messages (unicast or broadcast) supported by the Radiogram protocol.
- *Mobile Agent Naming (MAN)*. MAN provides agent naming based on proxies for supporting MAMM and MACC in their operations. It also manages the (dynamic) list of the neighbor sensor nodes which is updated through a beaconing mechanism based on broadcast messages.

- *Timer Manager (TM)*. It manages the timer service for supporting timing of MA operations.
- *Resource Manager (RM)*. RM allows access to the resources of the Sun SPOT node: sensors (3-axial accelerometer, temperature, light), switches, leds, battery, and flash memory.

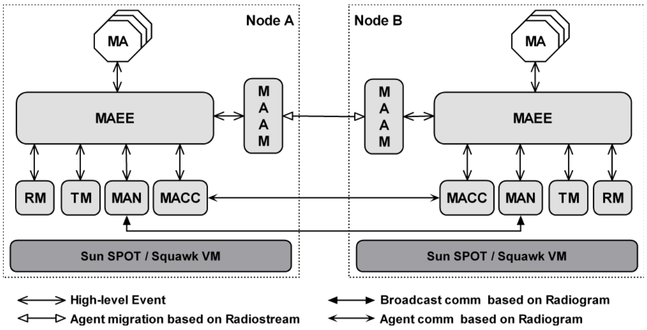

Fig. 3 MAPS software architecture

The dynamic behavior of a mobile agent (MA) is modeled through a multi-plane state machine (MPSM). Each plane may represent the behavior of the MA in a specific role so enabling role-based programming. In particular, a plane is composed of local variables, local functions, and an automaton whose transitions are labeled by Event-Condition-Action (ECA) rules *E[C]/A*, where *E* is the event name, *[C]* is a boolean expression based on the global and local variables, and *A* is the atomic action. Thus, agents interact through events, which are asynchronously delivered and managed by the MAEE component.

It is worth noting that the MPSM-based agent behavior programming allows exploiting the benefits deriving from three main paradigms for WSN programming: event-driven programming, state-based programming and mobile agent-based programming.

B. Agent Factory Micro Edition

AFME [11, 12, 13] is an open-source lightweight J2ME MIDP compliant agent platform based upon the preexisting Agent Factory framework [14] and intended for wireless pervasive systems. Thus, AFME has not been specifically designed for sensor networks but, thanks to a recent support of J2ME onto the Sun SPOT sensor platform, it can be adopted for developing agent-based WSN applications.

AFME is strongly based on the *Believe-Desire-Intention* (*BDI*) paradigm [15], in which agents follow a sense-deliberate-act cycle. To facilitate the creation of BDI agents the framework supports a number of system components which developers have to extend when building their applications: perceptors, actuators, modules, and services. Perceptors and actuators enable agents to sense and to act upon their environment respectively. Modules represent a shared information space between actuators and perceptors of the same agent, and are used, for example, when a perceptor may perceive the resultant effect of an actuator affecting the state of an object instance internal to the agent. Services are shared information space between agents used for data agent exchange.

The agents are periodically executed using a scheduler, and four functions are performed when an agent is executed. First, the perceptors are fired and their sensing operations generate beliefs, which are added to the agent's belief set. A belief is a symbolic representation of information related to the agent's state or to the environment. Second, the agent's desires are identified using resolution-based reasoning, a goal-based querying mechanism commonly employed within Prolog interpreters. Third, the agent's commitments (a subset of desires) are identified using a knapsack procedure. Fourth, depending on the nature of the commitments adopted, various actuators are fired.

In AFME agents are defined through a mixed declarative/imperative programming model. The declarative Agent Factory Agent Programming Language (AFAPL), based on a logical formalism of belief and commitment, is used to encode an agent's behavior by specifying rules defining the conditions under which commitments are adopted. The imperative Java code is instead used to encode perceptors and actuators. A declarative rule is expressed in the following form:

$$b1, b2, \ldots, bn > doX;$$

where *b1... bn* represent beliefs, whereas *doX* is an action. The rule is evaluated during the agent execution, and if all the specified beliefs are currently included into the agent's beliefs set, the imperative code enclosed into the actuator associated to the symbolic string *doX* is executed.

The AFME platform architecture is shown in Fig. 4. It comprises a scheduler, a group of agents, and several platform services needed for supporting, among the others, agents communication and migration.

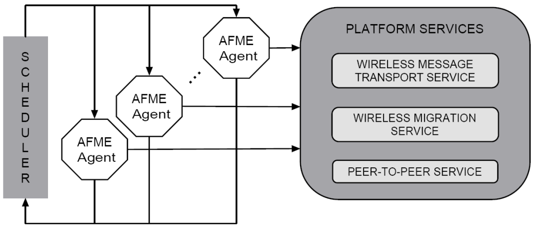

Fig. 4 AFME platform architecture

To improve reuse and modularity within AFME, actuators, perceptors, and services are prevented from containing direct object references to each other. Actuators and perceptors developed for interacting with a platform service in one application can be used, without any changes to their imperative code, to interact with a different service in a different application. In the other way round, the implementation of platform services can be completely modified without having to modify the actuators and the perceptors. Additionally, the same platform service may be used within two different applications to interact with a different set of actuators and perceptors. So, all system components of the AFME platform are interchangeable because they interact without directly referencing one another.

C. MAPS vs. AFME: A comparison

Both MAPS and AFME offer similar services for developing WSN agent-based application. Nevertheless, the definition of agents is based on different approaches. MAPS uses state machines to model the agent behavior and directly the Java language to program guards and actions. AFME uses a more complex model centered on perceptors, actuators, rules, modules, and services that define the agent behavior. They are both effective in modeling agent behavior even though MAPS is more straightforward as it relies on a programming style based on state machines widely known by programmers of embedded systems. Moreover, differently from AFME, MAPS is specifically designed for WSNs and fully exploits the release 5.0 red of the Sun SPOT library to provide advanced functionality of communication, migration, sensing/actuation, timing, and flash memory storage. An example is represented by the implementation of mobile agents through isolates, whose migration mechanism is directly offered by the SPOT Squawk JVM. Isolates are not used in AFME due to its employment as a more generic agent platform for CLDC-compliant devices. Apart from the agent implementation mechanism adopted, both platforms suffers from the current limitation of the Sun SPOTs which do not allow dynamic class loading, preventing from the possibility to support code migration (i.e. any classes required by the agent must already be present at the destination). Finally, MAPS allows developers to program agent-based applications in Java according to its rules so no translator and/or interpreter need to be developed and no new language has to be learnt.

To evaluate and compare the performance of MAPS and AFME two benchmarks have been defined according to [16] for the following mechanisms:

Agent communication. The agent communication time is computed for two agents running onto different nodes and communicating in a client/server fashion (request/reply). Two different request/reply schemes are used: (i) *data Back and Forward (B&F)*, in which both request and reply contain the same amount of data; (ii) *data B*, in which only the reply contains data. Comparison results are shown in Fig. 5. For agents with light data payload AFME performs better than MAPS; however, when the agent data payload overtakes 700 bytes MAPS starts performing better in the case *data B&F*.

Agent migration. The agent migration time is calculated for agent ping-pong among two single-hop-distant sensor nodes. Migration times are computed by varying the data cargo of the ping-pong agent. The obtained migration times are high due to the slowness of the SquawkVM operations supporting the migration process. Comparison results are shown in Fig. 6. AFME retains a higher performance migration mechanism.

IV. An Agent-Based Application Example

To demonstrate the effectiveness of agent-based platforms to support programming of WSN applications, a simple and exemplificative remote monitoring application has been developed. In particular, this section will show how differently the two Java-based platform MAPS and AFME allow defining the agent behavior. The proposed application example involves two sensor nodes and consists in the following three interacting agents:

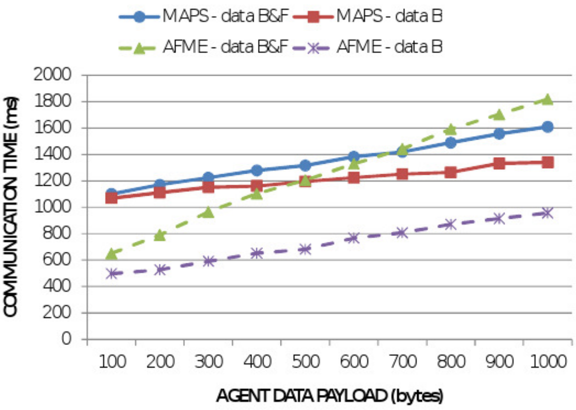

Fig. 5 Agent communication time comparison

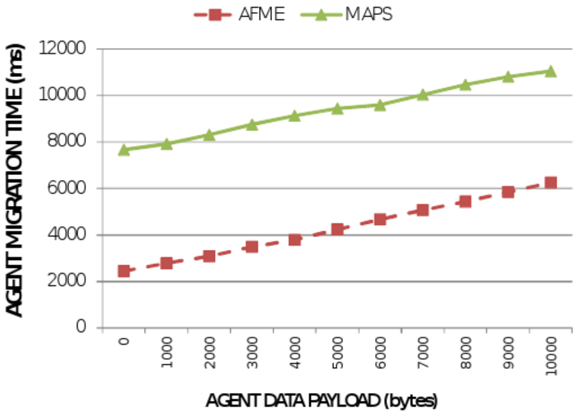

Fig. 6 Agent migration time comparison

- *DataCollectorAgent*, which collects data related to the Sun SPOT node sensors (accelerometer, temperature, light);
- *DataMessengerAgent*, which carries collected sensed data from the sensing node to the basestation;
- *DataViewerAgent*, which displays the received collected data.

The sequence of interactions among the three defined agents is shown in Fig. 7 through an M-UML sequence diagram [17]. The application execution is driven by the user by pressing a switch on the Sun SPOT on which the DataViewerAgent is running. Upon the user event the DataViewerAgent sends a remote message to the DataCollectorAgent (running on the other node) for starting its sensing operations. The agent therefore starts an internal timer to a particular value to begin its collecting activity: on timer expiration the agent acquires data from the onboard node sensors and collects them. As soon as the agent has acquired *numData* samples, it calculates a set of features (e.g. max, min and mean) for each of the sensor data types. Afterwards, the DataCollectorAgent creates the DataMessengerAgent which, carrying the computed features migrates to the DataViewerAgent node for data visualization. In case the user presses the switch on the node where the DataCollectorAgent is running, the agent sends an instantaneous message having the values of the last computed features. Finally, the remote monitoring activity terminates when the user presses again a switch of the Sun SPOT on which the DataViewerAgent is running.

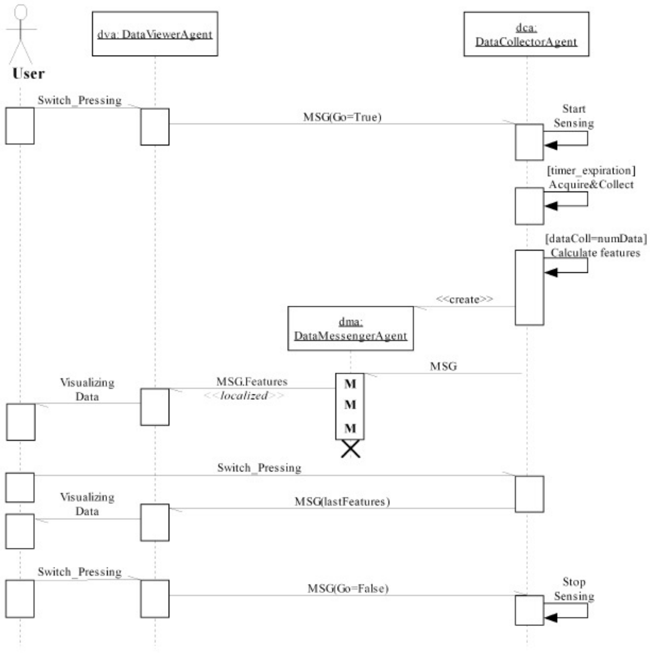

Fig. 7 M-UML sequence diagram for agents interactions

In the following subsections we describe how agent programming models offered by MAPS and AFME can be used to define the DataCollectorAgent behavior.

A. Agent definition in MAPS

As before illustrated, MAPS agents are modeled through a multi-plane state machine. In Fig. 8 the plane related to the DataCollectorAgent is depicted whereas a brief explanation is provided in the following. The *AGN_Start* event causes the transition from the agent creation state to the *IDLE* state whit the execution of an initializing code represented by the action *A0* (e.g. data structures initialization). In the *IDLE* state, when the network message (*MSG*) sent by the DataViewerAgent arrives and the guard *[go==true]* holds, the timer is configure and started for timing the sensors reading (action *A1*) and the agent transits to the WAITSENSING state. When the timer fires (see *TMR_Expired* event), the sensing operations are requested (action *A2*) to the three onboard sensors. When each of the three sensor data are available (see ACC_Tilt, TMP_Current and LGH_current events), their corresponding actions (*A5, A6, A7*) store the values on appropriate buffers. If *numData* samples for each sensor type have not been collected yet, the guard *[dataColl!=numData]* holds so that the agent returns to the WAITSENSING state waiting for the next sensing operations on the timer expiration. If at the contrary the necessary samples number is reached, sensor data are ready for being transmitted to the second sensor node. So, the set of the features are compute and the DataMessengerAgent is created (action *A9*). When the *AGN_Id* event, containing the agent id of the created agent, is received the set of the features values are passed to it (action *A10*). Regarding the WAITSENSING and the DATACOLLECTING states, if the user presses the switch, the last set of computed features are immediately sends to the DataViewerAgent through a remote message (action *A3*). Finally, when the event *MSG* is received and the guard *[go==false]* holds, the agent is terminated (action *A4*).

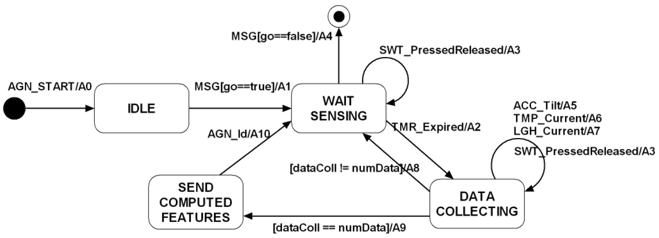

Fig. 8 MAPS-based DataCollectorAgent model

After having described the DataCollectorAgent plane, the code of some actions is provided in Fig. 9. In particular, the most significant part of the Java code related to the plane consists in the operations included into the set of the actions previously defined for the plane state machine.

```
A1:  Event timer = new Event(this.agent.getId(),
        this.agent.getId(), Event.TMR_EXPIRED, Event.NOW);
     timerID = this.agent.setTimer(true, 3000, timer);
A2:  Event temperature = new Event(this.agent.getId(),
        this.agent.getId(), Event.TMP_CURRENT, Event.NOW);
     temperature.setParam(ParamsLabel.TMP_CELSIUS,"true");
     this.agent.sense(temperature);
        //similar code for accelerometer and light
A3:  Event msg = newEvent(this.agent.getId(),
             dataViewerAgentID,Event.MSG, Event.NOW);
     msg.setParam("lastFeatures", this.computedFeatures);
     this.agent.send(this.agent.getId(),dataViewerAgentID,
                                             msg, true);
A6:  this.collectedData += event.getParam(
               ParamsLabel.TMP_TEMPERATURE_VALUE)+"-";
     dataCollTemp++;
A9:     // code for feature computation...
     this.agent.create("applications.demo.Messenger",
        null,this.agent.getMyIEEEAddress().asDottedHex());
A10: Event msg = new Event(this.agent.getId(),
              messengerAgentID, Event.MSG, Event.NOW);
     msg.setParam("features", this.features);
     this.agent.send(this.agent.getId(), messengerAgentID,
                                             msg, true);
```

Fig. 9 Java code for some of the DataCollectorAgent plane actions

B. Agent definition in AFME

The DataCollectorAgent specified trough the AFME design model is depicted in Fig. 10.

The components constituting the previous model are described in the following:

- 7 *Perceptors*. AccPerc, LightPerc and TempPerc are used to acquire data from the SunSPOT sensors. VerifyNumDataSamplesPerc is needed for perceiving if all necessary sensor data have been collected for features computation whereas VerifyFeaturesComputedPerc checks that all features (min, max, mean) have been computed on the collected sensor samples. Finally, TimerPerc checks when the

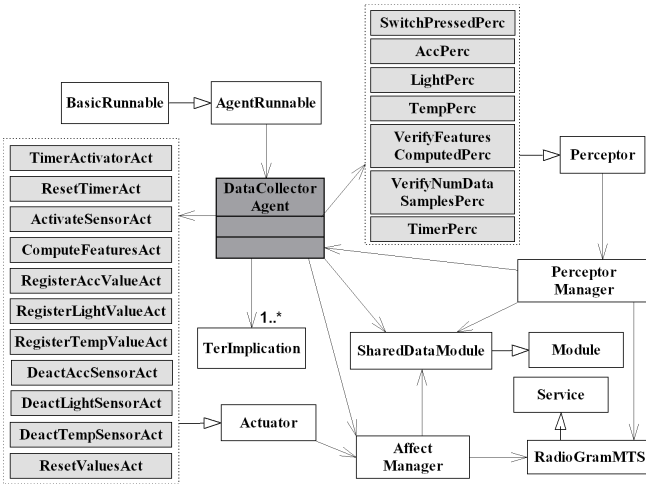

Fig. 10 AFME-based DataCollectorAgent model

timer expires and SwitchPressedPerc recognizes the user switch pressing.

- 11 *Actuators*. TimerActivatorAct and ResetTimerAct are used to activate/reset the timer of the sensor node for timing the sensor acquisition operations. RegisterAccValueAct, RegisterLigthValueAct, and RegisterTempValueAct allow storing the sensed data into the SharedDataModule for sharing them with the proper aforementioned perceptors. DeactAccSensorAct, DeactLigthSensorAct, and DeactTempSensorAct actuators are activated after the sensor readings and are needed to prevent the sensors perceptors from reading sensor data before the timer expiration. In particular, since all the agent perceptors, driven by the AFME runtime system, cyclically perceive the agent environment, and since the sensor data acquisition is made through the use of perceptors, the continuous data acquisition has to be avoided. For this reason, ActivateSensorAct is used to re-enable sensors reading after timer expiration. ComputeFeatureAct is responsible for the actual feature computation on the collected sensor data whereas the ResetValuesAct actuator is used for reinitializing all necessary data structure after a completed feature computation.

- *Rules*. TerImplication contains the auto-generated Java description of the agent behavior rules defined into a script file (see below).

- 1 *Module*. SharedDataModule is the shared memory space which stores the data samples sensed from the node sensors (accelerometer, temperature, light) and other useful data to be shared among perceptors and actuators.

- 1 *Service*. RadiogramMTS represents the transport service for data transmission to remote nodes or basestation.

In the following the basic rules defining the DataCollectorAgent behavior are described:

1. message(inform, sender(dataViewer, addresses("radiogram://”+DataViewerAgentNodeAddr)), ?content), !goFalse > par(timerActivatorAct, adoptBelief(always(goFalse)));
2. timerExpired > par(timerActivatorAct, activateSensorsAct);
3. temperature(?value) > par(deactTempSensorAct, registerTempValueAct(?value));
4. light(?value) > par(deactLightSensorAct, registerLightValueAct(?value));
5. acc(?accX, ?accY, ?accZ) > par(deactAccSensorAct, registerAccValueAct(?accX, ?accY, ?accZ));
6. numDataSampled > computeFeatures
7. featuresComputed(?computedFeatures) > par(resetValuesAct, inform(agentID(messenger, addresses("radiogram://”+ DataMessengerAgentNodeAddr)), values(?computedFeatures)));
8. switch_pressed(?computedFeatures) > inform(agentID(dataViewer, addresses("radiogram://”+ DataViewerAgentNodeAddr)), values(? computedFeatures));
9. message(inform, sender(dataViewer, addresses("radiogram://” +*DataViewerAgentNodeAddr*)), ?content), goFalse > resetTimerAct, deactAccSensorAct, deactLigthSensorAct, deactTempSensorAct;

The rule (1) enables the timer upon the reception of the message coming from the DataViewerAgent and creates the *goFalse* belief. Rule (2) states that after timer expiration the sensor reading operations are activated and also the timer is reactivated. Rules (3, 4, 5) are used for storing the sensor

```
    TempPerc:
....
public void perceive(){
   FOS currentFOS = manager.perManage("shareddata", 5);
   int activated= integer.parseInt(currentFOS.toString()
);
   if(activated == 1) {
      try {
         tempValue= EDemoBoard.getInstance().
                 getADCTemperature().getCelsius();
      } catch(IOException e){ e.printStackTrace(); }
      this.adoptBelief("temperature("+ value +")");
   }
}
....
    ActivateSensorAct:
....
public boolean act(FOS arg0) {
   System.out.println("ActivateSensorsAct..");
   m.actOn("shareddata", 2, null);
   return true;
}
....
    Shareddatamodule:
....
   // data structures declaration
   ...
public FOS processPer(int id)throws MalformedLogicExcep{
   ...
   else if(id == 5){
      return FOS.createFOS(""+temperatureSensorActivated);
   }
   ...
}
public FOS processAction(int id, FOS data)
                                  throws
                               MalformedLogicExcep{
   ...
   else if(id == 2){
      temperatureSensorActivated= 1;
      lightSensorActivated= 1;
      accSensorActivated= 1;
      return null;
   }
   ...
}
....
```

Fig. 11 Java code excerpt from the AFME DataCollectorAgent

data when are available and at the same time they disable the sensing perceptors. The rule (6) checks if *numData* samples have been acquired for each sensor type, and, in that case, features computation starts. Rule (7) verify that features have been correctly computed and if this is the case, the DataMessengerAgent is notified through a message. Rule (8) states that if the user presses the switch a message with the last computed features is sent to the DataViewerAgent. Finally, the last rule is for checking the reception of a message from the DataViewerAgent and since the *goFalse* belief has been previously inserted by the first rule, the sensing operations are stopped (timer is reset and sensors reading are disabled).

In Fig.11, a code excerpt of the AFME agent is provided and in particular, an example of *perceive* method (from the TempPerc perceptor), *act* method (from the ActivateSensorsAct actuator) and the SharedDataModule are shown.

V. Conclusion

In this paper we have presented several TinyOS-based and Java-based agent platforms for WSNs. In particular, we have described and compared MAPS and AFME in more details, two Java-based platforms offering similar services but through different agent programming models. The MAPS programming model is based on finite state machines and events for defining agent's behavior, whereas AFME provides a BDI-like agent model based on perceptors, actuators and rules. Experimentation experience with MAPS and AFME in the proposed case study and in other application domains suggests that both platforms are effective in supporting agent-based development of WSN application. However, agent programming with AFME is less straightforward than MAPS programming due to the BDI-like AFME agent model, which is more complex than the finite state machine model offered by MAPS. Moreover, finite state machine programming is a model often used in programming embedded systems so it may be more easily exploited by low-level programmers. Ongoing work is devoted to defining a solution for agent communication interoperability between MAPS and AFME agents which would enable the development of heterogeneous agent-based WSN applications.

***Abstract*—The paper presents an architecture and implementation that allows distributed execution of workflow applications in BeesyCluster using agents. BeesyCluster is a middleware that allows users to access distributed resources as well as publish applications as services, define service costs, grant access to other users and consume services published by others. Workflows created in the BeesyCluster middleware are exported to BPEL and executed by agents in a distributed environment. As a proof of concept, we have implemented a real workflow for parallel processing of digital images and tested it in a real cluster-based environment. Firstly, we demonstrate that engaging several agents for distributed execution is more efficient than a centralized approach. We also show increasing negotiation time in case of too many agents. Secondly, we demonstrate that execution in the proposed environment is reliable even in case of failures. If a service fails, a task agent picks a new equivalent service at runtime. If one of task agents fails, another of remaining agents takes over its responsibilities. The communication between the middleware, agents and services is encrypted.**

I. Introduction

INTEGRATION of various systems and components is one of the most crucial challenges that needs to be addressed today. In service-based environments this requires efficient algorithms for scheduling workflows i.e. selection of services for particular tasks while meeting optimisation goals. In the literature [1], [2] the workflow is usually defined as a directed acyclic graph $G(V, E)$ where vertices V denote tasks to be executed while edges denote time dependencies between the tasks. A workflow can be concrete if there is one service to be executed for each task or abstract, in which case there is a set of functionally equivalent services for each task, possibly with different QoS parameters. The latter almost always include execution time and cost and if needed others, such as reliability, reputation of the provider etc. One service needs to be chosen for each task such that a global goal is optimized with possibly meeting other QoS constraints. Typical optimisation goals include minimisation of execution time with an upper bound on the total cost of selected services which makes the problem NP-hard. Such workflows are executed by workflow engines which invoke services, control their statuses and transfer data.

II. Problem Statement

Workflows represent an integration of tasks, in which a set of alternative services may be defined (either manually or automatically) for each task. Alternatives may be statically linked to a task or dynamically assigned at runtime. Regardless of which service is selected for a task, the workflow should be executed in such a way that efficiency and reliability of workflow execution should be maximised. We assume that the workflow definition as well as the optimisation criteria and solver are already given [3] which means that services selected for particular tasks are known.

At this point, the problem becomes how to manage the execution of a distributed workflow application so that the following goals are optimized and maintained:

- efficiency — because of potentially high communication latency and low bandwidth of WANs, communication between services through agents close to interacting services is faster than through a distant centralised execution engine;
- reliability — since the node(s) on which the workflow execution engine runs as well as service locations may be geographically distributed, it is likely that at times connections may be lost; the solution should ensure reliable and continuous execution in such cases;
- security — all service invocations and data flows should be performed in a fully secure manner.

We present an agent-based distributed management mechanism that addresses all of the above and examine its performance in a practical example executed in a real environment.

III. Related Work

A. Workflow Types and Workflow Management Environments

Literature studies bring examples of many middlewares and environments for workflow execution. First and foremost, these do differ based on the target workflows to be executed. Scientific workflows usually focus on integration of computational services into chains executed on HPC resources such as clusters and supercomputers, or analysis of data acquired from input sensors or devices by services installed on powerful machines. Such workflows can span over various geographically distributed sites and virtual organisations forming grid systems [4], [5] and usually focus on data flow. There are several systems [4] that support such applications including Kepler [6], Gridbus, Triana [7], Pegasus [8], P-GRADE [9], Directed Acyclic Graph Manager (DAGMan), ICENI [10], UNICORE, Taverna, GridFlow, GrADS, Askalon, GridAnt.

978-83-60810-27-9/09/$25.00 © 2010 IEEE

Conversely, business workflows focus on discovery, selection and integration of services offered by various parties so that certain QoS parameters are met. Such workflows focus more on controlling the flow and often incorporate constructs such as choice, loop and other conditionals. Business workflows usually consider many more QoS parameters apart from the execution time and cost such as reliability, accessibility, fidelity, conformance, security etc. Systems such as Meteor-S [11], [12] focus on automating the process of service discovery and selection using an ontology-based approach. Selected services are executed automatically making service discovery, selection and execution almost fully automatic, based on the given workflow specification and given services and their descriptions. BPEL [13] is often used for describing business oriented workflows and includes control and data flows as well as service invocations. There are several execution engines for workflows specified in BPEL such as The ActiveBPEL Engine [14], bexee [15] or Silver [16].

Thirdly, in the context of pervasive and ubiquitous computing, workflows often react to events asynchronously and more importantly the context is considered for invocation of a service and changing the state. The latter is defined as information defining the state of an object [17]. As an example, uWDL [18] is used for describing ubiquitous workflows and allows specification of both the services as well as the context and service flow through the `node` and the `link` elements respectively.

B. *Existing Service-based Solution in BeesyCluster*

The already existing workflow support module in BeesyCluster developed by our research group [3], [19] contains a workflow editor, an optimiser and execution engine and has already been tested on a variety of scientific and business workflow applications, such as multimedia processing, numerical simulations [19] or business workflows [3].

BeesyCluster is a middleware that allows its users to invoke sequential or parallel applications exposed as services on registered system accounts on various clusters and servers. Such services can be assigned to particular workflow tasks in BeesyCluster's editor. The workflow editor is implemented by an applet. Created workflows are saved in BeesyCluster's database. Based on service execution times and costs, BeesyCluster's optimiser selects one service for each task so that the given criteria are optimised. It can optimise either a linear combination of the total cost of selected services and the workflow execution time or e.g. the execution time with a global constraint on the total cost of selected services. The execution engine is implemented within a Java EE server. For each workflow node a `SIMessageBean` which is a message driven bean is responsible for executing the service chosen for a particular workflow task by the optimizer is used. This is done within the `onMessage` method which is executed upon receiving a JMS message. For the given task, after the service has been executed, the bean copies output files to dedicated directories of services chosen for successor tasks and initiates execution of following tasks by sending JMS messages. The execution status of a particular node instance is updated in the database dynamically.

The drawback of this solution is centralized management of execution. If large data is passed between services, it needs to be passed through BeesyCluster which increases the workflow execution time. We propose to optimize this by launching several distributed JADE agents that would launch services for workflow tasks and act as local proxies for communication between the services. Comparison to other agent-based approaches is presented in Section V.

IV. Proposed Agent-based Solution

As stated in the previous section, BeesyCluster's execution engine is implemented within a Java EE server. This approach allows for easy execution management, but it can also create a bottleneck for efficient execution and a single point of failure. Should a problem with either the server or its network connectivity occur, the whole workflow execution may be at risk. This in itself is a serious limitation.

By using a set of well defined, industry standard conformant interfaces, we migrated the task of execution of a prepared workflow to an agent-based environment, which we nicknamed *BeesyBees*. By separating the two tasks we also gained a possibility of having a pluggable architecture, allowing for experimentation with different approaches to workflow execution. By implementing the execution management in mobile agents we take advantage of enormous flexibility of this environment.

In this paper, we concentrate on increased efficiency and reliability of the workflow execution, which is a main difference to original BeesyCluster's solution.

A. *Architecture*

The BeesyBees system is based on the JADE (Java Agent DEvelopment Framework) [20] agent system implementing the FIPA [21] communication and the OMG MASIF [22] management standards. It provides distributed and decentralized workflow execution for BeesyCluster using agents.

BeesyCluster itself can be regarded as a middleware that offers an easy-to-use WWW interface to access various accounts on various geographically distributed clusters and servers through a single account in BeesyCluster. This allows management of files and directories on such clusters and servers, compiling and running sequential and parallel applications with support for various queuing systems, a team work environment with sharing data and others. Furthermore, users can publish own applications as services within BeesyCluster and make them available to other BeesyCluster users. A provider can specify a cost the client would need to pay for invoking the service. BeesyCluster contains a subsystem for handling virtual payments between users. Access to clusters and servers as well as running particular commands, searching for and running services is also possible through the Web Service interface [23], [24].

Figure 1 shows a generalised diagram for BeesyBees system architecture. There are four types of agents implemented in the system:

- GateWayAgent — receives workflow descriptions in BPEL and spawns TaskAgents,
- GraphAgent — monitors the progress of workflow execution and gives a graphical representation of agent instances and decisions made,
- StatusAgent — collects reports on task execution states from TaskAgents and persist actual status of workflow realization,
- TaskAgent — executes a single workflow task. A group of TaskAgents executes the workflow cooperatively.

A workflow is composed using BeesyCluster's SIEditor applet, a tool for modeling workflows that consist of tasks with services assigned out of those defined in BeesyCluster. For the each task from one to few services can be chosen. First, the definition of the workflow to be run is fetched from BeesyCluster's database and saved in BPEL, which then is handed to the BessyBees system where it is received by the GateWayAgent. All the communication between BeesyCluster and BeesyBees is handled with appropriate web services. Then the GateWayAgent spawns TaskAgents in order to execute workflow's tasks.

TasksAgents negotiate the assignment of each task [25]. TaskAgent interested in executing a particular task sends its proposal including its matching score to all other agents. The score is an object which can be filled with various comparable metrics, like for example a load of a machine an agent resides on. When the agent receives other agent's execution proposals it agrees only when it is not interested in that particular task or it's matching score is lower. This process is represented in Figure 2. Finally, the TaskAgent which received approvals only, begins task execution. When the task is done the TaskAgent sends notification to all agents executing particular workflow, containing information which task has been done and using which service. Example of notification is presented in Figure 3.

The execution state of workflow's tasks is monitored by a StatusAgent. Messages sent by TaskAgents during workflow execution are monitored. These include information whether a task has been executed, or if there were problems with calling services. That data is saved persistently by the StatusAgent so it could possibly be used for recovery after the whole system crash. Additionally a GraphAgent which shows a graphical representation of a workflow execution can be turned on.

B. Efficiency

The implementation launches a certain number of software agents which negotiate which agents are responsible for execution of particular tasks. Secondly, the agents may run on a defined number of containers. This allows deployment and testing of both a fully centralized architecture in which one agent acts as a central management point or a fully distributed approach with several agents and containers. Obviously, the optimal number of agents and containers may depend on the size of the workflow as well as locations of actual services. Starting too many agents results in too much overhead for negotiation.

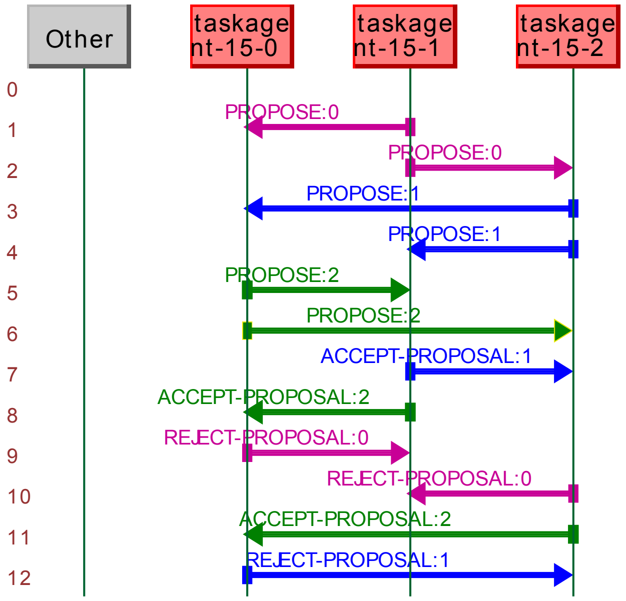

Figure 2. Negotiation between Agents

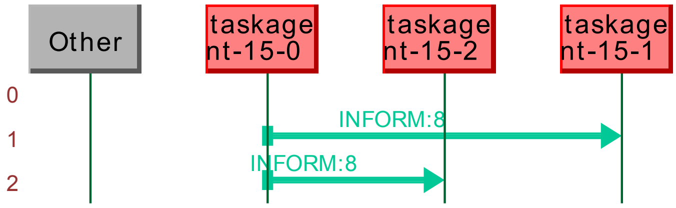

Figure 3. Notifications about Current Task Status

C. Fault tolerance

BeesyBees was designed with fault tolerance in mind. Currently, it is tolerant of service and TaskAgent failures. When either fails, the failure is recognised and either the respective flow path is restarted, or an alternative service is being sought and utilised. During task execution TaskAgent is blocking access to its assigned task by rejecting proposals concerning execution of that task. Thanks to this feature failure tolerance is achieved. When TaskAgent fails, nothing else is blocking an uncompleted task, so one of remaining agents picks it and proposes its execution to other agents. A service failure is detected after a specified number of unsuccessful retries. When this condition occurs an alternative service is chosen if available.

D. Security

At this point, we assume that the agent environment is managed by a group of trusted entities. We use security mechanisms implemented in JADE. Each container has its own certificate signed by our Certification Authority (CA) and it communicates with other containers using SSL.

Originally, BeesyCluster executes services on computing nodes using SSH. Each computing node has its own record

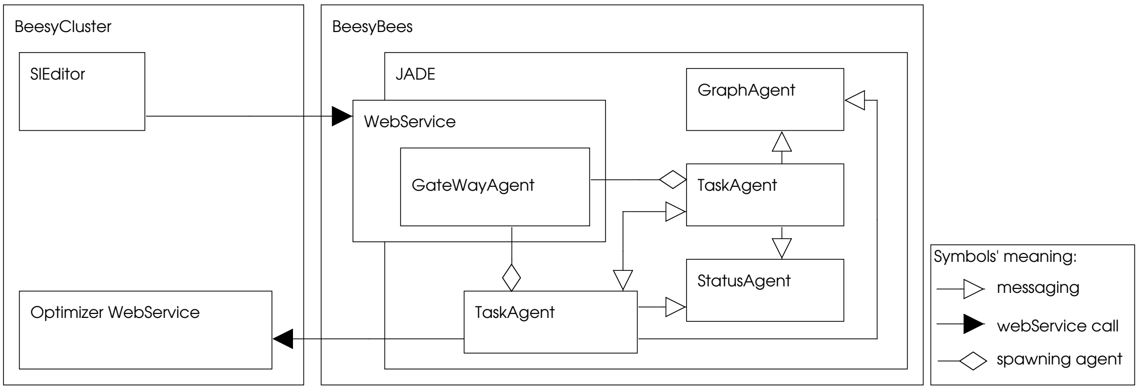

Figure 1. System Architecture

on the BeesyCluster's main server that contains its public key. In the agent-based approach we used a similar method. Each machine that contains an agent container has its own list of trusted computing nodes. Each agent can establish an SSH connection from a machine where it actually runs to communicate with computing nodes and invoke services.

The gateway agent is exposed as a Web Service and serves as a proxy between BeesyCluster and BeesyBees. The communication between BeesyCluster and the gateway agent is secured using HTTPS and certificates. There is always a possibility of attacks using holes that exist in software or solutions that we are depending on. In [26] such a problem as well as a way to mitigate its adverse effects is presented.

V. Other Agent-based Approaches to Workflow Management

One of similar projects we can mention is JBees [27] — a workflow management system based on agent technology combining collaboration agents and the coloured Petri net. As opposed to BeesyBees using BeesyCluster as a system for workflow creation, JBees makes use of built-in management agents providing user interface for the human workflow manager. Moreover resources in JBees, which can be compared to BeesyCluster services, are strictly integrated with the system and are represented by resource agents. The idea of process agents and storage agents is similar to BeesyBees task agents and state agents. Process agents are responsible for the execution of particular cases. Storage agents collect information from process agents (in JBees it is approached through the monitor agent, as opposed to BeesyBees where task agents communicate directly with the state agent) and make it persistent. As mentioned, resources in JBees are accessed by process agents requesting task execution through resource agents. In BeesyBees services are called directly by task agents. As for workflow description, JBees makes use of coloured Petri nets [28].

WS2JADE presented in [29] is a tool for runtime deployment and control of web services. It is of interest, because it uses the same agent system, JADE. The main goal of this project is integration of agent systems and web services, it is approached by representing each web service by a specialised agent. Similarly to JBees, web services are called through their associated agents. In order to call a web service, a client agent searches DF (Directory Facilitator, JADE built in service directory agent) for it, then if the service is not present, DF can trigger WS2JADE to look it up in the web service environment. If an appropriate service is found, the web service agent, which registers its service in DF, is created. Finally, the service is called by exchanging messages between agents.

SwinDeW-A [30] integrates services using WS2JADE by enhancing SwinDeW (Swinburne Decentralised Workflow) with agents. As opposed to BeesyBees using BeesyCluster's optimiser in order to choose best services for specified task, SwiNDew-A makes use of negotiation agents which are able to negotiate with a number of service agents. In order to choose the most suitable service, a Service Level Agreement (SLA) needs to be formed between the negotiation agent and each service provider. Agents can negotiate non functional parameters (such as time, cost, availability), which are similar to those proposed in BeesyCluster [3].

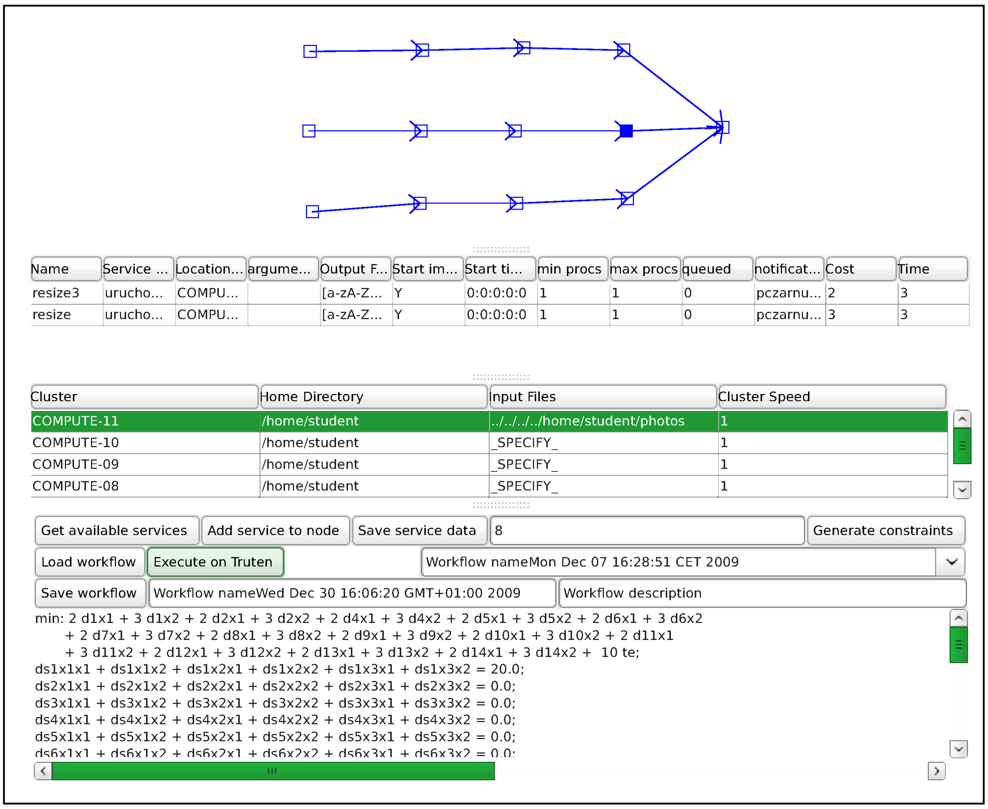
Finally, a relatively recent development is WADE (Workflow and Agents Development Environment) [31], which is an extension of JADE agent framework, facilitating both the possibility to define agent tasks according to the workflow metaphor and an architecture with mechanisms allowing administration of distributed WADE based applications. Workflows in WADE are expressed as Java classes.

VI. Simulations

A. Testbed Workflow and Environment

As an example, we have run a workflow application for parallel processing of RAW digital images in order to produce a Web album. The process uses standard steps in professional photo editing (`$1` is the input file name):

- `rawtotiff` — conversion from RAW to lossless TIFF. Implemented using the `dcraw` converter as `dcraw -T $1`



Name	Service ...	Location...	argume...	Output F...	Start im...	Start ti...	min procs	max procs	queued	notificat...	Cost	Time

```

Figure 7. Testbed Workflow in BeesyCluster's Editor

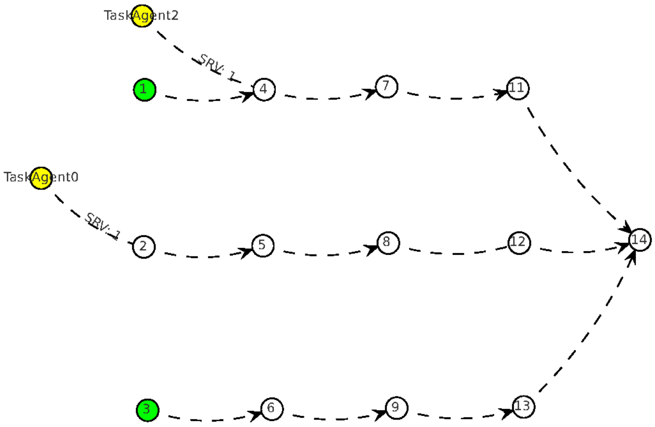

Figure 4. Visualisation of Workflow Execution

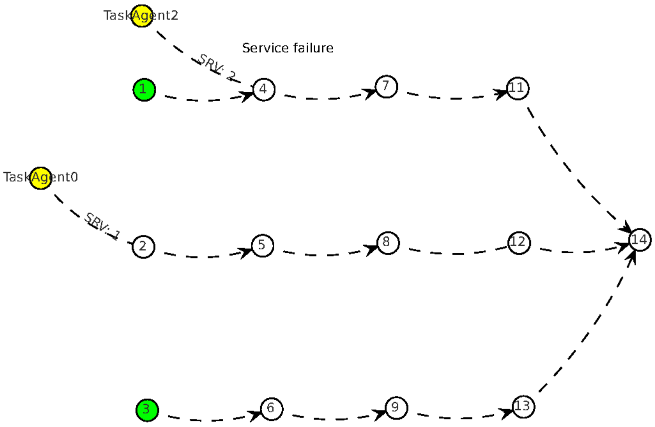

Figure 5. Visualisation of Workflow Execution with Service Failure

- `normalize` — normalisation of the image using ImageMagick's `convert` as `convert $1 -normalize $1`
- `sharpen` — sharpening the image implemented as `convert $1 -sharpen 1x1.2 $1.jpg`
- `resize` — resizing the image implemented as `convert $1 -resize 600x400 $1.jpg`
- `albumgeneration` — implemented by either `jigl` or `album`.

All those services are bash scripts executed through ssh. Input for each service contains pictures being processed.

Figure 7 presents the testbed workflow created in BeesyCluster's editor. Parallel paths include nodes running `rawtotiff`, `normalize`, `resize` and `sharpen` filters while the final node gathers resulting jpg images and produces

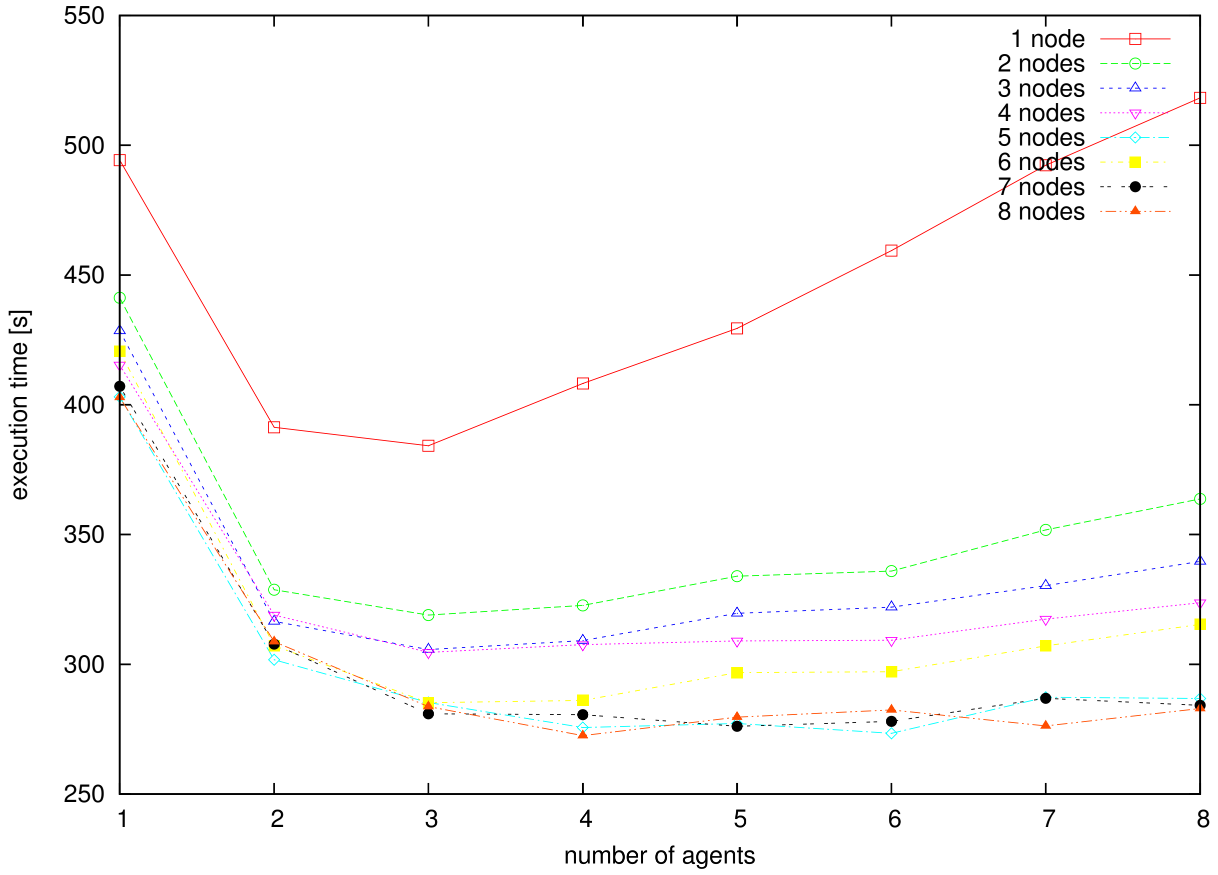

Figure 8. Execution Time

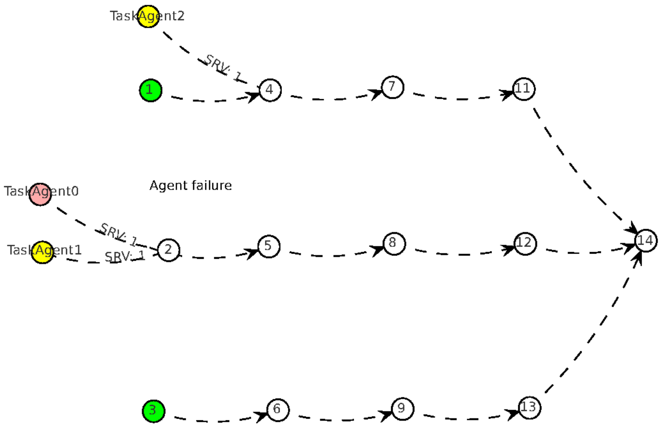

Figure 6. Visualisation of Workflow Execution with Agent Failure

a web album. For each node a primary and a backup services were deployed on a dedicated computer. Such a simple workflow was chosen on purpose, in order to facilitate the process of verification of experiment results with theoretical expectations.

There are several approaches to choosing appropriate services for tasks' execution. One is that following static optimisation done by BeesyCluster's optimiser before the run, task agents responsible for the given task call BeesyCluster's optimiser and fetch the selected service. Optimizer can consider such metrics like execution cost and time. Another approach, where knowledge about services is gathered during their execution and subsequently used to choose the best service considering metrics given, for example a probability of a service failure, was presented in [32]. If a particular service is not available or has a runtime failure, the agent selects the next best service for the task.

We have implemented a monitoring mechanism that shows the status of the workflow execution visually and updates it as the execution progresses. Figure 4 shows a snapshot of the testbed workflow being executed. Nodes 1–3 execute `rawtotiff`, nodes 4–6 execute `normalize`, nodes 7–9 execute `resize`, nodes 11–13 execute `sharpen` and node 14 executes `albumgeneration`. Figures 2 and 3 show communication between TaskAgents obtained by the JADE sniffing tool. They show the negotiation process described earlier and notifications about current task status sent to other TaskAgents respectively.

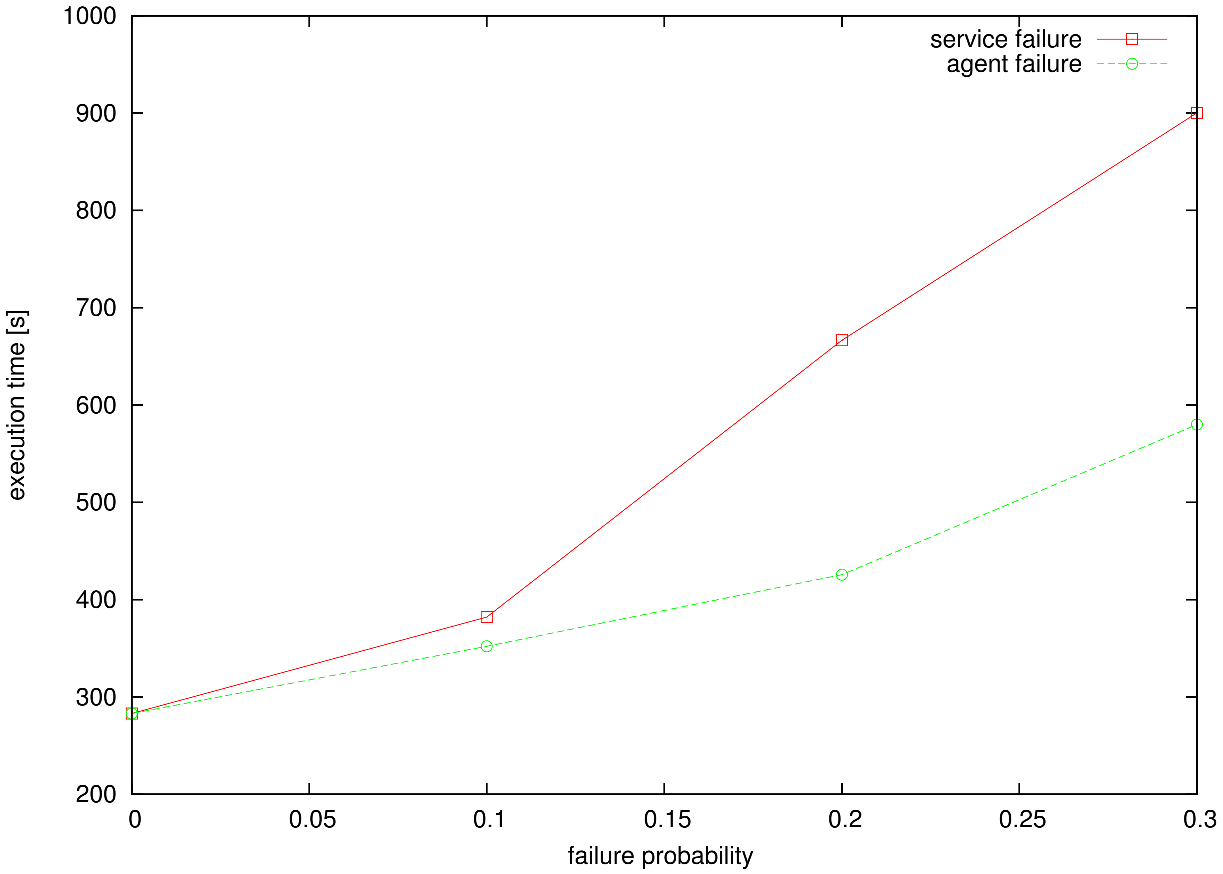

Figure 9. Execution Time in case of Failures

B. Optimization of Execution Time through Distributed Agent Processing

Figure 8 presents workflow execution time depending on the number of participating agents. They show execution times for processing the workflow with big files. There were 4 big files of 34MB each. Each of the series corresponds to a different number of system nodes on which agents work. The situation with only one agent and one agent node corresponds to a centralized environment, which performance should be similar to BeesyCluster's one because of using the same mechanism to invoke services. We can see that increasing the number of agents and nodes reduces the execution time, but only up to a certain number of agents. Further increase in a number of agents causes negotiation costs to offset any gains in execution time. In the testbed worklow there are three parallel paths and it can be seen that the results are best also for the number of working agents equal to three.

C. Mechanism for Fault-tolerant Execution and its Performance

We have been able to demonstrate that the execution environment is tolerant of faults in communication, service execution and agent execution. The workflow application can be completed successfully even if the following failures occur:

1) a service fails to complete after it has been invoked. As shown in Figure 5, if `taskagent2` detects a failure of service 1, it automatically switches to a functionally equivalent service 2 that executes the given task;
2) if a failure of a task agent occurs then another task agent takes over the responsibility of the former automatically. As shown in Figure 6, if `taskagent0` fails then `taskagent1` takes over its responsibility and the workflow execution can continue.

Figure 9 shows the total execution time of the worklow application assuming a certain probability of agent failure or service failure. It can be seen that execution time is getting higher with a higher probability of failure. If an agent fails, another one is given a chance for taking over the responsibility over its task and service. Again, it may fail with the given probability. For a given probability of agent or service failure, the final execution time is higher for the latter case. This is because for each task there is one agent but the service needs to be invoked four times because of four files being processed in each task. If any of the service invocations fails, a new service needs to be chosen, input files copied and again the service is invoked for the input files for the task.

VII. Conclusions

We described the architecture and its implementation that allows efficient, fault-tolerant and secure execution of workflows using agents. A standard execution management module would invoke remote services from one central server which would result in performance bottleneck and could fail if the server loses connections with the services. We have shown that for an optimal number of agents and containers, distributed management of workflow execution by agents is more efficient than a centralized approach. The distributed approach can complete successfully as long as agents supposedly located much closer to the services are able to reach the latter. We have been able to show that execution of a testbed workflow application for parallel processing of digital images completes successfully even if a task agent or a service fails.

***Abstract*—The capture of the execution state of agents in agent-based and multi-agent systems is a system feature needed to enable agent checkpointing, persistency and strong mobility that are basic mechanisms supporting more complex, distributed policies and algorithms for fault tolerance, load balancing, and transparent migration. Unfortunately, the majority of the currently available platforms for agents, particularly those based on the standard Java Virtual Machine, do not provide this important feature at the system-level. Several system-level and application-level approaches have been to date proposed for agent state execution capture. Although system-level approaches are effective they modify the underlying virtual machine so endangering compatibility. Conversely, application-level approaches do not modify any system layer but they provide sophisticated agent programming models and/or agent converters that only allow a coarse-grain capture of agent state execution.**

In this paper, we propose an application-level technique that allows for a programmable-grain capture of the execution state of agents ranging from a per-instruction to a statement-driven state capture. The technique is based on the Distilled StateCharts Star (DSC*) formalism that makes it available an agent-oriented type of recursive hierarchical state machines. According to the proposed technique a single-threaded agent program can be translated into a DSC* machine by preserving its original semantics. Although the proposed technique can be applied to any agent program written through an imperative-style programming language, it is currently implemented in Java and integrated into the JADE framework, being JADE one of the most diffused agent platforms. In particular, agents, which are specified through a generic Java-like agent language, are translated into JADE agents according to the JADE DSCStarBehaviour framework. A simple yet effective example is used to illustrate the proposed technique.

I. Introduction

AGENT-BASED and Multi-Agent Systems are developed around the concept of agent, a goal-directed, computational and interacting entity which acts on behalf of another entity (or entities) [20]. Such agent systems are supported by agent platforms that basically provide agent programming libraries and system-level services to support agent execution. An important system-level feature that an agent platform needs to include for the development of robust and fault-tolerant agent systems is agent state execution capture. In fact, agent checkpointing, persistency and strong mobility are mechanisms fully enabled by agent state execution capture. Agent checkpointing [13] is a technique for inserting fault tolerance into agent systems. In particular, it basically consists of storing a snapshot of the agent execution state and, later on, using it for restarting the agent execution in case of its failure. Agent persistency is a mechanism allowing saving an agent along with its state into the mass memory as a file. Archived agents can be later on loaded and resumed. Strong mobility [10] is an important feature of an agent that enables the migration of the agent state, data and code. Such mechanisms constitute the basis for supporting more complex, system-wide agent policies and algorithms for fault tolerance, load balancing, and transparent migration.

Unfortunately, even after more than one decade of research on agent systems, the majority of the currently available agent platforms, particularly those based on the standard Java Virtual Machine (JVM) do not provide this important feature at system-level. In fact, currently the standard JVM does not yet provide mechanisms to capture the state execution of Java processes. Nevertheless, several approaches have been to date proposed to overcome such an issue. They can be roughly taxonomized into three categories: system-level [4, 5, 14, 17], converters [3, 16, 15, 11, 12] and model-based [18, 9, 19]. The system-level approach modifies the underlying virtual machine to capture the execution state at process/thread level; however, the modified virtual machine is usually not compatible for agents previously developed. Conversely, converters and model-based approaches are application-level approaches that rely on specific, sometimes sophisticated, agent programming models and/or on converters at bytecode-level or source-code-level to allow for agent execution state capture. Although they do not require any virtual machine modification, the grain of capture of the agent execution state is usually coarse so that capture can be carried out only at specific points of agent execution. In fact, capture is either automatically driven by specific statements (in agent converters) or manually programmed by exploiting the reference agent programming models. Both techniques can be used only for agent-driven capture and not for an effective system-driven capture.

In this paper, an application-level technique for agent-driven and system-driven capture of agent state execution is proposed. Agent-driven capture is based on three key statements (checkpoint, persistence and move), whereas system-

* Corresponding author

driven capture is fine-grain and carried out on a per-instruction basis. A distinctive feature of the defined technique is the capture of the execution state in recursive and mutually recursive methods that can also contain key statements. The proposed technique is based on the Distilled StateCharts Star (DSC*) formalism that provides an agent-oriented type of recursive hierarchical state machine through which the agent program and its execution state can be represented. According to the technique, a single-threaded agent program formalized as a main method and ancillary methods is translated into a DSC* object, preserving the original agent program semantics. The technique is currently implemented in Java and integrated into the JADE framework [2]. In particular, an agent program, which is formalized through a simple Java-based Agent Language (JAL), is converted into a JADE agent compliant to a newly defined JADE behavior named DSCStarBehaviour. Conversion can be carried out in two modes: (i) driven by the statements *checkpoint*, *persistence* and *move*; (ii) instruction by instruction. The so obtained JADE behavior not only has the same semantics as the original agent program but also incorporates its execution state at run-time. A simple yet effective example, concerning an agent-based version of the Fibonacci program, is used to exemplify the proposed technique.

The rest of this paper is organized as follows. In Section II the DSC* formalism is defined as an enhancement of the Distilled StateCharts formalism [9]. Section III presents the proposed technique that is then exemplified in section IV by means of the Fibonacci agent example. Section V provides some details about the implementation of the proposed technique through Java and the JADE framework. Finally, conclusions are drawn and future work anticipated.

II. The Distilled StateCharts Star Formalism

The Distilled StateCharts Star (DSC*) formalism is based on of the Distilled StateCharts (DSC) formalism [9, 8] that was specifically defined for effective modeling of single-threaded agent behavior through hierarchical state machines based on ECA rules, OR-decomposition, history entrance mechanisms and UML-like execution semantics based on the run-to-completion step. In addition, DSC* introduce typical mechanisms of recursive functions/procedures so that DSC* machines are recursive hierarchical state machines [1]. A DSC* machine is formalized by the following tuple:

DSC* = <Σ, s_0, *fs, L*, Φ, *deep, defaultHistoryEntrance, defaultEntrance, defaultEntranceAction, V, star, return*>, where:

- Σ is the set of states including composite states (cs=ncs$\cup$pcs), which can be normal composite states (ncs) or procedure composite states (pcs), simple states (ss) and history pseudostates (hs). State notation is defined according to the hierarchical structure of the DSC*. In particular: (i) the notation A(B) indicates that the simple state B is encapsulated in the composite state A; (ii) the notation A(•) indicates that A is a composite state; (iii) the notation A(x), where x is a placeholder variable, indicates any state included in A (e.g. x=B).
- s_0 is the initial state.
- *fs* is the set of final states.
- *L* is the set of transition labels. A label is defined as the following ECA rule: *Event[Condition]/Action*. The semantics implies that if Event is processed and Condition is true, upon transition firing Action is first atomically executed and, then, the state transition takes place.
- Φ is the set of transitions among states. In particular, it is defined as follows: $\Phi \subseteq \Sigma \times \Sigma \times L$. Thus a transition is formalized as a triple <source state, target state, label>.
- *defaultEntrance* is a function that indicates the default entrance of each composite state. The default entrance is the transition sourcing from the initial pseudostate of a composite state and targeting a state encapsulated into the composite state. Default entrances are not included in Φ as initial pseudostates are implicitly associated to composite states and are not explicitly defined in Σ.
- *defaultEntranceAction* is a function that associates an action (if any) to the default entrance of composite states.
- *deep* is an attribute of a history pseudostate indicating deep history if true, shallow history if false. History mechanisms allow a partial (through shallow history pseudostate H) or full (through deep history pseudostate H*) recovery of the state history after re-entering into a composite state previously exited.
- *defaultHistoryEntrance* is a function that indicates the default history entrance (if any) of the history pseudostates. The default history points to the state to be entered in case history is not initialized, i.e. when the composite state containing the history pseudostate is entered for the first time.
- *V* is a set of variables hierarchically scoped according to the state structure. In particular, $V(x)=\{v_1(x),\ldots,v_n(x)\}$ is the set of variables declared in the x state.
- *star* and *return* are attributes of specific transitions which respectively support activation of and return from a procedure type composite state (or procedure state) that semantically behaves like a procedure in an imperative-style programming language. Thus the *star* transition represents the procedure call whereas the *return* transition represents the procedure return. Let A and B be two composite states, when the transition (*) from A to B is drawn, the transition (<<R>>>) from B to A is to be added too (see Figure 1). The CallB event is generated inside A and triggers the (*) transition, whereas the ReturnFromB event is generated inside B and triggers the (<<R>>) transition. Procedure call parameters are passed to B through the CPE_B event that is generated inside A just after the CallB generation. Return value is passed through the RPE_B event that is generated just after the ReturnFromB event. The procedure state activation and return semantics are as follows: if the DSC* is in the A state and the CallB event is processed, the transition (*) is fired so that a new instance of the B

state is entered and the B state parameters (if any) are actualized with the parameter values contained in the CPE_B event. When the B state has to complete, the ReturnFromB event and the RPE_B event, filled with the return value, are generated. Once the ReturnFromB event is processed by the DSC*, the transition <<R>> fires so that the B state instance is removed and the A state is entered through its shallow history pseudostate. The so defined mechanism is therefore equivalent to the procedure call mechanism; parameters are only passed by value. Procedure state recursion and mutual recursion among procedure states are also fully supported (see Section III).

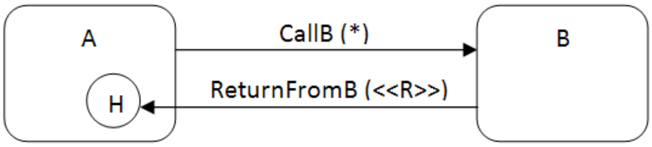

Fig. 1 Star (*) and return (<<R>>) transitions

The structure of a well-formed DSC* consists of a top state enclosing one procedure state, named main procedure state, which contains the initial state and the main final state, and zero or more secondary procedure states linked directly or indirectly to the main procedure state (see Section III for an example).

The execution semantics of a DSC* machine are defined in terms of an abstract machine, which embodies a DSC*, whose key components are:

- An event queue (EQ), which holds incoming event instances until they are dispatched;
- An event dispatching mechanism (EDM), which selects and de-queues event instances from EQ.
- An event processor (EP), which processes dispatched events.

The semantics of event processing is based on the run-to-completion (RTC) assumption implying that an event can only be de-queued and dispatched if the processing of the previous event is fully completed.

Given the last dequeued event by EDM, the main task of EP is to cyclically:

1. find out which transitions are enabled, i.e., which transitions could be fired based on the dequeued event;
2. select, among the enabled transitions, the transitions to be fired. Indeed, only one transition of a DSC* is step-by-step ready to be fired.

The algorithm executed by EP is reported in Figure 2 through a pseudocode notation.

The input to each step is given by the last recently dequeued event (current_event) and the DSC* execution control status, which includes the current state (current_state) of the DSC*, the dynamic history information associated to history pseudostates (history(hs_i), ∀i), and the stacks of the procedure states (stack(cs_j), ∀j). At the termination of each step, the output is given by the new DSC* execution control status.

```
1 :for each history pseudostate i
2 : history[i].init(defaultHistoryEntrance[i])
3 :for each procedure state j
4 : stack(j).init(null)
5 :current_state = $s_0$;
6 :while (current_state∉fs) do
7 : current_event = EQ.dequeue();
8 : enabled_transitions =
     enabled(current_state, current_event);
9 : if (enabled_transitions∉∅) then
10:  fired_transition = fire(enabled_transitions);
11:  if (return(fired_transition)) then
12:   pop(stack(source(fired_transition)));
13:  else
14:   if (source(fired_transition)∈cs)
15:    updateHistory(source(fired_transition))
16:   endIf
17:  endIf
18:  executeActionChain(fired_transition);
19:  if (star(fired_transition)) then
20:   j=target(fired_transition);
21:   push(stack[j], new instance of j);
22:  endIf
23:  current_state = nextconf(current_state,
                              fired_transition);
24: endIf
25:endWhile
```

Fig. 2 The DSC* execution semantics algorithm

Before starting the event processing loop, history pseudostates are initialized with the default history entrances, the stack of the procedure states is set to null and the current_state set to the initial state (lines 1-5). While the current_state is different from a final state (line 6), the current_event is dequeued (line 7) and successively processed. In particular the following steps are carried out: (i) the set of enabled transitions is computed on the basis of the current_state and current_event (line 8); (ii) if such a set is not empty the transition to be fired is selected among the enabled transitions (lines 9-10); (iii) if the fired transition is a <<R>> transition then the instance at the top of the stack of the procedure state which is the source of the transition is removed (lines 11-12); otherwise, if the source state of the fired transition is composite, its history pseudostates are updated (lines 14-15); (iv) the action chain of the fired transition is executed (line 18); (v) if the fired transition is a (*) transition a new instance of the target procedure state is added to its stack (lines 19-22); (vi) finally the new current state is computed on the basis of the current_state and the fired transition (line 23).

III. A DSC*-based Technique for Agent State Execution Capture at Application-level

The proposed technique translates an agent program, defined according to the schema reported in Figure 3, into a DSC* machine that is semantically equivalent to the agent program and contains its execution state at run-time. Translation can be carried out either per instruction basis (named full translation) or driven by key statements. The agent program, which represents a single-threaded agent, is composed of a main method (simply called main) from which the agent activity starts and zero, one or more supporting methods $\{m_1,..., m_N\}$, N>=0. Agent data can be declared at global level (GV) and at local level in each method (LVm_i). The supported control-flow statements are: sequential, selective (if-then-else), iterative (for and while), procedure call and return. Moreover the defined key statements are: (i) *checkpoint*, which captures the execution state of the agent and store it in memory; (ii) *persistence*, which captures the execution state of the agent and store it in a file; and (iii) *move*, which triggers the migration of the agent from the current location to a new location.

```
program Agent{
 GV //Declaration of Global Variables
 m1(param1,…,paramn_m1):return_value_m1{
  LV1 // Declaration of Local Variables
  CBm1 //code block of the method 1
 }
 …
 mN(param1,…,paramn_mN):return_value_mN{
  LVN // Declaration of Local Variables
  CBmN //code block of the method N
 }
 main(param1,…,paramn_main){
  LV_main // Declaration of Local Variables
  CBm_main //code block of the main
 }
}
```

Fig. 3 The schema of the Agent program

The structure of the Agent program is represented by the equivalent DSC* machine structure shown in Fig. 4. Each procedure is formalized as a procedure state, the global variables V(Active) are declared at the top state named Active, which is a normal composite state, the local variables of the main V(main) along with the main parameters P(main) at the main level, the local variables $V(m_i)$ of the supporting methods along with the method parameters $P(m_i)$ at the level of the corresponding procedure states. The Active composite state, which is embedded in the FIPA agent behavior template [6], is always entered through the deep history pseudostate to allow restoring the DSC* machine status to the status in which the DSC* machine was before leaving the Active state.

Each statement of the Agent program can be translated into a DSC* diagram. In the following we describe the translation patterns of the Agent program statements and, finally, we present a short version of the translation algorithm. We defined two types of statements: special statements, which include control-flow statements (if-then-else, while, for, procedure call, return) and key statements (checkpoint, persistence, move), and normal statements, which include all other statements different from the special statements.

In Figure 5 the translation of the normal statement is reported. The E event drives the execution of the `statement` bringing the DSC* machine into the S state which formalizes the control-flow status just after the execution of the `statement`. A new event E is generated to drive the control-flow to the next control-flow point. This translation is carried out if and only if the translation is full.

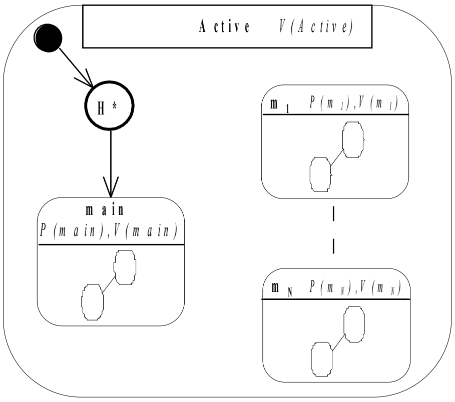

Fig. 4 The schema of DSC* machine of an Agent program

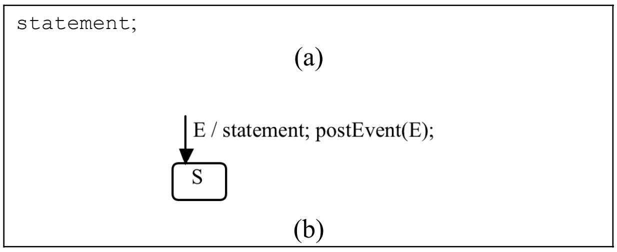

Fig. 5 Translation of the normal statement: (a) normal statement; (b) corresponding DSC* diagram

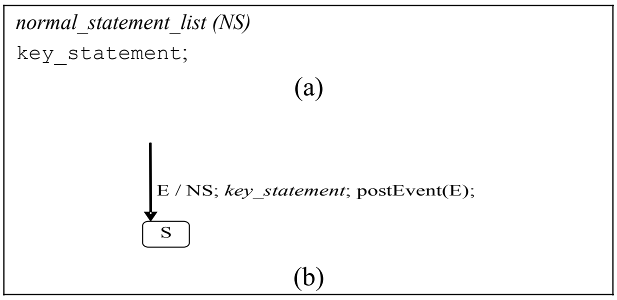
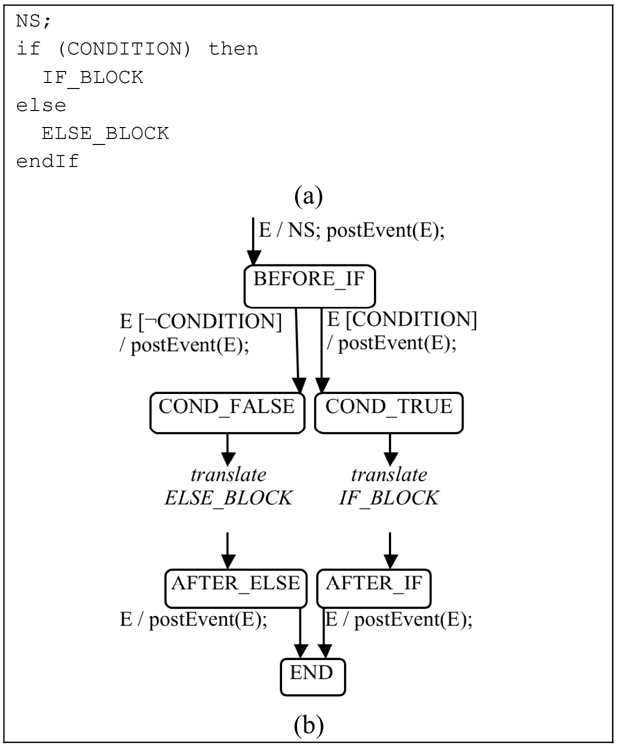
The translation of the `key_statement` is shown in Figure 6. In this case, the list of normal statements (containing one or more normal statements) which are before the `key_statement` are moved into the transition action before the key statement. This translation is carried out if and only if the translation is key-statement-driven; otherwise the translation is carried out as for a normal statement (see above).



normal_statement_list (NS)
key_statement;
(a)
E / NS; key_statement; postEvent(E);
S
(b)

Fig. 6 Translation of the key statement: (a) key statement; (b) corresponding DSC* diagram

The translation of the `if-then-else` statement is reported in Figure 7. The Before_If state indicates the control flow point before the execution of the `if-then-else` statement. Cond_True and Cond_False represent the states that indicate the points just after the `CONDITION` evaluation and before the execution of the `IF_BLOCK` and the `ELSE_BLOCK`, respectively. The After_If and After_Else states represent the points after the execution of the `IF_BLOCK` and `ELSE_BLOCK`, respectively. Finally the End state represents the point after the `if-then-else` statement.



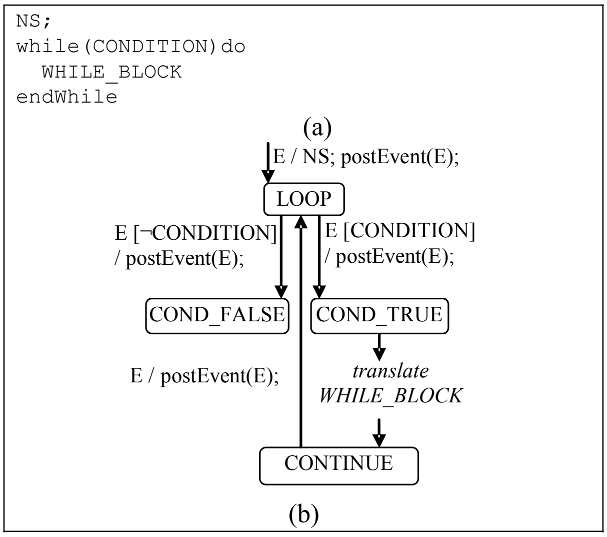
```
NS;
if (CONDITION) then
  IF_BLOCK
else
  ELSE_BLOCK
endIf
```

Fig. 7 Translation of the if-then-else statement: (a) if-then-else statement; (b) corresponding DSC* diagram

The translation of the `while` statement is reported in Figure 8. The Loop state indicates the control-flow point before the execution of the `while` statement. The Cond_True state represents the state indicating the point just after the `CONDITION` is evaluated true and before the execution of the `WHILE_BLOCK`. If the `CONDITION` does not hold the Cond_False state is reached which represents the control flow point after the `while` statement.

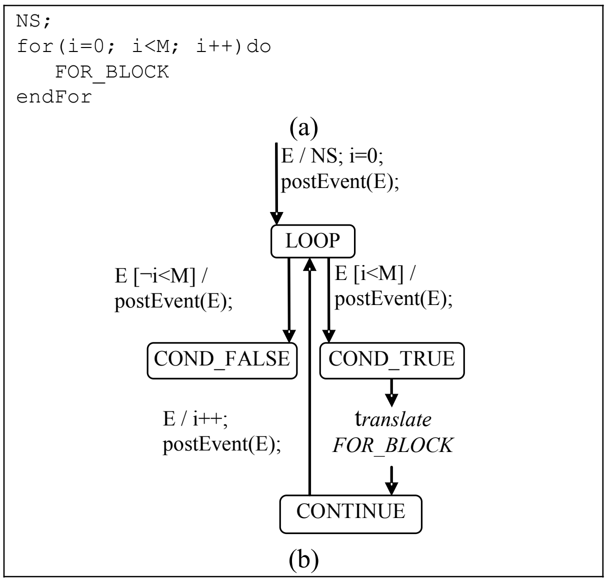
Figure 9 reports the translation of the `for` statement. The Loop state indicates the control-flow point before the execution of the `for` statement. The `for` counter `i` is initialized in the action of the transition above Loop. The Cond_True state represents the state indicating the point just after the `condition i<M` is evaluated true and before the execution of the `FOR_BLOCK`. If `condition` does not hold the Cond_False state is reached which represents the control-flow point after the `for` statement. The `for` counter `i` is incremented in the action of the transition from Continue to Loop. Of course, the `for` condition as well as the `for` counters can be easily generalized.

The translation of the `procedure call` is reported in Figure 10. To implement the call to the P2 method, the CallP2 and CPE_P2 events are sequentially posted. The former labels the (*) transition between P1 and P2. The latter contains the parameter values {PARAMETERS_P2} to be passed to P2. When the CPE_P2 event is processed, the parameters value are extracted and assigned. When the RPE_P2, generated in the P2 state (see translation of the `return` statement), is processed, the return value contained in the RPE_P2 event is extracted and assigned.



```
NS;
while(CONDITION)do
  WHILE_BLOCK
endWhile
```

Fig. 8 Translation of the while statement: (a) while statement; (b) corresponding DSC* diagram



```
NS;
for(i=0; i<M; i++)do
   FOR_BLOCK
endFor
```

Fig. 9 Translation of the for statement: (a) for statement; (b) corresponding DSC* diagram

The translation of the `return` statement is reported in Figure 11. The ReturnFromP2 and RPE_P2 events are sequentially posted. The former drives the <<R>> transition between P2 and P1. The latter contains the return parameter value to be passed back to P1.

The translator algorithm (Figure 12) converts an agent program (AP) defined as in Figure 3 into a DSC* diagram (AP*), preserving the AP semantics. In particular, for each method m of AP (line 1) the following steps are carried out:

(i) a procedure state pcs corresponding to m is created and added to AP* (line 2);

(ii) the variables P(m) and V(m) are added to pcs (line 3);

(iii) the initial state of pcs is defined along with the transition labeled by the CPE event, through which the method parameters could be passed, which connects s1 and s2 repre-

```

senting the control-flow starting point of m (lines 4-7); the tc variable represents the translation cursor pointing to the last created state from which translation is to be restarted;

(iv) the body of m is finally translated through translateCodeBlock. In particular, translateCodeBlock sequentially translates the statements belonging to the code block cb from the 1st to the k-th. Given the h-th statement (s_h) the following steps are carried out:

(i) if `full_translation` is false and s_h belongs to SS and contains directly or indirectly a key_statement then s_h is translated according to the translation patterns and NS is reset (lines 3-6); otherwise, s_h is inserted in NS (line 7);

(ii) if `full_translation` is true and s_h belongs to SS then s_h is translated according to the above described translation patterns (line 10); otherwise, s_h is translated as normal statement (line 11).

Fig. 12 A schema of the translation algorithm

IV. A Translation Example: Fibonacci Agent

To exemplify the technique presented in the previous section, the translation of a Fibonacci mobile agent, reported in Figure 13, is described. The agent is an extension of the Fibonacci algorithm with mobility: it moves across N locations to compute fibonacci(N) and, finally, prints out the result at the home location.

The translation was carried out both full and statement-driven; for the sake of exemplification, in the following we discuss the DSC* diagram of the Fibonacci agent obtained according to the key-statement-driven translation (see Figure 14). In particular, the `move` statement drives the translation so that the agent execution state can be captured before any migration and restored after migration. It is worth pointing out the DSC*-based modeling of the direct recursion: the Fibonacci procedure state has both a self (*) transition labeled by the CallFibonacci event and a self <<R>> transition labeled by the ReturnFromFibonacci event.

V. A JADE-based Implementation

The proposed technique is implemented in Java for the JADE framework that is one of the most diffused agent platforms [2]. The implementation comes with a translator program and a JADE add-on, named DSCStarBehaviour framework, which provides the programming abstractions supporting the definition of agent behaviors in terms of DSC* ma-

```
public class FibonacciAgent extends JALAgent {
 Location [] locations;
 public int fibonacci(int n){
  int x;
  int res1;
  int y;
  int res2;
  int res;
  if (n == 0 || n == 1) {
   move(locations[0]);
   return n;
  }
  move(locations[n]);
  x = n - 1;
  res1 = fibonacci(x);
  y = n - 2;
  res2 = fibonacci(y);
  res = res1 + res2;
  return res;
 }
 public void main(Location [] loc){
  int result;
  locations = loc;
  result = fibonacci(10);
  System.out.println("RESULT = " + result);
 }
}
```

Fig. 13 Fibonacci agent

chines. In particular, a Java-based agent program is converted by the translator into a JADE agent based on the DSCStarBehaviour. The agent program is defined through a Java-based agent language (JAL) which allows structuring agents as single-threaded Java programs using classes of the JADE framework and the three key statements (checkpoint, persistence, and move). The DSCStarBehaviour framework is an enhancement of the JADE DistilledStateChartBehaviour framework [7]; a simplified version of its class diagram is reported in Figure 15.

The DSCStarEvent extends ACLMessage so that the basic message processing mechanisms of JADE are completely reused. The DSCStarBehaviour extends CompositeBehaviour and implements mechanisms fulfilling the DSC* execution semantics. All DSC* composite states extend DSCStarBehaviour and are handled through the JADE Behaviour mechanisms. The other classes are abstractions of the main components of the DSC* formalism: variables and parameters of procedure states (DSCStarVariablesAndParameters), (*) transition (DSCStarStarTransition) and <<R>> transition (DSCStarReturnTransition) which are an extension of normal transition (DSCStarNormalTransition), and instances of a procedure state (VirtualInstance).

A simplified excerpt of the obtained FibonacciAgent class is reported in Fig 16 to provide a flavor of programming with the JADE DSCStarBehaviour framework. `FibonacciAgent` extends the basic JADE Agent class and contains the two procedure states `main` and `fibonacci` (lines 1-3). In the `setup` method all the simple states are defined along with the transitions; finally the `FibonacciAgent` behavior is started up (lines 4-28). In particular: (i) states `S1`-`S17` are declared, created and added to `main` and `fibonacci` as shown in lines 7-9; (ii) in line 10, the `root` behavior, which represents the encapsulating Active state (see Fig. 14), is created; (iii) the recursive (*) transition is defined in line 11; (iv) the transition `t2` between the `S12` and `S13` states (see Fig. 14) is defined in lines 12-24; two methods are defined for each transition: `trigger`, which defines the transition trigger *event[condition]*, and `action`, which defines the transition action, e.g. action of `t2`; (v) all transitions are added to the `root` which is added to the pool of active behaviors (lines 25-26); (vi) finally, the CPE_MAIN event, which triggers the execution of the FibonacciAgent, is created and posted (lines 27-28).

VI. Conclusion

In this paper we have presented a novel technique based on hierarchical recursive state machines for application-level capture of agent execution state. In particular, the technique uses the DSC* formalism to formalize agent programs writ-

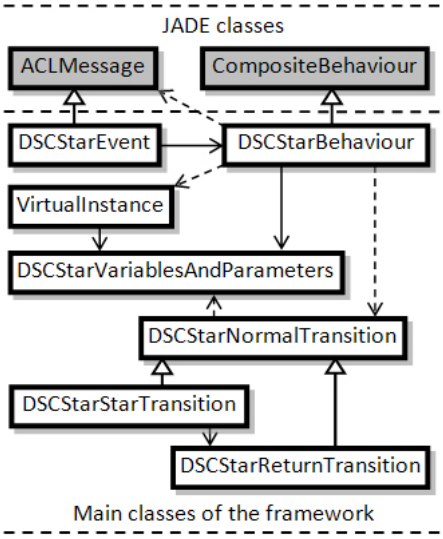

Fig. 15 The DSCStarBehaviour class diagram

ten in an imperative style language. The technique is currently implemented in Java for the JADE framework and allows obtaining JADE agents, whose behavior is based on the newly defined DSCStarBehaviour framework, which can be actively and passively checkpointed, made persistent and strongly migrated. On-going research efforts are devoted to (i) analyze the code and execution overhead introduced by the proposed application-level approach and (ii) implement the technique for other Java-based agent platforms.

```
public class FibonacciAgent extends Agent {
 private DSCStarBehaviour fibonacci;
 private DSCStarBehaviour main;
 protected void setup(){
  fibonacci=new DSCStarBehaviour(this,"FIBONACCI",..);
  main=new DSCStarBehaviour(this,"MAIN",...);
  Behaviour S1=new SimpleStateBehaviour(this,"S1");…;
  main.addInitialState(S1); main.addState(S2);…;
  fibonacci.addInitialState(S6);
  fibonacci.addState(S7);…;
  DSCStarBehaviour root =
     DSCStarBehaviour.createRootForDSCStar(main,...);
  DSCStarStarTransition t1 = new
          DSCStarStarTransition(fibonacci, fibonacci);
  DSCStarNormalTransition t2 = new
               DSCStarNormalTransition("T2",S12,S13){
   public boolean trigger(ACLMessage msg,...) {
    if (msg instanceof E) return true;
    return false;
   }
   public void action(...) {

***Abstract*—**We have explored principled mechanisms for converting a hierarchical organization to an edge type organization. Other than structural differences, organizations differ in information flow network and information sharing strategies. Beyond current effort, many other types of organizational adaptation are possible and require much further research that we anticipate to remain for future work. This article lays the foundation for automatic organizational adaptation.

I. Introduction

Hierarchical command and control (C2) structures are ineffective (Alberts and Hayes, 2003). *Power to the Edge* (PE) is an information and organization management philosophy that has superseded traditional organizational paradigms for C2. PE provides empowerment for edge members, as well as superior, interoperablem agile, shared awareness among all the members in the organization. PE provides adaptability in dynamic situations [6]. Man on the Loop (MOTL) complements PE with a set of computational tools for systematically altering organizational components for agile response to dynamics in large population multiagent systems [21, 25]. Reorganization is necessary to allow communities of agents or robots to reconfigure their organizational structure in agile response to changes in the environment.

We have explored principled mechanisms for converting a hierarchical organization to an edge type organization. Other than structural differences, organizations differ in information flow network and information sharing strategies. Many types of organizational adaptation are possible and require in-depth research that we anticipate to remain for our future work. This article lays the foundation for automatic organizational adaptation. We begin by outlining related work and background in section 2. In section 3 we present an approach to reorganization. Section 4 describes an implementation of a simulated testbed that will help us validate our salient concepts. Preliminary results and conclusions are in sections 5 and 6 respectively.

II. Backround

In highly dynamic operational environments, it is desirable for multi-agent systems (MAS) to be capable of self-directed structural reorganization. The organizational structure of MAS, whether based on a graph, hierarchy, federation, or other form, dictates the communication interactions between agents as well as the distribution of roles and authority throughout the system. When motivated to adapt, agents should do so without human intervention and in a manner that improves the overall performance of the system. Several motivating factors for reorganization will be discussed here as will current proposed methods for performing dynamic reorganization in MAS. Current research in the area of dynamic reorganization in multi-agent systems has yielded a few approaches in dealing with the problem of adaptation in uncertain and often hostile environments. Given the intelligent and autonomous nature of agents in MAS, individual agents must be capable of locally adapting their interconnection schemes with respect to other agents in the MAS. In addition, agents must be able to accept new roles and to comply with any restrictions or laws associated with these roles. Limitations of communication bandwidth, imposed by the environment or power considerations, or explicitly mandated due to security concerns, implies that agents may not, and probably will not, have a complete picture of the effectiveness and efficiency of the global system. With these limitations in mind, agents must adapt based on local perception of global performance [17].

The impetus directing reorganization varies widely. Common adaptation triggers are based on estimates of the overall performance of the MAS, timelines specifying that reorganization should take place at scheduled intervals, or structural requirements. Matson and DeLoach have described other adaptation triggers related to roles and contrast adaptation for timeline-based efficiency and for quality-based effectiveness [24]. They illustrate three scenarios resulting in a need for reorganization. The first of these relates to the situation in which the organizational objective demands a role that has not yet been assigned. In this situation, there may or may not be extra agents available to accept the required role. Second, a role that is currently assumed by an agent may be relinquished by that agent, resulting in incomplete role distribution as with the first scenario. Third, an agent may be forced to relinquish a role due to some internal fault or as a result of malicious activity. In this case, the system may not be informed of the need to reassign the lost role. similar triggers are described in [14]. These include allocation, reallocation, and exchange. In an allocation scenario, an agent has completed its task and is allocated a new task. In the reallocation scenario, an agent prematurely terminates its current task and is allocated a new one. In the final scenario, ex-

This work was supported by AFRL under contract FA8750-06-C-0138.

change, two agents swap tasks. Regardless of the adaptation trigger driving reorganization of a MAS, the desired outcome remains efficient completion of the system objective. A system of reorganization based on dynamic capability evaluation is presented in [26].

Matson and DeLoach's approach to reorganization of MAS first involves the evaluation of the system's ability to perform a desired task. Based on this evaluation, agents may decide to either proceed to satisfy the organizational goals, relax some goals, or abandon the process of reorganization and task acceptance altogether. The foundation of this approach is an organizational model consisting of goals, roles, agents, and capabilities. Based on this model, certain evaluative constraints are applied to the process. First, there must exist knowledge of which agents are available for inclusion in the system. Second, it must be determined what necessary capabilities exist in order to satisfy the demands of a role. Third, an assessment of the capabilities of all available agents must be made to determine their respective qualifications for acceptance of a given role. To perform this step, the authors have devised a capability taxonomy rooted at the abstract level. Leaf nodes of this taxonomy represent concrete functions and capabilities of an agent, such as the types of sensors (sonar, infrared, etc.) and motivators (wheels, tracks, etc.) the agent is equipped with. Finally, limitations applied to roles must be taken into consideration.

Considering these constraints, Matson and DeLoach formulated a six step evaluation process, which begins with the broad definition of system goals. Following this, the broad goals must be reduced into a simpler, structured format. Using this structured form of the system goals, the process determines all roles which will be required to complete the prescribed objectives. A *general purpose* method has been developed and discussed in [31]. This method is based on the organizational model for adaptive computational systems (OMACS) platform and has been shown to result in optimal network configurations. Another method for performing dynamic organization and reorganization is based on the principle of referral networks. [30] that describe such networks. In referral networks, agents make and sever connections with other agents in the system through the analysis of referrals provided by neighboring agents. An agent wishing to enter the network or alter its set of interconnections once within the network accepts referrals from surrounding agents. From these referrals, agents can form opinions regarding the quality of service provided by other agents and their respective trustworthiness. These are referred to as an agent's expertise and sociability [30].

Agents in referral networks use their knowledge of the trustworthiness and sociability of other agents in the system to decide which agents with which to sever communications or with which to add communication links. Agents that possess high trustworthiness and sociability rankings attract more agents. As the highly trusted and sociable agent gains connections with other agents, its degree increases and it therefore has a greater chance of being referred to other agents in the system. This, in turn, leads to a clustering of agents around the ones seen as the most fit. Fitness directly relates to trustworthiness and sociability. Clustering of this kind is linked closely to the concept of preferential attachment [5] and has been identified in many real-world networks, especially in the Internet. Referral networks are classical and useful, but other methods of reorganization exist. Some of these methods attempt to model biological and chemical organization methods. One such method, related to the concept of stigmergy, is referred to as the digital hormone model [27]. This model is based on the understanding that hormonal signals are used often in nature to form organizations of high complexity. In the digital hormone model (as it relates to agents or robots), agents emit activator or inhibitor signals, i.e. hormones, into their surroundings. Once diffused into neighboring agent regions, the agents in these regions combine the incoming hormone strengths with those already present in their area and adapt their behavior based on these recalculated hormone strengths. The actual reorganization process in the DHM requires four steps, which are repeated continuously, assumedly until some goal has been reached. These steps begin with agents assuming roles based on their abilities and associated rules which govern their behavior. Next, execution of roles takes place. This is followed by each agent transmitting and receiving digital hormones to and from their surrounding areas. The final step in this process involves updating each agent's view of the concentration of hormones in its surrounding area.

Some considerations to keep in mind when selecting an adaptation mechanism or creating a new one are the learning rate, stability, and global structure of the MAS formed by the mechanism [17]. Other considerations are given in [18]. In this, the authors present the question of which agents should be allowed to adapt in the event of a failure. Three possibilities are considered and include random agent sets, a single agent in the event of a team failure, and all neighboring agents in the event of a single node failure. Furthermore, the authors propose a candidate pool of available agents with which an adapting agent may establish a connection. These are limited to the set of all agents, ex-teammates of the adapting agent, or referred agents, as are used in referral networks. This is continues in [18] with this work by outlining a process by which agents adapt given the above noted constraints. The process begins with the construction of the candidate pool and proceeds with several filtering stages. Structural filtering and skill filtering are performed first, followed by degree filtering in which only candidates with the single highest degree are left to connect with the adapting agent.

A general overview of dynamic reorganization concepts and examines two metrics useful in examining MAS performance; society utility and agent utility is found in [16]. Society utility is further decomposed into the success of interactions, roles, and structures in the system. Agent utility is not clearly defined, as it differs from agent to agent in heterogeneous agent systems. In addition to these utility metrics, [15] classifies several types of reorganization "maneuvers." The first of these, pre-emptive reorganization, is a viable option in unpredictable environments where possible, or likely, events can be prepared for in order to take full advantage of them. Protective reorganization attempts not to take advantage of possible future events, but instead works to limit the negative effects of such events on the system. Exploitive reorganization takes place after the fact, and seeks to benefit from events that have already taken place. Finally, corrective reorganization attempts to lessen the damage caused by events which have previously occurred in order to maintain system usefulness. Specific methods for performing adaptation are not present in [16], but it provides many useful ideas for developing new methods or for elaborating on existing methods.

III. An Organizational Model

Next, we define salient attributes for a computational organization. We will begin by defining a set of parameters that characterize an organization. First, we will define capabilities.

1: A *capability* is basic agent ability with a degree in the range from 0.0 to 1.0. We will denote degree of a capability c with D(c).

We assume that there is no decay in capability and agents can only increase their capability. Furthermore, we assume capabilities are mutually exclusive. Let C denote a set of capabilities, which are required in the system for performing all tasks. I.e., C = $\{c_1,c_2,\ldots,c_n\}$. C is the set of all capabilities known by all agents. Each agent will possess each capability c_i to a different degree and may improve it by learning. This provides us with an n dimensional space of capabilities. Let's call this a C-space [21]. Next, we will define roles.

2: An action *role,* denoted with r, is a point in C-space that specifies a minimal capability profile to qualify an agent for the role.

For example, with two capabilities c1 and c2, <0.1, 0.5> is a role that an agent may adopt if it's capabilities c1 and c2 exceed 0.1 and 0,5 respectively [10].

To execute an action role, an agent senses its environment, picks the best rule to determine an action, and performs the action. Success or failure of actions performed are determined in the environment and not known a-priori. At best, an agent may determine a probability of success based on its role fitness to perform it. We'll call the rate of an agent's success its productivity.

Productivity is one of three components for an agent to determine its utility with respect to a goal. The second component is its synergy with others in that role. The third component is the level of fitness of an agent to the role. Fitness of an agent is the sum of ratios of its capability over required capabilities. We are now ready to define an agent's utility with respect to a role.

$$\text{Productivity} = \text{preference (A)} * \text{fitness (A, R)} \qquad (1)$$

3: The *utility* of an agent A, performing in a role R_i, denoted by $u(A, R_i)$, is a linear combination of its *productivity,* its *synergy* levels for that role, and its fitness, i.e.,

$$u(A, R) = P(A, R_i) + [(1/\text{sizeof}(R_i)) * \sum s(i, j)] \qquad (2)$$

Utility as defined here is intended to denote the relative satisfaction of an agent with a role. If this value is sufficiently high, an agent will be content with its current role. However, if this utility value is low, the agent will be inclined to change its role. As we will discuss norms later in this report, using individual utility as a basis for role change assumes a *selfish norm*. In general, norms are prescribed by a user, which in turn will affect agent decision making. So far, we've considered role changes motivated by utilities alone. However, a major intuitive motivator for role exchange is *opportunity*. In general, opportunity is determined by analyzing environmental attributes that suggest the degree to which adoption of a role by an agent will contribute to system or individual productivities. As an example, a midfielder may see the ball near the opponent's goal and determine that it has a good chance of scoring if it played a forward. Real world computations like this are very rapid and continuous, [19]. Opportunistic computing has also entered technical domains [28].

Agents need to continually, mentally quantify potential margins of system or individual productivity gains against all possible roles they could adopt. Whichever role candidate will yield the highest marginal gain will be the next role the agent will wish to take. The agent's choice of next role is a proposal that need to be presented to the organization and once processed; the agent may proceed with adoption of it.

For a vacant role, two temporal constraints of the role augment the notion of opportunity. The first is the immediacy of the need to occupy the role. Each open role will specify the urgency of the role. For instance, the team captain will assign a temporal urgency for each vacant role to be filled. Agents who vie for a vacant position, must meet the urgency constraint. Agents must dynamically compute their capability to transition into an open role. Naturally, this capability differs from an agent's innate abilities to perform action. It is not a personality trait. Also, it is not a universal agility or flexibility to take on roles in general. This capability differs with respect to each role and depends on the environmental circumstances. The second temporal constraint is the duration after which the role becomes obsolete and there will not be a need to occupy it. If the validity time window ends, we say such a role is expired. Agents must account for this constraint and should only consider a role if it is not yet expired.

In contrast to an action role, a role that is decision oriented is a manager role. An example of a manager role is captain of a football team.

4: *Rank* of a role r_i assigns a number to the role that reflects its relative importance in an institution. This is denoted by $\text{Rank}(r_i)$.

This is a highly simplified model of a role's valuation in an institution. Using this we introduce a notion of role order. The function "Rank" may return any natural number. The smaller the number the more preferred the role. Role r_j is the most preferred rank if $\text{Rank}(r_j) = 1$. Importance of a role is inversely proportional to its rank.

5: *Role Ordering* (RO) is an ordering of action roles. Each role is assigned a unique rank. I.e., <Rank (r_1) , Rank (r_2) , ….. , Rank (r_n) > specifies role ordering where $\text{Rank}(r_i)$ is the i^{th} position is the rank for i^{th} role.

If Rank(r_i)< Rank(r_j) then role corresponding r_i is preferred over the role r_j that has a smaller rank. RO sets up a trajectory in C-space.

6: A norm is a convention in the form of a rule shared by all individuals. It may govern role adoption with a set of rules. We denoted the set of norms by N.

For simplicity, we consider organizational norms to be mutually exclusive and non-overlapping. In this paper we will limit norms to rules that govern role change. An example of a norm that governs roles is that individuals incrementally improve their capabilities over time and are allowed to apply for a higher rank in the organization-- this is the *promotion norm*. Another norm that will govern roles is based on utilities. The *selfish* norm will only consider individual utilities whereas *beneficent* will only account for the society's benefits. We assume that norms are determined outside organizations. In our framework, Moe issues a norm.

7: A *department*, denoted by D_i, is a fixed number of agents who are performing the same role R_i. Each department will require a minimum number of individuals needed to occupy roles in that department at a given time. We assume that departments are static and will not change over time. If there is a significant change for a department such as the number of individuals required, a new organization is formed.

Since departments and roles have a one to one correspondence, ranking one prescribes an ordering on the other. We are now ready to define an organization.

8: An Organization is modeled as <C, R, D, N>, which is capabilities, roles, departments, and norms.

When an organization is initially populated by individuals, each agent adopts a role depending on its capability level. Each agent will aspire to occupy a role that is highest ranked in the organization.

After an organization is populated, it will experience reorganization where self-motivated individuals may change roles based on the promotion norm. This is shown in Figure 1.

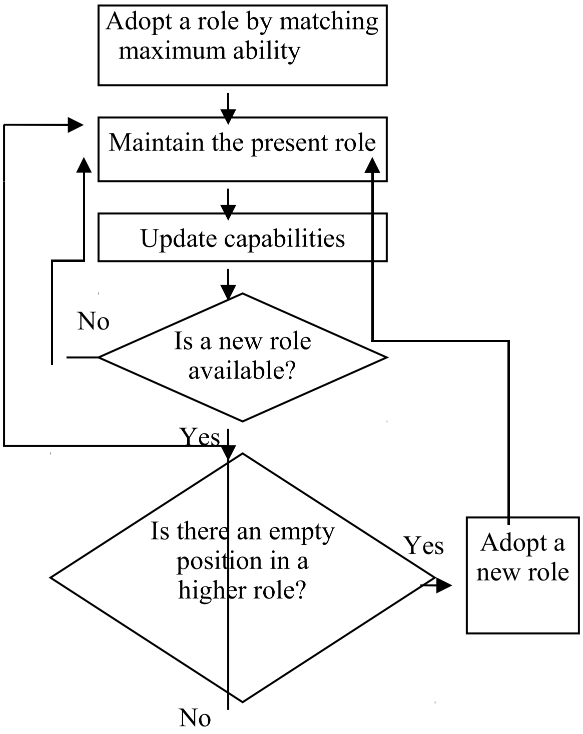
We assume that individuals dynamically change roles and move to different departments. To capture a snaphot of organizational configuration we define a *state* that will be defined later.

9: At any given time, the configuration of individuals in departments of an organization is the *state* of that department.

States change as often as individuals change their roles. Therefore, there can be many state transitions over time. State transitions are most significantly affected by a norm change.

Thus far, our model of an organization lacks characteristic concepts of agents that will occupy it. In the next section we introduce these notions.

10: A *synergy network* among a group of agents is a graph among agents where the arcs represent a real value between -1.0 and 1.0 indicating negative or positive influence between pairs of agents. We will use *s(i,j)* as an directed function that returns the synergy value between agents i and j. Synergy is not reflexive and not symmetric.



Adopt a role by matching maximum ability
Maintain the present role
Update capabilities
No
Is a new role available?
Yes
Is there an empty position in a higher role?
Yes
Adopt a new role
No

Figure 1. Flow chart for self-initiated promotion norm

Synergy between an agent agent A and another agent B is a degree of influence from B towards A. This can be positive or negative. We assume authority as a form of synergy. For example a manager role like a captain will have synergy towards players. Synergies change over time. One form of change is experience. Individuals in a department who interact with one another generally develop positive synergies towards one another that is proportional to the duration of time they remain the same department. However, this is not universally true and synergy change goes beyond departmental boundaries. What is important is how one agent's action enables another to perform its action.

Simply modeled, frequency of interactions between agents A and B that leads B to execute its role, increases synergy from A to B. If B is prohibited from executing its action due to A's action, then synergy decreases from A to B.

These changes in synergy cannot be simply determined from the organizational configuration alone. To recapitulate, Synergy changes are dynamic and dependent on interactions.

Beyond individual productiveness, an organization may produce something that is an emergent property and it is not attributed to a single individual. An example is scoring points that is a result of team work. Let's call this system productivity. Similar to an individual, we model a system utility that is a measure of the relative satisfaction of the organization.

11: *Organizational utility* is the sum of individual productivities plus balance of synergies among individuals in the organization.

12: A state of an organization is the combination of current, active norm and profile of roles occupying departments of the organization, i.e., composition of roles.

Since there are many possible role compositions and there are several possible norms, an organization can be in numerous states. A change in organizational role composition or a change in active norm will yield a state change. States of the system are completely observable and changes in states are under our control. Since state changes are not dependent on the sequences of past states, we can make the Markovian assumption. The nature of organizational state space fits a Markov decision process MDP. There are well known methods for solving MDPs such as the value iteration method [2].

IV. Implementation

In order to illustrate the implementation of reorganization, we have designed a model that will be implemented using Netlogo. Netlogo is a java based cross-platform multi-agent programmable modeling environment for simulating natural and social phenomenon. It is freely available online at http://ccl.northwestern.edu/netlogo/.

The Domain which we will use is a simplified version of the game of Soccer (i.e., see "http://en.wikipedia.org/wiki/Football_(soccer)".

The game in our simulation is designed in the following fashion.

Capabilities: In this simulation we assume each player has a set of capabilities associated with him, which may or may not be unique. The capabilities are variables that are subject to change with the progress of the game. In our game each player from the start of the game maintains his capabilities at the same level. The set of capabilities each player has are threefold: Speed, Accuracy with handling the ball, Ability to kick the ball (far/near).

Speed: This represents the speed with which a player moves across a field. His ability to chase the ball and move the ball along.

Accuracy: This sets the players accuracy in handling the ball in the field. His ability to tackle with the ball when the ball is within his reach is decided by this parameter. Accuracy of a player ranges between 20^0-100^0.

Kick: This ability of kicking a ball determines the distance a ball moves when a player kicks it.

The game is divided into a set of roles where each player can play only one role at a time. These are forward, Defender, Mid-fielder, and goal keeper. We omit details for brevity and space constraints.

Productivity: The productivity of each player is calculated according to the formula mention in the approach section the report although it had been adopted to each department to meet the requirement of the requirement of the department. The basis of calculation of productivity is mentioned in the above paragraphs describing the features of the department. The productivity of individual player is calculated and the productivity of the department is calculated basing on that. The team productivity is calculated considering the department productivities and the performance of the team as a whole. The productivities of the team are monitored in the graph in the user interface of the simulation.

Utility: the utility of each individual player performing in the designated role is calculated according to the earlier mentioned formula. The individual utility is how effective each person is performing in the designated role and the task at hand. We considered a randomly generated synergy while calculating the individual utilities. The department utility is calculated considering how effective those assigned individuals are at performing tasks and promoting the interests of the department. The utility of the team as whole has been calculated by considering the effectiveness of the departments performance in promoting the interests of the team , the synergies generated between the departments of the team and the overall performance of the team.

Norm: We implemented norm in this simulation. The norm in this game acts as the motivation or attitude with which the players play the game

We designed three norms, each of it differs from the others in unique way.

The norms implemented are Attack, Defend, Self-Gain. In the game the end user or MOTL gives the norm which governs the game.

Norms and reorganization:

Attack Norm: In this norm the players are expected to play with attack mode on their mind. The game is modifies such a way that there are more number of players in the forward department, four instead of three. With more number of players in the forward the game tends to be more aggressive at the cost of weakening the mid-field and defense departments. This is more offensive approach. The reorganization among the players is mainly motivated by the attack norm. The game starts normally and after a period of 500 clock cycles the system checks for any other player who has more capabilities to play in the forward. If it does not implicitly find one it calls for a reorganization and reassigns the roles to the players. The system does not look for best or worst performance it just does the reorganization until Moe is satisfied with it. Only Moe can instruct a system to stop reorganization. So Moe is the one who controls the extent to which she can permit reorganization.

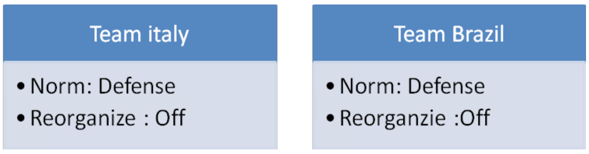
Defend Norm: In this norm the players are expected to play in a defensive mode. The defense department has four players instead of regular three. With more players in the defense the game tends to be more defensive at the cost of loosing aggression; i.e., by weakening the mid-field we also reduce the support to the forward department. After a period of 500 clock cycles, the system checks for players who can be more effective to play in the defense department, and calls for a reorganization. The system this way keeps reorganizing until it receives any instruction from Moe.

Selfish Norm: With this norm player's play in the regular department layout configurations. Instead of caring for the team, they play to maximize their productivity and improve their utility. When reorganization is initiated, the system checks if a player is suitable for the role she is playing. If the system considers the player can perform better in another role it calls for reorganization. This is performed by computing the average productivity of the department. If the player falls below the department average she is underperforming so she is replaced. The system maintains reorganizing until Moe aborts it.

Synergy: In this simulation, we take the average of the department's average productivity and compare it with the individual synergy. If player's productivity is more than the departments' productivity we assume she has positive synergy. If she is performing below his capability we assume that she has negative synergy. Each player in the game has a synergy with respective to their department.

V. Results

We consider two cases for exhibiting results of using our simulation
Case 1:



Team italy
- Norm: Defense
- Reorganize : Off

Team Brazil
- Norm: Defense
- Reorganzie :Off

Figure 4.

In the Case 1, we allow the simulation run for a time period of 11400 clock cycles.

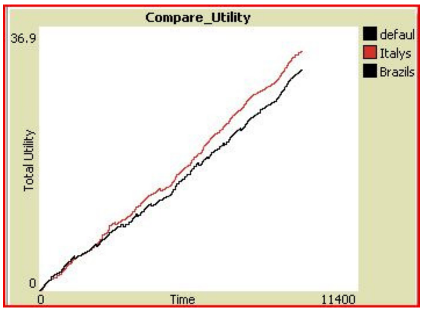


Figure 5.

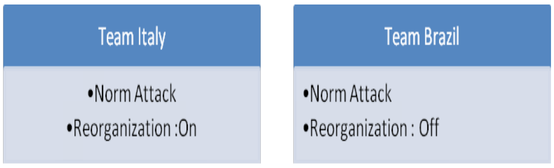
The resultant graph in figure 5 compares utilities between the respective teams. Both teams norms were set to "Defense".

Case 2:



Team Italy
- Norm Attack
- Reorganization :On

Team Brazil
- Norm Attack
- Reorganization : Off

Figure 6.

In this case we set the norm for both teams in "attack" mode. Reorganization switch is turned on for Italy and it is turned off for Brazil. There are three players in Defense and Mid-Field department and there are four players playing on the forward department. The resultant graph of utilities for teams at a time cycle of 11400 clock cycles is shown in Figure 7.

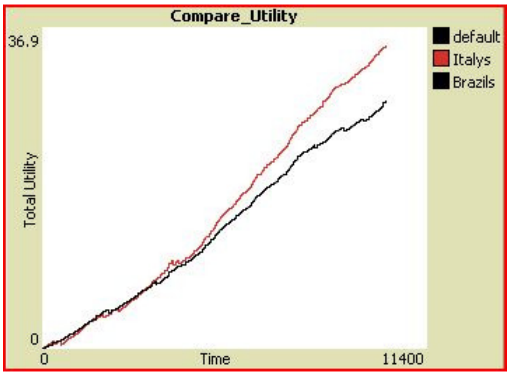


Figure 7.

At the time when the readings are noted the graph shows, Team Italy's utility 36.9 and Team Brazil's utility at 31.2. Due to the implementation of the reorganization algorithm the Team Italy has a considerable advantage over the opponents.

VI. Conclusions

We have made novel strides in managing massive agent organizations that contributes to development of our man on the loop paradigm. Our methodology allows for Moe to prescribe normative patterns of behavior, which in turn guide the reorganization process. Individuals most fit to play their current roles stay while others are directed to surroundings that augment their synergy. We have demonstrated with the popular game of simulated soccer but the results are generic and transfer to other domains.

Abstract—**Recently we have setup the goal of investigating new truly distributed forms of Ant Colony Optimization. We proposed a new distributed approach for Ant Colony Optimization (ACO) algorithms called Ant Colony Optimization on a Distributed Architecture (ACODA). ACODA was designed to allow efficient implementation of ACO algorithms on state-of-the art distributed multi-agent middleware. In this paper we present experimental results that support the feasibility of ACODA by considering a distributed version of the Ant Colony System (ACS). In particular we show the effectiveness of this approach for solving Traveling Salesperson Problem by comparing experimental results of ACODA versions of distributed ACS with distributed random searches on a high-speed cluster network.**

I. Introduction

As NATURAL phenomena are inherently distributed, we think that nature-inspired computing should allow a straightforward mapping onto existing distributed architectures. Therefore, to take advantage of the full potential of nature inspired computational approaches, we have setup the goal of investigating new distributed forms of Ant Colony Optimization (ACO hereafter) using state-of-the-art multi-agent technology.

In our recent work [1] we proposed a scalable multi-agent system architecture called ACODA (Ant Colony Optimization on a Distributed Architecture) that allows the implementation of ACO in a parallel, asynchronous and decentralized environment. The novelty of our approach is: (i) the problem environment is conceptualized and implemented as a distributed multi-agent system ([2], [3]) and (ii) ant management is reduced to messages exchanged asynchronously between the agents of the problem environment.

Existing computational approaches of ACO [4] are based on sequential algorithms, are highly synchronous and require use of global knowledge. While few parallel and distributed versions of ACO exist [5], they are mainly based on their sequential counterparts, thus hindering the potential gain through parallelization. For example, in [5] the authors propose a parallel, distributed, asynchronous and decentralized implementation of ACO. However, their approach requires maintenance of the globally best solution currently known using global update each time a better solution is found. Moreover, the authors' claim that "their implementation does not effect the accuracy, speed and reliability of the algorithm" is not supported by any experimental evidence.

The focus of this paper is to experimentally evaluate the feasibility of ACODA by considering a distributed version of ACO inspired by the Ant Colony System (ACS) [4]. In particular, we show the effectiveness of this approach at solving Traveling Salesperson Problem (TSP hereafter) by comparing experimental results of ACODA versions of distributed ACS with distributed random searches on a high-speed cluster network. The results clearly show that our distributed version of ACS based on ACODA preserves the nice heuristic properties of standard ACS, while also providing scalability by exploiting distributed computing architectures – multi-agent middleware in this case.

The paper is organized as follows. In Section II we present some background on ACO and distributed approach and we briefly review the ACS model that inspired our initial experiments. There are however notable differences between classic ACS and our distributed version based on ACODA (see Section V). In Section III we introduce ACODA architecture and underlying search algorithm. Section IV presents experimental results that support the effectiveness of our approach by comparing results obtained with running on ACODA our distributed version of ACS with other three distributed search methods. Section V presents related works, while Section VI presents our conclusions and points to future works.

II. Background

ACO is inspired by behavior of real ants. When ants are searching for food, they secrete pheromone on their way back to the anthill. Other colony members sense the pheromone and become attracted by marked paths; the more pheromone is deposited on a path, the more attractive that path becomes. The pheromone is volatile so it disappears over time. Evaporation erases pheromone on longer paths as well as on paths that are not of interest anymore. However, shorter paths are more quickly refreshed, thus having the chance of being more frequently explored. Intuitively, ants will converge towards the most efficient path, as that path gets the strongest concentration of pheromone. Artificial ants are programmed to mimic the behavior of real ants while searching for food. More details on the ACO metaphor can be found in [4].

In this paper we propose ACODA distributed approach for the implementation of ACO algorithms and show its effectiveness for solving TSP. The goal of TSP is to compute the shortest tour that visits each node of a complete weighted graph exactly once. The decision version of TSP is known to be NP-complete so it is very unlikely that a polynomial solution for solving TSP exists. So TSP is a good candidate for the application of heuristic approaches, including ACO.

The main and also new idea behind ACODA is to provide a multi-agent distributed architecture for modeling the problem environment. One or more anthills are located in this environment. Artificial ants originating from anthills will travel in the environment to find optimal solutions, following ACO rules. In order to approach TSP using ACO, the problem environment is modeled as a distributed set of interconnected graph nodes that are also anthills. Each graph node is modeled as a software agent that can host a population of ants. The ants travel between nodes until they complete a tour. Once they return to their originating anthill, they mark the solution with pheromone by retracing their path. The ants traveling is modeled as messages exchanged by the agents that represent the graph nodes.

Many ACO algorithms have been proposed in the literature. A good survey is [4]. While with ACODA we aim at proposing a general distributed framework based on agent middleware for different ACO algorithms, the ACO model considered in this paper is based on a particular version of ACO – the ACS system [4]. ACS is a sequential implementation of ACO that chooses to move ants in parallel instead of moving each ant until it finishes its tour. Our approach presents a few differences due to the ACODA requirements: (i) distributed architecture based on asynchronous message passing and (ii) avoid to use global knowledge.

ACO rules determine the amount of pheromone deposited on edges, the edge chosen by each ant on its way, and how fast the pheromone deposited on each edge evaporates. For this purpose we use the mathematical model of ACO that is used in ACS.

In ACS, ant k located at node i decides to move to node j using "pseudo random proportional rule" (1). Equation (1) chooses to directs the ant either to a completely random node or to a node of high desirability, and this decision is taken probabilistically.

$$j = \begin{cases} argmax_{l \in N_i}((\tau_{i,l})^{\alpha}(\eta_{i,l})^{\beta}), & \text{if } q \leq q_0 \\ J, & \text{otherwise} \end{cases} \tag{1}$$

where:

- α is a parameter to control the influence of $\tau_{i,j}$
- $\tau_{i,j}$ is the amount of pheromone deposited on edge (i, j)
- $\eta_{i,j}$ is the desirability of edge (i, j) computed as the inverse of the edge weight, i.e. $1/w_{i,j}$
- β is a parameter to control the influence of $\eta_{i,j}$
- q is a random variable uniformly distributed in $[0, 1]$
- q_0 such that $0 \leq q_0 \leq 1$ is a parameter that controls the selection between a random neighbor and most promising neighbor based on pheromone deposit and edge desirability
- J is a random node selected according to the probability distribution given by equation (2)
- N_i represents the set of neighbors of node i

An ant located in node i will randomly choose to move to node j with the probability $p_{i,j}$ computed as follows:

$$p_{i,j} = \frac{(\tau_{i,j})^{\alpha}(\eta_{i,j})^{\beta}}{\Sigma_j(\tau_{i,j})^{\alpha}(\eta_{i,j})^{\beta}} \tag{2}$$

where:

- α is a parameter to control the influence of $\tau_{i,j}$
- β is a parameter to control the influence of $\eta_{i,j}$
- j is a node reachable from node i that was not visited yet

Following equation (1), the ant makes the best possible move (as indicated by the learned pheromone trails and the heuristic information, i.e. the ant is exploiting the learned knowledge) with probability q_0, while it performs a biased exploration of the arcs with probability $(1 - q_0)$.

Better solutions need to be marked with more pheromone. So whenever an ant k determines a new tour V_k of cost L_k the ant will increase pheromone strength on each edge of the tour with a value that is inversely proportional to the cost of the tour.

$$\Delta\tau^k_{i,j} = \begin{cases} 1/L_k & \text{if edge } (i, j) \text{ belongs to found tour } V_k \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

When an ant travels along a given path, this traveling takes an amount of time that is proportional with the travel distance (assuming the ants move with constant speed). As pheromone is volatile, if a real ant travels more, pheromone will have more time to evaporate, thus favoring better solutions to be discovered in the future. We conclude that adding pheromone evaporation to our model can be useful, especially for solving a complex problem like TSP.

When an ant completes a tour it will retrace its steps marking the edges on the way with pheromone. The update will also take into account pheromone evaporation. Assuming an evaporation rate $0 \leq \rho < 1$, evaporation and pheromone update are implemented in ACS as follows:

$$\tau_{i,j} = (1 - \rho)\tau_{i,j} + \rho\Delta\tau^k_{i,j} \tag{4}$$

Ants use equation (1) to probabilistically determine their next step. Therefore they will often choose the edge with the highest pheromone, while the exploration of less probable edges is low. This behavior can be compensated by decreasing the pheromone on edges chosen by ants using a local pheromone evaporation process. This has the effect of making them less desirable, increasing the exploration of the edges that have not been picked yet. Assuming that $0 \leq \xi < 1$ is the local evaporation rate and τ_0 is the initial amount of

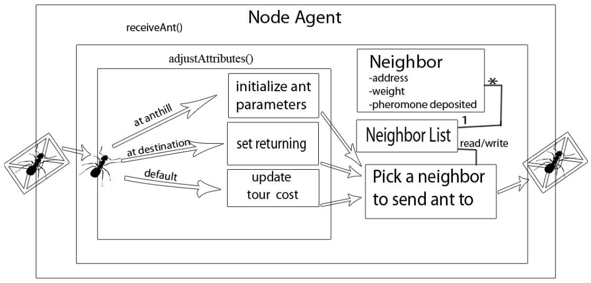

Fig. 1: Node structure in ACODA.

pheromone on each edge, whenever an ant traverses an edge it applies local evaporation by updating pheromone as follows:

$$\tau_{i,j} = (1-\xi)\tau_{i,j} + \xi\tau_0 \tag{5}$$

A good heuristics to initialize pheromone trails is to set them to a value slightly higher than the expected amount of pheromone deposited by the ants in one tour; a rough estimate of this value can be obtained by setting $\tau_0 = 1/(nC)$, where n is the number of nodes, and C is the tour cost generated by a reasonable tour approximation procedure [4]. For example we can set $C = nw_{avg}$ where w_{avg} is the average edge cost.

In order to observe the impact that evaporation has on the solutions, we have also considered a pheromone update scheme that does not include evaporation at all. In this case equations (5) and (4) are replaced with:

$$\tau_{i,j} = \tau_{i,j} + \Delta\tau^k_{i,j} \tag{6}$$

III. Architecture

In ACODA, the nodes of the graph are conceptualized and implemented as software agents [2]. For the purpose of this work, by software agent we understand a software entity that: (i) has its own thread of control and can decide autonomously if and when to perform a given action; (ii) communicates with other agents by asynchronous message passing. Each agent is referenced using its name, also known as agent ID.

The activity carried out by a given agent is represented as a set of behaviors. A behavior is defined as a sequence of primitive actions. Behaviors are executed in parallel using interleaving of actions on the agent's thread with the help of a non-preemptive scheduler, internal to the agent [3].

Node design (see Figure 1) must include a behavior for sending and receiving ants. Whenever an ant is received, the RECEIVE-ANT() behavior (see Table I) immediately prepares it and then sends it out to a neighbor node following ACO rules.

Ants are represented as objects with a set of attributes: cost of the currently search path (which becomes L_k when the ant completes a tour), pheromone strength (value of $\Delta\tau^k_{i,j}$), returning flag, best tour cost (value of the currently best tour that the ant knows, based on its search history) and a list of node IDs representing the path that the ant followed to reach its current location. The list is necessary for two reasons: i) the ant needs to retrace its steps in order to mark the tour with pheromone and ii) we need to avoid loops so only unvisited nodes are taken into account as possible next hops. Attributes are initialized when an ant is created and updated during the process of ant migration to reflect the current knowledge of the ant about the explored environment.

Nodes (represented as software agents) manage a list of neighbor nodes and best tour cost (the value of the currently best tour that the node knows, based on ants that traveled through this node). For each neighbor node we record the weight and the value of deposited pheromone of the corresponding edge. Note that each node and each ant maintain their own values of the best tours they encountered so far. So, whenever an ant is traveling through a node, the ant and the node are able to exchange and update their best tour information accordingly.

In our approach each node creates its own ant population thus becoming an anthill. Nodes calculate pheromone strength according to the tour cost (see equation (3)) and also update the ants' pheromone strength attribute. Additionally, nodes set the returning flag for returning ants, exchange ant information with other nodes, deposit pheromone when needed, and update the cost of the currently search path of an ant.

The structure of a node is presented in Figure 1. RECEIVE-ANT() behavior parses a received ant message, adjusts ant's attributes using ADJUST-ATTRIBUTES() method and sends it out to the address determined by BEST-NEIGHBOR() method. This happens whenever the agent's message queue isn't empty [3]. ADJUST-ATTRIBUTES() method sets returning flag and calculates pheromone strength using equation (3) whenever an ant has completed a tour. Ants that have returned to the anthill are re-initialized.

BEST-NEIGHBOR() uses the RANDOM-CHOICE() method determine the address of the node where to send the ant. When the ant returns to the anthill, the ant is sent to the first node from its list of visited nodes, popping it from the list, and the method DEPOSIT-PHEROMONE() is then called. LOCAL-EVAPORATE-PHEROMONE() together with DEPOSIT-PHEROMONE() implement pheromone update (deposits and evaporation). In order to implement different forms of ACO it is usually sufficient to modify the methods LOCAL-EVAPORATE-PHEROMONE(), DEPOSIT-PHEROMONE() and RANDOM-CHOICE() (see Section IV).

IV. Experiments and Discussions

In order to facilitate experimentation with ACODA, we created a distributed platform based on JADE framework [3] that can be configured to run on a computer network. The focus of the experiments was to show the effectiveness of ACODA to support distributed ACO-based algorithms for solving TSP. We configured ACODA platform on a high-speed cluster network of 7 computers and then we analyzed experimental results that we obtained by running (i) our distributed ACS-based algorithm and (ii) other distributed random search algorithms.

Setup. An experiment is structured as a fixed number of independent experimental rounds. A round consists of one

execution of an algorithm on ACODA, for a given set of parameters. All parameters are initialized at the start of each round. Experimental data are collected during each round. At the end of the experiment (when the fixed number of rounds is reached) these data are used to calculate performance measures.

ACODA is a distributed platform. Setting-up and running it on several computers assumes two stages: (i) initialization; and (ii) execution.

During the initialization stage: JADE platform is started, a number of containers are created (typically one container for each available machine), and finally node agents are created and evenly distributed on available containers of the JADE platform.

The experiment is ran during the execution stage. Experiment execution is controlled using special control messages. Control messages are distinguished from ant exchange messages using their conversation ID. Command messages have their conversation ID set to "command", while ant exchange messages have their conversation ID set to "ant". Command messages are given higher priority than ant exchanging messages.

An experimental round starts when all node agents receive a "start" command, and ends when all node agents receive a "stop" command. A designated node agent – called *MasterNode* is responsible with issuing commands and calculating performance measures. *MasterNode* counts the total number of ants that it receives. When this number reaches a given maximum value M, *MasterNode* stops the current round (issuing a "stop" command) and starts a new round (issuing a "start" command). Note that *MasterNode* is needed only for evaluation and consequently it is not part of the distributed approach.

Duration T_i of a round i is recorded by *MasterNode* agent as time elapsed between issuing a "start" and "stop" command. While the distributed ACO algorithm is running, minimum tour costs are passed from node to node via ants. Whenever a node agent updates its current value of the minimum tour, the time elapsed since the node received the "start" command is also recorded. When an experimental round is finished, *MasterNode* agent saves the experimental data collected during the round.

We cannot assume that the best tour recorded by *MasterNode* is actually the best tour computed during an experimental round. So we must determine minimum of the best tours computed by all node agents together with the time when this tour was found.

Let us suppose that we have n node agents and k experimental rounds. For each node agent $j \in \{1, 2, \ldots, n\}$, let $t_{i,j}$ be the time of the last update of the best tour performed by node agent j in round $i \in \{1, 2, \ldots, k\}$, and let $v_{i,j}$ be the cost of the corresponding tour. *MasterNode* agent will collect values $v_{i,j}$ and $t_{i,j}$ and will determine the solution v_i and associated time t_i in round i as shown in first two rows of Table II.

The experimental data that were acquired during all the rounds of an experiment are post-processed to calculate performance measures as shown in last five rows of Table II.

Initial performance analysis. We experimented with ACODA on increasingly complex search versions (see Table III) in order to establish its effectiveness for implementing ACO-based algorithms. We considered our ACS-based version of ACO, together with other three distributed search methods – Random Choices, Cost Only, and Pheromone Search. The first two are not ACO-based, while the third is ACO-based.

For the Random Choices (RC) version we replaced equation (1) with randomly choosing the next hop of an ant from the unvisited nodes – i.e. the deposited pheromone and the edge weights are ignored.

For the Cost Only (CO) version we choose the next hop using equation (2), setting $\alpha = 0$ and $\beta = 1$ – i.e pheromone deposits are not taken into account.

Pheromone Search (PS) is an ACO-based search that uses equation (1) to determine the next hop. PS allows all ants to deposit pheromone regardless of tour cost. For this model, the ACO parameters were set to the values recommended by [4] for the ACS algorithm: $\tau_0 = 1/(n^2 w_{avg})$, $\rho = \xi = 0.1$, $\alpha = 1$, $\beta = 5$.

Finally, the ACS-based version of ACODA uses the same parameters as PS, but it allows only the ants that found the best tour so far to deposit pheromone. For all searches, the total number of ants is chosen equal to the number of nodes n (for each node the ant population consists of a single ant) as recommended in [4].

Note that, as we focus on finding the best solution, we chose $q_0 = 0$ in Equation (1), thus avoiding the convergence to a suboptimal solution (this fact is relevant for PS and ACS versions).

We ran several experiments using the following benchmark TSP maps selected from TSPLIB [6]: eil51, st70, kroA100,

TABLE II: Calculation of performance measures.

$v_i = \min_{j=1}^{n} v_{i,j}$	v_i is the solution found by round i.
$t_i = \min_{j=1}^{n}\{t_{i,j} \vert v_{i,j} = v_i\}$	t_i is the time in which solution was found by round i.
$v_{avg} = (\sum_{i=1}^{k} v_i)/k$	v_{avg} is the average value of solutions found in all rounds.
$t_{avg} = (\sum_{i=1}^{k} t_i)/k$	t_{avg} is the average time in which solutions were found in all rounds.
$v_{min} = \min_{i=1}^{k} v_i$	v_{min} is the best solution found after carrying out all rounds.
$t_{min} = \min_{i=1}^{k}\{t_i \vert v_i = v_{min}\}$	t_{min} is the time taken to find the best solution in all rounds for the first time.
$T_{avg} = (\sum_{i=1}^{k} T_i)/k$	T_{avg} is the average execution time of the rounds in an experiment.

TABLE III: Algorithms implemented on ACODA. "nop" means that the corresponding function has an empty body for that specific case.

	RC	CO	PS		ACS	
evaporation	no	no	no	yes	no	yes
LOCAL_EVAPORATE_PHEROMONE()	nop	nop	nop	eq (5)	nop	eq (5)
DEPOSIT_PHEROMONE()	nop	nop	eq (6)	eq (4)	eq (6)	eq (4)
Observations:	no pheromone update	no pheromone update	all ants deposit pheromone		only the best tour is marked	
RANDOM_CHOICE()	random unvisited neighbor	eq (2) $\alpha = 0$, $\beta = 1$	eq (1) $\alpha = 1$, $\beta = 5$		eq (1) $\alpha = 1$, $\beta = 5$	

ch150. Note that the number in the map name indicates the number of nodes of the map, so for example map st70 contains 70 nodes. These maps were chosen to experiment with different values of w_{avg} and $\Delta w = w_{max} - w_{min}$ where Δw is the difference between the maximum and the minimum edge weight and w_{avg} is the average edge weight.

Taking into account that we create an agent for each node, it follows that for st70 problem 70 agents were created. These agents are evenly distributed on 7 computers, so 10 agents must be created on each computer for solving st70 problem.

We define an ant move as the action of transferring an ant from a source node to destination node along a given edge. The number of ant moves was chosen according to the proposal from [4]. There, 1000 moves per ant were chosen for a 19 node map. Taking into account the sizes of our maps and scaling up proportionally, we determine a number $M = 10000$ of ant moves for our experiments.

We ran 10 rounds for each experiment on networks of 7 computers with dual core processors at 2.5 GHz and 1GB of RAM memory. These workstations were interconnected using a high-speed Myrinet interconnection network at 2Gb/s.

In the CO model the ants pick the smallest available weight (i.e the nearest unvisited neighbor) with a greater probability than the rest. This strategy guides the ants to worse solutions than the RC model. As expected, in the RC model, the difference $v_{avg} - v_{min}$ is larger as the tours variate in cost more.

In Table V we considered both evaporation scheme suggested by [4] for ACS (equation (4); see rows marked with $evap = 1$ on Table V) and absence of evaporation (equation (6); see rows marked with $evap = 0$ on Table V). Note that the PS model has no significant benefit from using the ACS evaporation scheme with the recommended parameter values in [4]. As a matter of fact in most cases evaporation decreases the quality of the solutions, see Table V for $evap = 0$ the values of v_{min} and v_{avg} are better than those for $evap = 1$. This is not the case for the ACS version of ACODA where evaporation improves the solutions. This suggests there is still room for improvement in the PS model. However, further study is needed in order to establish wether the evaporation parameters should be adjusted or a completely new approach should be developed.

Our experiments (see Table V) clearly show that the ACODA versions that take into account pheromone deposits are much more efficient at determining good solutions since the values of v_{min} and v_{avg} from Table V are better than those in Table IV. The fact that all these variations can be easily implemented using ACODA supports the flexibility of this architecture, while the fact that the best results are obtained when pheromone deposits are taken into account shows the effectiveness of ACODA in supporting distributed forms of ACO.

V. Related work

TSP is a classic benchmark problem for heuristic search algorithms. With the advent of distributed computing technologies, distributed versions of heuristic algorithms for TSP were also proposed. However, based on our literature review, there are very few works that propose ACO-based truly distributed TSP algorithms. Moreover, there are even fewer proposals that utilize recent advances of multi-agent systems middleware for ACO-based TSP [5]. Nevertheless, we could find references to multi-agent approaches to ACO algorithms for other combinatorial optimization problems ([7], [8], [9]).

A closely related approach to agent-based distributed ACO is presented in [5]. There, both graph nodes and ants are

implemented as JADE software agents. Ants centralize information about pheromone deposits and nodes' best tour cost through a single ACL message exchange per node [3]. This procedure adds up to $2n$ messages per tour per ant, where n is the number of nodes. Each ant has to notify the node about its next hop and the cost of its tour in order for the node to be able to update its pheromone levels. This generates other n messages. When an ant completes a tour, it compares the tour cost with the collected best tours from the nodes. A best tour synchronization is triggered for all the nodes if a better tour has been found. This brings an additional overhead of n messages. So, [5] approach requires at most $4n$ messages per tour per ant, while our approach requires at most $2n$ messages: n messages (ant moves) to complete a tour and n messages to deposit the pheromone. We avoid the additional overhead of sending to nodes all the information necessary to carry out their tasks, as in ACODA this information is already contained in ant messages exchanged between nodes.

ACODA implementation reported here is based on the sequential ACS algorithm presented in [4]. There are however three notable differences: i) We avoid the explicit iterations of the standard ACS. An iteration lasts until each ant has found a tour. With the distributed architecture it would be time consuming to provide the synchronization necessary for implementing the explicit iterations, because it would cancel the main benefits of an asynchronous, distributed architecture; ii) In ACS, best tours are compared after each iteration, thus allowing only the best ant to mark its tour. Again, this would require synchronization and centralized computation and we avoid it by allowing all ants to mark their tours; iii) In ACS ants move synchronously, taking one step at a time, while in our approach ants move asynchronously.

Papers [8] and [9] propose JABAT – a JADE-based middleware for agent teams. JABAT supports distributed implementation and collaboration of population-based optimization algorithms. In particular, JABAT was applied to TSP. There is however an important difference between JABAT and ACODA. JABAT agents represent improvement algorithms, which basically means that improvement algorithms are sequential and they cooperate for solving a problem in a distributed way. ACODA agents provide a natural distributed model of the problem environment that is suitable for distributed ACO algorithms. Moreover, we could not find scalability studies referring to JABAT.

Paper [7] proposes a JADE-based multi-agent environment for dynamic manufacturing scheduling that combines intelligent techniques of ACO and multi-agent coordination. However, the focus in [7] is to evaluate the impact of ACO intelligence on multi-agent coordination, rather than to utilize multi-agent middleware for improving ACO. ACO intelligence is embedded into job and machine agents with the role of ants, which is different from ACODA where ants are passive objects exchanged by software agents that provide a distributed model of the problem environment.

In [10] authors compare a distributed form of ACS with flooding algorithm applied on resource discovery problem. They experiment with both algorithms using *ns-2* network simulation tool [11]. The down side of this is that no real execution time measure can be made using their approach. They showed that ACS is the better approach in terms of: best success rate, least number of hops and least traffic. The detailed algorithm and ACO parameters are not presented in order to duplicate their approach using our ACODA framework, for a realistic comparison. The differences between their approach and ACODA are: (i) resource queries are handled centrally at a single anthill, thus introducing single point of failure, (ii) they do not take edge weights into account as they are trying to solve the resource discovery problem, not the TSP problem, and (iii) ants are implemented as *ns-2* mobile agents, while in ACODA we are using JADE. Moreover, in practice there is no need for code mobility as every ant is governed by the same behavioral rules. So, in our approach we use "nodes as agents" to control ants' movement using messages, rather than using code (i.e. JADE agent) mobility.

Paper [12] proposes purely theoretical frameworks for multi-agent systems. No experiments or implementations are mentioned. The authors present a distributed form of ACO based on so called "smart messages" approach to multi-agent systems where agent mobility is used to implement complex communication over dynamic networks. They use delegate multi-agent systems to manage these smart messages in order to design a multi-agent approach for ACO. They do not present ways of representing the environment, determining convergence or stopping condition of ACO experiments.

In [13] authors thoroughly analyze multi-colony ACO algorithms applied on TSP. The main difference between their and our approaches is that they run a separate colony on each available processor. At predetermined points in time, the solutions are centrally collected and local search is performed on the best solution provided by each of the colonies. This is not a fully decentralized approach to ACO, as it requires synchronization and centralized sequential local search after each solution was centrally collected. Our approach is completely decentralized, parallel and asynchronous, and thus it could lend itself to heavy parallelization.

VI. Conclusions

In this paper we presented experimental results with our new multi-agent framework for truly distributed ACO. An initial implementation of the framework using JADE multi-agent platform was outlined. This implementation followed the ACO approach initially proposed for the ACS system. However, three important differences between ACODA and original ACS system were highlighted. This approach was initially evaluated on sample benchmark TSP problems. Experimental results were encouraging, as they clearly support the effectiveness of our proposal for distributed ACO, thus confirming the feasibility of our ACODA framework. We already identified suitable directions for future works: i) strengthen the scalability results by experimenting with this approach on larger TSP problems and larger computer networks; ii) support the generality of our framework by considering other forms of ACO rather than only ACS; iii) improve the ACODA architecture to enable experimentation with larger TSP problems than the current version of ACODA is able to support.

***Abstract*—The paper presents selected security aspects related to confidentiality, privacy, trust and authenticity issues of a distributed, agent-based computing. Particular attention has been paid to authenticity of and trust in migrating mobile agents executables, agent's trust in runtime environment, inter agent communication and security of agent's payload. Selected attack vectors against agent-based computing were described and risk mitigation methods and strategies were proposed and discussed based on presented cryptography measures. In summary expected effectiveness of proposed countermeasures was described.**

I. Introduction

AGENT-BASED computing based on conceptual software entities named *agents* (often *intelligent agents*) plays an important role in integration of various distributed systems and services. Agent paradigm describes agents as closed entities, existing within agent runtime environments (e.g. [1]), capable of percepting and effecting their environment and aware of their *mission*. Agents typically have a large dose of autonomy in pursuing their goals.

Systems incorporating agent paradigm rarely utilise single agents. More often whole *societies* of agents are employed, interacting socially to reach common goals. Typical examples of such interactions are negotiations, contracts, cooperation and coordination of common tasks. All such interactions are based on communication, which in most cases follows established patterns and norms [2]. Runtime environments for agents also try to follow a set of established rules and guidelines [3].

In heterogeneous, open agent environments, where both agents and agent environments originate from and are hosted by different organisations special attention must be paid to security issues—both agent's security and payload (data) security.

Risks may originate from social attacks (e.g. attempts at fraud, cheating, deception) and technical attacks (e.g. agent environment modifying agent's code or data; agents attacking their environment and creating a denial of service by overloading of selected resources or crashing the container etc.). Many authors addressed selected aspects of agent-based computing in recent years. Extensive research of threats and countermeasures was presented by NIST [4]. In a followup to this paper, Jensen [5] described a taxonomy of protection techniques for agents and agent platforms. The taxonomy was divided into two main groups:

- detective measures—methods to detect modifications of agent's code, agent's payload and agent environment;
- preventive measures—obfuscating of code, data, agent's route etc.).

A major role in those techniques is played by cryptography—digital signatures, encrypted code, one time passwords, session keys. A review of agent protection measures reflecting the social element of agent architectures (agent's context, autonomy, communication with other agents, mobility) was presented by Borselius in [6]. Moreover, author proposes the following ways of addressing threats coming from malicious servers:

- contractual agreements—where server platform operators enter into contract with customers, declaring safety of the environment and administrative practices crafted to avoid violation of customers' privacy or integrity of their data, agent code and computations;
- trusted hardware;
- trusted network nodes;
- fault tolerant computing techniques—i.e. cooperation of many agents, partitioning and duplication of data and redundancy in agents functionality;
- execution tracking—gathering and offering logs of agents activities;
- data encryption (however it should be noted that, once decrypted, data will be easily available to interested parties and also that communication is required to obtain decryption key);
- hiding of code and data in blackboxes [7];
- undetachable signatures carrying encoded constraints on permitted agents' code use—if those constraints are not met, messages sent by agents will not be signed by a host;
- sandboxes and code signing when agents' code meets requirements of security policy requirements (proof carrying code).

Computations carried out by use of encrypted functions were deemed prospect less.

Another attempt at protection methods taxonomy was made by Leszczyna [8]. In his paper he proposed to classify protective measures into following subgroups:

- runtime data protection,
- ensuring of mobile code immutability and security,
- event logging.

In addition, he proposed an extension of JADE agent platform protecting agents against tracking. His proposed solution [8] assumes use of trusted parties, encrypting agents route and possibly other data it carries en route between hosts, thus making it impossible for an attacker to determine where a given agent is coming from and its route, which in turn makes it difficult to deduct on agents' goals and findings. A drawback of this approach is a necessary requirement for agents to always return to a recent forwarding trusted party. In addition, nodes forming trusted parties must securely store encryption keys and correctly match them to returning agents.

Yet another JADE extension was proposed in [9], where Zwierko and Kotulski proposed an original method of ensuring mobile agent's integrity, combining protection of code, data and computational state. Their method was based on secret sharing scheme and zero-knowledge protocol.

A secure agent platform, based on Public Key Infrastructure (PKI), was described by Ismail [10]. Author points at the importance of protection of objects containing data from other agents or server data, because such objects may be referenced by a mobile agent. Java environment (sandboxes, memory protection) provides only a partial protection of data against destruction by a malicious mobile agent, because it lacks mechanisms which would allow definition of various access rights based on authentication or permit runtime evolution and delegation of such access rights during execution and communication as well as carrying such rights during agents migration. A proposed solution [10] is to introduce a mechanism of dynamic permissions exchange between cooperating agents. When migrating between hosts an agent needs to carry its permissions and export them to other agents already working on target host. To allow it agents must have means to mutually authenticate themselves. It was proposed that such mechanisms are to be provided by hosts using an external, trusted PKI. A trusted CA generates a key pair for each host (platform) and signs the public keys. Initially agents provide only minimal rights to other cooperating agents. As cooperation progresses those rights may be gradually extended. A *right* in this context means a particular method able to act on a particular object. In her deliberations author did not address agents' mobile nature, methods of rights protection, ease of implementation or expected gains. In her paper she defined requirements and analysed various authentication scenarios:

- of a client agent created by a local server;
- of a foreign (visiting) agent—a problem in this case is the necessary communication between a local and a foreign agent because of its impact on processing performance.

Access control lists (ACLs) were proposed for rights management and secure naming services and servers were proposed to allow communication where symbolic names are used as addresses. Each server uses a key-store mechanism to store its private key. Every agent has three relations (sender, owner, writer) with other entities (servers, users): Each of them signs agents' code, data and rights.

A protection against hostile hosts hosting agent platforms was proposed by Hohl [7]. Author stresses that protection of mobile agents against malicious servers and protection of agent environments against malicious agents are of equal importance. He describes attacks which can be carried by servers against agents' data, code and execution. Two main attack classes are distinguished:

- passive attacks—where agents' data, code and communication are spied upon / intercepted;
- active attacks—where agents' data, code, execution patterns and communications are subject to modifications, alterations and impairment.

A main concept addressed in [7] is a blackbox mechanism—blocking access to code and data. Author states, that it is not possible to construct an agent with a generic blackbox, but only with a time limited one. The stated reason is threat of dictionary attacks. He proposes to construct such a time limited blackbox with the use of transformations using random parameters (so called mess-up algorithms). However, this method ca not be applied to every kind of code and data. In addition, blackboxes may be vulnerable to various attacks, including sabotage, testing of limitations (e.g. finding agents' upper limit on price it is willing to pay) which lets an attacker uncover partially agents' data. Another problem is finding the right time limit of a blackbox. Too short limit may impede achievement of agent's goals and reveal its data and mission before it is accomplished. Setting the limit too long increases the chance of a successful attack against the blackbox.

II. Security issues in typical agent environments

Each type of computing has security considerations. Agent based computing is no different in this respect. Typical problems include: *authenticity* (who is the sender/author of a message), *confidentiality* (of sensitive/valuable data) and *privacy* (when personal data is carried/processed). Sometimes non-repudiation is also important. Cryptographic protocols are used to address these issues, mostly digital signatures and data encryption. Agents may sign messages to try to ensure its authenticity. As discussed later in this paper, this approach may be insufficient. All the mentioned security aspects of computations influence users trust in results—also known as results authenticity. Agent-based computing security mainly consists of:

- ensuring agent authenticity (is it really the agent sending data and not a malicious phantom (fake));
- trusted computing environment (including trusted agent platform — i.e. not introducing changes to agent's code or data; not interfering with agent actions unless it is necessary to protect itself against a malicious agent);
- authenticity of results—obtained results can be trusted to be original, not falsified;
- maintaining confidentiality of results during their transfer to recipient.

Typical agent environments [11][12][13] assume full trust in hosts and provide only a limited set of security tools — user authentication and cryptographic data tunnels (TLS/SSL). Moreover agent containers may be authenticated using digital signatures. Typically combinations of DSA/SHA1 and RSA/MD5 are used. MD5 algorithm is considered weak [14] as collision possibilities were detected. To start data signing it is necessary to provide a password deciphering a private key. It implies, that during agent activity either the password or the deciphered private key is accessible and visible, otherwise user engagement would be necessary on each signing attempt. Public key certificates are self-signed by corresponding private keys and must be distributed in advance to agent containers with the assumption, that each agent container uses identical combination of hash and signing functions. It implies full control over agent and hosting environment by users deploying agent-based applications. In addition, this environment should be isolated from threats coming from the Internet to ensure trust in results.

III. Attacks on agent environment and security assessment

Typical attacks on agent environments and agent-based computing lead to falsifications of computing results or disruption of agent activities. They include:

- undetected injection of hostile agent(s) posing as legitimate ones and deforming the results of agent interactions;
- snooping or substitution of messages;
- posing as a legitimate agent to damage or destroy data stored on machines hosting agent environment.

Unfortunately, neither JADE [11][12] nor other environments provide security to agents or authenticity of results because of several reasons: agents acting within a remote agent container are in an alien environment, thus are susceptible to remote interference (eavesdropping, intrusion, decompiling, interception of results, etc.). Agents in this situation are unable to securely store any sensitive data (e.g. signing keys, passwords, etc.) because at any time such data may be read by a host. Even SSL session keys are not protected because of these issues.

Current solutions in agent-based computing do not address any of the security postulates [10][4][5][8], i.e. neither really confidential communication is provided nor it is authentic. Proposed remedies are selective in their nature (i.e. nothing is gained by SSL encryption when session keys are readily available). Any solution in this area requires cooperation between agent and a trusted host to be effective [8].

IV. Improving security of agent-based computing

To solve the problem of authentic and confidential delivery of agent-based computing results to the originating party several assumptions should be made:

- hosts taking part in agent-based computing should be methodically designed, tested and reviewed, i.e. they fulfil the requirements of ISO Evaluation Assurance Level 4 [15]. Such requirements are in use when designing digital signature environments that are considered valid by authorities (government, legal system). Similarly, system projects should follow generally recognised software engineering safe practices, i.e. automatic architecture management and testing to ensure system resistance to most potential attacks.
- Public Key Infrastructure with PK certificates issued by recognised Certification Authorities (CA) should be designed and implemented.
- Agent environments should be extended to provide communication interfaces to host based services like signing, time stamping, session key generation, etc.

The solution proposed below is similar to the one described in [10]. However, it is based on the assumption of trusted hosts availability. We postulate, that without the support of trusted hosts the security of agent-based computing can not be attained. With these limitations in mind we envision a secure agent-based computing in a following way:

1) User (computation originating party) signs the agent's code and data, assuring the receiving host of agent's credibility.
2) Agent executes inside a monitored container, trusted not to modify agent's code or results.
3) For communication with other agents or originating host agent calls local trusted host provided services like: digital signing or time stamping. After obtaining either a time stamp certificate or a signature agent combines it with a message and sends it to a recipient. To provide in-transit data security either SSL tunnels may be utilised or, in their absence, messages can be encrypted with a session key enciphered by a recipient's public key. Encrypted session key is attached to a cipher text.
4) A receiving party, using trusted PK certificates of computers involved in computations, verifies the signature of a message, therefore gaining trust in its contents and its origin.

V. Summary

We analyse the security of a proposed approach:

1) A signed agent should convince each hosting computer about agent's code authenticity. Public key certificate of the originating party should be commonly available to allow any party to validate the signature and therefore identify agent's origin.
2) Data and results gathered or produced by an agent will be trustworthy if the environment in which they were obtained is sufficiently secure. Access to a public key certificate issued by a commonly recognised CA attests to the hosts credibility. The procedures of obtaining such a PK certificate ensure, that the host and the organisation running it is sufficiently trustworthy.
3) Similar arguments can be used to indicate, that trust can be extended to a hosting computer and its signature. Host security requirements create a similar level of confidence in its private (signing) key. Agents can not store any signing keys—even in an encrypted form — because at signing it would have to be uncovered and in a such case accessible to all observers.

Implementation of our proposals should significantly improve trustworthiness of agent based computing. They are not perfect, and additionally require a very high level of security for all computers and a PK infrastructure. In our approach it is also mandatory to develop new mechanisms of cooperation between an agent and a hosting computer, because agents can not hide any secret within themselves and such secrets are necessary to use cryptographic protocols. Currently we are working on implementation of our proposals as extensions to Jade environment. We expect to have some results sometime around half of next year and after verification of their efficacy and efficiency we plan to publish our findings.

***Abstract*—This article addresses the application of agent-oriented modelling to composing scenarios for simulating problem domains consisting of heterogeneous entities that include humans, physical subsystems, and software components whose behaviours depend on the situation at hand. The article presents an overview of agent-oriented modelling and addresses the application of agent-oriented modelling and simulation for context-aware crisis management and military urban operations. We develop an approach for constructing vignettes of situation-aware behaviour to be further simulated by means of software agents and describe the creation of practical context-aware training scenarios. Finally, the article explores a platform currently in use for possible execution of agent-based simulations. Our approach is applicable in practice for testing typical behavioural vignettes in specific scenarios using the platform. Unique benefit of the proposed approach is its usability to observe how real subjects form their decisions to behave in certain situations.**

I. Introduction

THIS article addresses the problem of composing practical computer-based training scenarios for context-aware crisis management and military operations in urban terrain. To achieve context-awareness, we utilize both agent-based and context-aware computing. The purpose of the latter is to let systems react to users based on their (simulated) environments. In other words, context-aware computing leverages context information to improve the interactions among users and their environments. The kinds of problem domains where our agent-oriented method can be applied consist of heterogeneous autonomous entities that include humans, physical subsystems, and software components whose behaviours depend on the situation at hand. Because of the complexity of such problem domains, all scenarios to be simulated should be carefully constructed to assure that they are realistic and useful. In this article, we describe the creation of context-aware scenarios for training purposes. In developing the scenarios, we use the top-down approach of *agent-oriented modelling* [1] where a problem domain is first conceptualized in terms of the goals to be achieved by a *socio-technical system*, the roles required for achieving them, and the domain entities embodying the required knowledge.

Conceptually, we consider models as abstractions reducing the complexity of a system for better understanding of its particular aspects and their impact on the system's behaviour. Naturally, application of a model ought to be "based upon the aspect of the agent's behaviour under investigation as well as the level of aggregation of individual agents and their effects" [15].

Running models of agents involved – simulations – show the effects of the behaviours of individual agents as well as provide information on the complex feedback dynamics required for the understanding of emergent behaviour by the system as a whole. As interactions between the agents involved are highly complex, performing simulations is the only way to predict their outcome. Appropriate simulations can help to understand the expected behaviour of an individual agent or an entire system over time.

A problem domain can be simulated by either developing a new simulation environment for it or by utilising an existing simulation environment. The first approach has been used by the third author in performing simulations of business-to-business electronic commerce [2], distributed manufacturing [3], cooperation between different stakeholders at airports [4], and aircraft turnaround processes at airports [5]. For all the problem domains mentioned, simulation environments were developed from scratch by using the JADE agent platform [6]. A new problem domain currently addressed by us is military operations in an urban environment. Differently from the other projects mentioned [2, 3, 4, 5], in that domain we intend to utilise an existing simulation environment, which is already used for training purposes by the Estonian Defence Forces, rather than developing one from scratch. In both cases, a problem domain at hand should be diligently analysed to enable realistic simulations. This article aims to generalise based on the projects mentioned and the ongoing project and offer an approach for constructing situations to be simulated by means of agent-oriented modelling. The rest of this article is structured as follows. Section II describes the related work in modelling and simulation. Section III gives an overview of agent-oriented modelling. Section IV describes the problem

978-83-60810-27-9/09/$25.00 © 2010 IEEE

domain of military operations in an urban environment. Section V designs by means of agent-oriented modelling the scenario to be simulated based on a given case study. Section VI illustrates platform-specific design of the case study scenario on the VBS2 simulation environment. Finally, Section VII draws conclusions.

II. Related Work

Context-aware computing is only gaining momentum. It has been pointed out at [16] that "the concepts of *situation, context, event, goal, intention, action, activity, behavior* need further studies from a number of different points of view, including the views of situation in linguistics, cognitive science, human factors, computer science and artificial intelligence, as well as in both industrial and military applications". The paper [14] emphasizes an extremely challenging nature of context-aware crisis management: "Uncertainty arises in these environments in several ways: (i) information can be incomplete, (ii) information can have varying degrees of confidence, (iii) information can be inconsistent or contradictory, (iv) information can be numeric but yet interpreted in terms of common sense approximations, and (v) information can evolve over time with respect to (i)–(iv)." The aspect of proper models in this context is difficult to underestimate, despite of its challenging nature. This environment, more than any other factor, strongly influences combat identification (e.g., cognitive processes, situational awareness, and visual discrimination), movement, and the capabilities of (the systems of) the contending parties [9].

III. Agent-oriented Modelling

Agent-oriented modelling proposed in [1] is a holistic approach for analysing and designing socio-technical systems consisting of humans and technical components. In the context of this article, a socio-technical system is a simulation system with "human-in-the-loop" simulation capabilities.

Agent-oriented modelling proposes a set of canonical models. The models for analysing a problem domain describe the functional goals of a socio-technical system to be designed, the quality goals describing how the functional goals should be achieved, the roles required for achieving the goals, and the domain entities capturing the knowledge to be represented within the system. Design models of agent-oriented modelling describe what human and man-made (e.g., software) agents are required for achieving the goals, what private and shared information these agents possess and process, and how they interact and behave. Analysis models and design models are complemented by platform-specific design models that describe the implementation of the socio-technical system on a particular software platform. The types of models proposed by agent-oriented modelling are represented in Table I. In addition to representing for each model the abstraction layer (analysis, design, or platform-specific design), Table I maps each model to the vertical viewpoint aspect of interaction, information, or behaviour. Each cell in the table represents a specific viewpoint. We will next give an overview of agent-oriented models proceeding by viewpoints.

From the viewpoint of *behaviour analysis*, a *goal model* can be considered as a container of three components: goals, quality goals, and roles [1]. A *goal* is a representation of a functional requirement of the socio-technical system. A *quality goal*, as its name implies, is a non-functional or quality requirement of the system. Goals and quality goals can be further decomposed into smaller related subgoals and subquality goals. The hierarchical structure is to show that the subcomponent is an aspect of the top-level component. Goal models also determine roles that are capacities or positions that agents playing the roles need to contribute to achieving the goals. Roles are modelled in detail in the viewpoint of interaction analysis. The notation for representing goals and roles is shown in Table II. This notation is used in Section V for presenting agent-oriented models in the example case study. Goal models go hand in hand with *motivational scenarios* that describe in an informal and loose narrative manner how goals are to be achieved by agents enacting the corresponding roles [1].

From the viewpoint of *interaction analysis*, the properties of roles are expressed by role models. A *role model* describes the role in terms of the responsibilities and constraints pertaining to the agent(s) playing the role. *Organisation model* is a model that represents the relationships between the roles of the socio-technical system, forming an organization [1].

From the viewpoint of *information analysis*, *domain model* represents the knowledge to be handled by the socio-technical system. A domain model consists of domain entities and relationships between them. A domain entity is a modular unit of knowledge handled by a socio-technical system [1].

From the viewpoint of *interaction design*, *agent models* transform the abstract constructs from the analysis stage, roles, to design constructs, *agent types*, which will be realized in the implementation process. Deciding agent types for simulation systems is simple because usually there is an agent type corresponding to each role. *Interaction models* represent interaction patterns between agents of the given types. They are based on responsibilities defined for the corresponding roles [1].

In this article, we represent interaction models by means of action events and non-action events [1]. An *action event* is an event that is caused by the action of an agent, like sending a message or starting a machine. An action event can thus be viewed as a coin with two sides: an action for the performing agent and an event for the perceiving agent. A message is a special type of action event—*communicative action event*—that is caused by the sending agent and perceived by the receiving agent. On the other hand, there are *non-action events* that are not caused by actions—for example, the fall of a particular stock value below a certain threshold, the sinking of a ship in a storm, or a timeout in an action. The notation for modelling both kinds of events is represented in Figure 1. Non-action events also include exogenous events. An *exogenous event* is a kind of event whose creating agent we are not interested in. As has been pointed out in [4],

Table I.
The model types of agent-oriented modelling

	Viewpoint aspect		
Abstraction layer	Interaction	Information	Behaviour
Analysis	Role models and organization model	Domain model	Goal models and motivational scenarios
Design	Agent models and interaction models	Knowledge models	Scenarios and behaviour models
Platform-specific design	Platform-specific design models		

Table II.
Notation for modelling goals and roles

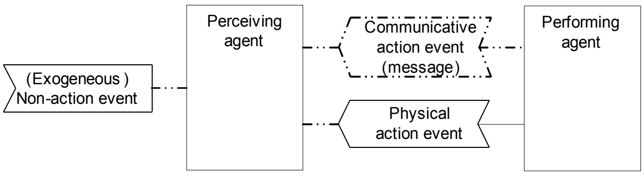
Symbol	**Meaning**
▱	Goal
☁	Quality goal
🯅	Role
――――――	Relationship between goals
– – – – – –	Relationship between goals and quality goals

exogeneous events need to be generated by the given simulation system. For example, the appearance of strangers in the scenario to be described in Section V can be modelled as an exogeneous event that is generated by the simulation system.

From the viewpoint of *information design*, it is essential to represent both private and shared knowledge by agents. An agent's *knowledge model* represents knowledge about the agent itself and about the agents and objects in its environment [1]. Knowledge model is particularly important when designing a simulation system from scratch. Since in the case study described in this article we rely on an existing simulation environment instead, we have chosen to represent knowledge only by the domain model.

Finally, from the viewpoint of *behaviour design*, we model how agents make decisions and perform activities. There are two kinds of models under this viewpoint. A *scenario* is a behaviour model that describes how the goals set for the system can be achieved by agents of the system. *Behaviour models* describe the behaviours of individual agents [1].

IV. Urban Operations



Perceiving agent
Communicative action event (message)
Performing agent
(Exogeneous) Non-action event
Physical action event

Figure 1. The notation for modelling events.

We use agent-oriented modelling in the context of urban operations. Compared to conventional wars between nation-states, multidimensional operations of modern warfare are asymmetric in several aspects. Operational environment in a future battlefield is irregular, characterised by high rate and rapid changes, but also considerable constraints. An example of this kind of operational environment is urban operations to be addressed in the next paragraph. Dimensions, as material (disparity of arms between the opposing sides), legal (disparate status of the parties of the conflict), and moral (sides are not morally equal) distinguish asymmetric conflicts from traditional warfare [11]. This multi-dimensionality makes the modelling and simulation of the environment of unconventional warfare complicated but for training purposes highly relevant task.

In the setting described, the nature of recent conflicts, where the population is targeted on the political, social, economical, and physical front, and the current rate of urbanisation, has shifted the attention to urban operations, maybe more than in any other time in history. It is also fair to assume that the battlefield of tomorrow is dominated by the urban environment. An urban area is a terrain where man-made construction and the presence of non-combatants are the dominant features. Urban operations are defined as all operations planned and conducted across the range of military operations on, or against objectives within, an urban area [7]. Urban operations have the following three facets:

- Urban area (terrain, a system of streets and buildings);
- Civilians (all non-combatants in operation area);
- Military operations (*interactions* of combatants of both sides in order to attain an object).

The combination of physical terrain, civilian population, and urban systems fundamentally distinguishes urban operations from other types of operations. To guarantee operational success, it is crucial to consider psychological readiness and especially limits of human capabilities of own forces. Creating working simulations of urban operations for the best possible training presupposes the ability to predict emergent behaviour of the agents in situations. Models must be able to deal with the dynamicity of human behaviour while taking account that it is not always rational. Behaviour is based on agents' sets of beliefs and a multitude of variables that potentially influence those beliefs: *individual*, *social*, and *information* background factors [12]. For military use, this aspect of modelling has been recently highlighted and referred as individual, organisational, and societal (IOS) models [10].

Because of the dynamic nature of urban environment, designing realistic scenarios for simulations of urban operations is not a trivial task. Neither is trivial the evaluation of such scenarios. Appropriate methods are required for coming up with realistic scenarios. One of such methods could be *agent-oriented modelling* that was described in Section III. It is noteworthy that the interaction, information, and behaviour viewpoint aspects of agent-oriented modelling that were explained in Section III rather well correspond to the respective social, information, and individual background factors for agents' behaviours mentioned above that originate in [12].

V. "Agentification" of Simulations

The dynamic nature of crisis management and urban military operations in particular is driving the need for new types of computational models that focus on human behaviour, especially on human behaviour in social units, such as organisations and societies ([10], p. 23). As was pointed out in Section IV, urban environment is characterized by uncertainty and intense *interactions* between various kinds of agents and between agents and their environments. In other words, one needs to introduce the context of interactions leading to situational awareness of the agents involved. A reasonable way to achieve that is by proper "agentification" of simulation scenarios based on agent–oriented modelling. By "agentification" we mean employing agent-related abstractions for modelling and simulation. "Agentification" is thus broader than just using software agents in simulations. Most military simulation environments available today view simulations in terms of objects to be manipulated rather than interacting agents. However, these environments can be used in an agent-oriented fashion but a different mindset is required for doing this. According to this mindset, models must deal with inherent uncertainty and dynamic adaptation that characterise human behaviour and should be capable for modelling both rational and non-rational behaviour ([10], p. 6). This kind of mindset can be achieved by using agent-oriented modelling for analysing the problem domain at hand and composing a simulation scenario for it. We will next illustrate this claim by the case study that is based on a game scenario for the field simulation to be used in training. The scenario has been worked out with the help of adventure games′ specialists [8]. The scenario is one of the scenarios that have been used, assessed, and elaborated in numerous psychological experiments [8]. We will next turn the scenario into the simulation scenario by using the kinds of models suggested by agent-oriented modelling and overviewed in Section III. We prove our point by using just a subset of agent-oriented models.

The first model to be created is the goal model that determines the overall purpose of the simulation and its subgoals. This model serves to discuss the purpose of the simulation with all the stakeholders involved: military commanders and experts, trainers, trainees, adventure games′ specialists, etc. As is reflected by Figure 2, the overall purpose of the simulation is to evacuate the building. Achieving the purpose can be divided into the following subgoals, each of which represents a particular aspect of the evacuation: penetrate into the building, help the injured, ensure safety inside, ensure safety outside, and collect and pass information. Each subgoal can, in turn, be divided into third-level subgoals. Figure 2 represents the refined subgoals for the "Help the injured" subgoal. For clarity, the other subgoals are elaborated in separate figures which we do not present here because of space constraints. Achieving a goal may be characterized by a quality goal which in the given context represents the criteria for evaluating the extent to which the goal in the simulation has been achieved. The goal model also shows the roles that are required for achieving the goals of the simulation scenario. The roles are separately modelled further on in this section.

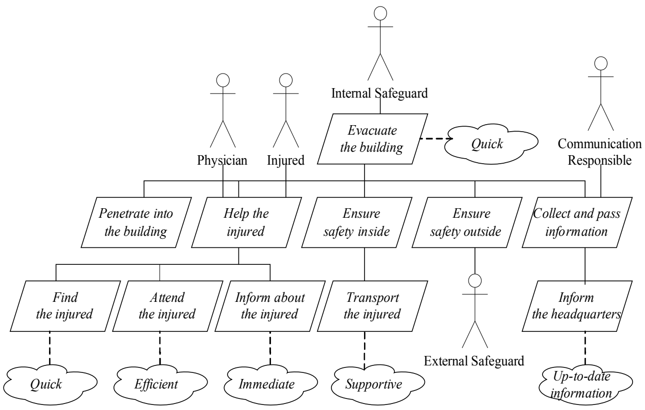


Figure 2. The goal model for the urban operation.

Table III presents a motivational scenario for the case study. The motivational scenario describes in a loose narrative manner how the goals represented in the goal model are to be achieved by agents playing the roles included by the goal model.

The roles put forward by the goal model are modelled in Tables IV - VIII. As usual, the roles are described in terms of the responsibilities and constraints applying to the agents that will perform the roles.

After having defined the goals and roles for the simulation scenario, we will characterize the relations between the roles involved. This can be done by the *organization model*. In our example, the organization model depicts relationships between the roles Injured, Physician, Internal Safeguard, External Safeguard, and Communication Responsible. It is also shown in Figure 3 that an agent performing the role Communication Responsible reports to an agent performing the role Headquarter. The role Headquarter is not a part of the simulation scenario because it is played by an external agent that collects information from an agent performing the role Communication Responsible.

We also need to describe the resources used by agents playing the roles to achieve the goals of the simulation scenario. In the simulation scenario, each *resource* is some unit of information used by agents. The resource types of the scenario are listed in Table IX. The second column of the table shows the roles related to the resources. Each resource is briefly characterized in the "Description" column.

Combining the organization model with resources yields us the domain model represented in Figure 4. As was described in Section III, *domain model* is a kind of conceptual model of a system which describes the entities embodying knowledge in the system and the relationships between them. According to the domain model shown in Figure 4, the resource type Injuries is associated with the

Table III.
The motivational scenario for the simulation

Scenario name	An urban rescue operation
Scenario description	The building that is located in the enemy`s territory and shielded our warriors was hit by a bomb. The rescue team has to perform the following tasks: • Penetrate into the building; • Find the warriors killed; • Find and evacuate the warriors injured; • Find and detonate possible explosives. During evacuation, the following events occur: • Civilians appear outside of the building; • Small cave-in occurs in the building.
Quality description	The building is in ruins, low, and dark. There are bodies and many obstacles in the building. Because of the danger of cave-in, the tasks have to be accomplished as soon as possible and definitely within 30 minutes. All the members of the rescue team are equipped with radio transmitters. The members of the rescue team have to provide other team members and the headquarter constantly with up-to-date information.

Table IV.
The role model for External Safeguard

roles Injured, Physician, Internal Safeguard, and External Safeguard. More precisely, information about injuries flows from an agent performing the role Injured to the agents playing the roles Physician and Internal and External Safeguard. The resource type Cave-In is associated with the roles Internal Safeguard and Communication Responsible, i.e., an agent performing the role Internal Safeguard informs an agent playing the role Communication Responsible about the cave-in. Also, an agent performing the role External Safeguard informs an agent playing the role Communication Responsible about the injured who has been evacuated. For this purpose we have introduced the resource type Evacuated which is associated with the roles External Safeguard and Communication Responsible. The last but not the least resource is that of the type Situation. This resource presents the information collected about the evolving situation in the urban operation. An agent performing the role Communication Responsible passes this information to an agent performing the role Headquarter.

Constraints	Precise information

As the final step of problem domain analysis, we represent the environments to be simulated and how they are related to the roles of the scenario. By an *environment* we mean a set of surrounding conditions for agents that mediates the interactions among agents and their access to resources [1]. We represent the environments by the environment model depicted in Figure 5. The simulation scenario involves two environments: City and Building. The roles Physician, Internal Safeguard, and Injured are enacted in the Building environment, while the roles External Safeguard and Communication Responsible are enacted in the City environment. The Injured role is enacted in both environments. The city consists of several buildings and the building contains several bodies and obstacles. All this may

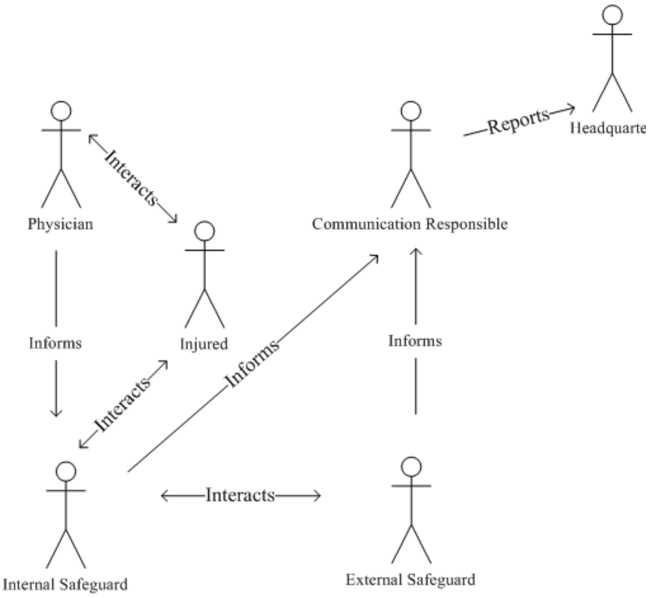

Figure 3. The organization model for the simulation scenario.

Evacuated	External Safeguard, Communication Responsible	Information about the injured who has been evacuated
Situation	Communication Responsible, Headquarter	Information collected from agents performing the roles Internal Safeguard and External Safeguard

sound trivial but is definitely required for creating the simulation scenario.

Having defined the goals for the scenario to be simulated and the roles comprised by the scenario, as well as the information resources involved by the scenario, their relationships to roles, and the environments in which the scenario occurs, we have created a minimal set of analysis models. Our next task is to design simulations in such a way that any role in the simulation system could be performed by either a human agent or a software agent. This enables to perform training simulations in teams of any size and evaluate the performance of individual human agents. We illustrate platform-independent design by presenting in Figure 6 an interaction model for the scenario. The interaction model depicted in Figure 6 includes the roles of three purposeful agents – External Safeguard, Internal Safeguard, and Communication Responsible – whose goals comply with the goals set for the simulation scenario by the goal and role models. In addition, the interactions involve the role Physician that is not represented in this figure. Corresponding to the notation represented in Figure 1 and according to the explanations provided in Section III, the interaction model represents the interactions between agents performing the above-mentioned roles as action events. In addition, the interaction model includes two non-action events representing the cave-in and appearance of strangers. Distinguishing between action events and non-action events is crucial in the simulation of military operations. We have decided to model the non-action events as exogeneous events because both of them are generated by the simulation environment. How these events can be defined for a particular simulation environment is exemplified in Section VI. Please note that the notation used in Figure 6 does not prescribe any order for the occurrence of events.

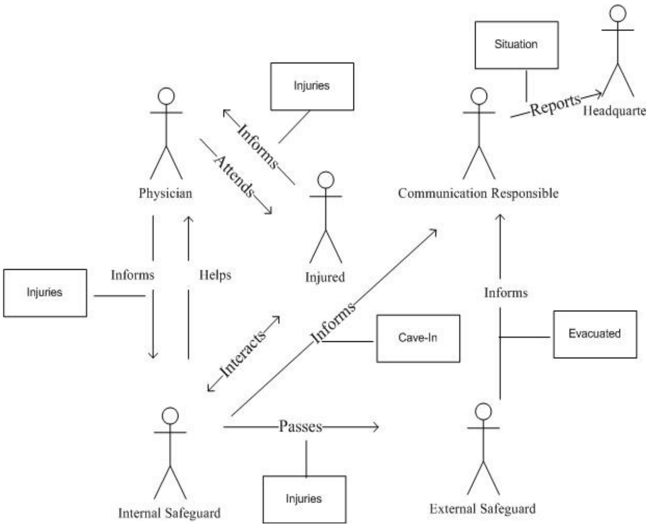

Figure 4. The domain model for the simulation scenario.

What does explicit capturing of interactions buy us in simulations? First of all, the simulation environment can generate exogeneous non-action events at different times within certain intervals. Second, the simulation environment can randomly vary interaction latencies between agents playing the roles. These aspects give us a freedom to

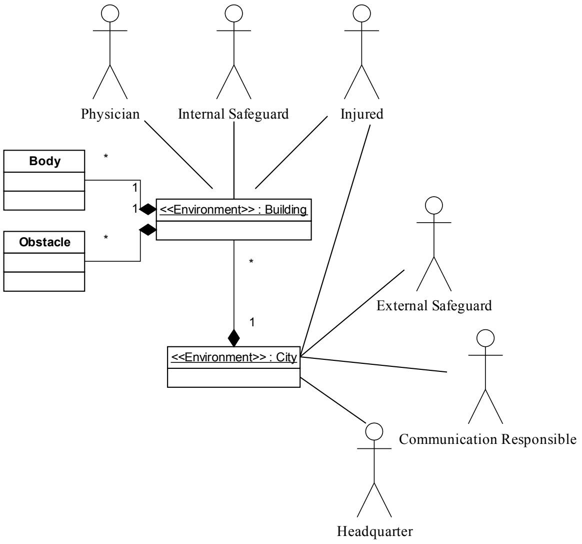

Figure 5. The environment model for the simulation scenario.

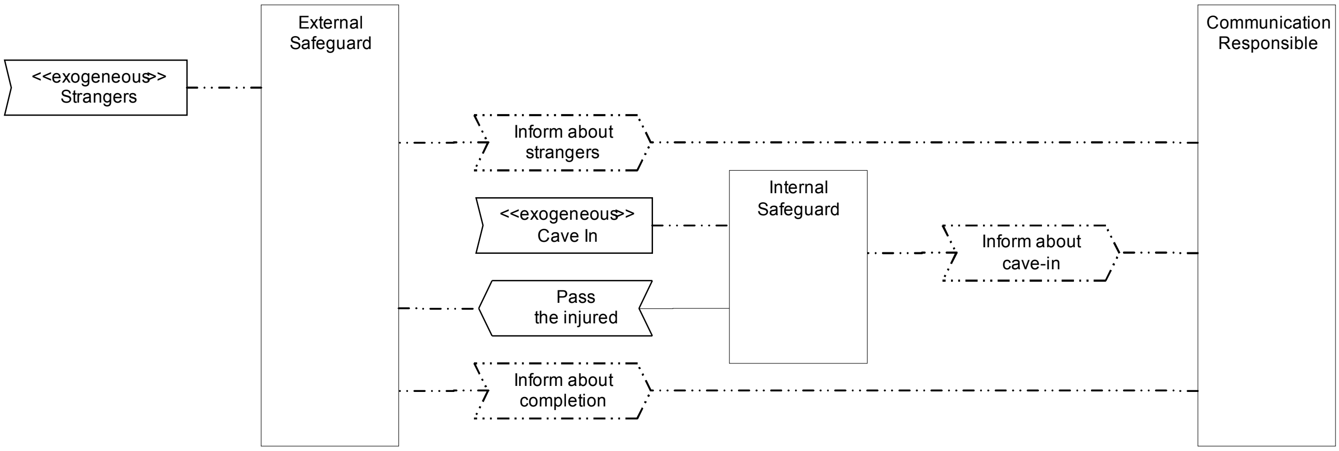

Figure 6. Interaction model for the scenario to be simulated.

manipulate with unpredictable environmental variables which are characteristic to real military operations. Third, we are not dependent of a group size because we can have one or more roles played by humans and the rest of the roles played by software agents. In such a way we can combine "real" interaction latencies with simulated ones. Since simulated latencies follow a random pattern, as a result we will have an *emergent behaviour* of a kind.

Mimicking an operational reality with this kind of design, we can find out how a human would react to different events occurring in the environment or caused by other agents. In addition, we can also experiment with various parameters that define the behaviours of individual agents. As the behavioural aspect is a complex one and therefore deserves further attention and research efforts by our multidisciplinary research team, we will address it as an important part of our future work. In this article we will confine the treatment of individual agent behaviours to a small example to be presented in Section VI.

VI. Platform-specific Design

We have chosen Virtual Battlespace 2 (VBS2, http://www.vbs2.com/) [13] as the platform for agent-oriented simulations. The rationale for this choice is twofold. First, VBS2 is one of the simulation platforms used by the Estonian Defence Forces. Second, VBS2 serves as a good example for simulation platforms that have been designed without agents on mind but that nevertheless can be used in an agent-oriented fashion. As implementing agent-oriented simulations is still work in progress, we illustrate platform-specific design for VBS2 by the snapshot shown in Figure 7. The snapshot reflects the experiments we have performed with VBS2 until now. The experiments have revealed that the agent-oriented analysis and design models presented and explained in Section V provide a sufficient backbone for performing agent-oriented simulations within the VBS2 environment. The details of such simulations are being elaborated and represented as a set of platform-specific models but the main structure of the simulations is in place. The snapshot shown in Figure 7 illustrates how the exogeneous event Strangers modelled in Figure 6 can be represented by means of VBS2.

VII. Conclusions

We have addressed composing computer-based training scenarios for context-aware crisis management. In this article, we described the creation of context-aware scenarios for training staff for military operations. The method we have applied for developing the scenarios is agent-oriented modelling [1]. We described how the problem can be modelled in an agent-oriented fashion by creating the goal model, role models, and domain model for the scenario and turning them into the environment model, interaction models, and platform-specific models. The contributions of this article are as follows:

- Employing agent-oriented modelling for structuring a networked domain so that it would lend itself to agent-oriented simulation;
- Offering a conceptual top-down approach for performing training simulations with VBS2 in teams of any size and evaluating the performance of individual human players;
- Enabling the manipulation with unpredictable environmental variables which are characteristic to real military operations.

Realistic training is a major concern of today's militaries. It is very difficult to train a person to deal with something that has not been defined. For asymmetric operations, and hence for urban operations, asymmetry is an inherent threat. Consequently, we need to develop our training scenarios in the direction of modelling human behaviour. It is especially important to create computational models of interactive human behaviours in a particular context. We intend to support this by agent-oriented behaviour models.

In a practical sense, our approach is applicable for testing typical behavioural vignettes in specific scenarios. Each role played by a software agent can be replaced by a real player in our approach. The unique benefit of the proposed approach is its usability to observe how real subjects form their decisions to behave in certain situations. Using agent-oriented modelling, we can explore the behaviours of humans forming parts of complex socio-technical systems. Through these observations we can eventually reach the level of flexibility required for simulating any complex socio-

technical system as a whole. We also plan to work out a visual environment for agent-oriented modelling that could be linked to several simulation platforms, both "conventional" and agent-oriented.

***Abstract*—Large-scale agent-based software solutions need to be able to assure constant delivery of services to end-users, regardless of the underlying software or hardware failures. Fault-tolerance of multi-agent systems is, therefore, an important issue. We present an easy and flexible way of introducing fault-tolerance to existing agent frameworks. The approach is based on two new types of mobile agents that manage efficient construction and maintenance of fault-tolerant multi-agent system networks, and implement a robust agent tracking technique.**

I. Introduction

AGENT technology represents one of the most consistent approaches to distributed systems development. *Software agents* can be defined as executable software entities with varying degrees of intelligence, autonomy, and the ability to communicate to each other in order to solve common problems. An important feature of some software agents is *mobility*, which enables them to move from one node in a network to another. Migration path is often chosen autonomously by the agent, and in general case it cannot be predicted.

Agents need an environment in which they can execute their tasks. A *multi-agent system* (MAS), or *agent framework*, represents a programming environment that controls agent's life-cycle and provides it with all the necessary mechanisms for task execution.

Multi-agent systems are applicable to a wide range of problems, such as information retrieval [11], mobile telecommunication networks [7], and power supply management [20], [21]. These solutions often employ physically distributed, interlinked agent frameworks, in combination with migrating agents. When compared to the standard client-server model, agent-based approach yields in improved performance and flexibility, reduced bandwidth requirements and, ultimately, cost.

Large-scale agent-based solutions are, as any software system, exposed to failures. Communication interruptions in systems comprising a large number of frameworks can occur due to traffic overload or hardware failures; agents carrying important gathered data might become lost because of a software glitch. These faults, however, must not affect the functioning of the system as a whole – power supply must not be interrupted because of a failed MAS node in the network. Fault-tolerance mechanisms should, therefore, be an important part of any MAS implementation.

Fault-tolerance techniques used in traditional distributed architectures are often static, require special infrastructural support, and restrict the functionality of agent frameworks [14]. Instead, multi-agent systems should employ dynamic properties of their agents in order to provide efficient, domain-independent fault-tolerant solutions.

EXtensible Java-based Agent Framework (XJAF) [9] is our own FIPA-compliant [5] MAS. It consists of a set of loosely-coupled modules called *managers*. Each module is responsible for handling a distinct part of the overall agent management process. Managers can be added dynamically and are recognized solely by their interfaces, allowing custom implementations. Multiple distributed instances of XJAF can be connected to each other, forming a tree-like network structure, with the primary instance representing the root of the tree.

XJAF has a built-in support for agent mobility. While pursuing their goals, agents can move freely among the connected instances of the environment. The process of agent location tracking is achieved through *forwarding pointers* [18]: when an agent moves from one XJAF instance to another, the originating instance keeps a migration pointer to the target instance. An agent can then easily be found by following a path through the tree of instances.

When it came to fault-tolerance, the original implementation of XJAF had two major drawbacks. First of all, the tree-like structure of interconnected instances was very fragile, as the breakdown of any one node would divide the network into two sets of mutually unreachable systems. There was also no easy way of reintroducing the repaired MAS to the network. Secondly, as the forwarding pointers technique kept no track of alternative routes, a migrating agent would have become lost if any intermediary MAS in its path broke. The implementation of location tracking was also not robust enough, as it, for example, did not include cyclic path management.

Our main motivation behind the presented work was to alleviate these problems and, by doing so, to improve fault-tolerance of our system. We propose a solution based on the introduction of two types of specialized mobile agents. We have replaced the tree-like structure of interconnected XJAF

978-83-60810-27-9/09/$25.00 © 2010 IEEE

instances with a fully-connected graph, and one of the main tasks of the introduced agents is to allow efficient construction and maintenance of the new organization. Additionally, the newly introduced agents have the job of building a fault-tolerant location tracking system, one that will allow for robust agent tracking mechanism. And although our initial goal was to improve the fault-tolerance of XJAF, our solution based on light-weight mobile agents can easily be applied to any MAS, as it is framework-independent, requiring only few changes to the underlying MAS implementation.

The rest of the paper is organized as follows. In Section II we provide an overview of the related work. Section III describes our approach to building and maintaining a network of multi-agent systems in greater detail. Section IV presents our solution to the robust agent-tracking problem. Finally, in Section V we draw a conclusion of the presented work and propose some future enhancements.

II. Related work

Agents are often used as low-level tools for assuring conditions and providing support for higher-level processes. For example, *middle agents* [6], [17] enable efficient flow of information, by acting as yellow page servers, data integrity protectors, and intermediaries between information requesters and information providers. FUSION@ [3] employs deliberate agents that perform intelligent load balancing, manage all communication to and from the MAS, supervise the integrity of other agents, etc. The main advantage of these approaches is flexibility, as existing agents (that is, functionalities) can be modified, and new agents can be added, all without disturbing the remaining parts of the system.

The benefits of using mobile agents in network management have been presented in [1], [12], and [16]. It has been shown that mobile agents enable flexible, dynamic network building, provide for efficient discovery of network elements that violate normal behavior, and offer remote maintenance features. As opposed to centralized administration systems, distributed agent architectures that host and dispatch light-weight mobile agents increase network management efficiency by reducing the traffic, especially in unstable network environments.

Significant part of the research effort regarding MAS fault-tolerance is oriented towards increasing robustness and failure resistance of agents themselves. This problem can usually be handled with *replication* techniques, such as those described in [2], [13], and [19]. The simplified idea behind these techniques is to keep multiple copies of an agent, distributed across a number of frameworks. In case the original agent fails, one of the copies automatically takes over its task execution process. Although agent fault-tolerance is beyond the scope of this paper, we apply the basic concepts behind the replication techniques to achieve robust agent tracking.

Fault-tolerance of a multi-agent system based on middle agents can be improved with a *swarming controller* [4]. The purpose of the controller is to reduce the chance of an agent becoming isolated. For this task, it relies on two components: (1) a *population manager*, which maintains an optimum number and distribution of mobile middle agents, so that there is always at least one alternative path for two agents to communicate; and, (2) an *information propagator*, which handles knowledge distribution, assuring that if any agent does become isolated, it can still access enough information to continue uninterrupted execution.

DimaX [10], [19] is an agent framework with a advanced, built-in fault-tolerance techniques. It uses interdependence graphs for evaluating the significance of every agent in the system, and maintaining an optimum number of replicas accordingly (process known as *adaptive replication*). The system also employs *host monitors*, low-level agents that try to perform early detection of failures and inform all interested parties about the problem in a timely manner. This would, for example, allow an agent and its replicas to leave the troubling environment, or to move important data from it. At the basis of the monitoring is a *heartbeat* technique, which agents in the system use to indicate their valid operational status to each other.

When it comes to fault-tolerance, certain aspects of the DimaX system are superior to ours. However, DimaX was designed and built around the concept of fault-tolerance. Our goal was to instead propose light-weight solutions that could be easily integrated into any existing MAS.

The problem of failed intermediary nodes in a forwarding pointers-based agent tracking system was addressed in [8]. The proposed directory service requires that every agent remembers up to *n* previously visited hosts, while each framework keeps track of up to *n* different positions of the agent. As the agent moves, these data sets are used to propagate information about the new host, providing a way of building alternative paths to the agent.

This solution to the problem of forwarding pointers is similar to ours. However, our solution offers increased flexibility. First of all, we assign handling of all transition-related information to a new type of agent, releasing the frameworks and actual mobile agents from keeping track of the migration process. Secondly, in the solution proposed in [8], *n* has to be chosen at design time, usually by analyzing the environment in which the system executes. We argue that it is difficult to choose a good value for *n*, mostly because component failure rate is not constant over time. Instead, we adapt the number of alternative paths to the agent's behavior – the more an agent moves across nodes, the more mobility is important to it, and we increase the number of alternative paths to it accordingly. However, for unstable environments, we also allow for the increment rate of number of paths to be risen and changed at run-time.

The Adaptive Agent Architecture (AAA) [14], [15] is a multi-agent system in which middle agents called *brokers* forward requests to and responses from registered agents. Since an operational broker is crucial for the functioning of the entire system, AAA comprises multiple brokers forming a team. Behavior of all team members is guided by a *teamwork theory*, which drives them to perform tasks that are beneficiary to the entire team. For example, if a registered agent becomes disconnected because its broker had failed, all remaining team members will have a joint commitment of reconnecting to the agent.

We have based the behavior of agents in our solution on the teamwork theory proposed in AAA – an agent that detects a failure of a MAS will have a commitment of informing other agents of the failure. However, in AAA, all brokers are located within the same system, and a broker can easily instantiate and add another broker. Our agents solve a more complex problem of creating and maintaining a network of physically distributed frameworks. In addition, we have included some optimizations of the teamwork theory. If an error occurs, not all team member will try to solve it. Instead, the order of problem solvers is organized by a simple procedure.

III. Building a reliable network

Distributed, interconnected multi-agent systems comprising mobile agents can provide efficient, flexible solutions for a range of problems, such as information retrieval, power supply management, telecommunication networks, etc.

XJAF has a built-in support for agent migration and a mechanism for distributed problem solving. Previously, multiple instances of the MAS were organized into a tree-like, hierarchical structure, as depicted in Fig 1. During start-up, each instance (except for the top-level, primary) would inspect the address of its parent node and then register itself with it. But, although easy to built, the tree structure was characterized by a single point of failure, that is a breakdown of any one node in the tree would make all of its sub-nodes unreachable by the rest of the system, and vice versa. In addition, the system did not allow for an easy reintroduction of a repaired MAS.

In order to overcome this problem, we have redesigned the inter-MAS connection system so that it organizes XJAF instances into a graph-like structure. The produced graph is fully connected. This approach is optimal as it introduces no significant overhead and it makes the process of finding a path to the target MAS a trivial issue.

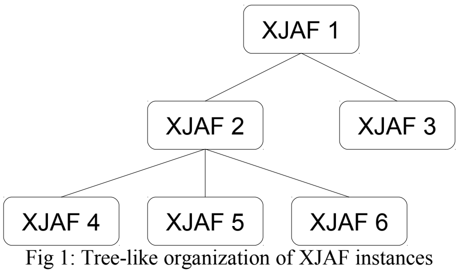

Fig 1: Tree-like organization of XJAF instances

Each MAS contains a list of all other systems in the network. A record in this list is a triplet (*Address, State, Timestamp*). *Address* is the physical address of the neighboring MAS, whereas *State* is its active state, as perceived by the current MAS (e.g. *running, unresponsive*, etc.). *Timestamp*s are an efficient way of selecting between mutually exclusive messages [8]. If an agent receives two messages about a MAS, one informing it that the MAS was started, other that it was shut down, the agent can use the timestamp of each message to determine whether the MAS is currently active (i.e. it was down, now it's up) or whether it is actually unreachable (i.e. it was up, now it's down).

The connection graph is maintained by a special type of mobile agent named *ConnectionAgent*. Each MAS in the network has a single instance of this agent residing in it. *ConnectionAgent* performs the tasks of adding a new MAS to an existing graph, as well as detecting a broken MAS and informing the remaining instances of the failure. As discussed earlier, the benefits of using a mobile agent in network management are lower demands on network traffic and system resources, and improved, distributed control, which becomes especially important in unstable environments.

A. Registering a new MAS

In the previous implementation, a newly created instance of XJAF, *X1*, would have had a single parent MAS to register with. In that configuration, however, a problem might arise if the parent MAS is not available (e.g. due to a failure) during the start-up of *X1*. So instead of having a single parent to register with, *X1* will now scan a predefined range of addresses until it finds the first available MAS. In order to optimize the scan, an administrator can narrow the range as much as possible, but at the same time keeping a sufficient number of possibilities.

After finding an available MAS, *X1* will create an instance of a *ConnectionAgent*, which then takes over the registration process. *ConnectionAgent* is a light-weight mobile agent that follows a simple registration algorithm. It migrates from one node in the network to another, spreading information about the newly created system.

ConnectionAgent keeps a list of all multi-agent systems it has detected so far. Upon arriving to a node in the network, the agent synchronizes its own list with that of its current host. As a result of the synchronization process, the host receives information about the agent's originating MAS, while the agent receives information about all systems the host is connected to. During this process, timestamps are used to select between mutually exclusive messages related to the same MAS, as described earlier. If the synchronization has resulted in any changes (i.e. the agent has learned about some new nodes in the network), *ConnectionAgent* will update its own list and send those changes to the originating MAS.

The agent then chooses next unvisited MAS from its list, and moves there. If there are no more unvisited systems, the process of adding the new MAS to the network has completed successfully, and the agent returns home. There, it continues to execute steps related to detecting a broken MAS, as described in the next sub-section.

Pseudo-code for the *ConnectionAgent*'s registration algorithm is as follows:

```
when (arrived_to_MASx) →
  mark_MASx_as_visited;
  new_MAS_list = synchronize_with_MASx;
  if (not empty(new_MAS_list))
  {
    update_my_list(new_MAS_list);
    ok = send_new_MAS_list_home;
  }
  else
    ok = ping_home;
   if (not ok)
    terminate_and_reverse_reg_process;
  next = get_next_unvisited_MAS;
  if (exists(next))
    move_to(next);
  else
    move_to(home);
```

After the synchronization process, the agent tries to communicate with its originating host. It will try to send it the list of any newly discovered multi-agent systems, or simply "ping" it, if there are no new systems in the result of the synchronization. In any case, the return value of this communication is used to indicate whether the originating MAS is still up and running or whether it had broken in the meantime. If the agent detects a failure of its originating MAS, it will terminate and reverse the registration process, as described in the next sub-section.

Fig 2 (a) depicts a scenario in which a new XJAF instance, *X1*, needs to be added to an existing network comprised of three frameworks: *A*, *B*, and *C*.

When the *ConnectionAgent* is created, only *C* will be in its list. After migrating to *C* and performing the synchronization with it, the *ConnectionAgent* will receive information about the two remaining instances, *A* and *B*. At the same time, *X1* will become registered with *C*. The agent will also send information about newly discovered systems to its originating MAS. This situation is shown in Fig 2 (b). The agent will then repeat the process two more times, visiting *A* and *B* and synchronizing information with them. Finally, it will have no more unvisited instances, meaning that the network is fully built, as shown in Fig 2 (c).

B. Detecting a broken MAS

Upon the successful completion of the registration process, the agent will return to its originating host, where it will continue to execute steps related to maintaining information about the state of the network. However, two problematic situations might occur during the registration: the originating MAS might fail, or the agent might become lost, e.g. due to failure of its current host.

In order to overcome these issues, *ConnectionAgent* needs to keep a heartbeat connection with its originating host. That is, it will communicate with the host at regular intervals, in, among other things, trying to detect its failure. The failure is handled by reversing the registration process – going back through the list of previously visited network nodes and informing them of the broken MAS. Similarly, if the originating MAS doesn't receive any communication request from the agent within a certain time threshold, it will initialize and dispatch a new instance of *ConnectionAgent*, restarting the registration procedure.

In a built network of multi-agent systems, *ConnectionAgents* maintain a heartbeat connection to each other, in order to detect failures. Being guided by the teamwork theory, an agent that discovers a problem will inform other agents about it.

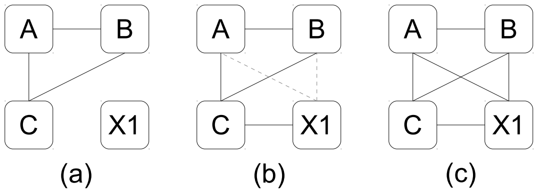

Fig 2: Adding multi-agent system X1 to an existing network

Agents execute asynchronously and independently, so many instances can detect the same failure at the same time and start informing each other, resulting in an unnecessarily increased usage of bandwidth and system resources. To prevent this from happening, we introduce an algorithm for controlling the heartbeat connection.

Multi-agent systems in the network are ordered by their respective timestamps (i.e. start-up times). We will say that *A* is *above B*, if it has earlier timestamp than *B*. Similarly, *A* is *below B* if it has later timestamp than *B*. Each *ConnectionAgent* keeps a heartbeat connection only with agents directly above and directly below it. Therefore, failure of a MAS will trigger a reaction in two agents. An agent that is below the broken MAS will forward this information only to agents below itself. At the same time, it will establish a new heartbeat connection with the *ConnectionAgent* residing in the first available MAS that is above the broken one. Similarly, an agent that is above the broken MAS forwards the information to all agents above itself, and establishes a new heartbeat connection with the *ConnectionAgent* residing in the first available MAS below the broken one. By following this simple set of rules, *ConnectionAgents* can easily detect and handle even multiple failures of a series of nodes.

While informing other agents of a broken MAS, *ConnectionAgent* again relies on timestamps. If, for example, the broken MAS is rebooted before the agent has finished informing other participants of the problem, there will be two agents operating in the network: one telling that the MAS is down, and the other telling that the MAS is up. But, because the second agent is carrying a later timestamp, the correct state can easily be selected.

IV. Fault-tolerant agent tracking

The forwarding pointers approach is an efficient and easy way of tracking agent's whereabouts. As shown in Fig 3, if an agent moves from XJAF1 to XJAF2, and later to XJAF6, there will be a pointer from the first to the second, as well as from the second to the third host in the path. The pointers are used to forward any messages directed to the migrating agent.

However, if XJAF2 (or, in general, any node in the agent's path) breaks, the agent will be lost. As there are no backup paths, the originating framework is unable to determine the current host of the agent. The same holds if only the communication link between any two nodes in the path fails.

Combination of the newly integrated graph-like organization of XJAF instances and the concepts behind replication techniques described earlier can be efficiently used to develop a robust agent tracking system. The algorithm is, again, implemented in a form of an agent, named *RemnantAgent*, making the solution suitable for any MAS.

Each mobile agent in the system has one or more instances of a light-weight *RemnantAgent* assigned to it, with a single instance residing in each MAS node in the path. A *RemnantAgent* can be considered to be a light replica of the agent. It responds to two events triggered by the agent's migration. The first event is signaled when the agent moves from one node to another. The event is dispatched to all but the agent's target MAS. The handler of this event can be described by the following pseudo-code:

```
when (agent_moved_from_X_to_Y) →
  agent_here = false;
  locations_after_this.push_back(Y);
  all_nodes_in_path.remember(X);
  all_nodes_in_path.remember(Y);
  // propagate migration backwards
  foreach (N in all_nodes_in_path)
    if (not N in locations_after_this)
      inform(N, agent_moved, X, Y);
```

RemnantAgent holds the two sets of information: (1) an unordered list of all nodes in the agent's path, and (2) a list of locations the agent has visited after leaving the *RemnantAgent*'s node. The second list is used for iterative reconstruction of alternative paths, while the first list is used to propagate elements of the second list. That is, whenever an agent moves from one node to another, this information is propagated backwards to all nodes in the path. Back nodes are identified by belonging to the list of all nodes in the path, but not to the list of future locations. All *RemnantAgents* that handle this event will propagate the information to all back nodes, which might seem as unnecessary and traffic-heavy. However, this approach is required as any node, or a link between any two nodes, might break at any time.

The second event triggered by the migrating agent is sent only to the agent's target MAS, signifying the agent's arrival. The handler for this event is as follows:

```
when (agent_arrived_from_X) →
  agent_here = true;
  locations_after_this.clear();
  all_nodes_in_path.remember(X);
```

Consider a scenario in which there are 4 multi-agent systems, *A*, *B*, *C*, and *D*, comprising a network, and there is an agent (marked as ☺) originating in *A*. In the pursuit of its goal, the agent moves from *A* to *B*, as shown in Fig 4 (a). The migration triggers a creation of a *RemnantAgent* in *A*, which remembers that agent went to *B* (indicated by → *B*). Each host builds the unordered list of all frameworks interactively, by being part of the migration, or by propagating migration between other hosts. So after the first step, both *A* and *B* have the same list (*A*, *B*): *A* has built its list by sending the agent to *B*, while *B* has built its list by receiving the agent from *A*.

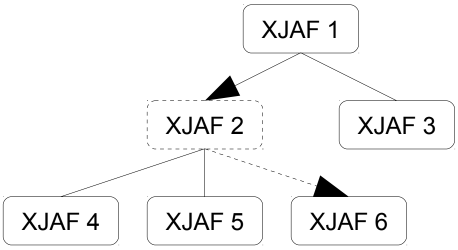

Fig 3: If XJAF2 fails, any agents that have through it are lost

Next, the agent moves from *B* to *C*, as shown in Fig 4 (b). *RemnantAgent* in *B* remembers the new position (→ *C*) and, after comparing this list with that of all nodes in the path (*A*, *B, C*), propagates the migration back to *A*, informing it of the change. *RemnantAgent* in *A* updates the position of the agent, keeping the previous value (→ *B*, *C*). If the agent continues to move, this time from *C* to *D*, the migration process will create another instance of *RemnantAgent* in *C* and trigger the location update in all previous instances. This situation is depicted in Fig 4 (c).

Now, suppose *A* needs to deliver a message to the migrating agent. *RemnantAgent* in *A* has the following list of locations: *B*, *C*, *D*. The last known location is *D* so it forwards the message directly there. But, let's say that there is a problem with the communication link between *A* and *D*, because of which the message cannot be delivered directly. To solve this issue, *RemnantAgent* in *A* inspects the previous host of the migrating agent and tries to deliver the message through it. So it forwards the message to *RemnantAgent* in *C*, which then, by looking at its own list of locations, delivers it to *D*. Similarly, if even *C* is down, the message can still be delivered, by going through *B*. In total, there are 4 alternative paths available:

1. *A* → *D*
2. *A* → *C* → *D*
3. *A* → *B* → *D*
4. *A* → *B* → *C* → *D*.

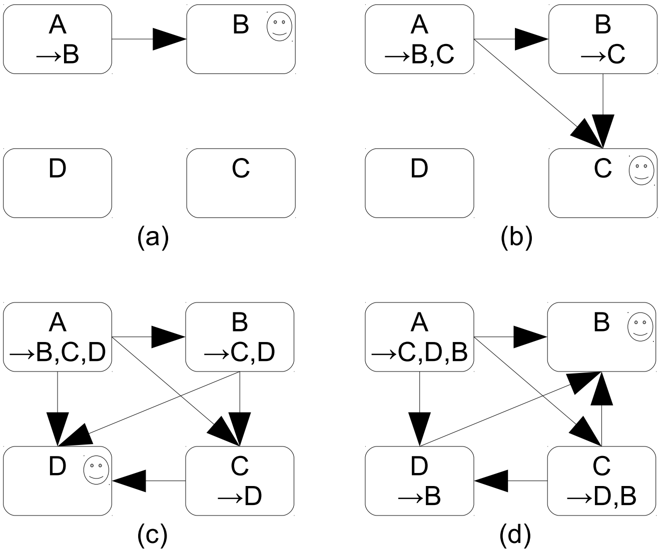

Fig 4: Robust agent tracking system

By going from the last known location backwards, each *RemnantAgent* will try to deliver the message in the shortest path possible.

Cyclic paths can also be easily handled. If, for example, the agent chooses to move from *D* back to *B*, the path tracking algorithm is similar, only this time *B*, as the current host, clears its list of locations, while all other nodes set *B* as the last known location of the agent. In addition, *A* will remove the previous instance of *B* from its list of locations. The final situation is depicted in Fig 4 (d). Again, there are 4 possible ways of reaching the agent from *A*:

1. $A \rightarrow B$
2. $A \rightarrow D \rightarrow B$
3. $A \rightarrow C \rightarrow B$
4. $A \rightarrow C \rightarrow D \rightarrow B$.

To improve the fault-tolerance of the tracking system even further, migration from each host can trigger the creation of *n* additional instances of *RemnantAgent*. These instances would then be distributed across different MAS nodes. Each new node can serve as an additional intermediary step in a path to the agent. The parameter *n* is configurable, and can be changed at run-time to reflect the overall system stability.

V. Conclusion and future work

Fault-tolerance of agent frameworks is an important issue. Large-scale agent-based systems need to be able to function in an uninterrupted fashion, assuring constant delivery of services to end-users. The underlying agent technology must, therefore, be capable of overcoming problems that emerge due to software or hardware failures.

The goal of the work presented in this paper was to offer a light-weight, yet efficient solution for improving fault-tolerance of existing agent systems. This has been achieved by the introduction of two types of mobile agents: (1) *ConnectionAgent* for building and maintaining reliable networks of distributed MAS instances, and (2) *RemnantAgent*, in charge of providing efficient agent tracking mechanisms by introducing robustness to the original forwarding pointers technique. All presented functionalities can be easily integrated in any existing MAS, with minimal changes to the underlying implementation.

Our future work on the subject of MAS fault-tolerance will be concentrated on providing flexible and robust agent replication and timely fault-detection techniques.

Abstract—**Argumentation, initially studied in philosophy and law, has been researched extensively in computing in the last decade, especially for inference, decision making and decision support, dialogue, and negotiation.**

This paper focuses on the use of argumentation to support intelligent agents in multi-agent systems, in general and in the ARGUGRID project[1] and Agreement Technology action[2]. In particular, the paper reviews how argumentation can help agents take decisions, either in isolation (by evaluating pros and cons of conflicting decisions) or in an open and dynamic environment (by assessing the validity of information they become aware of). It also illustrates how argumentation can support negotiation and conflict resolution amongst agents (by allowing them to exchange information and fill in gaps in their incomplete beliefs). Finally, the paper discusses how arguments can improve the assessment of the trustworthiness of agents in contract-regulated interactions (by supporting predictions on these agents' future behaviours).

I. Introduction

ARGUMENTATION, initially studied in philosophy and law, has been researched extensively in computing in the last decade, especially for inference, decision making and decision support, dialogue, and negotiation [1], [2], [3].

Simply stated, argumentation focuses on interactions where parties plead for and against some conclusion. In its most abstract form [4], an argumentation framework consists simply of a set of abstract *arguments* and a binary relation representing the *attacks* between the arguments. By instantiating the notion of arguments and the attack relation, different argument systems can be constructed, predominantly based upon logic. One such system is assumption-based argumentation (ABA) [5], [6]. Here, arguments are computed from a given set of *rules* and are supported by rules and *assumptions*. Also, an argument attacks another argument if the former supports a claim conflicting with some assumptions in the latter, where conflicts are given in terms of an underlying notion of *contrary* of assumptions. Rules, assumptions and contraries are defined in terms of an underlying logic *language*. Different choices for this language give different instances of ABA.

Argumentation provides a powerful mechanism for dealing with incomplete, possibly inconsistent information. It is also fundamental for the resolution of conflicts and differences of opinion amongst different parties. Further, it is useful for "explaining" outcomes generated automatically. As a consequence, argumentation is a useful mechanism to support several aspects of agents in multi-agent systems. Indeed, agents are goal-driven, self-contained entities with partial information on the environments in which they are situated (including other agents inhabiting these environments), with conflicting goals, but often in need to cooperate in order to achieve these goals (e.g. because resources controlled by other agents are needed to achieve these goals). Cooperation is supported by communication in multi-agent systems, and opinions as well as explanations are often exchanged amongst communicating agents.

The potential of *argumentative agents* has been/is being explored in two European activities: the EC-funded ARGUGRID project and the COST-funded Agreement Technologies action.

The *ARGUGRID project* developed a grid-based platform populated by rational decision-making agents associated with service requestors/providers and users [7]. Within agents, argumentation as envisaged in ABA is used to support decision making, taking into account (and despite) the often conflicting information that these agents have, as well as the preferences of users, service requestors and providers [8], [9], [10]. In the ARGUGRID platform, argumentation is also used to support the negotiation between agents [10], [11] on behalf of service requestors/providers/users. This negotiation takes place within dynamically formed virtual organisations [12]. The agreed combination of services, amongst the argumentative agents, can be seen as a complex service within a service-oriented architecture [13]. The ARGUGRID approach has been validated by way of industrial application scenarios in e-procurement and earth observation [7], [8], [9].

The *Agreement Technologies action* aims at developing computer systems in which autonomous agents negotiate with one another, typically on behalf of humans, in order to come to mutually acceptable agreements [14], [15]. Agreement Technologies include argumentation, negotiation, and trust computing, as well as combinations of these.

In this paper we review some of the achievement to date of these activities, in providing argumentative agents and validating them against other approaches and in applications.

The paper is structured as follows. In section II we give some background on abstract argumentation and ABA. In section III we illustrate ways in which argumentative agents can take decisions. In section IV and V we describe the use of ABA for conflict resolution and negotiation, respectively, amongst argumentative agents. In section VI we review a

[1] www.argugrid.eu

[2] www.agreement-technologies.eu

possible integration of arguments with statistical information in trust computing. In section VII we conclude.

II. Argumentation

This section gives essential background on logic-based argumentation, focusing on abstract argumentation [4] and assumption-based argumentation [5], [6].

Abstract argumentation frameworks [4] are pairs (Arg, att) where Arg is a set of arguments and $att \subseteq Arg \times Arg$ is a binary relation representing attacks between arguments.

The main purpose of argumentation theory is to identify which arguments in an argumentation framework are rationally "acceptable". Several notions of acceptability have been proposed in the literature on argumentation, some providing an "intrinsic" measure of argument strength (e.g. [16]), whereby the acceptability of an argument depends on its internal logical structure, others giving a "dialectical" measure (e.g. [4], [17], [18], [19]), depending exclusively on attacking arguments.

An example of dialectical measure for abstract argumentation frameworks is given by *conflict-free extensions*, namely sets X of arguments such that there is no argument in X which attacks another argument in X. Another example is given by *admissible extensions* [4], namely sets X of arguments that are conflict-free and capable of defending themselves against every attacking argument (namely for every argument Y that attacks X, there is some argument in X that attacks Y). A further example is *preferred extensions* [4], namely (subset) maximal admissible extensions. These examples of dialectical measures are all "qualitative", based predominantly on the capability of arguments to defend themselves. "Quantitative" dialectical measures have been proposed too (e.g. [19]).

Assumption-based argumentation (ABA) frameworks [5], [6] can be defined for any logic specified by means of (inference) *rules*, by identifying sentences in the underlying logic *language* that can be treated as *assumptions*. Intuitively, *arguments* are deductions (in the chosen logic language) of a conclusion (or claim) supported by a set of assumptions. Then, *attacks* against arguments are always directed at the assumptions supporting the arguments. More precisely, an attack by one argument against another is a deduction by the first argument of the *contrary* of an assumption supporting the second argument.

The inference rules may be domain-specific or domain-independent, and may represent, for example, causal information, or laws and regulations. Assumptions are sentences in the language that are open to challenge, for example uncertain beliefs ("it will rain"), unsupported beliefs ("I believe that some service provider is reliable"), or decisions ("I will purchase a specific service"). Typically, assumptions can occur as premises of inference rules, but not as conclusions. In general, the contrary of an assumption is a sentence representing a challenge against the assumption. For example, the contrary of the assumption "it will rain" might be "the sky is clear". The contrary of the assumption 'I will purchase a specific service" might be "I will purchase a different service" (where I only need one service). The contrary of the assumption "I believe that some service provider is reliable" might be "there is evidence against that service provider being reliable".

Given arguments and attacks, several qualitative dialectical measures of acceptability have been deployed within ABA [5], [17], [6], including conflict-free, admissible and preferred extensions. Query answering with respect to these dialectical measures is implemented, for any ABA framework given as input, in the CaSAPI system[3] [20], [21], [22]. Here, queries represent claims whose dialectical validity with respect to a chosen notion of extension is under scrutiny.

III. Argumentation for decision-making

Qualitative decision theory [23] has been advocated for quite some time as a viable and useful alternative to classical quantitative decision theory [24], when a decision problem cannot be easily formulated in standard decision-theoretic terms using decision tables, utility functions and probability distributions. A number of qualitative approaches to decision making, e.g. [25], [26], [27], [28], have been put forward, with argumentation-based decision making amongst them (e.g. [27]). In decision-theoretic terms, argumentation can be used as a model to compute a utility function which is too complex to be given a simple analytical expression in closed form. Argumentation has been proposed for decision making under certainty (where the outcomes of decisions are known to the decision maker) [8], [9], strict uncertainty (where the outcomes of decisions are uncertain and no probabilistic information is available) [29], [30], [31], [32], [10], and also for decision under risk (where some probabilistic information is known) [16], [33], [34]. Argumentation has also been used to support practical reasoning [35], [36], and decision support systems [37], [38], [39]. Further, arguments can be seen as supporting "values", as in value-based argumentation for decision-making [40]. Finally, argumentation can be used for computing decision tables, utility functions and probability distributions in classical quantitative decision theory [41].

Here we summarise two different uses of ABA (see section II) to support decision making under certainty [8], [9] and under strict uncertainty [10].

We consider the following decision problems:

- Let $\mathcal{D}$ be a (non-empty) set of alternative decisions.
- The outcomes of decisions are individual states $s \in \mathcal{S}$ (if under certainty) or sets of states $S \subseteq \mathcal{S}$ (if under uncertainty).
- States can be seen as sets of "goals" of (or benefits for) the decision maker, which can be represented as sentences in a given set $\mathcal{G}$.
- Preferences over goals may be optionally specified, e.g. in the form of weights (positive integers). These can be expressed by a mapping $w : \mathcal{G} \rightarrow \mathbb{N}$. The case where all weights are the same is equivalent to the case where no weights are specified.

[3] http://www.doc.ic.ac.uk/~dg00/casapi.html

- Rather than being known a-priori, outcomes of decisions are determined from a belief base $\mathcal{B}$. The beliefs "entailed" by this base correspond to states.

Decisions may correspond to products, including e-procurement products [8], earth observation products [9], commodities [10] etc. For these decision problems, argumentation can be used to determine the relative value of different decisions, to single out decisions with "top-most" value and for explaining decisions.

Under certainty, and assuming all goals have equal weight, decisions with top-most value can be defined as "dominant" decisions, where

- a decision $d \in \mathcal{D}$ is *dominant* if and only if the outcome $s \in \mathcal{S}$ of d is such that, for any alternative decision $d' \in \mathcal{D}$, if $s' \in \mathcal{S}$ is the outcome of d', then $s \supseteq s'$.

This is the approach taken in [9].

Alternatively, decisions with top-most value are decisions resulting in states that are upper bounds of partial orders over states. Under certainty, a partial order $\sqsupseteq$ over states can be given as follows:

- a state $s \in \mathcal{S}$ is *strictly preferred to* a state $s' \in \mathcal{S}$ (denoted $s \sqsupset s'$) if and only if
  1) there exists a goal $g \in \mathcal{G}$ such that $g \in s$ but $g \notin s'$, and
  2) for each goal $g' \in \mathcal{G}$, if $w(g') \geq w(g)$ and $g' \in s'$ then $g' \in s$;
- a state $s \in \mathcal{S}$ is *preferred to* a state $s' \in \mathcal{S}$ (denoted $s \sqsupseteq s'$) if and only if $s \sqsupset s'$ or $s = s'$.

This partial order is used in [10] to define a partial order over decisions under strict uncertainty, as we will see below.

Note that, when all weights are the same, $s \sqsupseteq s'$ is equivalent to $s \supseteq s'$.

In [8], [9], the belief base maps features of products to goals of the decision maker. For example, a hotel with rooms costing less than 50£ may be believed to be cheap (where the price is a feature and being cheap is a goal) [9]. Further, in the case of e-procurement for an e-ordering system [8], an e-ordering system with a 3-year flat cost may be deemed to decrease costs. Here, features determine univocally (with certainty) goals. The belief base is represented as an ABA framework from which the following arguments can be built:

(i) "choose decision d because d allows to achieve goal g"
(ii) "do not choose d because some other decision allows to achieve goal g and I am not sure d does"

(see [8], [9] for formal details). Arguments of type (ii) attack arguments of type (i) and vice versa. Then, dominant decisions, as given above, correspond to admissible sets of arguments for the given ABA frameworks. ABA thus allows to compute dominant decisions and explain these decisions (by presenting the arguments). Moreover, in [9] we also propose a different argumentation semantics based on counting (and resulting in a numerical, rather than Boolean value for arguments) and links this semantics to dominant decisions when weights are given (see [9] for details).

In [10], the belief base encodes again a mapping between features and goals, but using information that may be incomplete (e.g. that a good school is located in the vicinity of a real estate property) and that may lead to conflicts/inconsistencies (e.g. that a real estate property is in a safe area and is not in a safe area).[4] As a consequence, decisions correspond to sets of states, where different states correspond to different assumptions (completing the information) and different resolutions of the conflicts. These resolutions (states) are preferred extensions, in the argumentation sense (see section II), and they can be compared using the standard minimax criterion from decision theory, using the following notations:

- for a given decision $d \in \mathcal{D}$, let $cred\_pref(d)$ be the set of all $s \in \mathcal{S}$ such that s is satisfied in some preferred extension of the belief base extended by d;
- for any set of states $S \subseteq \mathcal{S}$, let $min(S)$ be a state such that for each goal $g \in \mathcal{G}$, g is satisfied in $min(S)$ if and only if g is satisfied in every state in S.

Then

- a decision $d \in \mathcal{D}$ is *minimax-preferred to* a decision $d' \in \mathcal{D}$ if and only if
  - $min(cred\_pref(d)) \sqsupseteq min(cred\_pref(d'))$

  where $\sqsupseteq$ is as defined earlier.

This notion of minimax-preference is equivalent to a purely argumentative preference notion between sets of states, defined using the following notion:

- for a given decision $d \in \mathcal{D}$, let $scept\_pref\_state(d)$ be the state $s \in \mathcal{S}$ consisting of all goals holding in all preferred extensions of the belief base extended by d.

Then,

- a decision $d \in \mathcal{D}$ is *sceptically-preferred to* a decision $d' \in \mathcal{D}$ if and only if
  - $scept\_pref(d) \sqsupseteq scept\_pref(d')$.

The fully argumentative notion of sceptically-preferred and the partially argumentative, partially decision-theoretic notion of minimax-preferred are equivalent [10]. Top-elements of the partial orders given by either notions are decisions with top-most values.

Overall, the two approaches considered use argumentation for different purposes: on one side, [8], [9] encodes a fully decision-theoretic notion of dominance into an ABA framework, and uses argumentation to "explain" dominant decisions under certainty; on the other side, [10] uses argumentation to deal with conflicts and incomplete information for decisions under strict uncertainty, and a sceptical semantics to mirror a minimax decision-theoretic criterion.

IV. ARGUMENTATION FOR CONFLICT RESOLUTION

Complex multi-agent systems are composed of heterogeneous agents with different, possibly incomplete beliefs and

[4] Note that, in ABA, assumptions are used as premises of rules to represent incomplete information that can be "completed" by making suitable assumptions. Also, assumptions are used to render rules defeasible, thus paving the way to resolving inconsistencies.

different, possibly conflicting desires. Conflicts may thus arise amongst agents for (at least) two reasons. Firstly, agents may make different assumptions to fill gaps in their beliefs, where some of these assumptions may be incorrect, and decide on incompatible, conflicting actions due to misinformation. Secondly, even if agents share the same information, they may still disagree if they have conflicting desires.

Due to ABA's suitability in dealing with incomplete and conflicting information, agents' beliefs and desires can be represented in ABA [42], [43]. Following an existing trend of work in argumentation for conflict resolution (e.g. see [44]), in [45] we use ABA to resolve conflicts between *two agents*. These conflicts arise when the agents have different goals, g_1 and g_2, and different decisions, d_1 and d_2, having those goals as respective outcomes, according to their respective individual belief bases. These bases are assumed to be represented as ABA frameworks. Here, rules are used to represent beliefs about the achievement of desires as well as factual information.

For both agents, the goal belongs to a conflict-free extension of the agent's ABA framework, extended with the agent's decision. The agents' objective is to resolve the conflict, by agreeing on a common goal g and a common decision d such that g is a variant of both g_1 and g_2. For example, in a service-oriented architecture, if the two agents represent two service requestors from the same organisation, with different requirements but with the shared goal of obtaining some service of a certain type, then

- g_1 may correspond to obtaining a service s_1 of that type, by purchasing it (decision d_1),
- g_2 may correspond to obtaining another service s_2 of the same type, by purchasing it (decision d_2), and
- g may correspond to obtaining a service s of that type, by purchasing it (decision d), where s may be one of s_1 or s_2 or a new service.

Here, the original choice of s_1/s_2 by the agents may be dictated by their lack of knowledge of the other agents requirements or of the availability and characteristics of services. For example, the first agent may know that s_1 fulfils some requirement of the second agent while the latter may be unaware of this. By passing information to the second agent, the first agent may be able to persuade the second to purchase s_1 (in this case s would be s_1). Thus, conflict resolution amounts to identifying a goal that is the outcome of a decision in conflict-free extensions of either belief bases (ABA frameworks) after the agents have shared factual information (e.g. that s_1 fulfils some requirement).

Alternatively, this conflict resolution can be achieved by "merging" the two ABA frameworks. The merge eliminates misunderstanding between agents, allows to revise the agents' incorrect assumptions and takes into account desires from both agents. To satisfy desires from both agents, the mechanism of concatenation is used to merge rules. Upon a successful concatenation merge, both agents' desires may be satisfied (if they can be satisfied). Details of this approach can be found in [45]. Here, a dialogical counterpart to the merge is also sketched as a more realistic approach to conflict resolution.

V. Argumentation for negotiation

The need for negotiation arises when autonomous agents have conflicting interests/desires but may benefit from cooperation in order to achieve them. In particular, this cooperation may amount to a change of goals (as in conflict-resolution, see section IV) and/or to the introduction of new goals (e.g. for an agent to provide a certain resource to another, even though it may not have originally planned to do so). Typically negotiation involves (fair) compromise.

Argumentation-based negotiation is a particular class of negotiation, whereby agents can provide arguments and justifications as part of the negotiation process [46]. It is widely believed that the use of argumentation during negotiation increases the likelihood and/or speed of agreements being reached [47]. Argumentation can be used to support the decision-making taking place prior to or during negotiation. Moreover, argumentation can be used to conduct negotiation, by supporting the resolution of conflicts giving rise to the need of negotiation and by filling in information gaps and rectifying misinformed beliefs.

In [10] we propose the use of ABA to support decision making under strict uncertainty (as described in section III) prior to the agents engaging in negotiation. The negotiation takes place between a buyer and a seller (e.g. of services) and results in (specific forms of) contracts, taking into account contractual properties and preferences that buyer and seller have. The negotiation is guided by a "minimal concession" strategy that is proven to be in symmetric Nash equilibrium. Adopting this strategy, agents may concede and adopt a less-preferred goal to the one they currently hold (namely a goal with a smaller weight, according to the presentation in section III) for the sake of reaching agreement. Thus, agreement amounts to compromise. This approach has been extended in [48] to incorporate rewards during negotiation. These rewards in turn can be seen as arguments in favour of agreement.

In [11] we study the use of a form of ABA, given in [49], for improved effectiveness of the negotiation process, in particular concerning the number of dialogues and dialogue moves that need to be performed during negotiation without affecting the quality of solutions reached. The focus here is on negotiation of resources in resource reallocation settings. This work complements studies on protocols for argumentation-based negotiation (e.g. [50]) and argumentation-based decision making during negotiation (e.g. [10]) by integrating argumentation-based decision making with the exchange of arguments to benefit the outcome of negotiation. Agents engage in dialogues with other agents in order to obtain resources they need but do not have. Dialogues are regulated by simple communication policies that allow agents to provide reasons (arguments) for their refusals to give away resources; agents use ABA in order to deploy these policies. We assess the benefits of providing these reasons both informally and experimentally: by providing reasons, agents are more effective in identifying a reallocation of resources if one exists and failing if none exists.

VI. Argumentation for trust computing

Computing trust is a problem of reasoning under uncertainty, requiring the prediction and anticipation by an agent (the evaluator) of the future behaviour of another agent (the target). Despite the acknowledged ability of argumentation to support reasoning under uncertainty (e.g. see [16]), only Prade [51], Dondio & Barret [52] and Parsons et al [53] have considered the use of arguments for computing trust in a local trust rating setting. Dondio & Barret [52] propose a set of trust schemes, in the spirit of Walton's argument schemes [54], and assume a dialectical process between the evaluator and the target whereby the evaluator poses critical questions against arguments by the target concerning its trustworthiness. Prade [51] proposes an argumentation-based approach for trust evaluation that is bipolar (separating arguments for trust and for distrust) and qualitative (as arguments can support various degrees of trust/distrust). Parsons et al [53] define an argumentation logic where arguments support measures of trust, e.g. qualitative measures such as "very reliable" or "somewhat unreliable".

There are several non-argumentation based methods to model the trust of the evaluator in the target. Sabater and Sierra [55] classify approaches to trust as either "cognitive", based on underlying beliefs, or "game-theoretical", where trust values correspond to subjective probabilities and can be modelled by uncertainty values, Bayesian probabilities, fuzzy sets, or Dempster-Shafer belief functions. The latter approach is predominant nowadays for trust computing. However, Castelfranchi and Falcone [56] argue against a purely game-theoretic approach to trust and in favour of a cognitive approach based upon a mental model of the evaluator, including goals and beliefs. Moreover, some works (e.g. [57]) advocate the need for and benefits of hybrid trust models, combining both the cognitive and game-theoretical approach.

In recent work [58], we propose a hybrid approach for constructing Dempster-Shafer belief functions modeling the trust of the evaluator in the target by combining statistical information concerning the past behaviour of the target and arguments concerning the target's expected behaviour. These arguments are built from current and past contracts between evaluator and target, and are integrated with statistical information proportionally to their validity. Concretely, in a service-oriented setting, the statistics are drawn from past behaviour of the target in the delivery of agreed services and, following [59], a classification of this behaviour as "good" (the service was delivered as agreed), "bad" (the service was not delivered as agreed) or "inappreciable" (the evaluator cannot judge the delivery of the service). Clearly, the more "good" behaviour the target has shown in the past the more likely the evaluator will be to trust it. The arguments are drawn from contracts regulating the delivery of services, as follows:

- a forecast argument supporting the claim of not trusting the target (as far as delivering a service is concerned) if there is no guarantee on the quality of that service in the form of a written contract clause;
- a forecast argument supporting the claim of trusting the target if there exists a guarantee in the form of a contract clause;
- an argument attacking the forecast argument for trusting the target if the target has in the past "most often" violated existing contract clauses.

The applicable arguments and attacks form an abstract argumentation framework (see section II). They are combined with the statistics in accordance to their strength, measured using the method of [19].

This method of measuring trust extends a standard method for trust [59] that relies upon the statistical information only. The two methods have identical predictive performance when the evaluator is highly "cautious", but the hybrid method gives a significant increase when the evaluator is not or is only moderately "cautious". Moreover, with the hybrid method, target agents are more motivated to honour contracts than when trust is computed on a purely statistical basis. The comparison between the two methods is performed within a simulated setting (see [58] for details).

VII. Conclusion

Argumentation, initially studied in philosophy and law, has been researched extensively in computing in the last decade, especially for inference, decision making and decision support, dialogue, and negotiation.

This paper has summarised some of the uses of argumentation

(i) to help agents to make decision, either in isolation (by evaluating pros and cons of conflicting decisions) or in an open and dynamic environment (by assessing the validity of information they become aware of)
(ii) to support negotiation and
(iii) conflict resolution amongst agents, and
(iv) to improve the assessment of the trustworthiness of agents in contract-regulated interactions.

The paper has focused on contributions to (i)–(iv) developed within two European initiatives: the EC-funded ARGUGRID project and the COST-funded Agreement Technologies action.

***Abstract*—Advanced network infrastructure plays an important role in the e-Science environment to provide high quality connections between largely distributed data sensors, and computing and storage elements. However, the quality of the network services has so far rarely been considered in composing and executing scientific workflows. Currently, scientific applications tune the execution quality of workflows neglecting network resources, and by selecting only optimal software services and computing resources. One reason is that IP-based networks provide few possibilities for workflow systems to manage the service quality, and limit or prevent bandwidth reservation or network paths selection. We see nonetheless a strong need from scientific applications, and network operators, to include the network quality management in the workflow systems.**

Novel network infrastructures open up new possibilities in network tuning at the application level. In this position paper, we discuss our vision on this issue and propose an agent based solution to include network resources in the loop of workflow composition, scheduling and execution when advanced network services are available. We present the first prototype of our approach in the context of the CineGrid project.

***Index Terms*—Quality of Service, Semantic web, Advanced Network, Scientific Workflow, e-Science**

I. Introduction

ADVANCED network infrastructure plays an important role in the e-Science environment to provide high quality connections between largely distributed data sensors, and computing and storage elements; by enabling large scale data movement between different devices and nodes, applications which require extremely large scale data movement can be enabled. However, The quality of the network connections and services has rarely been taken into account by current scientific workflow management systems, because 1) traditional IP-based networks provide limited reservation capability for workflow engines; 2) the existing e-Science applications assume available network connections as non-changeable services, and seek customized solutions at software level to optimise computing processes and data storage; and 3) the existing applications mainly consider the functionality of the e-Science services, and limited support has been provided for including (network) quality requirements for the services in the composition, enactment and execution of workflows.

Still advanced network services are essential for many scientific applications, where data transmission delays become a bottleneck of the global performance of the application [1], [2] . Without the quality guarantee at the network level, the global workflow quality requirements can not be assured. Several strategies have been tried to improve the workflow performance in these cases, such as caching data in a closer location to the computing element [3], [4], or reducing the load of computing tasks by reusing the previous computed results [5]. However, for applications that require data streams from remote data sensors, such as in [6], those solutions will not be sufficient, and advanced network services are crucial to accelerate large data transfer between the distributed application components.

The recent emergence of advanced network infrastructures for e-Science enables tuning of network performance at the application level. For instance, the hybrid network architecture [7] can provide connections on different layers based on the same physical fibre; this allows applications to reserve dedicated circuits for transferring very large quantity data. By including network resources in the scheduling loop, the high level application gets an extra opportunity to optimize execution and improve performance.

These new opportunities come with some challenges. Not all network infrastructures provide the network services for reserving specific connections or allocating network bandwidth; the service invocation in different network domains is often proprietary and not easily extensible, and makes request for network service provisioning across sites difficult [8]; scheduling network resources requires knowledge on the current state of the network, which implies the existence of a sophisticated monitoring system.

In this paper, we discuss the challenges in including network resources in scientific workflows, and propose an agent based architecture to accomplish this goal and realize application level quality tuning of network resources. We apply this in the context of an ongoing project, CineGrid [9]. The paper is organized as follows; first, we will review the state of the art in this field, and then present our solution and the first prototype of our system.

II. Resource QoS in scientific workflow

The quality of a service is often expressed as set of quality attributes. Sabata presented a QoS taxonomy in which QoS attributes are grouped into *metrics* and *polices* [10]. The metrics include quantifiable attributes for measuring application performance (namely performance metrics), security (security level) and importance, while the polices refer to the qualitative attributes for specifying service level and management polices.

A QoS attribute is typically represented as a triple (attribute name, value, the range of the value), and timeliness and accuracy are the most often cited performance metrics. A description language such as QML [11] aims at a generic model for specifying different categories of quality attributes.

Since the development of services are highly application dependent, and the quality description models are often proposed by different society, semantic web based technologies have been widely used for describing QoS attributes [12]–[14], and to integrate different QoS models [15]. While composing a workflow, services at different abstraction level will naturally have different model on the quality; a semantic model for matching these quality attributes and mapping them will be essential.

From the perspective of a scientific workflow life cycle QoS is relevant to four aspects: composition, selection, execution control and provenance. In the following sections we briefly review the existing work on each issue.

A. QoS aware workflow composition

A workflow composition process that is QoS-aware must: 1) compose a service of the highest quality and 2) determine the quality of the composition process itself. The first goal is achieved by computing the global quality starting from the QoS attributes of constituting services [16]. Graph reduction is a widely used approach [17]; a pre-defined set of logic patterns define certain reduction rules which can be used to simplify the logical dependencies among constituting services. From the reduction rules, the quality parameters are computed; for instance the computing time of two sequentially connected services is computed as the sum of the quality of each of them, the computing time of a two parallel services is computed as the maximal one from them. The second goal requires modelling the quality attributes of the semantic links between services, the composition quality of the workflow can then be evaluated by the semantic fit and the reliability of the selected service in the workflow [16].

B. QoS aware service selection

Searching for suitable services from available resources is a basic procedure in composing a workflow. QoS aware service selection implies two steps: properly formulating the requirements and selecting resources that meet these requirements. Rosenberg proposed a QoS enabled description language, the Vienna composition language (VCL) [18], to specify an abstract flow for workflow composition. The VCL defines an abstract workflow as four parts: feature definition, feature constraints, global constraints and the business protocol (the desired workflow language). The feature constraints and global constraints include both functional constraints and QoS attributes. The problem of resource selection has been formulated differently. A commonly used formulation is *shortest path finding in a weighted graph*, in which the available services are represented as a directed graph according to the service types, and the graph nodes are labelled by the quality attributes of the service [19]. Well known shortest path finding algorithms include Bellman-Ford and Dijkstra's. These algorithms exhibit optimal performance because of their greedy search strategy and avoid backtracking operations during the search; however, the minimal cost path found by the algorithms is often not the most optimal solution if there are multiple constraints on the quality attributes. Therefore, the problem has also been formulated as a multi constraint optimal path problem [20], or multi objective optimization problem. Ant colony optimization (ACO) is a meta heuristic search approach proposed in [21], [22] for discovering minimum cost path in a graph, and for solving NP-hard combinatorial optimization problems. Fang et al, [23] applied ACO in service selection and proposed a multi objective ACO approach which can simultaneously optimize several objectives. Genetic algorithm in searching optimal paths, and constraint programming or Integer programming methods are also widely used for the multi objective optimization problem.

C. QoS aware workflow execution

Workflow execution is the mapping of workflow processes to underlying computing resources and the scheduling of the execution sequence. Task based scheduling is a straightforward approach, in which the workflow tasks are submitted to the local manager of the computing infrastructure. Several researchers have instead proposed a workflow level scheduling that takes into account future task performance [24]; this approach will achieve higher performance and better resource utilization than only using local resource managers. Multi objective optimizations are widely used to formulate the problem of QoS aware scheduling. Avanes proposed a constraint programming based approach to search for best match between workflow requirements and the available computing resources [25]. The basic idea is to describe the quality requirements and resource dependencies as constraints by partitioning the workflow into different parts based on its patterns and their QoS requirements. One of the contributions from Avanes work is that the network dynamics has been also included in the procedure of constraint resolving. Resource provision plays an important role to improve the fault tolerance and the performance of the workflow [26]. Basically, provisioning can be either static or dynamic. Advance reservation is a typical static provisioning mechanism, and several batch based schedulers support it. Based on the high level quality requirements, the workflow engine reserves computing resources and time slots from the Grid resource manager. One of the disadvantages of static provisioning is its overhead on the total cost for computing the workflow. To improve this, Raicu et al. [27] proposed multi level scheduling strategies, in which the application level scheduler is able to interact with the low level resource manager to tune the requirements at runtime. This approach introduces a dynamic component in the provisioning process.

D. QoS and provenance

The provenance service tracks the events occurred in the workflow execution, and allows scientists to trace the evolution of data computed in the workflow and to obtain insights in the experiment processes. Moreover, provenance data can also be used to debug errors of the workflow execution and optimize the workflow design. The Open Provenance Model (OPM) [28] emerges as a standard model to represent workflow provenance information. Including QoS information of the workflow processes and the execution in the provenance model allows scientists to analyze the quality of the services and the workflow scheduling. In [29], the provenance service is provided by a QoS aware middleware, which records the changes of the service quality as events. Evaluating trust and reliability of the provenance data itself has also been discussed in the literature [30]. However, research on the provenance model which includes the QoS information of the workflow processes is still in its very early stage.

III. Problem and challenges: network QoS and scientific workflows

Our research interest focuses on the inclusions of the network quality of service in the high level e-Science workflows. Workflow systems have been recognized as an important tool to manage the invocation of lower level network services and the security related routines [31]. In SC09, the VLAM workflow system [32] demonstrated allocation of workflow modules over specialized network connections. Several e-Science environments already recognized the importance of the network resources reservation in the context of workflow scheduling, for instance in [33]. When including network resources QoS in a scientific workflow, we have to solve several issues:

1) We need a representation and mapping mechanism between the user level requirements and the quality model of underlying network resources. When mapping high level workflow processes to low level resources, the abstract quality descriptions of the workflow also have to be translated to the proper quality constraints on the underlying resources.
2) A good network resource monitoring system is essential in using QoS in the system design, execution and evaluation [34]. A workflow description composed from carefully selected resources or services does not imply that the actual execution will achieve the desired performance. The quality guarantee of the workflow execution is a dynamically adapting procedure between the workflow engine and the actual state of the resources involved in the workflow execution, unless one can guarantee a priori that all the resources perform at their best state. A problem is that monitoring quality metrics of the network resources in the workflow context is also in its initial state. Truong proposed a monitoring framework for Grid services, which monitors the resources from four different levels: machine, network path, middleware and application [34], and derives the QoS value for the reliability and availability of the machines, network paths and middleware from the monitoring.
3) We need to optimize the negotiation between the workflow engine and the underlying network resource manager, for both resource provisioning and tuning the scheduling of workflow (or replacing workflow components). This is made more difficult by the ad-hoc APIs adopted by the different network providers, which prevent a generic solution.
4) In a scientific workflow we need to schedule multi level resources to support real time applications. Solving multi-level constraints between heterogeneous resources requires different optimization searching technologies in the problem space and it is time consuming compared to the state updates of the underlying resources. For instance, discovering suitable network paths often involves not only searching connected intra-domain paths between network devices, but also inter-domain exchange of topologies. Further, the evolution of the underlying network state make scheduling more difficult.
5) We need to adapt the provenance model to include the (network) quality of service information, and to let the logging facility obtain such information and record it in the database. The current provenance model mainly focuses on the evolution of the data, and uses certain partial relation to indicate the dependencies of the data process; it does not explicitly include the quality of actual services when the data was produced. Such information can be very important for improving the scheduling strategies utilised by the workflow engine.

We propose a QoS ware planner which covers the life-cycle of workflow not only at composition, but also scheduling and execution. Our system tackles the issues we just summarised above.

IV. Design requirements and system design

We had two alternatives when we looked at the inclusions of QoS aware functionalities in a scientific workflow system: 1) re-engineer the functional components of an existing workflow system to include the QoS support, or 2) consider the existing workflow systems as legacy systems, and provide QoS support as plugged components to the system. Each alternative exhibits advantages and disadvantages. In the context of our research, we chose the second approach; one of the motivations is that generic functional components can be encapsulated as reusable tools which can serve different specific scientific workflow systems to get QoS support.

A. Design requirements

We can highlight three scenarios where network QoS support can be applied: QoS aware resource selection, resource provisioning and quality assured workflow execution. The designed system thus needs to meet the following functional requirements:

1) The system must include QoS aware resource discovery and selection of network resources. Network resources and the quality attributes are necessarily described, and a search tool is provided to check the suitable resources based on the input requirements.
2) The system should be able to generate a resource provisioning plan for selected resources based on the input requirements. The plan is made based on the provisioning services that the available network infrastructure provides.
3) The system should be able to generate workflows handling large data movement between network resources with guaranteed data transfer quality, and wrap the generated workflow as a service which can be executed standalone or included in a third party workflow.
4) At runtime, the system should provide monitoring services to track the actual quality of the network resources. It should also provide interfaces for third party workflows to invoke during their provenance procedure to record all the runtime information.

B. Agent based technologies

The Agent Oriented (AO) methodology complements the object and component oriented methods with knowledge related notions to manage system complexity [35], and emerges as an important modelling and engineering approach for constructing complex systems, such as workflow management systems. The concept of *agents* originated in the mid-1950s as *a 'soft robot' living and doing its business within the computer's world* [36]. Wooldridge distinguished three types of agent architectures: deliberative, reactive and hybrid [37]. The difference between the deliberative and reactive architectures is that the former incorporates a detailed and accurate symbolic description of the external world and uses sophisticated logic to reason about the activities, while the latter one only implements a stimulus-reaction scheme. Reactive architectures are easier to implement but lack a subtle reasoning capability. Hybrids of the two schemes are commonly used. During the past two decades, agent based models, in particular reactive models, have been applied as an advanced technology in modelling and constructing complex system. Agent frameworks, such as FIPA [38], abstract the structure of basic agents and define standardized communication languages to represent interactions between agents, which facilitate the implementation of agent based applications.

JADE (Java Agent DEvelopment Framework) is a free software and distributed by Telecom Italy [38]. Fully implemented in java, Jade realizes a FIPA compliant multi agent middleware. In our project, a number of reasons motivate us to choose JADE as the implementation framework. First, the Jade platform can be distributed across machines and the configuration can be controlled via a remote GUI. The Java language makes the development portable; the Jade framework allows agents move from one machine to another at runtime. Moreover, being compliant to the FIPA protocol, Jade provides a standard architecture for scheduling agent activities, which makes the inclusion of high level functionality easy, e.g., adding a Prolog module for activity reasoning. Finally, the ontology enabled agent communication between agents promotes seamless integration between the semantic network description, QoS aware searching modules, underlying models of workflow descriptions, and other necessary functional components of our system.

C. An agent based QoS workflow planner

We propose an agent based architecture, composed of a *QoS aware workflow planner (QoSWP)* and five more agents: *a Resource Discovery Agent (RDA), a Workflow Composition Agent (WCA), a Resource Provisioning Planner (RPP), a QoS Monitor Agent (QMA)* and *a Provenance Service Agent (PSA)*. Fig. 1 illustrates a conceptual schema of our agent system.

Fig. 1. An agent based solution to adaptive QoS aware workflow management.

The QoSWP coordinates the other agents to select suitable services, to propose optimal network connections between the services, and to create the necessary scripts for the workflow engine to invoke the requested services. A typical use case scenario will illustrate the role of each component (see Fig.1). The QoSWP receives the request for data process services and the service requirements from the user (step1). After that, the RDA reads the description of the resources and the network topologies from the registry, and searches suitable data sources and destinations, and network paths between them (step2). The RDA returns a list of qualified candidates, and sorts them based on the quality metrics of each candidate (step3). From the candidates, the QoSWP selects the best one, and request WCA and RPP to generate a resource provisioning plan and a data transfer workflow (step4 and step5), both of which will be executed by the workflow engine (step6). At run time, the QMA monitors the actual state of the resources and checks whether the global quality required by the workflow is satisfied (step7). Based on the states updated by the QMA, the QoSWP decides whether the resources of the workflow should be adapted. The provenance service records events in the resources provisioning, allocation, and combine the actual state of the quality attributes with the log data (step7).

V. Prototype and Use Case

The research is conducted in the context of CineGrid. An important mission of the CineGrid project is to provide a dedicated network environment to connect distributed parties from different domains to share large quantities of very-high-quality digital media, such as the high definition video material used in the movie industry.

We are prototyping our ideas using a small portion of the CineGrid infrastructure as a test bed. Four locations in Amsterdam host CineGrid resources and are connected via dedicated and configurable circuits provided by SURFnet [39]. The results reach beyond the workflow field, and they can be beneficial to understand how advanced network connections enhance the digital media delivery in the academic and education context.

In this section, we will demonstrate how the designed architecture works in a use case, and discuss the technical considerations to prototype the system.

A. A CineGrid use case: QoS guaranteed high quality media on demand

We are focusing on a *digital media delivery on demand* use case: the goal is to retrieve media material from the infrastructure, and request quality guaranteed connections to deliver the data to qualified nodes for further processing, such as playback or visualization. Using the proposed agent framework, the use case will be prototyped as follows:

1) The user uses the schema provided by the system to describe the name and properties of the media, and to specify the quality requirements for visualizing the data.
2) The QoSWP parses the user input and creates queries for the RDA to look for data sources of the media;
3) Based on the input requirements, the RDA looks for the data repositories which contains the required media, and the visualization devices which meet the required playback quality. Then the RDA looks for all possible network paths between the sources and the visualization devices.
4) The RDA returns a list of candidates in the form of (source, destination, path) triplets, and the candidates are ordered based on the quality they provide. The QoSWP selects the best candidate from the list and send it to the RPP and WCA to make resource provisioning plan, and to create a workflow which can deliver the media from the source to the visualisation device, and to play it back in the visualization device.
5) To help RPP and WCA make the provision plan and the workflow compliant to a specific workflow engine, the QoSWP also explicit tells the RPP and WCA what language of the third party engine will use.
6) After receiving the scripts generated by the RPP and WCA, the QoSWP sends them to the third party engine to execute the provisioning plan and the delivery plan.

B. Semantic resource description

The CineGrid community uses semantic web technologies to describe the services, devices and the network topology. The UvA team in the project have developed two ontologies. The Network Description Language (NDL) [40] models the different levels of a network infrastructure: physical, domain, capability, layer and topology[1]. The CineGrid Description Language (CDL) [9] describes the services and resources on top of the network infrastructure[2]. Fig. 2 shows concepts defined in the CDL. Using these two languages, we have described the resources in the research test bed. Four locations (UvA, SARA, De Waag and the Dutch Film and TV institute) in Amsterdam are connected with up to two dedicated switchable 1Gbit/s links, which can be dynamically changed between locations using the openDRAC [41] network provisioning software used by SURFnet.

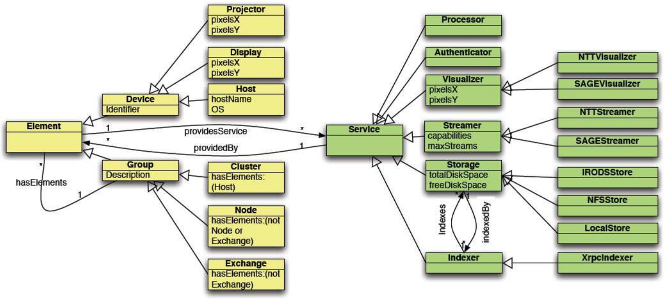

Fig. 2. The schema of the CineGrid description language.

C. QoSAWF: an abstract workflow description language

Based on the experience of early work [18], [42]–[44], we propose an ontology for describing abstract workflows (*qosawf.owl*). It defines the basic concepts of workflow processes, pre/post/execution conditions of the process, media data, and quality attributes, as shown in Fig 3. The description of the user request is described as an object of the *Request* class, and a *Request* consists of one or more *Processes* which can be accessed via the *request_Functionality* property. A *Process* class uses *pre_Condition* and *post_Condition* to indicate the requirements for *Data* the process requires and generates, and the quality for the required data. The *Process* class also uses *execution_Condition* to indicate the service quality for the process. In the current definition, *Data* contains two specific types: *Media* and *Scientific_Data*. And the service quality is modelled as set of *Quality_Attributes*. Based on the QoS taxonomy defined in [10], *Quality_attribute* can more specifically be *Precision*, *Timeliness*, *Reliability* and *Security_Level*. In our case, where the pre and post conditions consist of requirements for data and the data quality, *and_Condition* and *or_Condition* are the two most important types. Using the above ontology, a user is able to formulate a request for obtaining and playing

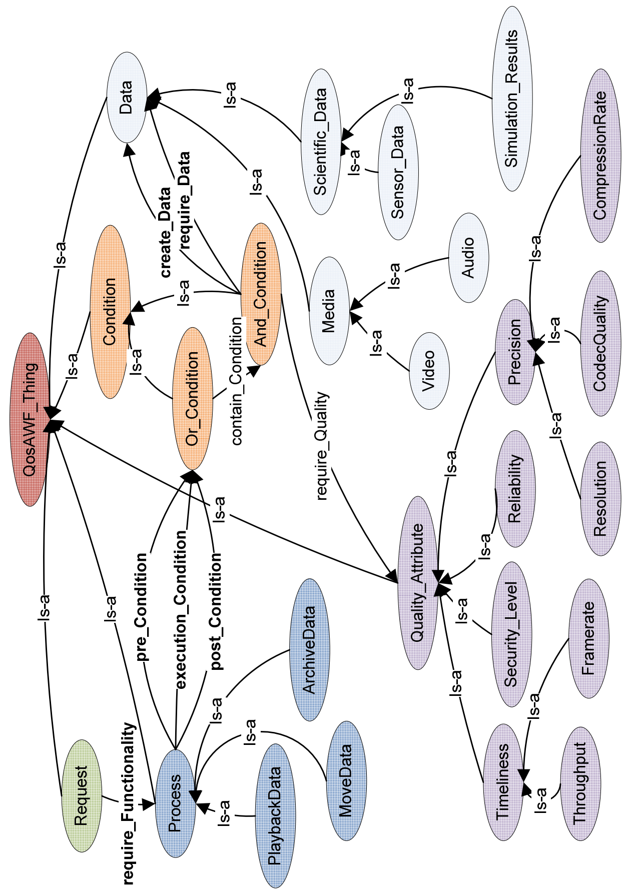

Fig. 3. The concepts defined in the qosawf schema.

back a specific video material with a minimal resolution and frame rate. Fig. 4 shows the graphical representation.

D. First prototype

We have compared different options to realise the resource search mechanism; we have evaluated several Query languages (RQL, RDQL, N3, Versa, SeRQL, SPARQL) and Rule languages (SWRL, Prolog/RDF lib, JESS etc.). We have finally chosen the RDF library of SWI-Prolog; its triple based manipulation interface is easy for the high level language we use to implement the agents (Java); it is also easy to access the runtime state of the triples. Finally, the Prolog language provides effective solutions to realise graph path findings.

The FIPA [38] standards provide a suitable architecture to implement distributed agents in our system. The Agent Communication Language (ACL) allows agents to exchange messages using an explicitly defined semantic schema, which allows seamless integration between agents and remote Ontology knowledge bases.

In the current prototype, the RDA receives the URI of the user requirements and network resources from the QoSWP. The RDA parses the given abstract workflow and searches the resource description; it returns results in the form of (storage host, visualization host, path, quality rank).

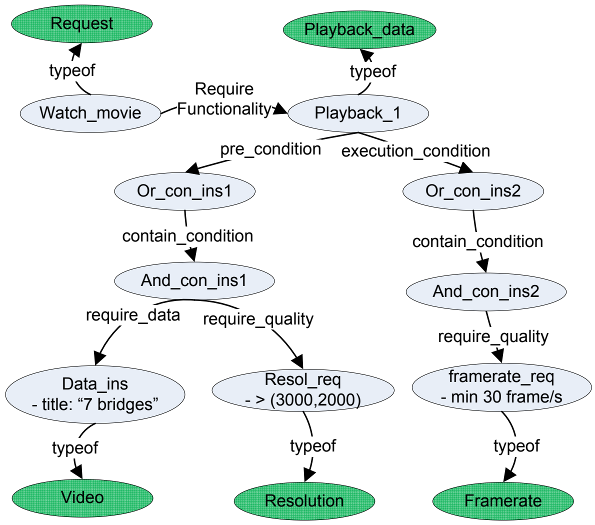

Fig. 4. An example of abstract workflow description.

VI. Summarizing remarks

In this paper, we have reviewed the state of the art of the QoS aware workflow management. We have discussed different technologies for realizing QoS aware resource discovery, workflow composition, scheduling and adaptation. In the review, we can summarize several issues:

1) Semantic technologies play an important role in modelling QoS attributes and mapping quality description between different layers of resources in workflow system.
2) QoS aware service selection has been tackled using different solutions: minimal cost path finding in a weighted graph, multi objective optimization or integer (constraint) programming. For selections with constraints of different QoS attributes, multi objective optimization is a better solutions.
3) The QoS of network resources have been tried in workflow system in different ways: using workflow to manage network services, for interactively creating network connections from the workflow, or scheduling part of the workflow in the resources which have special quality connections. These solutions focuses on runtime part of the network resource allocation, which is often tightly coupled with the specific network service.

Based on the existing work, we have proposed an agent based solution to include QoS aware network resources planning in the loop of workflow composition, provisioning and execution. We have proposed an RDF based schema for describing the data and QoS requirements in an abstract workflow.

The research is conducted in the context of the CineGrid project; however, the results of the research aim to be generic and applicable for any e-Science applications which suffer from the bottleneck of transferring large quantity data over not optimal networks. We will develop the QoSWP as a generic service for legacy workflow engines to support QoS aware network resource selection, provisioning and invocation of network services for transferring data. Moreover we will define a provenance model which includes the causality relations between scientific data and the quality of the utilised resources. This will allow scientists to investigate the dynamics of the underlying resources allocation and to optimize the workflow scheduling strategies. The work described in the paper is still in its early stage. The research will proceed as follows. Firstly, we will prototype the RDA to enhance an early version of the CineGrid portal developed in the UvA for QoS aware network resources discovery. Secondly, we will realise the WCA and RPP; we will use the VLEWF-Bus system [45] as the first test case for the underlying third party workflow engine. Thirdly, we will focus on the QMA and PSA. The OPM will be used as starting model to develop PSA.

Acknowledgment

We would like to thank the National e-Science Research Center and the Dutch national and education network SURFnet, through the GigaPort Research on Network (RoN) project, for sponsoring this research.

International Workshop on Advances in Business ICT

ABICT is organized within a framework of the International Multiconference on Computer Science and Information Technology (IMCSIT), and is focuses on Advances in Business ICT approached from a multidisciplinary perspective. The ABICT will provide an international forum for scientists/experts from academia and industry to discuss and exchange current results, applications, new ideas of ongoing research and experience on all aspects of Business Intelligence.

We kindly invite contributions originating from any area of computer science, information technology and computational solutions for different applications areas, data integration and organizational implementation of ABICT, as well as practical ABICT solutions.

Topics include (but are not limited to):

- Advanced Technologies of Data Processing, Content Processing and Information Indexing
- Business Applications of Social Networks
- Business Data Mining and Knowledge Discovery
- Business Intelligence, Business Analytics
- Business Rules
- Business-oriented Time Series Data Mining, Analysis, and Processing
- Data Warehousing
- Information Forensics and Security, Information Management, Risk Assessment and Analysis
- Information Systems in Enterprise Management
- Information Technologies in Enterprise Logistics
- Information Technologies in Enterprise Management, Information Systems,
- Service Oriented Architectures (SOA)
- Knowledge Management
- Recommender Systems
- Semantic Web and Ontologies in Business ICT
- Virtual Enterprise
- Web-Based Data Management Systems

A method for consolidating application landscapes during the post-merger-integration phase

Andreas Freitag, Florian Matthes, Christopher Schulz
Technische Universität München
Boltzmannstrasse 3, 85748 Garching bei München
Email: {Andreas.Freitag, Florian.Matthes, Christopher.Schulz}@in.tum.de

***Abstract*—Mergers and acquisitions (M&A) have become frequent events in today's economy. They are complex strategic transformation projects affecting both - business and information technology (IT). Still, empirical studies reveal high failure rates regarding the achievement of previously defined objectives. Taking into account the role and importance of IT in modern business models, the consolidation of application landscapes and technical infrastructure represents a challenging exercise performed during the post-merger-integration. Unfortunately, not many artifacts in the form of tangible concepts, models, and methods exist facilitating the endeavors of merging IT.**

After providing a broad overview on relevant literature in the area of M&A from a business and IT perspective, this article presents a method artifact for consolidating application landscapes in the course of a merger. It originates from the approach applied during a case study in the telecommunication industry where the application landscapes of two formerly independent lines of business have been merged.

I. Introduction

For almost 100 years *mergers and acquisitions* (M&A) have been used as a strategic management instrument in many enterprises [1]. In the 21st century, the appearance of corporate consolidations and reorganizations remains remarkably high, whereas M&A are not single events, but rather an integral part of modern business strategies [2]. A typical driver for M&A is the realization of increased market power through inorganic growth, resulting in economies of scale and cost reductions [3]. Penzel [4] for instance, speaks of annual cost savings between 10% and 20%. Moreover, new markets may be conquered through the enlargement of the product and service portfolio in order to realize economies of scope [4].

Although the two terms "merger" and "acquisition" in M&A are often used as synonyms, both words denote slightly different things and should not be misperceived [5]. Whereas the terms are sufficiently defined and consistently applied in the Anglo-Saxon publications (especially in the United States), German literature still lacks a commonly accepted distinction between both concepts [6]. However, looking on M&A from an *information technology* (IT) perspective, it is sufficient to consider M&A as any type of enterprises' fusion under one economic authority, independent from the legal status of the participants.

Despite their frequent occurrence, approximately 50% of all M&A succeed [7]. Gerds [1] even reports a failure rate higher than 60% which is confirmed by a multitude of empirical surveys [8], [9]. Several studies evaluate risks and common pitfalls in order to identify key success factors for M&A planning and *post-merger-integration* (PMI) projects. Our literature research resulted in the subsequent list, which is mutually agreed upon by the majority of authors ([10], [11], [12], [13], [14]), even though they apply different languages and terminology:

- Clear business vision - committed, explicitly described, and measurable
- High aspiration level, definite directions, common performance indicators
- Stakeholder management, effective communication, and corporate cultures
- Project organization (structures and processes)
- Coordinated and holistic planning of business and IT
- Consistent decisions for business and IT
- Knowledge management
- Risk management
- Realize growth and demonstrate early wins

Given that the majority of enterprises are characterized by intensive usage of IT today [15], [16] as well as regarding the items of above's list, it becomes obvious that IT also should be taken into consideration during M&A. According to the Gartner study "IT Spending and Staffing Report 2008" [17], typical investments for IT account for around 3.4% of the annual revenue. Even if for many of these enterprises' IT presently still plays an inferior role by supporting main business processes only, medium to large size companies cannot be imagined without it. Unfortunately, the significance of IT is often undervalued in the course of M&A and resulting *integration* endeavors [18], [16]. This argument is underpinned by the work of Johnston and Yetton [19], who emphasize that the IT division can be critical to merger success in M&A of large enterprises particularly during the intractable activities of the PMI phase.

In this article, the term integration refers to post-merger-integration phase of a merger or an acquisition. Although sometimes the term is differently defined when taking a closer look on current literature [20], [21], integration can be regarded as a logical consequence realizing a strategic decision in comprising the totality of changes and process steps necessary for the consolidation of two different entities. In the following, the terms integration, merge, and consolidation are used interchangeably for ease of reading. Furthermore, this

article considers an integration as a complete amalgamation of two or more entities resulting in one remaining entity.

The integration of IT includes the consolidation of two or more heterogeneously evolved application landscapes which previously supported different businesses. In the case of a complete integration, those landscapes are consolidated entirely, hence coupling solutions and green field approaches are not considered. Consequently, in the aspired future application landscape each single functionality is realized non-redundantly by one dedicated application. When it comes to specific artifacts facilitating the integration of application landscapes in the course of M&A projects, little literature exists, both in academia as well as in practice [22], [23], [19]. In this regard, an artifact refers to all innovations attempting to create utility for an organization: constructs, models, methods, and instantiations as specified by [24]. The present article proposes a method for consolidating historically independently grown application landscapes originating from a case study in the telecommunication industry in which two *lines of business* (LoB)s have been integrated. Thereby, the planning and implementation was based on the *enterprise architecture* (EA) framework *TOGAF* (The Open Group Architecture Framework) [25], which was tailored in order to fit to the specific merger context.

The remainder of this article is structured as follows: Section II provides a solid overview on existing M&A literature covering the business and IT view on the topic. In Section III, a method for integrating two different application landscapes is presented as applied in the case study. Finally, Section IV concludes by summarizing the article and outlining further fields of research.

II. Related Work

When addressing the challenge of IT integration in the course of the merger business and IT related sources have to be taken into account. First group of literature focuses on the overall M&A process and conditions from a business point of view while the second group explicitly copes with merger relevant IT topics. Complementing both views, we also examine a representative subset of *enterprise architecture management* (EAM) literature, which provides a holistic view on an enterprise with regard to concepts and ideas addressing M&A challenges like consolidating application landscapes.

Approaching M&A from a business stance, the work of Bänzer et al. [26] constitutes a comprehensive and widespread overview. By differentiating between a general planning, execution, and integration phase, it thoroughly investigates on the different forms, activities, organizational impacts, constraints, and artifacts which designate M&A projects. Nonetheless, the role and importance of IT is solely motivated by a high-level IT due diligence checklist [26]. The in German-speaking countries well known book of Jansen [6], gives a systematic introduction to the topic of M&A from a business point of view. Once again, IT is not in the scope of this work. Gerds and Schewe [1] shed light on M&A by elaborating a so-called “recipe for success” regarding beneficial post merger achievements. In providing several case studies from global positioned enterprises, the work points out main differences between top performer and M&A average. Nonetheless, the significance of IT is not elaborated on in detail. Further literature proposes specific taxonomies, calculation rules, and financial metrics to evaluate the outcomes of a merger [7]. However, IT mostly plays a minor role [27] or is even entirely omitted [28]. In summary, due to their business focus this group of literature sets the overall context of the merger but does not provide specific artifacts for the consolidation of IT.

Tackling M&A from an IT perspective, the work of Miklitz and Buxmann [22] points out four different integration strategies for application landscapes. The authors present a concrete design artifact for selecting applications expressed by a decision model which targets at the standardization of the landscape. Unfortunately, their article refrains from evaluating the model in practice. Penzel and Pietig [14] propose a so-called “Merger Guide” structuring bank mergers into time slices and dimensions. The authors highlight the importance of IT, represented through a proper dimension in the merger process and spend a dedicated chapter dealing with IT during M&A. Besides pointing out relevant system integration strategies, system transition plans, and a layer model of a bank’s system architecture, the work also considers data migration and the shutdown of obsolete systems. Nevertheless, Penzel and Pietig do not provide concrete methods or key deliverables to carry out the transformation from multiple application landscapes to one.

Considering current literature in the domain of EAM, M&A is mostly addressed as one possible field of application and in a brief manner only. Ross et al. [29] observe, that a certain maturity level of EAM is a prerequisite to manage M&A. Nevertheless, the authors do not explicitly address EAM processes or methods, but rather present several M&A case studies. Niemann [30] shortly sketches a merger situation as well as the implications on the application and infrastructure landscape during the development of planning scenarios without providing a method to deal with this type of situation. Focusing on the general management of integration projects, Winter examines a series of case studies. He identifies M&A as one major trigger for integration projects [21] and motivates the need for a situation specific integration method being applied in the course of a PMI phase. Keller [31] dwells on mergers within IT application portfolio management. He consciously creates the link between EAM and M&A by presenting the ladder of integration and the basic pattern of application consolidation. Still, no specific method is proposed aiming at consolidating application landscapes.

Due to their high practical relevance and continual increasing awareness amongst academia, EA frameworks are a valuable source when it comes to M&A. While frameworks such as Zachman [32] only classify the descriptions of an EA, The Open Group Architecture Framework (TOGAF) [25] also provides elements to establish a sustainable architecture function in an organization and proposes an *Architecture Development Method* (ADM). However, since EA frameworks are a collection of best practices covering a broad range of use cases, relevant parts of the chosen framework have to be selected and explicitly tailored to the specific needs. The same applies to the case of M&A.

In the reviewed literature, concrete M&A artifacts for merging IT are rarely addressed. Most notably, the consolidation of application landscapes is not elaborated in detail. In the majority of cases, the authors differentiate between the general strategies for IT consolidation: cherry picking, steamroller, co-existence and green field approach [19], [31], [22], [33]. Unfortunately, these depicted suggestions remain rather general and abstract. In contrast, the method proposed in subsequent Section explicitly copes with the consolidation of independently evolved application landscapes, ranging from initial clarification of the common business vision to planning of a roadmap on an application level.

III. Method to consolidate application landscapes

A. Preliminary considerations

A M&A situation between two companies whose business models rely on IT inherently entails the complete integration of the application landscapes during the PMI phase in order to realize the intended synergies. Following a theory-building approach from one or more case studies as motivated by Eisenhardt and Graebner [34], this section suggests a method artifact for application landscape consolidation. Thereby, the method is based on a case study from the telecommunication industry, hence the focus lies on theory building rather than testing the designed artifact. After a brief introduction to the case study, the resulting method is presented in the first part of this section. Subsequently, the article continues by describing each method step in detail. In doing so, every single step is accompanied by the respective part of the case study printed in italic letters.

B. A case study from the telecommunication industry

The telecommunication group comprises two lines of business (LoB)s - fixed line and mobile business. The newly-defined corporate strategic goal driving the merger of both LoBs was to increase customer satisfaction achieved by high service quality during each contact. Another major requirement was the responsive support of personalized marketing campaigns providing customers with product and service offers in a timely manner. Consequently, the need for an integrated *customer relationship management* (CRM) had been identified. Both LoBs acted in different competitive environments with individual business models, products, and processes but with partly identical customers. Furthermore, their CRM application landscapes have been developed independently to a large degree in the past.

In order to establish an integrated CRM supported by a common application landscape, the commissioned CRM project team used the presented method to fulfill subsequent core tasks:

- develop a comprehensive and corporate-wide approved vision for CRM consisting of the business target picture and the architectural blueprint
- gain transparency about the current CRM application landscapes of both LoBs in addition to their associated costs
- develop the target CRM application landscape as well as general architecture principles for the subsequent implementation initiatives
- elaborate an implementation roadmap, taking into account the existing CRM roadmaps of each individual LoB

Thereby, it was especially important to balance between strategic corporate goals and operative process and data requirements of the various sales and service divisions at the two LoBs. Both had to be considered in the target application landscape. At this point in time, the parallel business project which was in charge to work out the common target business processes was not completed. Therefore, a stable structure to coordinate the business and the IT project was required to start work immediately and integrate the different requirements relevant to the common CRM later on.

C. Method overview

The presented method is based on the EA framework TOGAF [25] and provides an approach for consolidating application landscapes driven by a merger and acquisition activities. Typically, the main IT integration work is performed during the PMI phase by means of one to more dedicated project(s). Figure 1 shows the stringent top-down approach which has been derived from the TOGAF Architecture Development Method (ADM). The ADM, as one core element of TOGAF, describes the holistic development of architectures (i.e. business, information systems, and technology architecture) following 11 distinct phases. Therefore, the method allows to interlink IT consolidation activities with general integration work conducted in other domains, e.g. business processes, resources, or staffing.

The final deliverables of the presented method artifact consist in a *business target picture*, an *architecture blueprint*, and an *implementation roadmap*. Table I provides short a definition of each term. After pointing out basic information and main context of the case study in which the method was successfully applied, the different steps of the artifact are explained in detail. At the same time, each individual step is exemplified by the experiences made and the challenges encountered during the execution of the case study.

D. Detailing the method

1) Design and establish governance model: Before working on the project's core task, i.e. the consolidation of application landscapes in the course of the PMI phase, an overall *governance model* is established. The main rationale behind is to provide a binding working environment and to form a foundation for all subsequent method steps performed by the responsible project team. As major constituents, the governance model gives information about the project organization, clear

TABLE I
KEY METHOD DELIVERABLES AND THEIR DEFINITION

Name	**Description**
Business target picture	An explicitly documented common corporate vision for the respective functional scope.
Architecture blueprint	A description of the target application landscape on a logical level.
Implementation roadmap	A list of individual steps of change laid out on a time line to show progression from the baseline application landscape to the target application landscape.

responsibilities, conductive rules for collaboration, reporting, as well as effective escalation paths. Besides the formal governance model, the overall project success strongly relies on the management of multidisciplinary stakeholders and the establishment of adequate communication and information activities.

The project steering committee of the telecommunication company was given the mandate to act as the required cross-LoB decision board by forming an interim architecture board for the time of the project. In total, the CRM project had to manage a group of nearly 50 stakeholders. This included representatives of various business units (e.g. CRM, marketing, sales, and product management department), IT, and controlling from both LoBs, who had to be regularly informed about the transformation progress. Fortnightly information sessions were scheduled to present and discuss relevant architecture views.

2) Understand and document business target picture: During the second step, the mandate of the application consolidation project including the functional scope, rights, and responsibilities, is specified in more detail and formally agreed upon. The functional scope is defined with the help of *architecture segments*, which according to TOGAF are *"a detailed, formal description of areas within an enterprise, used at the program or portfolio level to organize and align change activity."* [25]. The business target picture is thoroughly analyzed and documented in order to derive the strategic requirements, which will drive the development of the *target application landscape*.

The clarification of the business target picture for CRM of the company was based on a study about CRM market trends in the telecommunication sector, an analysis of the company strategy and business goals, as well as interviews with selected executive management representatives of both LoBs. It included the substantiated requirements from a business point of view, which had to be addressed by the target application landscape. The definition of the functional scope of CRM was achieved in close coordination with the corporate-wide enterprise architecture initiative. This initiative had the mandate to develop an overarching architecture model consisting of non-overlapping segments which represent distinct business domains (e.g. CRM, billing, product management, or logistics). Based on the elaborated segment structure, responsibilities considering the business and IT requirements could be non-ambiguously mapped. By this means, the CRM project team was able to develop the target application landscape for the agreed CRM segment, while routing requirements to their respective projects. For instance, requirements which resulted from the business target picture for CRM but related to different segments. Additionally, a set of architecture principles was derived from the business target picture as main guidelines to ensure a strategy-aligned execution of the implementation roadmap.

3) Develop capability map: In this step, a common language and structure for the relevant segments of the consolidation project is established among the multidisciplinary stakeholders. This is especially important to ensure a high degree of acceptance and sustainability for the solution to be developed in the course of the project. A *capability map* is used to break down the relevant architecture segment. Again, this article adheres to the definition of TOGAF, where a capability represents *"an ability that an organization, person, or system possesses"* [25]. According to TOGAF, capabilities are typically expressed in general and high-level terms, e.g. customer contract management or campaign management.

The defined CRM segment was detailed using a CRM capability map to provide a common terminology and structure among the different stakeholders from business units, IT, and controlling of both LoBs. The commonly agreed cross-LoB definitions for the CRM capabilities have been identified during a series of workshops with business and IT representatives. Afterwards, the functional view of the capabilities was complemented with major business objects, including definition of ownership and depending information flows. As a mean of communication, a graphical representation of capabilities and assigned business objects was elaborated.

4) Develop architecture vision: The *architecture vision* depicts a high-level view on the as-is and target enterprise architecture, according to the priorly elaborated business target picture. As one key element of the architecture vision, the architecture blueprint describes the target application landscape on a logical level. It is needed to analyze and compare existing application landscapes in order to support the selection of the target applications. To facilitate the comparison of the different applications, logical *architecture building blocks* (ABB)s which cluster functional and non-functional requirements, are assigned to the capabilities identified in previous step. Thereby, an ABB *"represents a (potentially re-usable) component of a business, IT, or architectural capability"* [25] as defined by TOGAF.

The CRM target application landscape was described on a logical level, according to the formulated CRM business target picture. The architecture blueprint was worked out in a series of workshops with subject matter experts and business and IT representatives of both LoBs. The various requirements from the CRM business target picture could ultimately be classified and consolidated on the basis of the capabilities. Afterwards, the planned IT support for the elaborated capabilities was described in the form of ABBs before key business objects were mapped to those ABBs in order to define data mastership and information flows derived from data usage. To ensure consistency regarding further IT initiatives in the company, the resulting architecture blueprint was also cross-checked in terms of feasibility against other segments. At this point, the business requirements which have been refined and detailed by the parallel ongoing business project were incorporated in the identified ABBs.

5) Capture baseline: In order to select the applications that optimally support the elaborated architecture blueprint, the baseline of existing applications is captured. Different applications are compared on the basis of information about their lifecycle, functional, non-functional, and financial criteria. Thereby, the developed architecture blueprint including capabilities and architecture building blocks is applied as a common reference structure to make results comparable.

To define the major applications from both LoBs that support the described architecture blueprint, the baseline of existing CRM applications was captured. To compare nearly 150 applications, a tool-based inventory with lifecycle information, functional and non-functional requirements, as well as financial properties was created. The analysis of the baseline did also include already planned changes within the application landscapes of both LoBs and existing migration roadmaps. Depending on the main functionality identified with subject matter experts from business and IT of both LoBs, each application was assigned to those ABBs it supports. This allowed for a direct comparison between the functionality offered and as-is costs of both application landscapes on ABB and capability level.

A brief illustration of assignment of applications to ABBs is depicted in Figure 2. In this example, the business segment "Customer relationship management" consist of the two distinct capabilities: "Contract management" including three ABBs, and "Campaign management" containing two ABBs. In the depicted scenario 1, ABB 1 and ABB 2 of the capability contract management are realized by the functionally enhanced application of LoB2 (APP 2). For ABB 3, a new application (APP 7) is needed to meet the common requirements. The capability campaign management is best supported by an application of LoB 1 (APP 5). Note that the business objects described above are not shown in this example.

6) Evaluate alternative target application landscapes: To select the optimal target application landscape, different alternatives are evaluated against functional and non-functional requirements attached to the respective ABBs. In each case, the required migration steps towards the target application landscape are elaborated and documented (e.g. functional extensions, data migration, or retirement).

In the case of the telecommunication company, three different target scenarios were evaluated. In each case, the required migration steps towards the target application landscape have been derived by the project team, additional subject matter experts of business departments, and IT of both LoBs.

7) Evaluate financial impact: To support the decision for one target application landscape, a corresponding business case is worked out. The calculation has to encompass estimated transformation costs, current operation and maintenance costs, as well as estimated saving potentials. Costs are structured according to LoB-specific cost center structures, but for an in-depth comparison a common reference is necessitated. The different alternative target application landscapes can be evaluated using the formerly elaborated capability map which is extended through the application of a novel controlling approach allowing to analyze costs and benefits of the transformation on capability level [35]. Finally, the step is concluded with the decision for one target landscape.

Due to the project scope, an IT cost case model was applied in the case of the telecommunication company. The estimated costs and saving potentials on application level were structured and communicated using a CRM capability map which was extended by financial information. In follow-up projects, the IT cost case model was complemented to a full business case by incorporating benefits identified on the business side.

8) Plan implementation roadmap: Finally, an implementation roadmap (cf. Figure 3) for the selected target application landscape is elaborated. The business vision is broken down into major milestones, which realize concrete business value (e.g. establishment of a common information base). The required activities concerning the different application landscapes can be grouped in workpackages according to these milestones. In addition, those applications that have to be modified (e.g. functional extensions, data migration, or retirement) can be assigned to each of these workpackages.

The implementation roadmap represented a step-by-step migration plan for the preferred scenario. It points out the sequence of projects to be carried out in order to build

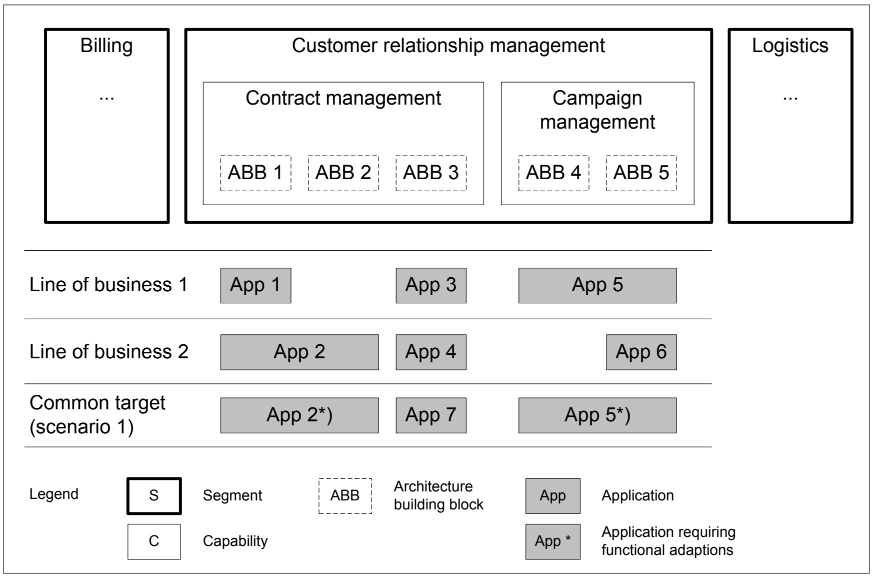

Fig. 2. Exemplary assignment of different LoBs' applications to the elaborated architecture building blocks

one common CRM application landscape. Additionally, the developed roadmap considered all formerly existing projects of each LoB and highlighted resulting dependencies.

9) Implementation governance and change management: Lastly, an adequate *implementation governance* has to be established in order to guide the following implementation projects. According to TOGAF [25], implementation governance provides an architectural supervision of the implementation. Therefore, a common set of recommendations and guidelines is formulated. Regular checkpoints are established along the implementation process to guarantee conformance with the defined target architecture and ensure the realization of the estimated business value. Furthermore, a proper change management establishes procedures to identify needs and manage changes in order to adjust the implementation roadmap if necessary. Implementation governance and change management have to be closely integrated into general integration activities.

The set of architecture principles defined in step 2 ensured a strategy-aligned execution of the developed implementation roadmap and change management was organized. By reasons of the continuous character of these two activities, the project organization was formally closed and the responsibility was handed over to the line organization.

E. Conclusion

This section presented a method for consolidating application landscapes by following a theory-building research approach. In the presented case study, the defined core tasks have been achieved in time and budget. Due to the successful accomplishment, the method has been debriefed as a reference method for the respective telecommunication company. The main benefits of the method perceived by the project sponsor and the participating stakeholders were

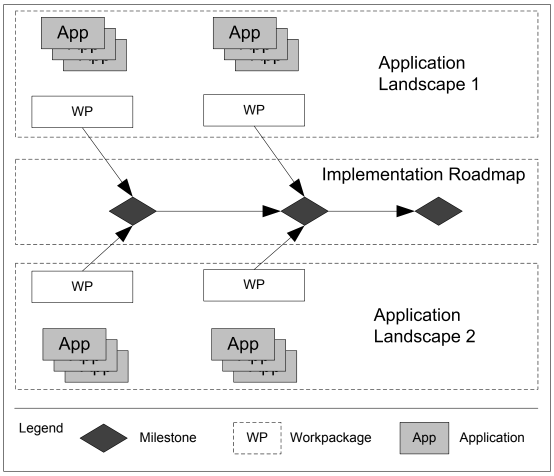

Fig. 3. Exemplary implementation roadmap

- the consistent planning, from corporate strategy for CRM to IT implementation,
- the stringent methodology, transparent and traceable for business and IT,
- the establishment of a common terminology and a common understanding for CRM, and
- the strong involvement of key stakeholders.

These benefits generated in this PMI project tie in with the general key success factors for M&A presented in Section I.

IV. Outlook & Discussion

M&A can be seen as complex and intricate company-wide transformation projects attempting to integrate two formerly disjunctive business entities. Unfortunately, they are often leading to disillusioning economical results or complete failure. Due to the fact, that IT is an integral part of the business model in many industries, its importance during an M&A should not be underestimated. However, the selected literature analyzed in this article does not provide relevant artifacts, i.e. concepts, models, and methods helping to meet the challenges of an IT integration. In particular with regards to the complete consolidation of different application landscapes in the course of a merger, no comprehensive approach exists to the knowledge of the authors.

By examining a real-world case study in which two differently administered lines of business had to be integrated from a business and IT perspective, this article proposes a method artifact aiming at consolidating formerly independently evolved application landscapes. As one core concept of the presented method, capabilities proved to be valuable in serving as a stable foundation between business and IT when assessing two landscapes from a functional, non-functional, as well as financial point of view. Furthermore, the document also showed how an adapted TOGAF Architecture Development Method (ADM) can be successfully applied in the context of M&A.

The method requires further evaluation and justification in order to prove its applicability and relevance for the merger context. While the artifact has been established as a standard method in the respective telecommunication company, it is currently re-applied in the course of an application landscape consolidation project of two German software companies. In this vein, the artifact could be further on extended by a distinctive role and organizational model depicting the different actors and their respective points of action during the method. Moreover, specific context factors of M&A as described by business resources (e.g. [1], [15]) should be taken into account when refining the method. In a subsequent step, concrete architecture viewpoints validated by means of complementary case studies should be designed and evaluated.

In all, this article presents an initial foundation when studying IT integration during M&A situations. The depicted method is one of several artifacts which is useful in supporting the consolidation of application landscapes during the PMI phase.

Hybridization of Temporal Knowledge for Economic Environment Analysis

Maria Antonina Mach
University of Economics
Department of Knowledge and Information Management
53-345 Wroclaw, Poland
Email: maria.mach@ue.wroc.pl

***Abstract*—the paper is devoted to the concept of hybridization of temporal knowledge in an intelligent reasoning system. Hybridization is a special kind of integration, where heterogeneous knowledge is transformed in order to obtain a uniform one, but information on temporal characteristics and on core features of knowledge being transformed is preserved, and may be also used for reasoning. It may be said, that integration serves as means of hybridization, but only if at least two conditions are fulfilled: if integration is source-oriented, and the knowledge sources are kept autonomous.**

In the paper we present in detail the concept of integration, the conditions that are to be fulfilled if the integration is to serve as the means of temporal hybridization. We show an application area for a hybridized knowledge, namely the analysis of economic environment of an enterprise. We present an example of a hybridization procedure.

Keywords: integration, hybridization, temporal knowledge, temporal intelligent system.

I. Introduction

THE increasing complexity of an environment, in which modern enterprises operate, entails the more and more complex formal descriptions of this environment. This in turn leads very often to a problem of heterogeneous representations. Economic environment is of heterogeneous nature, so is its formal representation (based very often on different sources) and in order to perform a coherent reasoning by an intelligent system, all fragments of the representation must be unified.

In the paper we present the problem of using knowledge coming from different sources to perform an analysis of enterprise's environment. This environment changes in time, therefore we assume, that the analysis is performed by a temporal intelligent system that is a system, which explicitly and directly performs temporal reasoning. Such a system contains not only a fact base, a rule base and an inference engine – as any intelligent system – but also contains explicit time references both in representation and reasoning layers.

The reminder of the paper is organized as follows. In Section one we show how integration may be perceived as a mechanism of temporal knowledge hybridization. Section 2 is devoted to basic approaches to data and knowledge integration – they are very shortly presented and discussed in context of hybridization. In section 3 we present in detail the idea of temporal knowledge hybridization. In the same section we present an example of the integration process leading to a hybridized knowledge obtained from two temporal knowledge bases. The paper ends with a summary section. Some additional information, needed to make the example in Section 3 more readable, is presented in Appendix A and Appendix B.

II. Integration as Mechanism of Knowledge Hybridization

There can be several sources of knowledge about enterprise's environment: databases, data warehouses, Business Intelligence systems, or other information systems used by an enterprise, as well as text documents.

For an intelligent system to reason correctly, it is necessary that it reasons not only about economic environment as a whole, but also about its fragments – that is, about particular fragments of knowledge encoded in the representation layer. Therefore the integration process must preserve the original knowledge fragments. The process of transforming heterogeneous temporal knowledge, leading to a uniform representation, but at the same time preserving information on temporal characteristics and on core features of knowledge being transformed, is called a temporal hybridization. It can be therefore said that the integration process in a temporal intelligent system is a mechanism of knowledge hybridization, where knowledge concerns enterprise's environment.

III. Basic Approaches to Data and Knowledge Integration

Lawrence and Baker [LABA01] perceive integration as a process of merging notions and knowledge from single sources, resulting in a coherent view of the whole knowledge contained in these sources. It is a point of view of knowledge-based intelligent systems. It stresses a specific role of knowledge integration in management supporting intelligent systems. Generally speaking, by a heterogeneous knowledge base we mean a base of a diversified form, structure and origin [OWOC01].

The question of knowledge integration can be viewed from different perspectives and in different contexts. The problem is discussed in detail e.g. in [MAOW04], here we present a short summary in Table 1.

TABLE 1.
TYPES OF INTEGRATION. SOURCE: OWN ELABORATION.

CRITERION	TYPES OF INTEGRATION
Integrating system operations	virtual materialized
Direction of integration process	Source-oriented Client-oriented
Changes in sources being integrated	Domain integration Semantic integration
Aim of integration	Procedural integration Declarative integration
Objects being integrated	Mono-object integration Poli-object integration
Context of integration	Functional database text agent, other

In case of the task of temporal analysis of enterprise's environment, it seems that one should speak about the following types of integration:

a) virtual – because temporal representations of environment's elements are integrated before reasoning is proceeded, therefore there is a mediating system between knowledge sources and an user;
b) source-oriented – because the tasks of the systems are left unchanged, while changes appear in the sources, thus reflecting changes in the environment, and the system has to respect these changes;
c) semantic – while integrating knowledge before reasoning, a temporal intelligent system has to solve conflicts arising from e.g. different granulations of changes of elements in enterprise's environment;
d) declarative – the main aim of the integration process is to obtain an uniform representation for further reasoning, the tasks of the system remain unchanged during the integration process, while the system is not aimed at delivering the *at hoc* information;
e) integration that keeps the sources autonomous but at the same time integrates them (hybridization);
f) mono-object – the sources being integrated before the reasoning process starts are of the same type: temporal knowledge bases.

The most important question in the process of hybridization of temporal knowledge is to respect changes in knowledge sources and to keep the sources autonomous. Only in such case information on temporal characteristics and on crucial features of knowledge being integrated is preserved. Therefore if the integration is to be used as a mechanism of hybridization, should be, first of all, source-oriented (b), and should keep the sources autonomous (e) – these are the two basic conditions of a temporal hybridization.

IV. TEMPORAL HYBRIDIZATION PROCESS

A temporal intelligent system, aimed at analyzing changes in enterprise's environment, uses many different kinds of knowledge, because the environment is heterogeneous, complex and dynamic. Elements of enterprise's environment may be of qualitative, quantitative or mixed nature. To represent them in a temporal intelligent system, one has to use also qualitative, quantitative and mixed temporal formalisms. Moreover, the system should be able to reason both about each group of elements (a so-called detailed view), and about all the elements treated as a whole (a so-called general view). To obtain a coherent view of all the elements, the hybridization of temporal knowledge about particular elements of the environment has to be done.

From the economic point of view, the heterogeneity of knowledge in the system may be perceived as:

a) heterogeneity of sources: knowledge can be gained from different sources – see introduction;
b) heterogeneity of features: because elements of the environment can be viewed as different features to be represented in a different way.

From the computer science point of view, in a temporal intelligent system we may find the following types of heterogeneity:

a) logical heterogeneity – because we assume, that elements of the environment are represented by means of logical formalisms;
b) temporal heterogeneity – because the above formalisms are temporal logics, as the features represented have an explicit temporal aspect to be captured;
c) reasoning heterogeneity – because for each group of environment's elements a different inference mechanism is needed. Each group of elements is represented in a separate knowledge base, each of which has a separate inference mechanism linked with it. Moreover, taking into account different characteristics of environment's elements, the inference mechanisms do not need to use the same inference strategy.

In our opinion there is no need to develop a new particular technique for integration of representations. The integration itself serves only as a mechanism of hybridization of knowledge about enterprise's environment. Any integration tool or technique may be used, if only it fulfills the two main conditions, pointed out in Section 2 (namely the condition <b> and <e>). Of course, the more conditions (formulated in section 2) fulfilled by the integration tool/technique, the more useful it is for a temporal intelligent system.

Consider a simple example of an integration procedure, leading to hybridization of temporal knowledge. Assume there is an enterprise that wishes to start a TV channel. The enterprise has two knowledge bases:

a) a base of legal knowledge concerning licenses – as a license is required to start a TV channel;
b) a base of knowledge concerning the influence of dollar's exchange rate on capital barriers to entry to a mass-media market (knowledge gained from an expert).

The knowledge bases are of the following form (simplified to make the example clear):

a) legal knowledge base – formalized in the LTR language[1]

```
if TT1: license(issuing authority, enterprise)
     TT2: is_issued(TT1)
     Occurs(TT2)
 Then occurs(valid(TT1), instant(TT2))

 If  TT2: valid(TT1)
      Occurs(TT2)
 Then Holds_on(valid(TT1), period(TT3))
 Period(TT3) Equals(5y, 50y)
```

b) knowledge base on capital barriers to entry – formalized in the Prolog+CG language [KABB00], designed to formalize conceptual graphs[2]. As the knowledge base is temporal, the original conceptual graphs notation has been augmented with fuzzy temporal references, taken from [KALC05].

```
  [CRB]  -  actn  ->  [change]  -  manr  ->
[proportionally] :-
  [sit  =  [fluctuations]  -  attr  ->  [fre-
quent],
  -  ptnt  ->  [DER]  ]  <-  tref  -  [TR  =
[[GCGty: #ctx] - TAgo -> [month: {}@3]]
<- TOvr].
  (if  during  the  past  3  months  frequent
fluctuations  of  DER  has  been  observed,
then CRB changes proportionally)

  [CRB] - actn -> [lower] :-
    [sit = [decrease] - ptnt -> [DER]] <-
tref  -  [TR  =  [Year:  2004]  -  Tsnc  ->
[GCGty: #end]].
  (if since the end of 2004 the decrease
of  DER  has  been  observed,  then  CRB  low-
ers)
```

where: CRB – capital barriers to entry, DER – dollar exchange rate.

In this example we observe the problem of the logical heterogeneity (two different representation formalisms), the heterogeneity of features being represented (two different kinds of barriers to entry – legal and capital ones), and the heterogeneity of temporal granulation – for the legal knowledge, the granulation may be established for one year, while for the knowledge about DER the more accurate granulation is one day (this is so because of a different pace of changes in the case of law and in the case of DER).

A sample procedure of integration of the above knowledge bases may be as follows:

a) transformation of granulations to obtain an uniform one;
b) establishing a reference time point;
c) choosing a final representation formalism;
d) transformation of time ontologies to obtain an uniform one;
e) conversion onto the final formalism and merging of the two knowledge bases.

Ad a)

It seems natural that a common granulation for both knowledge bases should be one day. It is so because it is easier to present years in terms of days than inversely. Under such circumstances the knowledge base about the DER remains unchanged, while the second rule in the legal knowledge base is transformed according to the new granulation:

```
 If  TT2: valid(TT1)
      Occurs(TT2)
 Then Holds_on(valid(TT1), period(TT3))
 Period(TT3) Equals(1825d, 18250d)
```

We assumed, for simplicity, that each year equals 365 days.

Ad b)

A reference time point is needed for further ontology standardization. We propose that the reference point be a day on which integration is done, e.g. r_0= 07/09/2006.

Ad c)

The choice of the final temporal representation formalism depends on time ontology and on the integration technique. In our example we deal mainly with time intervals (validity period of a license, a period in which changes of DER are observed). Therefore one of the possible common formalisms may be Allen's interval algebra [ALLE81], [ALLE83]. There are several reasons that justify this choice:

- the LTR theory (used to formalize the legal knowledge base) is partly based on Allen's algebra,
- Allen's algebra in turn derives from the first order predicate calculus,
- the conceptual graphs (used to formalize the second knowledge base) are easy to convert on 1st order predicate calculus – see Appendix B.

Ad d)

Ontology standardization means establishing, what temporal objects are in both knowledge bases, and converting them onto the final temporal formalism. In the example there are the following temporal objects:

- event: license issuing, proportional change of a barrier, lowering of a barrier, lowering of DER, fluctuations of DER,
- fact: validity of a license;
- agent: issuing authority,
- constant: interval [1825d, 18250d] – to be denoted as t_2,
- variable: enterprise, license,
- interval: 3 months before the reference point r_0 – to be denoted as t_3, an interval from the end of 2004 to the reference point r_0 – to be denoted as t_5.

Ad e)

[1] The basic concepts of the LTR theory are explained in Appendix A.

[2] A short explanation on conceptual graphs is given in Appendix B.

To convert both knowledge bases onto Allen's interval algebra, we introduce two predicates: HAS(what, who) and DURATION (interval, length). After conversion all the rules (both bases merged together), using the time ontology established in step d) are of the following form:

OCCURS(ACAUSE(issuing_authority, license_issuing), t_1) ⇒ OCCURS(license_issuing, t_1)

OCCURS(license_issuing, t_1) ⇒ HOLDS(license_validity, t_2) ∧ HAS(license, enterprise) ∧ MEETS(t_1, t_2) ∨ BEFORE(t_1, t_2) ∧ DURATION(t_2, [1825, 18250])

OCCURRING(frequent_fluctuations_DER, t_3) ⇒ OCCURS(change_CRB, t_4) ∧ DURATION(t_3, 90) ∧ BEFORE(t_3, t_4) ∨ MEETS(t_3, t_4)

OCCURS(decrease_DER, t_5) ∧ ECAUSE(decrease_DER, t_5, lower_CRB, t_6) ⇒ OCCURS(lower_CRB, t_6) ∧ BEFORE(t_5, t_6) ∨ MEETS(t_5, t_6) ∨ OVERLAPS(t_5, t_6) ∧ DURATION(t_5, [(2004 12 31), r_0])

The main advantages of the above sample integration procedure are standardization of formalisms and preserving temporal information. The main disadvantage, on the other hand, is that in the final knowledge base there is no possibility to encode fuzzy temporal references. This means that we have lost a part of information. This disadvantage is due partly to the choice of Allen's algebra, partly to the problems with formalizing fuzzy intervals, and partly to simplification of the procedure, to make the example clear.

What needs to be stressed is that after the above integration procedure both original knowledge bases remain unchanged, the third knowledge base is added to them, and therefore the two basic conditions of temporal hybridization are fulfilled.

V. Conclusions

In practice the most popular and the most widely used are the tools and techniques of semantic integration. If it is assumed that the main aim of integration is to create a coherent representation of information from different sources, and to enable reasoning based on heterogeneous sources, it becomes obvious that semantic, conceptual integration is indispensable.

There are many advantages of using hybridized knowledge in enterprise's intelligent systems. Let us point out the following ones (see also [IWFA95], [OWOC03]):

- "openness" of knowledge – caused by its variety – allows for a more accurate reflection of a domain being analyzed;
- a model of hybrid knowledge makes analysis and prediction of domain's behavior easier. This has been proven in the context of hybrid systems [IWFA95], but is valid also in context of hybrid knowledge;
- knowledge built upon independent sources is more unquestionable, reliable and trustworthy than knowledge built upon a single source.

The other advantages of using hybridized knowledge and maintaining heterogeneous knowledge bases in the reasoning system are as follows:

- each element of the economic environment is represented in a separate knowledge base (knowledge "openness") which leads to a precise representation of elements having different characteristics;
- easy analysis of economic elements – when elements are represented separately, the system can easily capture their features and take them into account during the reasoning process;
- reliability of knowledge about economic environment – using several knowledge sources before integration, if these sources concern the same economic element, allows to improve the level of knowledge reliability. Of course it is assumed that in case of any contradictions there is a method of eliminating them, but this question is beyond the scope of this paper.

We do not address in the paper problems concerning maintaining hybridized knowledge bases, such as problems of knowledge coherence or knowledge validation. The detailed discussion on these problems can be found e.g. in [OWOC01] or [MAOW04] – the procedures used to ensure knowledge coherence, and the procedures of knowledge validation and verification are similar to those used in the case of typical, non-hybridized knowledge bases.

Appendix A. Basic Concepts of the LTR Theory

The detailed description of the theory can be found in [VIYO98]. Table 2 contains a summarization of the most important LTR features.

Table 2.
Basic features of the LTR theory. Source: [VIYO98].

Legal Temporal Representation (LTR)	
Time ontology	Elements: points, intervals, durations, clock-calendar constants Relations: <, *begin, end, next, previous, ImmediateBefore, ImmediateAfter*
Time theory	IP theory axioms + discreteness axioms + „immediateness" axioms
Temporal constraints	Qualitative point-point, metric over points, qualitative interval-interval, qualitative point-interval, unary over durations
Temporal qualification	Temporal tokens
Incidence theory	Predicates: holds, occurs, holds_at, holds_on Axioms: *holds* and *holds_on* homogeneity

Some features in the above table need a few words of commentary.

a) IP theory – point-interval time theory by Vila and Schwalb [VISC96];

b) Discreteness axioms – the authors of the LTR theory assume time to be discrete, although not always discrete time is sufficient. In our example however we can have discrete time, as law does not change in a continuous way (or at least we may assume it doesn't);

c) Predicates – based on Allen's time theory. The Holds predicate is used both for points and intervals. The holds_on predicate concerns holding of a feature over an interval, and holds_at – holding of a feature in a time point. It may be disputable, whether there really is a need for multiplying the variants of the Holds predicate.

The most important feature of the LTR theory, that needs more explanation here, concerns the so-called temporal tokens. They are used to link propositions with their times, which means a temporal qualification of propositions. Tokens may also be predicates' arguments. The method comes from a temporal arguments method (see e.g. [HAUG87]), where time is introduced as one or more additional arguments, for example:

Valid(act, t1, t2)

Tokens, instead, link propositions with the time of occurrence, e.g.:

Valid(act, tt1)

Which allows for the following interpretations: begin(tt1) = 01/01/1990 – the starting point for token tt1; or period(tt1) = [01/01/1990; 31/12/1990] – an interval over which a token tt1 is valid. It can be therefore said that a token represents a special temporal case of a temporal proposition.

A law article is formalised in the LTR theory as a rule or rules that express relations between the occurrences of events (under certain conditions) and their effects, being the holding of certain features. The LTR language is a rule one, and does not need any assumption on reasoning method.

Appendix B. Some Remarks on the Conceptual Graphs

The conceptual graphs notation has been originally introduced by Sowa [SOWA00]. A conceptual graph is a bipartite, directed graph with two kinds of nodes: notions and relations. It may be encoded graphically, with rectangles representing notions and ovals representing relations; or as text, where notions are in square brackets and relations are in parenthesis. The formalism derives from semantic networks. We have chosen this notation because conceptual graphs have some advantages, such as:

- they are legible, easy to understand, and at the same time it is a strictly formal notation,
- they are useful for representing AI problems, e.g. formalizing natural language sentences,
- they are easily expressed in KIF and first order logic, which allows using CG rules in many types of reasoning systems.

The version based on conceptual graphs needed slight modifications in relation to widely accepted CG notation, because of Prolog+CG language's particular requirements. They are as follows:

a) we could not use the AGNT relation, because, according to formal requirements, only a living being may be an agent. Therefore, instead of writing e.g. [remain] – AGNT -> [OP], we used to write: [OP] – ACTN -> [REMAIN], where ACTN stands for action;

b) the premises are time-stamped (relation Tref, graph name: TR), while conclusions are not – there are only general references such as "past", "future", linked with the CRB variable by a PTIM relation. This is so, because the validity period of conclusions is not always the same as the validity period of premises. In our opinion, there is no justification for using the same time reference in premises and conclusions;

c) according to the Prolog+CG notation, relations' names are given without parenthesis;

d) according to the Prolog+CG notation, if the graph has several branches, they are separated by commas.

As we stated earlier, the original Sowa's notation was augmented with fuzzy temporal references.

Independent Operator of Measurements as a Virtual Enterprise on the Energy Market

Bożena Matusiak
University of Lodz,
Department of Computer Science
Matejki 22/26 Str.
90-237 Łodź
bmatusiak@wzmail.uni.lodz.pl

***Abstract*—The independent Operator of Measurements (IOM) is a new energy market actor that will implement a remote access to the metering data and stores, as well as aggregating and delivering them in real time to all market participants as an independent service-placed "above the market" enterprise.**

In that sense IOM, with an adequate infrastructure of ICT has become a virtual company with real effect - where, thanks to its distributed and virtual activities on the energy market - achieves it, synergizes the whole market and activates the necessary and accurate real-time decisions of other market participants.

IOM is a virtual unit (not necessarily constrained by any single location) from the point of view of the access to the Market.

The Energy market (EM) in Poland, where IOM will be set up, has become closer to the full liberalization, energetic efficiency, enhanced competitiveness and contribute to the smart grids potential.

This article presents the issues of ICT and the creation of new business models for the above-described virtual enterprise, which manages measurement data at the EM in Poland.

I. Introduction

A FUTURE model of EM assumes a development towards to the smart grid together with: an implemented AMR-AMM infrastructure (fig.1), intelligent bi-directional communication power meters for metering load power, many sources of distributed generation using among other renewable energy sources and their settlements with market aggregators on an intra day (real-time) market. The current market design in Poland is presented in some detail in: [7], [12], [13].

An essential element of this market will be the virtual access to the measurement data, collected and aggregated from the bi-directional smart multimeters measuring the media (like electricity, gas, heat, heating), aggregate of any scale, which share any eligible market participant as a service.

Real Smart Utility – a model for the future utilities of any type on the EM — -is an actor trading and marketing on the energy market, which, thanks to virtual technologies manages the flow of information in real time. It can precisely manage and balance its needs as well as the manufacture and sale of energy (prosumers, system manufacturers, small manufacturers or EM traders).

There are some barriers for the development of such market (technical, financial, legal, information technology) that need to be resolved, and that are associated with the following problems:

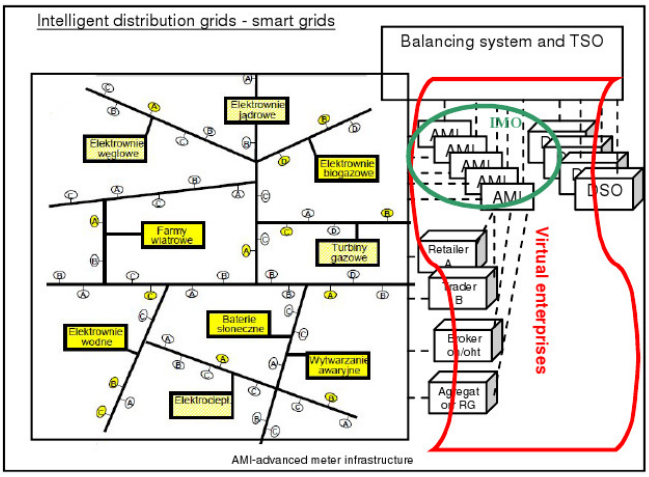

Fig. 1. The technical infrastructure required for the realization of intelligent network-general concept and the location for the IOM. (A, B, C, D: energy consumers), source: the basis on information from: www.ure.gov.pl

- Bi-directional flow of energy and information in real time (demand response) and implementation of the intelligent bi-directional remote power meters.
- Communication between market operators in real time.
- Monitoring network in real time.
- Operating and monitoring systems - operating in real-time and also effective integrating with AMI infrastructure.
- Adequate telecommunication infrastructure for data management systems.
- Power meters data management systems for the independent metering operator (IOM) - as a company with access to market participants and to the high quality, useful measurement data in real time.

Directive EU 2006/32 p. 13 defines the basis for the use and access to smart meters for customers and points out the need for billing based on actual energy consumption.

The main barrier to progress in work on smart metering are investment costs and scale of the complexity of possible solutions and the number of participants as well data obtained for instance every day for each hour (or more) for each end users.

II. Metering Market Model

Currently, the market value of the energy is built around a primary object of manufacturing and trade - that is energy.

The analysis a market value defined in such a way reveals the weaknesses of the current market model. Mainly these arise from the presence of many distributors on the market which are operating on different, often internally regulated basis. This results in poorly organized connections between the other market participants - especially energy traders. Formal and legal rules which are contained in the Comprehensive Distribution Agreements (CDA) as well as in the IRiESDs only require from operators to expose the measurement data at specified times schedule but they are often in different formats, and in practice the timetable is not respected. The companies send the estimate and poor data to fulfill the terms of settlements with clients because of the lack of the adequate data. In addition, current regulations and a system of metering and billing create difficulties, if not actually preventing prosumers activities.

In the proposed target market model, where the value chain on the EM has been defined there is space for the market integrator and operator of measurement data - IOM company, which is separated from transmission and distribution operators (TSO and DSOs). A key role here is, however, the implementation of smart metering and data management system for all EM. The value chain on the EM is presented in Fig 2.

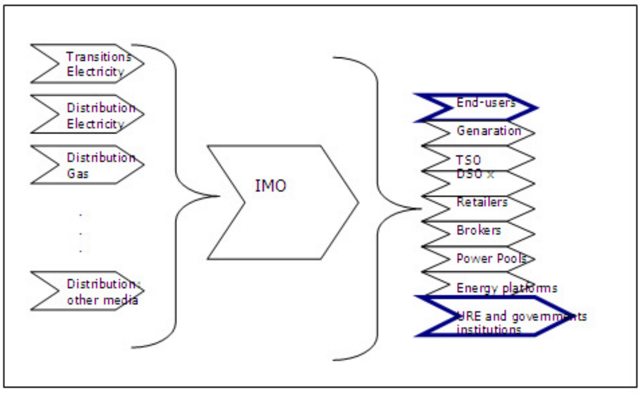

Fig 2. Metering market value chain (with IMO) in the target model of energy market. Development on the basis of [2],[3].

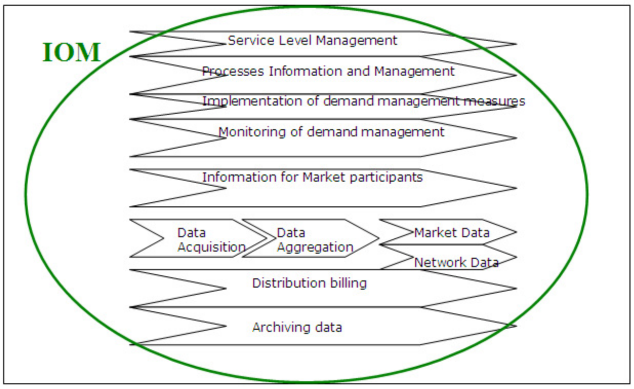
The role of the Independent Operator of Measurements will be: [1], [2]:

- Conducting regulated business activities centered around the acquisition and data processing devices (all tariff groups and data from the station medium / low voltage) obtained from the DSOs and the TSO and forwarding to the relevant players, empowered by law now and for future market players.
- Keeping the central repository of data measuring on the energy market.
- Measurement data processing and aggregating for those who needs the data from the IOM.
- Provision of services in information sharing on the energy market.
- Support competitiveness within the energy market through the actual separation and maintenance of the independent flow of information from the DSOs to the retailers.
- Providing a unified communication channel and standards, providing a base of information to the seller, regardless of his area of operation.
- Keeping archives of the measurement data, thus relieving DSOs from the necessity of maintaining a measurement data store other than necessary for their own needs.

III. Business Model for IOM

In Fig. 3 the main business processes for IOM are presented and described.



IOM
Service Level Management
Processes Information and Management
Implementation of demand management measures
Monitoring of demand management
Information for Market participants
Data Acquisition
Data Aggregation
Market Data
Network Data
Distribution billing
Archiving data

Fig 3. IOM- Main Business Processes. Development on the basis of [2], [3].

The most important business process, however, for the IOM is providing the highest quality and accuracy of the measurement data to all stakeholders of the market.

IV. ICT for Advanced meters infrastructure

ICT needs to be considered in specific areas of innovative technology solutions: the measurement data terminals for market participants, technical infrastructure for data transmission, information systems management measurements, users tools for measurement data and their household appliances etc.

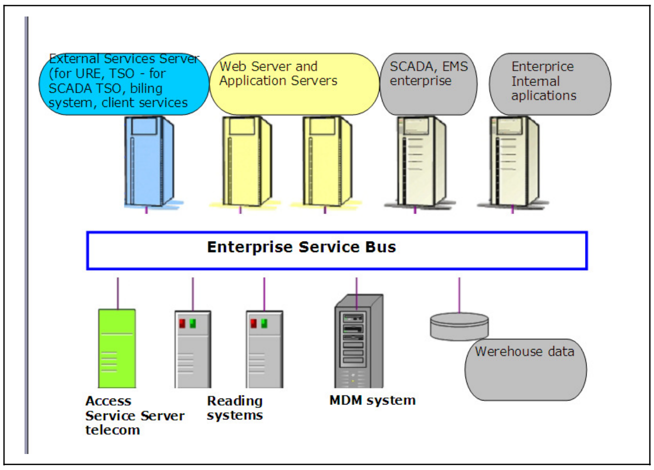
Focusing only on the functionality of the data transmission system (excluding technology and communication standards, measuring meters the same: for all client household appliances, data reading and MDMS system) should be taken into account in following technological solution [5]:
Matching transition capacity to telecommunications traffic expected at different levels and using different technologies and network (LV and MV Network, plc, GPRS, LAN, wireless SDR, dedicated wired network, etc.):

- Respect traffic at one MDMS - up to 1 million meters - the reading of load profiles once a day every 5 hours, Standards: EDIFACT standard, IEC 61986, XML (plain) PTPiREE standards.

- Respect traffic at a hub of data - for 1000 meters. Standard Communications: DLMS / COSEM.

MDMS requirements:

- Scalability up to several million customers.
- Response time to an event with the counter <1min.
- The possibility of transmission of the command "off" in time <5min.
- The precise specification of the interfaces at the design stage to the meter reading systems, billing systems, SCADA and / or EMS systems, asset management systems.
- An Ease of publication / access data.
- MDM Systems towards to Architecture Service Oriented - SOA (Service Oriented Architecture)
- Corporate Bus Services (eng. Enterprise Service Bus) - adds a layer of a multilayer of information systems architecture that enables the use of the concept of SOA in a corporate environment. Its task is to join and disconnect services for the corporate information system.



External Services Server (for URE, TSO - for SCADA TSO, billing system, client services
Web Server and Application Servers
SCADA, EMS enterprise
Enterprise Internal aplications
Enterprise Service Bus
Werehouse data
Access Service Server telecom
Reading systems
MDM system

Fig 4.ICT architecture design for IOM. Development on the basis of [5].

Currently, software solutions offered projects for Smart Metering and MDM systems are based on SOA (fig. 4).

In Poland, first projects presented by IBM and WINUEL are combining their software components such as a solution to support measurement and data acquisition (applications from Winuel) with WebSphere ESP solutions. The aim is jointly constructed and offered by the system (presentation - May 2010) designing its modularity, orientation towards support of open standards and flexibility to adapt to the requirements of the final customer.

Connected components there are:

1. Data acquisition system with different types and models of energy meters.
2. The system of central collection and validation of measurement data in a uniform format.
3. Handling the system of measuring consumers.
4. Grid measurement service system.
5. Bus Integration -WebSphere ESB that enables the connection of multiple acquisition systems and the conversion of interfaces to a common standard CIM. Bus will also allow the connection of other systems belonging to other utilities participating in the typical business processes of the AMM
6. WebSphere Process Server system to automate common business processes of the AMM
7. Dashboard's Websphere Business Space – allowing end users a comprehensive surveillance and monitoring of the AMM system based on defined KPI's (Key Performance Indicators), portfolio (procedures) tasks according to defined business processes AMM.
8. System Websphere Business Monitor - for the calculation of defined KPIs (Key Performance Indicators).

V. Conclusion

The main advantages of setting up the IOM according to the energy market analysts are as following [2]:

1. Providing quality service to the mandatory exchange of the measurement data in the process of mutual settlements, in the process of changing the supplier (a temporary regime of access to data) etc.

2. Ensuring neutrality and equal access to information for all market participants:

- Enhancing the competitiveness of the market: a real separation from the DSOs.
- Increased attractiveness for new entrants due to the elimination of barriers to the access of data.

3. Maintenance and use of open standards for the exchange of information between market participants:

- The advantage is the smaller number of standards to develop.
- Maintaining the freedom of market participants to choose their supplier of measuring tools (DSO can select the setting of solutions providers of smart meters).

4. Reducing the amount of work needed (changes) in existing systems:

- Each participant in the market fully integrates with only one player: the IOM;
- Reducing costs and the elimination of financial barriers for the entry of new players (especially for retailers).

5. Ensuring finance transparency of new business projects (smart projects) by all market participants.

6. Simplifying data collection on the market and customer behavior.

7. Opening up the EM in terms of power system data exchange with network operators in Europe.

However pilots are needed to implement, both remote reading (such as the implementation of the company Energa: Converge system, system-Amateur Radio) as well as ICT systems, built in SOA architecture, where virtual platforms for trade and management of the measurement data acquisition and archiving are in the IOM set of services.

Work on standardization, smart metering, acquisition, storage, sharing and reporting, and management of the measurement data through the ICT systems are currently in progress. However, due to the complexity of the issues involved and the scale and diversity of systems already operating on the market this is envisaged to be a highly expensive and complicated design.

Appendix

Short definitions of the term "**virtual**":

1. *Virtual*- means: such as: almost, virtually- so it is something that has potential (through the development and implementation of the new ICT tools-it is greater then ever before). The characteristics of the object does not physically exist, or exists in a sparse and economical form. 'Nearly' and 'almost' does not mean 'better' or 'worse'. Usually it is something more than just a physical object, being value-added and built on its virtual features.

2.*Virtual* means digital – that is, a facility that can be stored in computing systems and databases (broad approach).

Virtual Energy Market: (virtual actors), - approach to the construction of the structure of the market applying a similar model to the Internet and using its potential of communication and information processes for the management at the EM.

CVPP – Commercial Virtual Power Plant- - distributed generation, the object dispersed, potentially possible, flexible, dynamically variable in its action, quickly responding to market needs and the energy balance system. CVPP applies intelligent information management systems and knowledge. All processes can not be managed without the support of ICT tools. CVPP is a virtual organization dispersed with EM actors, managed by information management systems that aggregate the market in terms of "above the network" [9].

Abbreviations

DSOs – Distribution System Operators

TSO – Transition System Operator

AMI – Advanced Metering Infrastructure

AMM –Advanced Metering Management system

AMR- Advanced meter reading

MDMS Measurements Data Management System

CVPP Commercial Virtual Power Plant

IRiESD - the policy for DSO activities

CDA – Comprehensive Distribution Agreement (in Polish: GUD- Generalna Umowa Gystrybucyjna)

URE- Energy Regulator on the EM which regulate a policy and principles of market (in Polish: Urząd Regulacji Energetyki).

***Abstract*—In the paper, a novel two level algorithm of time series change detection is presented. In the first level, to identify non-stationary sequences in processed signals preliminary detection of events is performed with short-term prediction comparison. In the second stage, to confirm changes detected in first level a unique changes similarity method is employed. Detection of changes in non-stationary time series is discussed, implemented algorithms are described and results produced on exemplary four financial time series are showed.**

I. Introduction

INFORMATION on changes in analysed time series is relevant to detect alarm situations, in particular, when signals are processed in real-time systems. Implementation of dedicated algorithms to event detection from non-stationary time series requires considering many factors, such as statistical and frequency-domain data characterisation, different type of short- and long-term changes, time lags between events or sampling frequency. Results given with such algorithms are helpful in advanced data analysis, prediction and finally—decision making process.

Our research are aimed at advanced algorithms of time series change detection, based on statistical approach, signal analysis [4] and employing immune paradigm to event detection support [15]. In particular, we proposed a method to gain information on early symptoms of significant changes by analysis of short-term prediction efficiency [14], [16], [13], [15] through comparison between zero-order-prediction (ZOP)/zero-order-hold (ZOH) model [1] and adaptive Holt predictor [9]. Proposed method is suitable for a particular type of changes in signals, for example occur in financial time series which consist of many non–random components. We also showed that application of artificial immune systems techniques [8], [21] is a way to improve event detection and thus prediction efficiency (especially prediction error variance). In the paper [15] we proposed original idea of implementation immune based approach to early detection of significant changes in time series (long term changes of mean value), where detection is decomposed into two stages: fast detection of nonselfs (employing fast statistical and prediction procedures) and then more accurate (and more time–consuming) recognition of the nonself type and the system recovery. In the papers [15], [18], [17] an improvement of this idea aimed at long term event detection were described.

The aim of this paper is to provide detection method of changes in diagnostic signals to early detection of emergency situations. It has been designed for monitoring a set of diagnostic signals (medical, technical, financial ones) to capture differences, i.e. unusual behavior of selected signal (process variables). Such solution may be implemented as detector of rapid changes in signal (for example alarm situations as dangerous changes of technical process temperature, liquid pressure) or exceeding the threshold valued of process limitations (technology losses minimisation).

We present and analyse two-level algorithm of change detection in time series, based on simultaneous processing of two time series of fixed length in a moving window, to capture unique changes—which occur only in one of two processed diagnostic signals, i.e. are not results of the same external factors. In the first stage, preliminary detection of events is performed with one-step-ahead prediction comparison given with methods dedicated to stationary or non-stationary data [19], [1], [13]. In the second stage, to confirm changes detected in first level, a unique changes similarity method is employed.

Proposed event detector is tested on financial time series—stochastic processes with unknown random inputs, which are hard-predictable and difficult to perform reliable statistical analysis, compared to technical ones. Therefore, efficient event detection in financial ones with proposed algorithm will indicate its applicability to technical time series (as a starting point for further implementation and adjustment in order to detect well-defined, specific changes).

In this paper, we describe the detection algorithm as a part of large detectors set capable of—through two signals

This work was supported by the European Regional Development Fund, Grant no. UDA–POIG.01.03.01–12–171/08/00.

concurrent processing—handling possible event patterns in processed time series. Such idea can be further developed as an autonomous event detector and implemented as one component (e.g. agent) of available set supervised by T-lymphocyte (immune-like event detector [15]).

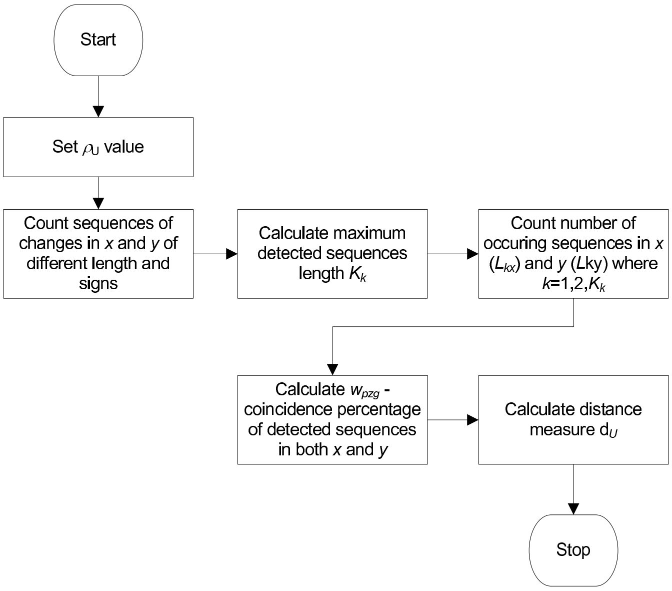
II. Event detection from time series

Event detection from time series is aimed at identifying short and long term periods of uncommon series behaviour, analysed in moving window, to detect a change in stationarity due to random external factors. Event detection task may be viewed as finding corresponding probability distribution [13], [14], [16] or as unsupervised classification task (one-class classification) where one may describe only one class and a method to distinguish between possible object (decision boundary between normal and anomaly class) with appropriate (training set tested) mapping function [19].

Considering long-term signal changes, detection of short-term "announcing" events may be a way to perform faster computation compared to classical, but robust statistical procedures of long-term changes detection. Such events may precede statistical properties changes in processed series and generate the need of adjust of assumed analysis window width, i.e. change of detection delay thus probabilities of false alarm and undetected events [12].

An implementation of given algorithmic method depends on input data properties (statistical, frequency, dimensionality, completeness), attributes of events (amplitude, duration, periodicity, applicability, coincidence, delay) or permissible detection error. Many algorithms require adjusting parameters and signals selection to specific conditions of dataset. In practice, usually the most important is appropriate selection of classification algorithm which directly affects the detection reliability and a possibility of implementation for heterogeneous data sets.

An application of a detection method suitable for dataset requires is to find specific attributes of events and the use of dependencies between processed signals and occurring events (often delayed). To achieve this aim, a number of methods can be exploited to time series quantitative analyses, such as analysis of the frequency of events [10], analysis of trends, patterns and characteristics similarity [12] or statistical methods for testing deviants and outliers, algorithms based on neural networks, genetic algorithms [11] and other data mining techniques applied to event detection from time series [7], [10], including methods based on similarity measures, in particular distance ones [22]. However, reliable results produced by such algorithms usually depend on length of series or learning [15] and highly accurate estimation of parameters such as mean value, information about trend, dynamics parameters and random component dispersion—which are an input for statistical tests [20]. In this paper we focus on methods based on similarity measures and signal analysis.



Start
Set ρ_U value
Count sequences of changes in *x* and *y* of different length and signs
Calculate maximum detected sequences length K_k
Count number of occuring sequences in *x* (L_{kx}) and *y* (*L*ky) where *k*=1,2,K_k
Calculate w_{pzg} - coincidence percentage of detected sequences in both *x* and *y*
Calculate distance measure d_U
Stop

Fig. 1. A block diagram of unique changes similarity algorithm.

III. A unique changes similarity method

Considering event detection from one time series, unusual behavior (non-stationarity) may be recognised as abrupt changes of mean value (visible as deviations exceeding fixed threshold), sequences of changes (of the same or different signs) or patterns understood as specific configuration of deviations. Considering a pair of time series, original (unique) event detection may be viewed as a selection of events occurring only in one processed dataset. To capture such events we propose distance-based similarity measures [5] applying in a moving window.

One of novel measures, designed and developed for a particular problem is an unique changes similarity method (distance-like one), first mentioned in our earlier papers [5], [17], denoted as method U and measure dU. It is dedicated to identify unique changes which are considered as sequences of deviations of the same sign with different sequence length (1,2,...,N) exceeding an arbitrary fixed threshold—ρ_U in two processed diagnostic signals of the length N (constant moving window width N is assumed).

The goal is to calculate a similarity coefficient—distance measure dU (see equations 1–3) based on counting of sequences of fixed length (subsequences of different length or signs are treated as different ones). A block diagram of such detection for one sample (for assumed window width N) is shown in figure 1.

'Distance measure' term is used instead of *distance* or *metric* because all required conditions related to formal definition of metric are not satisfied, in particular symmetry condition.

To compute dU value three partial calculations are performed (eq. 1–3). Coincidence percentage of detected sequences of deviations in analysed signals is calculated as:

$$w_{pzg} = w_p \sum_{k=1}^{K_k} k \cdot \min(L_{kx}, L_{ky}) \tag{1}$$

where L_{ks} denotes a number of sequences of length k in series s (x or y). To compute coefficient wp the following formula is employed:

$$w_p = 1/(\sum_{k=1}^{K_k} k \cdot \max(L_{kx}, L_{ky})) \tag{2}$$

Finally, distance measure dU is computed as:

$$\mathrm{d}U = 1 - w_{pzg} \tag{3}$$

Notice, in case of similar sequences in both series dU will have 0 value ($wpzg$ near 1). As threshold ρ_U value, standard deviation in moving window or its multiplicity may be used, however, arbitrary adjusting may be valuable.

To avoid an impact of time delay between events, for instantaneous values of computed distance measures dU, a tolerance (denoted as L_{tol}) is assumed as permissible delay between analysed signals. For each time instant t, a number (L_{tol}) of distance measures dU_n is calculated for time instants n ($n = t - L_{tol} + 1, \ldots, t$). Finally, d$U_n$ for which the lowest value was obtained is taken as the measure dU between two subseries for sample t.

IV. Two-level change detection algorithm

Proposed algorithm is designed to different types of diagnostic signals. We have chosen financial time series as difficult ones to perform event detection or forecasting because of existing many non-random components. Notice, that financial time series are available from heterogeneous sources, however, causal-consecutive dependencies between time-lagged events are possible.

Proposed hybrid algorithm performs detection in two steps:

1) preliminary detection of short-tem non-stationarities in signals;
2) unique changes detection with method U (see eq. 1–3).

Considering detection **in the first level**, we have chosen an approach based on one-step-ahead prediction error comparison with methods efficient for stationary and non-stationary data [14], [16], performed for both signals separately.

Autocorrelation of daily increments of typical financial time series is statistically insignificant [3], thus during usual behavior no autocorrelation of daily returns may be expected [1]. The most efficient short-term prediction (the minimum variance error) is achievable by extrapolation of averaged returns [15], i.e. by the ZOP or ZOH model [1], [15]. To predict non-stationary data, three-parameters adaptive Holt method is employed (parameters α, β, γ adjusted for each sample) [13], which is more flexible than classical one [9]. The comparison allows to basic identification of non-stationarities, i.e. non-random components (advantage Holt method over ZOP/ZOH) in relatively short time and low computational resources consumption.

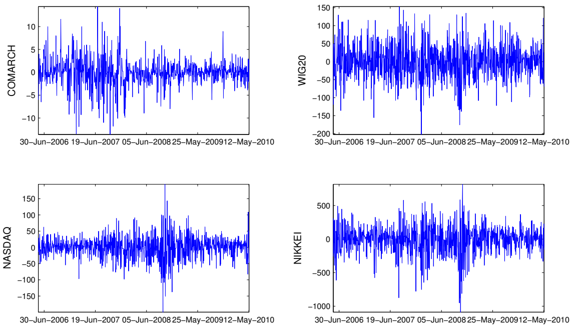


Fig. 2. Examined financial time series - daily returns (one-day increments).

In the second level, two signals are taken to calculate unique changes similarity measure (dU) thus differences between found sequences of deviations. Finally, change in a signal is found after non-stationarity confirmation with dU value exceeding fixed threshold ρ_U. In this stage, only unique (original), non-stationary sequences are selected (accuracy depended on ρ_U).

Detection schema described above provides a possibility of minimizing false alarms as a result of identifying changes that are, in fact, random fluctuations. In addition, proposed two-level algorithm decrease computation time consuming which through switching similarity detection method U for relatively small amount of samples only.

V. Calculation results

Four financial time series, individual (Comarch) and aggregated (WIG20, Nikkei, Nasdaq), has been used as exemplary dataset to analyse the proposed two-level detection algorithm. We have chosen local (Comarch, WIG20) and global time series (Nikkei, Nasdaq) from 2006–05–22 to 2010–05–14 (1040 samples).

Financial time series (see daily returns depicted in fig. 2) represent stochastic processes with unknown random inputs (in the simplest approach, such series can be considered as Wiener processes). Acceptable detection results obtain on such hard-predictable sequences of samples allow to assume that proposed solution applied to diagnostic signals generated by technical devices (which don't contain many variable components) will result in more accurate event detection.

For each processed time series, subsequent samples were taken to compute one-sample-ahead prediction with naive method (level 1; exemplary results of preliminary detection are shown in table I—for all analysed series non-stationarity identified for about 5%) while distance measure dU was calculated in moving window of constant length $N = 22$ samples (see fig. 1) between series 1 and 2 and in a reverse order (because of asymmetry of dU measure mentioned above). Processed signals were unified with standard deviation to achieve comparable orders of magnitude.

In the example discussed in this paper, to provide detection reliability, threshold sequence length was fixed to $\rho_{PC} = 3$.

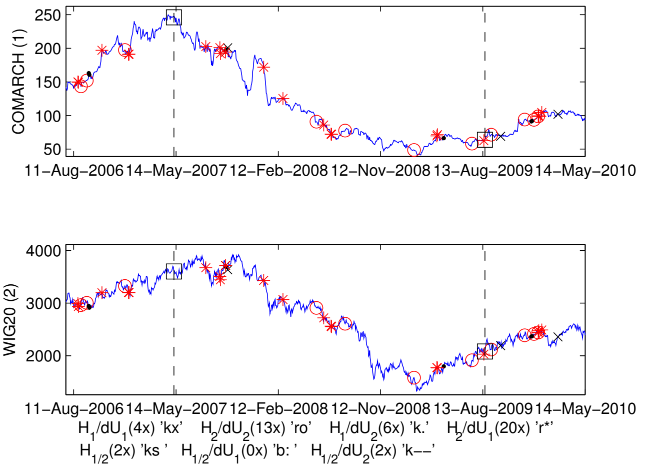

Fig. 3. Results of change detection for Comarch (1) and WIG20 (2)—depicted with solid lines—with proposed two-level algorithm. Recognized non-stationarity in series no.1 confirmed with dU_1 denoted as 'cross' (H_1/dU_1) and dU_2—as 'dot' (H_1/dU_2); non–stationarity in series no.2 confirmed with dU_1—'asterisk' (H_2/dU_1) and dU_2—'circle' (H_2/dU_2); changes H_1 and H_2 detected for the same samples—'square' ($H_{1/2}$), changes ($H_{1/2}$) confirmed with dU_1—'dotted line' and with dU_2—'dashed line'.

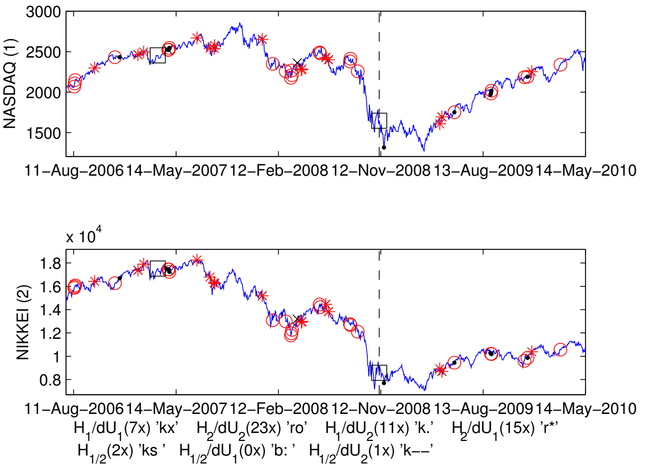

Fig. 4. Results of change detection for Nasdaq (1) and Nikkei (2)—depicted with solid lines—with proposed two-level algorithm. Description of symbols: see fig. 3.

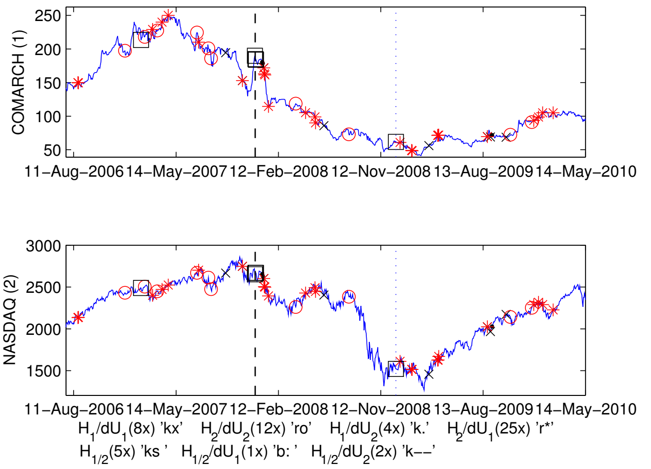

Fig. 5. Results of change detection for Comarch (1) and Nasdaq (2)—depicted with solid lines—with proposed two-level algorithm. Description of symbols: see fig. 3.

The main parameter of the second-stage detection level (ρ_U) was set to 1 as an equivalent of signals standard deviation after performed unification. Values of these parameters were selected in an experimentally way (related to properties of four analysed time series) to achieve the smallest number of false alarms and undetected events.

Detection results produced with proposed two-level algorithm are depicted in figures 3–6 (with the sampled series in the background). The figures show confirmations of changes with short-term prediction comparison in the first level (denoted as H_1 and H_2) and distance measure dU in the second level (eq. 1–3).

It may be seen in figures 3–6 that proposed method allows to detect local changes (denoted as 'cross', 'asterisk', 'circle' and 'dot'—see figure 3 caption), obtained with simple H_1 or H_2 confirmation with method U, and long-term changes, i.e. reversal in a trend (see vertical lines in fig. 3–6).

In the first case, a number of short-term changes were detected correctly, however, false alarms were found for some samples. Application of non-stationary detection confirmation (level 1) significantly reduces overall number of detected events (see table I and figures 3–6 caption).

In the second case, H1 and H2 changes are synchronised (non–stationarities detected in one signal only are rejected), which is illustrated as 'squares' in figures 3–6, and then—confirmed with dU_1 or dU_2 measure. This is relevant step to eliminate false alarms.

VI. Conclusions

Proposed two-level algorithm of change detection in time series may be viewed as an inspiration for construction efficient detectors, adaptable to signal properties. It was found as a suitable for short- and especially long-term changes of mean value through confirmation of non-stationary subsequences of processed signal. Acceptable detection results obtained on financial time series (stochastic processes with unknown random inputs, with many non-random components) allow to assume applicability end effectiveness for other types of time series, in particular, diagnostic signals generated by technical devices.

Calculation results presented in this paper show that to achieve reliable detection of symptoms of rapid changes in long-term trends in one processed time series, processing of series set of the same class (in the paper—financial ones) is valuable. Depending on the set (pair) of signals taken to calculate distance measure, detected changes may occur for different samples. This issue will be developed towards (1)

TABLE I
EXEMPLARY RESULTS OF DETECTION OF NON-STATIONARY SUBSEQUENCES IN PROCESSED TIME SERIES

Time series (total number of samples: 1040)	Comarch	WIG20	Nasdaq	Nikkei
Number of detected non-stationary subsequences with one-step-ahead prediction comparison	60	50	42	59
Percentage	5.77%	4.81%	4.04%	5.67%

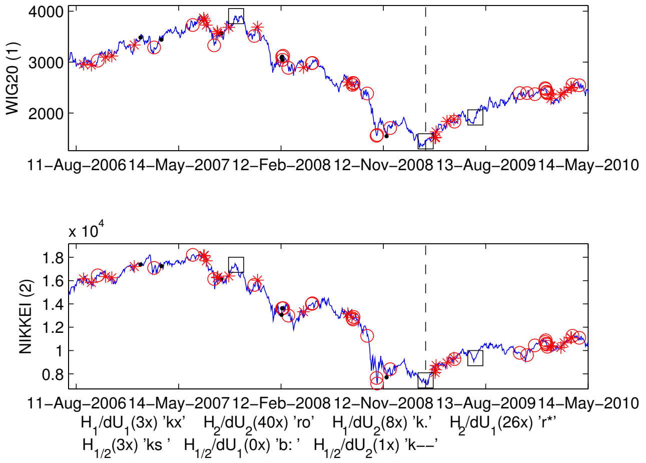

Fig. 6. Results of change detection for WIG20 (1) and Nikkei(2)—depicted with solid lines—with proposed two-level algorithm. Description of symbols: see fig. 3.

events recognition and (2) forecasting for one selected (based) signal through processing signals sets consist of many time series datasets.

Further research will be focused on implementing and testing of the proposed solution for technical diagnostic signals, especially processed in real-time systems. Studies will be required on implementation and testing of similarity methods dedicated to specific changes and patterns appearing in analysed signals, including time delays between events and elimination of false alarms. Further improvement appears to be obtained by modification of described distance measures towards variable length of subsequences taken to compute measure dU (to this aim, fuzzy logic rules may be employed).

Possibility of adjusting parameters (threshold values, window widths, etc.) seems to be a promising way for further enhancement of the presented method which is suitable for the idea of immune-based adaptive detection, in particular as one of many detectors supervised by T-lymphocytes.

STRATEGOS: A case-based approach to strategy making in SME

Jerzy Surma

Abstract—**Making strategic decisions in an enterprise is one of the most difficult problems of management. It is a result of unstructured character of such decisions which are made in conditions of high uncertainty. This issue is particularly important in case of Small and Medium Enterprises (SME), where Chief Executive Officers (CEO) are lacking support in this area and most often act intuitively, being convinced that their business is unique. Recent researches on decision-making point out the substantial influence of referring to analogies and self-experience in strategic problems. Accordingly it is proposed to use case-based reasoning to build STRATESOS - the strategic decision support system. Then, the system was verified in a survey by dozens of CEOs from SME. The results of the survey are promising and show the remarkable correspondence of the proposed solution with expectations and strategic behavior of CEOs.**

I. Introduction

SMALL and medium enterprises play a key role in the contemporary market economy. Strategic decision making in this kind of companies is one of the crucial issues taken into consideration in management [1]. In order to cope with the uncertainty and complexity, SME decision-makers seem to behave according to bounded rationality theory [2]. They determine certain level of preferences and as soon as the choice which satisfies the set up criteria becomes available, they accept it. In this approach CEOs are looking for satisfactory choices, not for optimal ones. The major challenge of decision making is uncertainty, and the major goal of decision analysis is to reduce this uncertainty [3]. To deal with the increasing complexity of the environment, the SME entrepreneurs create ‘shortcuts’ in their thinking. In this context there are two possible approaches [4]: routine (habitual and reactive) and intuitive decision making. As we can see developing and formulating the strategy of an enterprise is related to the fundamental questions concerning experience, knowledge and intuition of managers. In case of any new problem, when deductive reasoning is limited, it turns out that appealing to experience is by all means a rational behavior. As Thagard points out, “analogies can be computationally powerful in situations when conceptual and rule-based knowledge is not available” [5]. As strategic management is concerned, the team from Harvard Business School [6] made similar statements: „Reasoning by analogy is a common form of logic among business strategists. Facing a novel opportunity or predicament, strategists think back to some similar situation they have faced or heard about, and they apply the lessons from that previous experience“. Using analogies in strategy planning has been thoroughly researched both by means of case study analysis [7] and experimental research with the use of the NK-model [6]. Using the NK-model and referring to the concept of business landscape made possible to conduct formal research on using analogies in complex decision situations. On other the hand this approach has been subject to criticism, which suggested referring to other paradigms and hybrid approaches to reasoning [8].

The use of the mentioned model of CEOs behaviors may be used in creation of information decision support systems. In this context, the Case-Based Reasoning (CBR) seems to be the suitable paradigm for practical usage–vide chapter II. The concept and the prototype of strategic decision support system will be presented in chapter III (implementation issues) and IV (case-based reasoning cycle). The empirical verification is described in chapter V, and final conclusions are presented in chapter VI.

II. CASE-BASED REASONING FRAMEWORK

The research problem mentioned above might be solved, at least partially, by applying the case-based reasoning. It results from the following characteristics of these system [9]. Firstly, a particular case is the basic element of knowledge representation. Subsequently, the acquisition of knowledge consists of analyzing the particular cases from past experience and therefore it is not necessary to establish rules in order to generalize knowledge. Secondly a relatively easy update/expansion of the system through adding new cases, which follows the process of remembering one’s experiences. And finally excellent and credible justification for the recommendations (solutions) for business users. These ex-

This work was financially supported by the Ministry of Science and Higher Education in the budget for 2008-2010 as a research project.

ceptionally favorable characteristics result, first of all, from expert knowledge gained through relying on specific, individual cases solved by an expert in the past. Additionally a great opportunity is based on the CBR working cycle described in the figure 1, reflecting reasoning by analogy [10], where: New Case – the new problem, Retrieved Case – the retrieved case that is similar to the New Case , Solved Case – the solution that is adapted from Retrieved Case and is proposed to the New Case, Tested/Repaired Case – verify/test of the Solved Case, Learned Case – retain in the case based Tested/Repaired Case. However, so far there has been no thorough research on applying case-based reasoning to support strategic decision making. There has also been no reliable empirical research conducted to verify this approach and to assess how useful it actually is in the strategy making practice. At the same time global consulting companies have been building systems of databases containing information on the strategy consulting projects they have carried out with a possibility to adapt them for new clients.

III. Strategos Implementation

Based on the case-based reasoning framework, the prototype of strategic decision support system STRATEGOS was created. In order to function, case-based reasoning framework requires three main components: case representation, general knowledge representation, and similarity measure.

Case representation

The case representation should reflect the company itself (company description), its market environment (context description), and one or more strategic decisions taken in this particular situation. In order to establish it properly we conducted several surveys with CEOs of the selected SMEs. Based on those interviews and the research on the case representation for SMEs [11] the following case description was established as the set of the attributes that are taken into account:

1. Company description: market share, location, products/services, number of employees, sales volume (trends in at least two years period), sales volume (export), EBITDA (trends in at least two years period), B2B/B2C.
2. Context description: industry, industry life cycle phase, Porter five forces analysis (threat of substitute products, threat of the entry of new competitors, intensity of competitive rivalry, bargaining power of customers, bargaining power of suppliers).

The act which is chosen as a solution for the current problem, is based on the list of all the combinations of product/market decision based on the Ansoff matrix (product × market) [12], and positioning decision based on the Porter's generic strategies [13]. The complete case representation is representing the case in time T_1 (planned act/decision – after reuse phase) and T_2 (realized act/decision – after revise phase) – see figure 2. Additionally, all information included in the case representation might be enhanced with text, images, files, hyperlinks, etc.

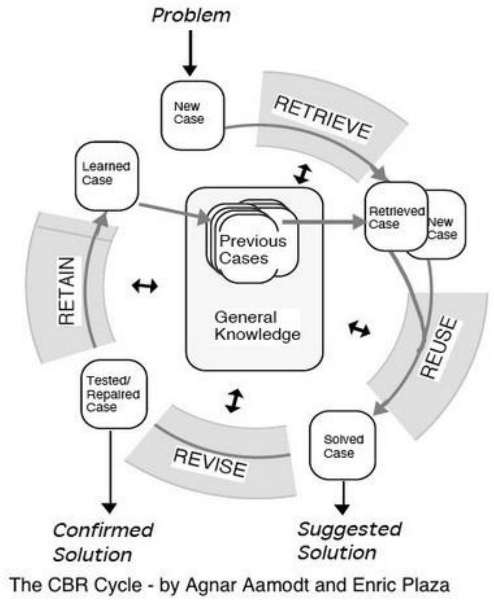

Fig. 1 Case-based reasoning cycle [10]

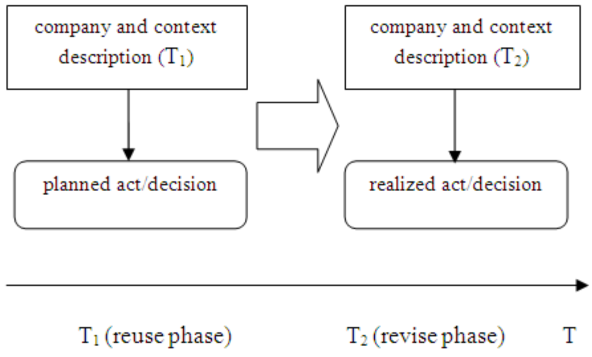

Fig. 2 Case representation in STRATEGOS

Similarity measure

Most of the case-based approaches retrieve a previous case based on the superficial syntactical similarities. The same is true in the STRATEGOS implementation where similarity measure merges the company and context description (in moment T_1 – fig.2) in one vector $a = (a_1, a_2, \ldots, a_n)$ of attribute values. If we denote by A_i the domain of the i-th attribute, then similarity measure is:

$$s: A_1 \times A_2 \times \ldots \times A_n \rightarrow [0,1]$$

and similarity between the input case a^I and retrieved case a^R is:

$$s(a^I, a^R) = 1 - \frac{\sum_{i=1}^{n} distance(a_i^I, a_i^R)}{\sum_{i=1}^{n} w_i}$$

where $w_i \in [0,1]$ is the weight of i-th attribute, and the *distance*$(a^I_i, a^R) \in [0,1]$ equals to the normalized Euclidean distance in the case of numeric attributes and the discrete distance measure (which takes the value 0 if $a^I_i = a^R_i$ and 1 otherwise) in the case of categorical variables [14]. Due to this similarity measure, it is possible at least to limit “false analogies” [6], cases that are importantly dissimilar and not useful as reference examples.

General knowledge

One of the critical issues is connected with general knowledge (domain ontology) representation. This knowledge is important during the re-use phase of the case-based reasoning cycle. Thanks to this knowledge it is possible to adapt the proposed solution from the retrieved case to the new case. Unfortunately, the strategic decision process is extremely complex, and it is difficult to represent the ontology completely. Despite this, we decided to use general knowledge in our approach as a warning system in situations where the solution proposed is unrealistic for formal reasons. There are the warning examples expressed as the if-then rules:

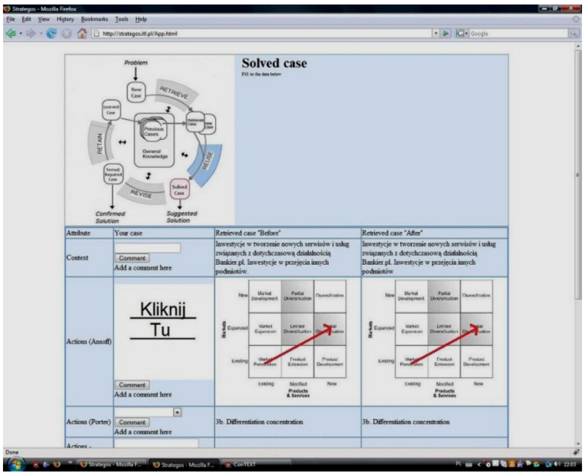
1. Inappropriate case retrieval based on the rule: “**if** the new case company and the retrieved company are in the different industry life cycle phase **then** the proposed decisions might be wrong**”**

2. Inappropriate proposed solution based on the rule “if the company has just started to penetrate the market with current products **and** proposed decision is: intensive foreign market development **then** this is risky and unrealistic proposal”

IV. STRATEGOS CBR CYCLE

Based on the CBR cycle (see fig.1) and the formal description the entire STRATEGOS decision making functioning will be described. We assume that the specific input problem is given by the CEO. The task is to establish the proper strategic decision (act) for the given problem. The STRATEGOS problem solving cycle consists of 4 phases:

1. **Retrieve:** The solution is retrieved from the case base basing on the similarity between the new case and cases already stored in the case base. The retrieved cases are shown to the user ranked based on the similarity value. Every choice is verified through the general knowledge in order to avoid unrealistic proposals.
2. **Re-use:** After the retrieve phase, it is possible to establish an act for the new case (see figure 3), after that the new case is called a solved case. The main goal of this phase is to give inspiration and/or verification, as well as propose rational choices based on the retrieved cases to the management board. Finally every proposed solution is verified by the general knowledge.
3. **Revise:** The solved case that was established in the previous phase has a planned strategic decision (see figure 2). This is a kind of proposal for the strategic actions plan. The most important goal of the revision phase is to recognize what has actually happened with that company after the strategic decision was taken. It is important to underline that the result does not depend only on described situation and made decision. In reality, there are several factors of different type such as economic trend, customers’ behavior, organizational atmosphere in the company etc. that have impact on the final result. Those factors may be provided in documents attached to case description.



Solved case

Fill in the data below

Actions (Porter)	Comment Add a comment here	3b. Differentiation concentration	3b. Differentiation concentration
Actions -			

Fig. 3 The view on the STRATEGOS user interface

4. **Retain:** Finally the tested/repaired case is placed into the case base as a lesson learned for the future re-use – a learned case. The quality of learned cases is a crucial problem in the whole CBR cycle, because quality of suggested solution directly depends on this. It should be emphasized that the lessons learned might be negative as well.

As we can see, maturity and quality of STRATEGOS as a decision making tool for supporting real life decisions, does not only depend on technical issues like similarity measure, knowledge representation, etc. The main issue is to gather a valuable set of cases, and this requires long and time consuming co-operation with management boards.

V. EMPIRICAL EVALUATION

First empirical tests of STRATEGOS system were conducted based on pattern cases and real cases. Case base of the system was completed with 454 pattern cases prepared on the basis of standard knowledge in the field of strategic management. Real cases have been prepared basing on 13 IT companies listed on the Warsaw Stock Exchange. The fundamental objective of the tests was to evaluate the quality of recommendations proposed by the system by using the quality measure reflecting similarities between test (real) case and sample case. The results of this technically-oriented test were positive and were already published [15].

The target user of the system is a CEO of a SME. In this context a survey among some CEOs was conducted. They were shown how the Strategos system prototype works. The test group was selected by the target selection and it is composed of 44 CEOs from SMEs operating mainly in TMT (Technology, Media, and Telecommunication) industry. That kind of industry was selected in such a way, to present CEOs functioning in a strongly competitive and innovative market, posing significant strategic challenges. It is important to underline that 14 out of 44 CEOs have analyzed head listed companies, which in turn involves the great level of transparency of that company and the ongoing verification of CEO's activities by the market. All analyzed CEOs were male, average age over 40 years, and in average more than 11 years experience as CEO. Almost everyone admitted lack of formal education in basics of strategic management.

Table I.
List of Variables For Strategos Evaluation

Variable	Explanation
Support	Strategos is supporting me in the real strategy decision problems
Education	Strategos is teaching me in strategy management
Decision making	Strategos is generating a final solution for my strategy problems

CEOs were also asked to evaluate the Strategos system after the presentation of entire working cycle simulation, using sample case as illustration. Table I presents variables for registered CEOs evaluations. Accordingly, table II contains the summary of CEOs evaluations in three key matters.

Table II.
Results of Strategos Evaluation By CEO's

Statement	Support	Education	Decision making
Definitely no (1)	0,0%	0,0%	40,9%
No (2)	2,3%	2,3%	56,8%
I do not know (3)	9,1%	4,5%	2,3%
Yes (4)	43,2%	54,5%	0,0 %
Definitely yes (5)	45,5%	38,6%	0,0 %
Summary	**100%**	**100%**	**100%**

As we can see the results of evaluation are positive, i.e. there is almost 90% approval in the context of decisions support, as well as education. To sum up, our system was warmly approved by potential users. The results mirror real CEOs approach, where Strategos is treated as strategic decision support system, and not a system presenting what has to be done. CEOs eagerly commented on the work of the system and stressed their interest in using it in reality, if the conditions of respective quality and cases capacity would be fulfilled, what was underlined in quality assessments.

What is particularly interesting is the analysis of CEOs evaluations concerning the inferences produced by Strategos system i.e. imitation (cases from the same industry) and similarity (cases from the different industries) – vide table III. Table IV presents the evaluations of CEOs in terms of using different inferences in the system.

Table III.
List of Variables: Imitation & Similarity

Variable	Explanation
S Imitation	I find useful cases of companies from my industry in STRATEGOS case base
S Similarity	I find useful cases of companies from other industries in STRATEGOS case base

Table IV.
Results of Evaluation: Imitation & Similarity

Statement	S Imitation	S Similarity
Definitely no (1)	0,0%	0,0%
No (2)	0,0%	0,0%
I do not know (3)	6,8%	9,1%
Yes (4)	38,6%	54,5%
Definitely yes (5)	54,6%	36,4%
Summary	100%	100%

The basic question was related to the interest and will to devote time for profound analysis of companies' cases in terms of imitation and similarity. As we can see from the received answers, both aspects generated big interest. Obviously, the interest in competition's cases was the biggest, but results were also high in case of similarity. It shows a great openness of CEOs to business inspirations, some of them were particularly stressing the importance of those inspirations. The attitude of CEOs, which was full of humility towards experience of other companies, is a very positive sign in favor of acceptance of deduction paradigm used in STRATEGOS system. Taking into account received evaluations, we can state that in the studied group of CEOs, the hypothesis that referring to deduction on the basis of cases (through implementation in the described system) is an understandable and acceptable support for strategic decisions making process in management.

VI. Final Remarks

The analyzed CEOs displayed humbleness towards experiences of other companies and many times they interpreted the case base as a sort of their own memory extension. The analyzed CEOs combined acceptance of STRATEGOS with a strong feeling of limitation of reasoning appealing solely to analogies and experience. They treated the system as an inspiration or verification for their actions, being fully aware that every decision-making situation is unique and unrepeatable. It seems that this awareness will not be the same for the entire population of CEOs of SMEs. It also seems probable that CEOs of SMEs would reject STRATEGOS as a theoretical tool or to fall for the opposite tendency, namely accept its suggestions automatically. Such automatic acceptance of the system, lack of knowledge connected with superficial similarities may lead to critical decision-making errors and to huge problems for the company.

The STRATEGOS system will be extended in two directions. The main effort is focused on the proper ontology, where the company can be represented in the case base by a set of cases ordered in time (episode), so we can have the whole life-time history of the company led by the strategic decision. This is a problem of building dynamics memories called in a literature episodic-based reasoning [16]. Secondly the complete approach in strategy decision making requires deeper semantic similarities based on the object-oriented similarity [17]. The current version of the system is available on the web page: www.strategos.pl [18].

Acknowledgment

Author thanks to thank MSc students Jakub Tomiczek and Mateusz Chrzęst, who implemented the STRATEGOS prototype during work on their master's thesis.

***Abstract*—The aim of this paper is to evaluate what electronic commercial and business opportunities firms and organizations in this modern world have and which opportunities are best suited for them. The paper categorizes and describes currently available e-business tools in the electronic business model proposed by Timmers. The next part discusses the tools and activities for creating successful implementations of e-business within companies and organizations, in particular, business intelligent tools, strategic management tools, electronic forms, and competitive intelligence. The paper then offers general recommendations and a summary of which tools used for which purposes depending on the size of business and organizations.**

I. Introduction

INDUSTRIAL society is changing in front of our eyes to the society, in which the information and knowledge play the major role. There is a global information infrastructure that processes and transmits an increasing amount of data and information. The order of the Industrial Revolution was to maximize the quantity with the least cost. The goal of the information revolution is the highest possible quality at a reasonable price in the shortest possible time.

In the information society a human is searching for his place again. New technology allows him to become a passive and easily driven consumer of information, on the other hand, however, allow him to become their active producer. Convergence of information, communication and multimedia technologies, create new business opportunities in the upcoming decades which will play a key role in the economy and public life.

Worldwide, we can see the results of massive expenditure on information and communication technologies that cause the changes of business and commerce. Between 1980 and 2005 the private business investment in information technology increased from 34% to 50% of the total capital invested. How to effectively invest the money? Companies invest into information systems to achieve strategic business and marketing objectives: operational excellence, perfection of new products, services and business models, intimate knowledge of customers and suppliers, improve decision making, competitive advantage and survival. The interdependence between business and information system capabilities is growing. Changes in strategy, rules and business processes require changes in hardware (HW), software (SW), in data storages and telecommunications equipment. Often, if the company wants to do something, it depends on what the information system allows.

II. Types of e-business

Since 2000, the Economist Intelligence Unit publishes an annual ranking of the world's largest economies in readiness for e-business. Criteria for assessing the readiness for e-business were developed by the Economist Intelligence Unit in cooperation with the IBM Institute for Business Value. This is a summary of factors that indicate how the market is open to Internet opportunities. This indicator express how the country is open in terms of e-business. Evaluation methodology is undergoing continuous modification.

E-business is a way of communication and commerce using the Internet as the main instrument or other networks and is seen on a wider scale than e-commerce, much as it is itself a subset of trading business. E-business is a series of processes, pursuing a specific goal, involving more than one agency and implemented by electronic means.

E-commerce means using the most modern information communication technologies to increase the effectiveness of relationships among companies and among individual consumers. It includes not only error-free electronic transmission of information and documents, but mainly signing contracts or strategic business partnership over the Internet. E-Commerce is a series of processes associated with the course of commercial transactions carried out by electronic means

E-marketplace is a virtual, on-line marketplace, where supply and demand meet online. Its main advantage to the ordinary "stone" market is the possibility of efficient and convenient prices comparison, and the comparison of delivery and payment conditions and especially the technical parameters of each product.

The **E-procurement** term can be very loosely described as "obtaining", "providing" something over the Internet. Practically this is the part of e-commerce, based on the needs of shoppers. Its basic feature is the creation of value, hence the cost savings for the buyer. For its realization the main reason is the reduction of transaction costs. Other advantages of e-procurement are rebate, reduced inventories at the customer, better control of the process, minimizing cash transactions and integration with the information systems of customer and supplier.

E-marketing is the opposite of the e-procurement. Businessmans are selling products through a network, where the driving force in this case is the seller (supply). Its essence is to attract customers and convince them about the quality and convenience offered to purchase goods or services. E-mar-

978-83-60810-27-9/09/$25.00 © 2010 IEEE

keting is primarily focused on the value creation (increase in turnover and revenue) for the seller.

A. E-commerce models

Business-to-business (B2B)

Business-to-business means secure communication, transmission of documents, concluding business contracts and establishing long term business relationships between companies. This kind of activity is particularly associated with using the Internet to facilitate communication in the supply chain. Relationships between individual firms on the B2B market are almost always formally adjusted by the contracts.

The specific models of the B2B are for example the e-commerce models by P. Timmers [10]

- Value chain service provider, specializes in one of the functions of the value chain (such as payment or logistics) in order to obtain a competitive advantage by differentiating.
- Value chain integrator, focuses on integrating multiple steps of the value chain and on evaluation of the potential of information flow between these steps as further added value.
- 3rd party Marketplace, in its basic form it is a user interface to the catalog of products or services which may be extended with special services such as advertising, brand, payment, logistics, orders or comprehensive service to ensure the implementation of secure transactions. An example of a business relationship B2B marketing can be a single event (e.g. conference, backed by well-known and trusted company in the field) if necessary.

Business-to-consumer (B2C)

Business-to-consumer means the sales of goods to the end user via the Internet or other information and communication technologies, without direct physical contact with the customer's dealer. B2C are typical for single networking vendor - the consumer, with no long term contractual underpinning.

The typical models of B2C by P. Timmers are:

- E-shop is comparable to the catalog sales, the catalog is in this case in the form of web pages and communications between buyers and sellers take place mostly in electronic form. E-commerce must address the issue of payment and delivery of goods. From the perspective of transaction costs seem ideally the intangible goods (tickets, software, trips). Transaction costs are often an impediment to trade in goods, whose unit price is very low.
- E-mall is a set of e-commerce under one roof or under the common umbrella of one brand. It is essentially analogous to the giant shopping malls. When you specialize in a particular market segment, the commercial center is becoming a center for the entire industry.

Consumer-to-business (C2B)

C2B model means that the customer offers in the system price he is willing to pay and the seller is considering whether to accept the bid.

Among the models of electronic commerce (according to the classification of P. Timmers) that make e-business from the e-commerce, that means those models that offer additional services, are:

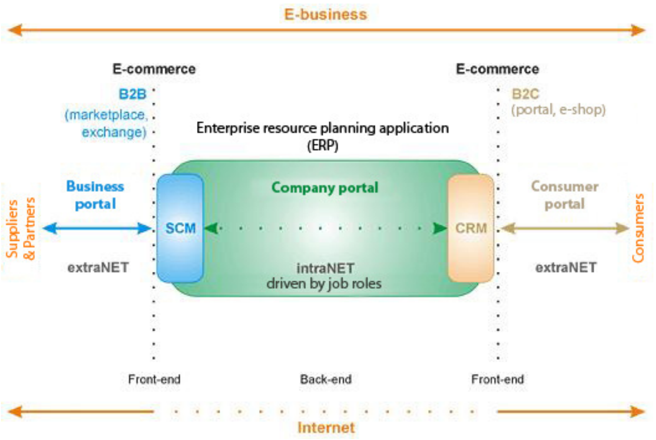
- Virtual communities, which is a fundamental value generated by members of the community (customers or partners) who add their information into the basic environment that guarantees by provider.
- Collaboration platform is a set of tools and information environment for cooperation between businesses. It may be focused on design for example. Business opportunities can be found in the management of all services (fees) and sales (licensing) of special tools.
- Information brokerage represents a wide range of new value-added services to the amount of data, which are located on open networks, or derived from integrated business operations such as drawing up a customer profile, brokering business opportunities, investment advice, etc. Specific categories of services are provided by certification authorities.

B. Implementing the concept of e-business

For the implementing of e-commerce in practice, it is necessary to address the following areas:

- Deployment of business and information portals. The portal is the gateway to information and serves the information via web browsers, allowing access from mobile devices. It represents a single and personalized access to information services and content that is targeted to the business processes of all participants - customers, employees, suppliers or partners - and with regard to the available means of communication. Through an information portal, users can create and manage content and content authors can generate and grade reports, documents, web pages, without deeper knowledge of Internet technologies.
- Support for modern forms of communication.
- Unification and management all communication channels.
- Investments in information systems security. To mitigate risk and minimize losses in case that a risk event occurs. Complement the specification of security policy elements of PKI (Public Key Infrastructure) enables the deployment of digital signature.
- Business Process Integration, Technology Integration (subject to satisfactory comprehensive e-business solution is the integration of the entire corporate information system at the user interface, data structures, data exchange and applications). There is also required integration with financial and logistical services. To benefit from the competitive and strategic benefits of e-business solutions, it is necessary to integrate fully all customers, partners and

suppliers into a single on-line network and focus on key processes. Others that are not directly related processes, they are left to specialized firms (e.g. logistics).



Note: SCM - Supply Chain Management; CRM - Customer Relationship Management

Fig. 1. E-business solutions, source [9]

All of the listed changes are linked to sufficiently significant organizational changes, and create conditions for digital business. Digital firm can be defined in different ways. For our purposes, we will apply the following definition: "Digital business is one in which nearly all organizationally significant business relationships with customers, suppliers and employees are digitally enabled and mediated, where the main business processes are implemented through a digital network embracing the whole organization or a multi-organization" [8].

Digital firms may react to their environment faster than traditional firms. They are more flexible in terms survival in a turbulent environment. The digital business is time-lag and shift in space standard. Time shift means that the transaction is a continuous 7 x 24 hours per week and not only on working days in a limited period of time. Spatial shift means that the sale takes place on the global market without national borders. Work is performed there, which is advantageously feasible in the world. E-business can expect intensified competition and interaction of traditional and new businesses, projects, policies and rules and end e-business in today's terms (every business is e-business).

III. Strategic management

Strategic or institutional management is the conduct of drafting, implementing and evaluating cross-functional decisions that will enable an organization to achieve its long-term objectives. [11] It is the process of specifying the organization's mission, vision and objectives, developing policies and plans, often in terms of projects and programs, which are designed to achieve these objectives and then allocating resources to implement the policies and plans, projects and programs. A balanced scorecard is often used to evaluate the overall performance of the business and its progress towards objectives.

Strategic management is a level of managerial activity under setting goals and over Tactics. Strategic management provides overall direction to the enterprise and is closely related to the field of Organization Studies.

A. *Strategy formulation*

Strategic formulation is a combination of three main processes which are as follows:

- Performing both internal and external as well as both micro-environmental and macro-environmental situation analysis, self-evaluation and competitor analysis.
- Concurrently with this assessment, objectives are set. These objectives should be parallel to a timeline; some are in the short-term and others in the long-term. This involves crafting vision statements (long term view of a possible future), mission statements (the role that the organization gives itself in society), overall corporate objectives (both financial and strategic), strategic business unit objectives (both financial and strategic), and tactical objectives.
- These objectives should, in the light of the situation analysis, suggest a strategic plan. The plan provides the details of how to achieve these objectives.

B. *Strategy evaluation*

Measuring the effectiveness of the organizational strategy, it is extremely important to conduct a SWOT analysis to figure out the strengths, weaknesses, opportunities and threats (both internal and external) of the entity in question. This may require to take certain precautionary measures or even to change the entire strategy.

Strategic management techniques can be viewed as bottom-up, top-down or collaborative processes. In the bottom-up approach, employees submit proposals to their managers who, in turn, funnel the best ideas further up the organization. This is often accomplished by a capital budgeting process. Proposals are assessed using financial criteria such as return on investment or cost-benefit analysis. Cost underestimation and benefit overestimation are major sources of error. The proposals that are approved form the substance of a new strategy, all of which is done without a grand strategic design or a strategic architect. The top-down approach is the most common by far. In it, the CEO, possibly with the assistance of a strategic planning team, decides on the overall direction the company should take. Some organizations are starting to experiment with collaborative strategic planning techniques that recognize the emergent nature of strategic decisions.

Strategic decisions should focus on Outcome, Time remaining, and current Value/priority. The outcome comprises both the desired ending goal and the plan designed to reach that goal. Strategic management requires paying attention to the time remaining to reach a particular level or goal and adjusting the pace and options accordingly. Value/priority relates to the shifting, relative concept of value-added. Strategic decisions should be based on the understanding that the value-added of whatever you are managing is a constantly changing reference point. An objective that begins with a high level of value-add may change due to influence of internal and external factors. Strategic management by definition is managing with a heads-up approach to outcome, time and relative value, and actively making course corrections as needed.

IV. BI tools purchase possibilities

If a company or organization decides to purchase business intelligence tools, the choice is always driven by the price, utilization and consequent size of the company. Even at the turn of the millennium, BI tools were a privilege of big companies with huge budgets only that made it worthwhile to invest considerable sums in implementing solutions to the corporate network or individual workstations. Today, this kind of acquisition of BI tools still has a lot to offer, but thanks to their robustness and costs it is unacceptable option for small businesses.

On the other hand, there is a form of Software as a Service, simply SaaS. SaaS is a quite new technique in the world of IT which allows you to hire a software application only when there is a requirement of such an utility. The main reasons for its popularity are high services, low costs and less maintenance.

In the software as a service model, the application, or service, is deployed from a centralized data centre across a network - Internet, Intranet, LAN, or VPN - providing access and use on a recurring fee basis. Users "rent," "subscribe to," “are assigned”, or "are granted access to" the applications from a central provider. Business models vary according to the level to which the software is streamlined, to lower price and increase efficiency, or value-added through customization to further improve digitized business processes. [18]

V. Improving the data quality

The main sources of information within companies and institutions are now both operating systems supporting the company (ERP, SCM, CRM) and external databases (dials address, municipality, telephone directories, business register, etc.). These resources are not usually able to provide questioner the information of desired quality. The reason is that data are stored in many places, on different platforms in different structures and formats. The problem is the quality of data. The data are often incomplete, contain errors, invalid values are stored in the structures unsuitable for analysis and do not contain history.

A. Tools for selection, transformation, transmission and data integration

Obtain quality information now means to transfer data into the relevant structures of the data warehouse. **Data warehouse** is a database containing the consolidated data from all available resources, optimized for reporting, analysis and archiving. The data warehouse integrates and stores data from both internal and external sources.

To transfer data into the data warehouse are used ETL (extraction, transformation, loading) tools. The extraction means the ability to take data from the widest range of data sources of different types. Transformation is a gradual series of operations to prepare the extracted data to be retrieved from the data warehouse. Many of the data obtained from the extraction is still not nearly ready to load into storages. Among the reasons why not, it is mainly the mismatch between data from different sources and their incompleteness. There are applied the checks, additions or changes in data transfer on the same formats and inconsistencies elimination, data consolidation - the unification of the main entities and the calculation of aggregation by major entities. To clean the data tools containing typical samples of impurities are used. Load means inserting data into its own physical space data warehouse.

Implemented ETL means primarily program implementation of data pumps, testing their time requirements and setting operating parameters. Parameters of the ETL tools are supported platforms and their connectivity (range of supported source and target systems), support for metadata management, the possibility of multiphase pump operation according to schedule, the level of support for workflow, logging level data pump, and support data processing in real time. Trend in the ETL tools is merging with the tools for managing metadata and tools for ensuring data quality, as well as their delivery, together with the standard database engine. [3]

EAI tools (Enterprise Application Integration) - EAI can be characterized as a set of approaches, methods and technologies that allow us to connect initially often incompatible solutions, or partial information systems.

The process of EAI from the perspective of the data is based on the following principles:

- elimination of semantic inconsistency of data that arises from different perspectives on the data in various applications (e.g. differences in customer address records)
- removal of content data inconsistency, which arises from the existence of duplication (e.g. two different applications registered address of the customer, but only one of them has been changed)
- minimisation the fragmentation of data (providing a comprehensive view of data)

EAI works unlike ETL tools in real time, they were created in a layer of transactional systems and their purpose is to integrate primary systems in a company or organization, and reducing their mutual interface. [5]

B. Applications for data storage

Applications for data storage provide the processes to storage, updating and data management. These include data warehouses, data marts, operational data store and data staging areas.

Data Warehouse is a central data repository, where the requirement for consistency is crucial (DW must provide "a single version of the truth"). Integrated data warehouses are presently considered to be the best solution.

Data Marts are separated data repositories for individual applications or departments. They are problem-oriented data warehouses to implement flexible ad hoc analysis.

Operational Data Store (ODS) are supporting analytical databases - a central repository, processing the key data in nearly real time. The data processing operations needed to ensure of data quality are carried out by ODS and it also integrates relevant data from different systems (examples might be the validation of address information identifying the type of identification number, or tracing and correction of incorrect data). At the operational level of the data storage are also clearly and conspicuously identified and described the various data elements; there are agreed technical and semantic definitions (metadata).

Data Staging Areas (DSA) are used for temporary storage of selected data from source systems from their own processing to other database components of BI solutions. Their purpose is to accelerate the selection of data used for initial storage of the non transformed data from these systems.

C. Data quality

Data quality is one of the basic characteristics of data warehouses and operational data stores. Data quality is not one of their automatic features, but nowadays the necessary one. Data quality can be defined in different ways, in this case we choose a simple definition - high quality data are those which correspond to reality, they are complete and consistent.

If you want to work with high-quality data, you must ensure that there are five basic characteristics:

- Completeness - the need to identify and treat the data that are missing or inapplicable,
- Standardization - all data should match the requested format,
- Consistency - no data may contain values that represent conflicting information,
- Uniqueness - if there are duplicate entries, they must be removed
- Integrity - data should include all the defined relationships to other data. [1]

Data quality is at present designed by the majority of suppliers of information technology as a set of two processes - **data profiling** and **data cleaning**. These processes are periodically repeated and reflected in the data warehouse environment. The result is a complex process in the literature called the Data Supply Chain. DSC is an automated process in which the first phase are extracted data from data sources, whether internal or external, in the second phase are analyzed the data sources and data are cleaning is performed. In this second phase the data profiling (identifying types of data defects, quantifying the number of individual defects, identifying synonyms and homonyms, the evaluating completeness in terms of supporting business processes and conformity assessment of attributes with their definitions) and data cleaning (standardization, verification against internal and external dials, correction of address data, identification of redundant records and householding identification are implemented. [2]

Thus processed data are then stored in the warehouse. Data warehouses are typically updated regularly it means that all processes of the DSC are recurrent.

D. Metadata

As well as data quality, a quality description of its contents is a necessary component of any modern information system. It means how was the content created and how is the content being used - metadata. Recently the importance of metadata, as the principal means of determining the content and status of information systems, increased significantly. The underlying reason for the existence of metadata (defined as data about data) is that they add context and meaning into inaccurately described cluster of information. The main advantage of the existence of metadata is the ability to facilitate understanding of the principles, capabilities and content of the various information systems.

Metadata in the company can be divided into technical metadata - that is, information about setting up various information systems and relevant technical processes and substantive metadata - information about the substance of the solution, thus adding context and importance of individual values (and not only in terms of content meaning of that word - as understood in the organization, but also in the form of computing - how it is possible to reach a value of that expression).

Ensuring the sufficient quality of data and their description is mainly the task for their users. The main reason for the progressive transfer of responsibility for ensuring data quality and description of the importance of individual data elements is that the users who work with them in a long term know the data better than anyone else. The data are produced by information systems that are developed on the requirements of their users and the completeness, consistency, accuracy, uniqueness and integrity of data is ensured.

Metadata make sense to individual information. At the same time the tools and processes to ensure data quality, help you to capture, manage, share and provide error free and accurate data. In practice this means that by the involvement of these solutions into an integrated information system, we can obtain a simpler and better quality work of all components involved in the decision-making at all levels of management - if the person who decides on the basis of certain data understands the meaning of the data well, he or she can make the right decisions at the right time and right place. They also support the building of confidence in the data - if users understand the meaning of the data while the data is correct, then they gain confidence in these data and it will result in a streamlining of their work and increase of efficiency of the support elements (development of new solutions) - if end-users understand the state and content of the solutions, they can effectively specify their requirements for further development and this development can also be faster and more efficient. [5]

The final aim of the described tools is to provide readable, organized and analyzable in real-time, information available from a peak of corporate databases and external sources, which can be widely used at the management of a company or an institution. As the managers have ensured quality data, they gain a quick overview of the functioning of the company or institution and can devote their time to the processes leading to positive change of the situation. Quality data allow the management of an organization in accordance with knowledge.

VI. Competitive intelligence

A broad definition of competitive intelligence is the process of defining, gathering, analyzing, and distributing Intelligence about products, customers, competitors and any aspect of the environment needed to support executives and managers in making strategic decisions for an organization.

Key points of the definition above are:

- Competitive intelligence is an ethical and legal business practice, as opposed to industrial espionage which is illegal.
- The focus is on the external business environment. [14]
- There is a process involved in gathering information, converting it into intelligence and then utilizing this in business decision making. CI professionals emphasize that if the intelligence gathered is not usable (or actionable) then it is not intelligence.

A more focused definition of CI regards it as the organizational function responsible for the early identification of risks and opportunities in the market before they become obvious. Experts also call this process the early signal analysis. This definition focuses attention on the difference between dissemination of widely available factual information (such as market statistics, financial reports, newspaper clippings) performed by functions such as libraries and information centers, and competitive intelligence which is a perspective on developments and events aimed at yielding a competitive edge [15].

The term CI is often viewed as synonymous with competitor analysis, but competitive intelligence is more than analyzing competitors — it is about making the organization more competitive relative to its entire environment and stakeholders: customers, competitors, distributors, technologies, macro-economic data etc.

Organizations use competitive intelligence to compare themselves to other organizations ("competitive benchmarking"), to identify risks and opportunities in their markets, and to pressure-test their plans against market response (war gaming), which enable them to make informed decisions. Most firms today realize the importance of knowing what their competitors are doing and how the industry is changing, and the information gathered allows organizations to realize their strengths and weaknesses.

With the right amount of information, organizations can avoid unpleasant surprises by anticipating competitors' moves and decreasing time response. Major airlines change hundreds of fares daily in response to competitors' tactics. They use information to plan their own marketing, pricing, and production strategies.

Resources, such as the Internet, have made gathering information on competitors easy. With a click of a button, analysts can discover future trends and market requirements. However, competitive intelligence is much more than this, as the ultimate aim is to lead to competitive advantage. As the Internet is mostly public domain material, information gathered is less likely to result in insights that will be unique to the company. In fact there is a considerable risk that information gathered from the Internet will be a misinformation and will mislead users.

As a result, although the Internet is viewed as a key source, most CI professionals should spend their time and budget gathering intelligence using primary research — networking with industry experts, from trade shows and conferences, from their own customers and suppliers, and so on. Where the Internet is used, it is to gather sources for primary research as well as information on what the company says about itself and its online presence (in the form of links to other companies, its strategy regarding search engines and online advertising, mentions in discussion forums and on blogs, etc.). Online are subscription databases and news aggregation sources which have simplified the secondary source collection process are also important

Organizations must be careful not to spend too much time and effort on old competitors without realizing the existence of any new competitors. Knowing more about your competitors will allow your business to grow and succeed. The practice of competitive intelligence is growing every year, and most companies and business students now realize the importance of knowing their competitors.

VII. Conclusion

The goal of digital tools implementation into business processes is to get a good position in developing e-market as well as to offer better services for customers. Main attention is focused on the problems that have to be solved in connection with the implementation of e-business in companies and institutions.

Use of the business intelligence tools, along with the emphasis on the quality of strategic management in a company or institution and the high quality used and data sources relevant to the issue (competitive intelligence), creates conditions for the choice of form and development of the e-business within the company. Other critical attribute is the size of the company and especially its global strategy.

In Table I, you can see the opportunities and recommendations for various companies (according to the number of employees). One of the authors of this article is a chairman of the regional section of the Czech Society for Systems Integration for North Moravia and Silesia (www.cssi-morava.cz) and maintains frequent contacts with representatives of management of many companies. The results shown in the table were made on a series of guided interviews with these managers.

Current indications suggest that a firm that does not pay attention to the possibilities of e-business offers, might become unattractive to their customers, therefore, managers should set out the recommendations given due attention.

In recent years the use of the new information technologies leads to a significant increase in market places (globalization) and convergence fields. Innovation becomes a key factor in the development of companies and the role of the client (active customer) is being significantly changed. Due to information and communication technologies the network character of all industrial sectors is growing and ITC also changes the structure of costs in almost all sectors.

Economic laws of "a world of bits" are being gradually penetrated into the" world of atoms" and informatics does fundamental changes in almost all sectors of the economy [6]. By our team work intensively with three business intelligence tools of different formats. Unfortunately we have no detailed information directly from the private sector, because firms guard their sensitive data and don't let us look under the cover, but on the basis of many simulations we have obtained enough information on the findings above.

ACKNOWLEDGEMENT

This work was supported by project No.SGS SP/2010167. The authors would like to thank the reviewers for their extremely useful comments and suggestions that substantially improved the quality of the final version.

TABLE I.
OPPORTUNITIES FOR DIFFERENT COMPANIES AND ORGANIZATIONS, SOURCE [AUTHOR]

	Tiny or small company		Medium company		Big company	
Deployment of business and information portals	yes	Very cheap, great opportunity for e-marketing or e-commerce	yes	e-marketplace	yes	e-marketplace, e-procurement, both including electronic payment
Support of the modern communication forms	yes	Very fast, very cheap	yes	Very fast, great way to keep in touch with all employees	yes	Very fast, great way to keep in touch with all employees
Integration of communication channels	yes		yes		yes	
Implementation of the PKI elements	no	Very expensive	?	Expensive but useful for security	yes	Very good for security
Strategic management support	?	Too much work to prepare the strategy but good results	yes	It is essential to have a strategy	yes	It is necessary to have a strategy
BI tools (way of purchase)	?	If yes, the best solution is to rent the "SaaS"	yes	To rent the "SaaS" or to buy a local installation	yes	To buy a local installation
Data storage	yes	Data marts	yes	Data warehouses	yes	Data warehouse staging areas, operational data stores
Data profiling	no	Not possible	yes	Good for future work with data	yes	Good for future work with data
Data cleaning	yes	Good for future work with data	yes	Good for future work with data	yes	Good for future work with data
Competitive intelligence	no	Expensive, needs to be regularly updated	yes	Essential to succeed	yes	Essential to succeed

Computer Aspects of Numerical Algorithms

Numerical algorithms are widely used by scientists engaged in various areas. There is a special need of highly efficient and easy-to-use scalable tools for solving large scale problems. The workshop is devoted to numerical algorithms with the particular attention to the latest scientific trends in this area and to problems related to implementation of libraries of efficient numerical algorithms. The goal of the workshop is meeting of researchers from various institutes and exchanging of their experience, and integrations of scientific centers.

Topics

- Parallel numerical algorithms
- Novel data formats for dense and sparse matrices
- Libraries for numerical computations
- Numerical algorithms testing and benchmarking
- Analysis of rounding errors of numerical algorithms
- Languages, tools and environments for programming numerical algorithms
- Numerical algorithms on GPUs
- Paradigms of programming numerical algorithms
- Contemporary computer architectures
- Heterogeneous numerical algorithms
- Applications of numerical algorithms in science and technology

***Abstract*—The authors consider the impact of the structure of the matrix on the convergence behavior for the GMRES projection method for solving large sparse linear equation systems resulting from Markov chains modeling. Studying experimental results we investigate the number of steps and the rate of convergence of GMRES method and the IWZ preconditioning for the GMRES method. The motivation is to better understand the convergence characteristics of Krylov subspace method and the relationship between the Markov model, the nonzero structure of the coefficient matrix associated with this model and the convergence of the preconditioned GMRES method.**

I. Introduction and Motivation

MARKOV chains are a particularly robust and wide used tool for analyzing a variety of stochastic (probabilistic) systems over time.

A CTMC (Continuous-Time Markov Chain) may be represented by a set of states and a transition rate matrix $\mathbf{Q}$ containing state transition rates as coefficients. To compute the steady-state probabilities we must solve a (homogeneous) sparse system of linear equations, of the form $\mathbf{Q}^{\mathbf{T}}\mathbf{x} = \mathbf{0}$, of size equal to the number of states in the CTMC. $\mathbf{Q}$ is a singular matrix demanding adequate methods to solve the equation. Solving the equation system generally requires applying iterative methods, projection methods or decomposition methods but occasionally (for the need of an accurate solution) direct methods are used as well. The rich material concerning the methods mentioned above can be found in [13].

In this article we consider one of the Krylov subspace methods, namely the GMRES method. This method was first introduced by Y. Saad in the article [12] as the method to solve linear systems of equations. GMRES for Markov chains was studied in the article [11]. The full GMRES algorithm is guaranteed to converge in at most n steps, but it is not useful for large systems of equations, because a good approximate solution is often computed quite early, after very few iterations. In the literature, we find results, which would provide an upper bound on the convergence rate of the GMRES [9]. The traditional bounds of the residual are expressed in terms of eigenvalues of $\mathbf{Q}$ and the condition number of the eigenvector matrix. It is of limited practical interest because we need the condition number, which is typically not known. For any matrix determination of its condition number is a task of the complexity $O(n^3)$. In practice, it is difficult to use the theoretical knowledge about the convergence of the GMRES method.

One of the tools used in the convergence analysis of GMRES are numerical experiments. We perform numerical experiments to help us understand the effect of nonzero structure of the matrix on the convergence characteristics of preconditioned Krylov subspace methods. We try to provide some properties of the coefficients of the matrix $\mathbf{Q}$, which affect the convergence of the method GMRES and the preconditioned GMRES.

One of the famous preconditioning techniques is incomplete factorization, for example IWZ factorization. The incomplete WZ factorization is originally described in our previous works [3], here we discuss its performance for Krylov subspace methods like GMRES.

Basing on our previous investigation we consider impact of the incomplete WZ factorization on the GMRES method for the numerical solution of Markov chains. We study relationship between the number of iterations, the convergence rate of the GMRES method and properties of the matrix $\mathbf{Q}$. Research was carried out for two models. The first model concern matrices associated with some abstract model. These matrices have not got any structure. The second model concern matrices known from the literature as the epidemic model and this matrix has got a structure.

The rest of the paper is organized as follows. Section II presents the problem. In Section III Krylov subspace are reminded. Section IV recall briefly the IWZ preconditioning. Section V presents two test models. Section VI describes conducted numerical experiments. Section VII contains some conclusions.

II. CTMCs and the Steady-State Solution

While modeling with Markov chains, in a steady state (independent of time), we obtain a linear equation system like following;

$$\mathbf{Q}^T\mathbf{x} = \mathbf{0}, \qquad \mathbf{x} \geq \mathbf{0}, \qquad \mathbf{x}^T\mathbf{e} = 1 \qquad (1)$$

where $\mathbf{Q}$ is a transition rate matrix, $\mathbf{x}$ is an unknown vector of states probabilities and $\mathbf{e} = (1, 1, ..., 1)^T$. The matrix $\mathbf{Q}$ is a square one of size $n \times n$, usually a big one, of rank $n - 1$, sparse, with dominant diagonal.

```
1) choose:
    • an initial approximation $\mathbf{x}^{(0)}$
    • a subspace $\mathcal{K}$ spanned by $\mathbf{V} = [\mathbf{v}_1, \ldots, \mathbf{v}_m]$
    • a subspace $\mathcal{L}$ spanned by $\mathbf{W} = [\mathbf{w}_1, \ldots, \mathbf{w}_m]$
2) $\mathbf{r}^{(0)} \leftarrow -\mathbf{Q}^T\mathbf{x}^{(0)}$
3) $\mathbf{y} \leftarrow (\mathbf{W}^T\mathbf{Q^T}\mathbf{V})^{-1}\mathbf{W}^T\mathbf{r}^{(0)}$
4) $\mathbf{x}^{(0)} \leftarrow \mathbf{x}^{(0)} + \mathbf{V}\mathbf{y}$
```

Fig. 1. A basic projection step for the equation $\mathbf{Q}^T\mathbf{x} = \mathbf{0}$

III. Krylov subspace methods — GMRES

In this section we recap the basics of projection methods.

The projection methods consist in approximating the solution vector with a vector from a small-dimension subspace. Such approximations are repeated until our approximation is sufficiently close to the solution — in some sense the projection methods are iterative methods.

The projection methods need more space than iterative methods (because they have to store huge basis vectors of subspaces), but can converge faster than classical iterative methods — although the convergence rate is much better for the matrices 'more beautiful' in their structure than the ones arising in solving Markov chains.

A. The Projection Step

To solve a linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ by a projection method first we have to choose two subspaces of dimension m from the n-dimensional space:

- $\mathcal{K}$ which is a subspace containing the approximation;
- $\mathcal{L}$ which is a subspace defining constraints for selection of approximation from $\mathcal{K}$.

Let the subspace $\mathcal{K}$ be spanned by $\mathbf{V} = (\mathbf{v}_1, \ldots, \mathbf{v}_m)$. The approximated solution is in $\mathcal{K}$ so it can be written

$$\mathbf{x} = \mathbf{V}\mathbf{y}$$

where $\mathbf{y}$ is an m-dimensional unknown vector. To find $\mathbf{y}$ we require that the residual vector $\mathbf{b} - \mathbf{A}\mathbf{x} = \mathbf{b} - \mathbf{A}\mathbf{V}\mathbf{y}$ be orthogonal to the subspace $\mathcal{L}$ spanned by $\mathbf{W} = (\mathbf{w}_1, \ldots, \mathbf{w}_m)$, that is:

$$\mathbf{W}^T(\mathbf{b} - \mathbf{A}\mathbf{V}\mathbf{y}) = 0,$$

and then (if the matrix $\mathbf{W}^T\mathbf{A}\mathbf{V}$ is nonsingular):

$$\mathbf{y} = (\mathbf{W}^T\mathbf{A}\mathbf{V})^{-1}\mathbf{W}^T\mathbf{b}.$$

If we know an initial approximation $\mathbf{x}^{(0)}$ we will rather seek a difference $\mathbf{d}$ between the exact solution $\mathbf{x}$ and $\mathbf{x}^{(0)}$: $\mathbf{x} = \mathbf{x}^{(0)} + \mathbf{d}$. Setting $\mathbf{r}^{(0)} = \mathbf{b} - \mathbf{A}\mathbf{x}^{(0)}$ we are to solve the equation

$$\mathbf{A}\mathbf{d} = \mathbf{r}^{(0)},$$

what can be done with the described above projection step.

A basic projection step for our equation 1 (where $\mathbf{A} = \mathbf{Q}^T$ and $\mathbf{b} = \mathbf{0}$) is shown in Figure 1.

```
1) $\mathbf{v}_1 \leftarrow \mathbf{v}/||\mathbf{v}||_2$
2) for $j = 1, 2, \ldots, m$:
    a) $\mathbf{w} \leftarrow \mathbf{A}\mathbf{v}_j$
    b) for $i = 1, 2, \ldots, j$:
        i) $h_{ij} \leftarrow \mathbf{v}_i^T\mathbf{w}$
        ii) $\mathbf{w} \leftarrow \mathbf{w} - h_{ij}\mathbf{v}_i$
    c) $h_{j+1,j} \leftarrow ||\mathbf{w}||_2$
    d) $\mathbf{v}_{j+1} \leftarrow \mathbf{w}/h_{j+1,j}$
```

Fig. 2. The basic Arnoldi process for a subspace $\mathcal{K}_m(\mathbf{A}, \mathbf{v})$

The most efficient method for general, non-symmetric coefficient matrices (like $\mathbf{Q}^T$) are methods based on Krylov subspaces. A Krylov subspace is defined by its dimension m, a matrix $\mathbf{A}$ and a vector $\mathbf{v}$:

$$\mathcal{K}_m(\mathbf{A}, \mathbf{v}) = \operatorname{span}\{\mathbf{v}, \mathbf{A}\mathbf{v}, \mathbf{A}^2\mathbf{v}, \ldots, \mathbf{A}^{m-1}\mathbf{v}\}.$$

Many of such methods require that an orthonormal basis be found for the Krylov subspace. Unfortunately, classical Gram-Schmidt orthogonalization is numerically poor. To deal with it there are two main kinds of methods: Arnoldi process (which is a modified Gram-Schmidt orthogonalization) and Lanczos methods (originally for symmetric coefficient matrices but generalized in some ways).

B. The Arnoldi Process

The Arnoldi process [1] on its own (see Figure 2) generates the orthonormal basis $\mathbf{V} = (\mathbf{v}_1, \ldots, \mathbf{v}_m)$ for the subspace $\mathcal{K}_m(\mathbf{A}, \mathbf{v})$ and an upper Hessenberg matrix $\mathbf{H} = (h_{ij})$:

$$\mathbf{H} = \begin{pmatrix} h_{11} & h_{12} & h_{13} & \cdots & h_{1,m-1} & h_{1m} \\ h_{21} & h_{22} & h_{23} & \cdots & h_{2,m-1} & h_{2m} \\ 0 & h_{32} & h_{33} & \cdots & h_{3,m-1} & h_{3m} \\ 0 & 0 & h_{43} & \cdots & h_{4,m-1} & h_{4m} \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & 0 & \cdots & h_{m,m-1} & h_{mm} \end{pmatrix},$$

which represents the linear transformation $\mathbf{A}$ restricted to $\mathcal{K}_m(\mathbf{A}, \mathbf{v})$ with respect to the basis $\mathbf{V}$, that is $\mathbf{H} = \mathbf{V}^T\mathbf{A}\mathbf{V}$.

The original Arnoldi process applied to a linear system $\mathbf{A}\mathbf{x} = \mathbf{b}$ is called *the full orthogonalization method* (FOM) [10] but a better approach is *the generalized minimum residual* algorithm (GMRES) [12]. Both the methods are shown in Figure 3. They differ only in one step — how to find the vector $\mathbf{y}$ (but both the procedures are projections [12]).

The GMRES algorithm is very popular in its iterative form. In the iterative GMRES after computing the new vector $\mathbf{x}^{(0)}$, the new residual $-\mathbf{Q}^T\mathbf{x}^{(0)}$ is checked if it is sufficiently close to $\mathbf{0}$. If not, the whole algorithm is repeated with the new $\mathbf{x}^{(0)}$ as the initial guess.

One of the advantages of this method is no fill-in generation (because the matrix $\mathbf{Q}$ is only used in the matrix-vector multiplication), the other is the fast convergence rate. The

```
1) choose $\mathbf{x}^{(0)}$ and $m$
2) $\mathbf{r}^{(0)} \leftarrow -\mathbf{Q}^T\mathbf{x}^{(0)}$
3) $\beta \leftarrow ||\mathbf{r}^{(0)}||_2$
4) $\mathbf{v}_1 \leftarrow \mathbf{r}^{(0)}/\beta$
5) for $j = 1, \ldots, m$:
    a) $\mathbf{w} \leftarrow \mathbf{Q}^T\mathbf{v}_j$
    b) for $i = 1, \ldots, j$:
        i) $h_{ij} \leftarrow \mathbf{v}_i^T\mathbf{w}$
        ii) $\mathbf{w} \leftarrow \mathbf{w} - h_{ij}\mathbf{v}_i$
    c) $h_{j+1,j} \leftarrow ||\mathbf{w}||_2$
    d) $\mathbf{v}_{j+1} \leftarrow \mathbf{w}/h_{j+1,j}$
6) FOM only:
   find $\mathbf{y} = (y_1, \ldots, y_m)$ from the $m \times m$ Hessenberg
   system $\mathbf{Hy} = \beta\mathbf{e}_1$
7) GMRES only:
   find $\mathbf{y} = (y_1, \ldots, y_m)$ minimizing $||\beta\mathbf{e}_1 - \bar{\mathbf{H}}\mathbf{y}||_2$
   where $\bar{\mathbf{H}} = (h_{ij})$ is an $(m+1) \times m$ upper
   Hessenberg matrix
8) $\mathbf{x}^{(0)} \leftarrow \mathbf{x}^{(0)} + \sum_{i=1}^{m} \mathbf{v}_i y_i$
```

Fig. 3. The FOM and GMRES methods for the equation $\mathbf{Q}^T\mathbf{x} = \mathbf{0}$

iterative GMRES algorithm is also convenient to vectorize [5] and parallelize [4]).

One of the problems which materialize when using the GMRES method is to select the optimal parameter m. The lower the value of the parameter m, the shorter loop and thus the less calculation time and space. Additionally, the vector $\mathbf{v}$ is also shorter.

IV. IWZ Preconditioning

The convergence rate of iterative methods depends on properties of the coefficient matrix of the linear system. If matrix $\mathbf{Q}$ is ill-conditioned, this can make the convergence of iterative methods slow. One way to prevent such problems is to transform the system (1) into an equivalent system (having the same solution), but with better numerical properties. Such a transformation can be done by preconditioning, that is by converting the system (1) into:

$$\mathbf{M}^{-1}\mathbf{Q}^T\mathbf{x} = \mathbf{0}, \qquad \sum_{i=1}^{n} x_i = 1, \qquad \mathbf{x} \geq \mathbf{0}, \qquad (2)$$

where the nonsingular matrix $\mathbf{M}$ (known as a preconditioner) approximates the matrix $\mathbf{Q}^T$ in a manner. The system (2) has the same solutions as (1) but it is (hopefully) better conditioned.

The matrix $\mathbf{M}$ should have the following properties:

- its use should entail low memory requirements;
- its inverse should be cheaply applicable;
- the transformed problem (2) should converge faster (in computational less time) than the original problem.

There is a clear conflict among these three requirements, especially for the construction of general purpose preconditioners.

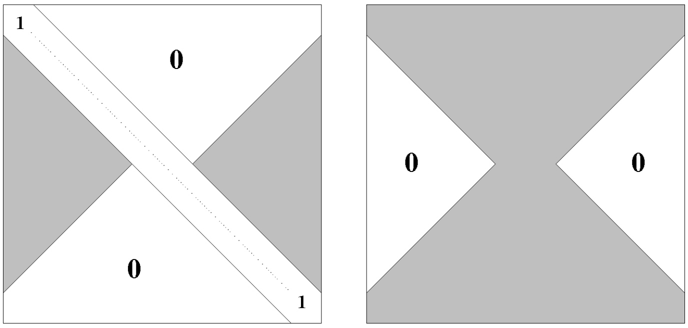

Fig. 4. The form of the output matrices in the WZ factorization (left: $\mathbf{W}$; right: $\mathbf{Z}$)

Generally, computing and using a good preconditioner is an expensive task consisting of finding the matrix $\mathbf{M}$ and its inverse. If the preconditioning is to be used, that cost should be refunded by reduced number of iterations needed to acquire required accuracy — or by using the same preconditioner for various linear systems.

The preconditioner matrix is usually built on the basis of the original coefficients of the matrix $\mathbf{Q}$. In [2] preconditioners for Krylov subspace methods for solving large singular linear systems arising from Markov modeling are considered. The incomplete WZ factorization is originally described in our previous works [3]; here we only recall it. The WZ factorization consists in decomposition of the given matrix ($\mathbf{Q}^T$ in the paper) into a product of two matrices: $\mathbf{W}$ and $\mathbf{Z}$ (Figure 4).

Incomplete WZ factorization (denoted IWZ) is based on the described above WZ factorization, where we find matrices $\widetilde{\mathbf{W}}$ and $\widetilde{\mathbf{Z}}$ (of the form of matrices $\mathbf{W}$ and $\mathbf{Z}$ shown in Figure 4) and the product $\widetilde{\mathbf{W}}\widetilde{\mathbf{Z}}$ is a kind of approximation for the matrix $\mathbf{Q}^T$.

In IWZ computations are conducted as in complete WZ factorization, but new non-zero elements (w_{ij} and z_{ij}) arising in the process are dropped if they appear in the place of a zero element in the original matrix $\mathbf{Q}^T$. Hence, the factors together have the same number of non-zeros as the original matrix $\mathbf{Q}^T$. It is worth noting that we got the inverse of $\widetilde{\mathbf{W}}$, because [14]:

$$\widetilde{\mathbf{W}}^{-1} = (-1) \cdot (\widetilde{\mathbf{W}} - \mathbf{I}) + \mathbf{I} \qquad (3)$$

$$(\text{just like} \quad \mathbf{W}^{-1} = (-1) \cdot (\mathbf{W} - \mathbf{I}) + \mathbf{I}). \qquad (4)$$

After IWZ we have:

$$\mathbf{Q}^T = \widetilde{\mathbf{W}}\widetilde{\mathbf{Z}} + \mathbf{R}_{WZ}, \qquad (5)$$

where $\widetilde{\mathbf{W}}$ and $\widetilde{\mathbf{Z}}$ are (respectively) matrices of the form of $\mathbf{W}$ and $\mathbf{Z}$ from Figure 4 and the remainder matrix $\mathbf{R}_{WZ}$ is supposed to be small in a sense.

V. The test models

Two models are chosen to test: an abstract model (Model I) and a model of epidemics known from literature (Model II). Parameter d was introduced for the characterization of the matrixes. So, d is an average number of non-zeros in a row/column of the matrix.

TABLE I
ESSENTIAL CHARACTERISTICS OF THE MATRICES USED IN TESTS

Group	Matrix ID	n	nz	d
I	1	100	1190	11.9
II	2	100	388	3.88
I	3	1500	37955	25.3
II	4	1500	5873	3.9
I	5	3000	120590	40.2
II	6	3000	11636	3.9

TABLE II
THE TEST MATRIX ATTRIBUTES FOR A 2D MARKOV MODEL.

ID	7
N_x	64
N_y	16
n	1105
nz	9457
d	8.56

A. Model I

In this section we describe matrices corresponding to the model I. Matrices (with IDs from 1 to 6) used in tests were generated by the paper authors on the basis of some abstract queuing models — the matrices are infinitesimal generators of Markov chains describing these models — and they are neither symmetric nor anyway structural. In Table I the essential characteristics of the matrices are presented (n is the number of rows/columns of the matrix, nz is the number of non-zeros in the matrix, $d = nz/n$).

For these matrices we can observe, that the matrices might have the same size and a different value of the parameter d. The matrices were divided into two groups, the first group include matrices with $d > 8$, the second group include matrices with $d \leq 8$.

B. Model II

The matrix from model II was generated from a standard two-dimensional model [6], [7]. Table II shows the test matrix attributes for a 2D Markov model. This particular example has been taken from [8], [7]. The model is discussed there and it has been used to compare different solution methods in [13].

The state of the chain is described as a two-dimensional vector. In the first dimension, the state variable assumes all values from 0 through N_x; in the second dimension the state variable takes on values from 0 through N_y. The states of such a chain are described with two numbers (u, v), $u = 0, \ldots, N_x$, $y = 0, \ldots, N_y$ (here $N_x = 64$, $N_y = 16$) and transitions are only allowed from (u, v) to (u', v') if $|u' - u| \leq 1$ and $|v' - v| \leq 1$. There was assumed — as in [6] — that only some transition from each state are permitted. This two-dimensional Markov chain model allows for transitions from any non-boundary state to adjacent states in fixed directions (chosen from North, South, East, West, North-East, North-West, South-East, South-West). A sample scheme of the model (with allowed directions: South, East and North-West) is shown in Figure 5.

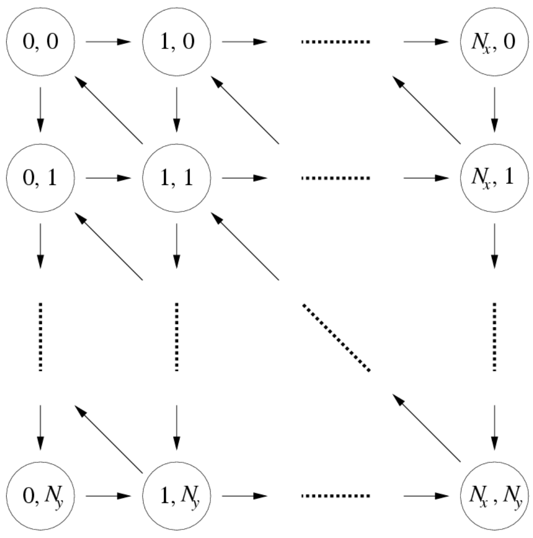

Fig. 5. A sample scheme of a two-dimensional Markov chain.

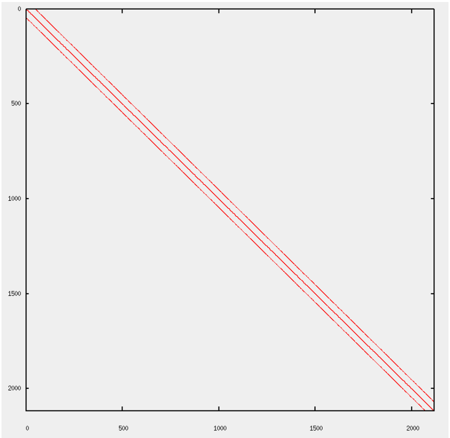

Fig. 6. The structure for the model II matrix

The matrix describing the two-dimensional Markov chain has a structure shown in Figure 6.

VI. EXPERIMENTAL RESULTS

The experiment was performed on a Pentium IV 2.8GHz computer, 1GB RAM, with Debian GNU/Linux operating system. We used high-level programming language, namely Octave.

A vector $\mathbf{x}^{(0)} = (x_i^{(0)})$ with $x_i^{(0)} = \frac{1}{i}$ was chosen as an initial vector. (We chose $x_i^{(0)} = \frac{1}{i}$ because the starting vector can be selected almost freely, but its elements should not be equal — $x_i^{(0)} = \frac{1}{i}$ fulfils this condition.) As a measure of accuracy of the solution we chose:

$$\varepsilon^{(k)} = ||\mathbf{0} - \mathbf{Q}^T \mathbf{x}^{(k)}||_2. \quad (6)$$

Accuracy has been studied experimentally for the matrix of model I and model II. We study both the number of iterations needed to achieve a given accuracy, and the rate of convergence. The stopping criterion used is that the 2-norm of the residual $||\mathbf{Q}^T \mathbf{x}^k||_2$ is less than e^{-15}

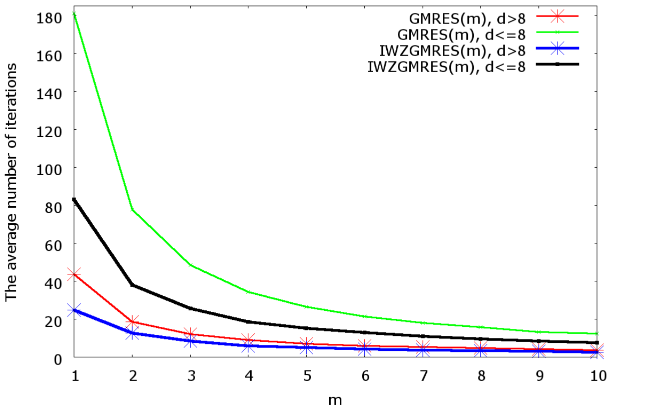

Fig. 7. Relationship between the parameter m and the average number of iterations needed to achieve accuracy e^{-16} for GMRES method and IWZGMRES method, for matrices of Group I ($d > 8$) and II ($d <= 8$).

A. Number of iterations

Table III shows numbers of iteration used to achieve a given accuracy for selected parameters m for two methods: GMRES(m) alone (denoted GMRES(m)) and GMRES(m) preconditioned with IWZ (denoted IWZGMRES(m)).

Figure 7 shows the relationship between the parameter m and the average number of iterations needed to achieve a given accuracy. The average number of iterations is counted for two groups of matrices. First for the group with $d > 8$ (matrix number 1, 3, 5) and the second group of matrices with $d \leq 8$ (matrix number 2, 4, 6).

Applications that may be present at the table III and Figure 7 are as follows:

- With the increase of parameter m the average number of iterations needed to achieve the assumed accuracy of the method GMRES(m) and IWZGMRES(m) decreases inversely.
- For each matrix from the first group number of iterations needed to achieve the assumed precision for the selected value of parameter m is almost the same. Analogous relationship can be seen for matrices of the second group. It means that regardless of the size of the matrix the number of iterations needed to achieve a given accuracy is the same and depends on the parameter d.
- In the method IWZGMRES(m) the number of iterations needed to achieve a given convergence is less than the GMRES(m) method, regardless of the parameter m and the parameter d.

Let us define the coefficient $p(m)$, which shows the relationship between the number of iterations needed to achieve (given the convergence e^{-16}) in the method of GMRES(m) and the method IWZGMRES(m).

Let $I_{IWZGMRES(m)}(m)$ mean the number of iterations needed to achieve the fixed accuracy of the method IWZGMRES(m) depending on the parameter m

Let $I_{GMRES(m)}(m)$ mean the number of iterations needed to achieve the fixed accuracy of the method GMRES(m) depending on the parameter m.

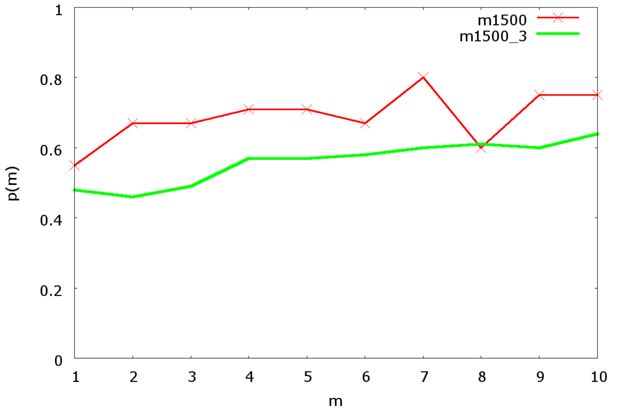

Fig. 8. Relationship between the parameter m and the value of the coefficient $p(m)$ for matrices 3 (m1500) and 4 (m1500_3)

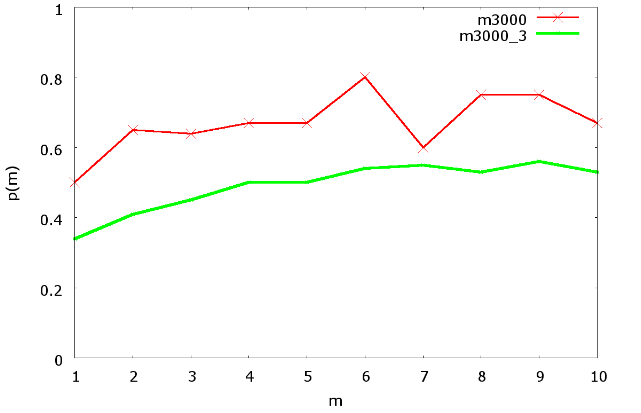

Fig. 9. Relationship between the parameter m and the value of the coefficient $p(m)$ for matrices 5(m3000) and 6 (m3000_3)

Let

$$p(m) = \frac{I_{IWZGMRES(m)}(m)}{I_{GMRES(m)}(m)}.$$

Figure 8 shows the relationship between the parameter m and the value of the coefficient $p(m)$ for the matrices 3 and 4 in Table II. Matrices have size 1500 and vary in the value of the parameter d. Figure 9 shows the relationship between the parameter m and the value of the coefficient $p(m)$ for the matrices with the numbers 5 and 6 in Table II. Matrices have size 3000 and vary in the value of the parameter d.

Figures 8 and 9 show how the value of the parameter m influence the convergence. The conclusions are:

- With the increase of parameter m (where m changes from 1 to 10) the value of the coefficient of $p(m)$ grows.
- Value of the parameter $p(m)$ for the matrices of group I is higher than for the matrices in group II.
- For the matrices of the group II growth factor $p(m)$ is more uniform than for the matrix of the group I.

Let

$$p = \max_{1<=m<=10} |p(m)|.$$

TABLE III
NUMBER OF ITERATION k NEED TO ACHIEVE A GIVEN ACCURACY $\varepsilon^{(k)} = e^{-16}$ FOR THE SELECTED OF THE VALUE PARAMETER m.

	$m = 1$		$m = 5$		$m = 10$	
ID	GMRES(m)	IWZGMRES(m)	GMRES(m)	IWZGMRES(m)	GMRES(m)	IWZGMRES(m)
1	45	29	8	6	4	3
2	87	69	17	13	8	7
3	44	24	7	5	4	3

5	42	21	6	4	3	2
6	271	92	32	16	15	8

TABLE IV
VALUE OF THE PARAMETER p FOR MATRICES OF THE MODEL I

ID	*p*
1	0.8
2	0.8
3	0.8
4	0.64
5	0.8
6	0.56

TABLE V
VALUE OF THE PARAMETER $p(m)$ FOR THE MATRIX OF MODEL II FOR DIFFERENT VALUES m

m	*p(m)*
5	0.86
14	1.0
25	1.33
29	1.14
33	1.0
41	1.0
49	1.0
61	0.67

Now, p can be interpreted as a number that indicates how many times GMRES(*m*) method can be faster, if we use IWZ as a preconditioning method.

Table IV shows the value of p for the matrices of model I.

From table IV it can be deduced that the matrices of group I, the coefficient p is the same regardless of the size of the matrix and the rate is 0.8. While for the matrices of group II ratio p decreases with increasing size of the matrix.

Table V provides a value for $p(m)$ for model II. The value of $p(m)$ is the highest for $m = 25$ and for $m = 33$, $m = 41$, $m = 49$ is a constant which means that preconditioning has no effect on the rate of convergence, and for example $m = 61$ this ratio is less than 1 which means that the method IWZGMRES(61) is faster convergent than the GMRES(61).

B. The convergence rate of the GMRES

Figures 10 and 11 present relationship between the number of iterations and the convergence $\log(||Q^T x_i||_2)$ for the matrices with the number 3 and 4 for methods GMRES(*m*), IWZGMRES(*m*) for a few selected values of parameter m. The plot shows that the higher value of the parameter m, the more rapidly convergent is the method GMRES(*m*). Analogously, the higher value of the parameter m means that IWZGMRES(*m*) method is faster convergent.

The convergence curve $\log(||Q^T x_i||_2)$ as a function i is almost of the same shape for a particular parameter m for the GMRES(*m*) method and the IWZGMRES(*m*) method, only for the IWZGMRES(*m*) method the curve is shifted upwards. It means that the IWZGMRES(*m*) method is faster convergent than the GMRES(*m*) method.

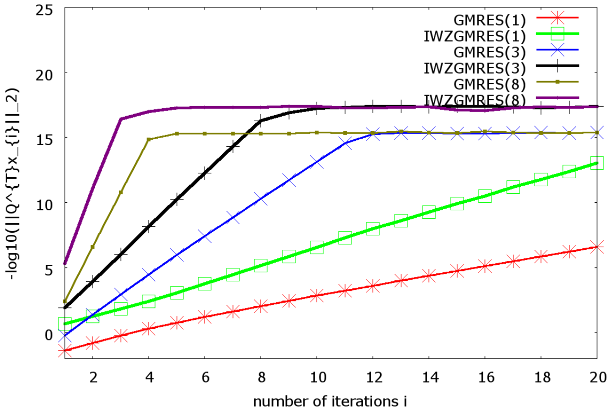

Fig. 10. Plot of the convergence curve $\log(||Q^T x_i||_2)$ as a function of i for the matrix 3

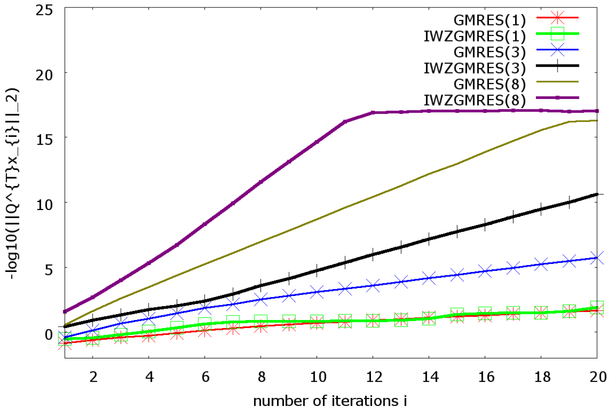

Fig. 11. Plot of the convergence curve $\log(||Q^T x_i||_2)$ as a function of i for matrix 4

Figures 12 and 13 show relationship between the number of the iterations and the convergence $\log(||Q^T x_i||_2)$ for matrices size, respectively 1500 and 3000 with different parameter d for the GMRES(*m*) methods and the IWZGMRES(*m*) methods for the parameter $m = 8$. The plots show that the GMRES(*m*) method and the IWZGMRES(*m*) method are faster convergent for matrices 3 and 5 than for matrices 4 and 6. The rate of the convergence depends on the d of the matrix and not on its

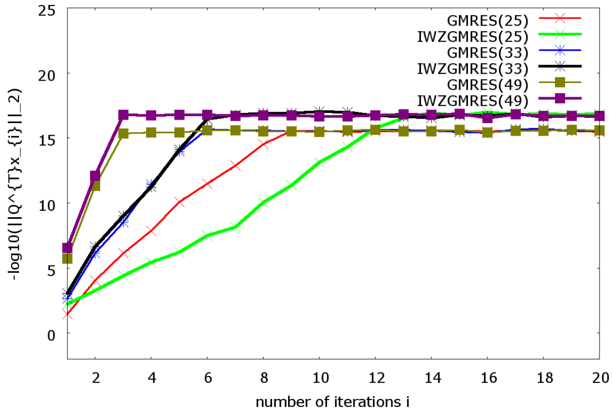

Fig. 14. Plot of the convergence curve $\log(||Q^T x_i||_2)$ as a function of i for the matrix of the model II

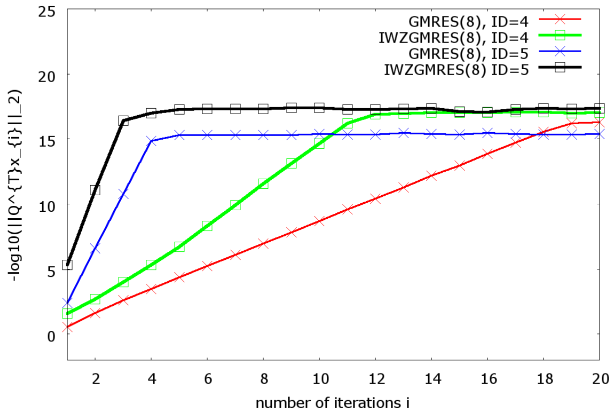

Fig. 12. Plot of the convergence curve $\log(||Q^T x_i||_2)$ as a function of i for the matrix 3 and 4

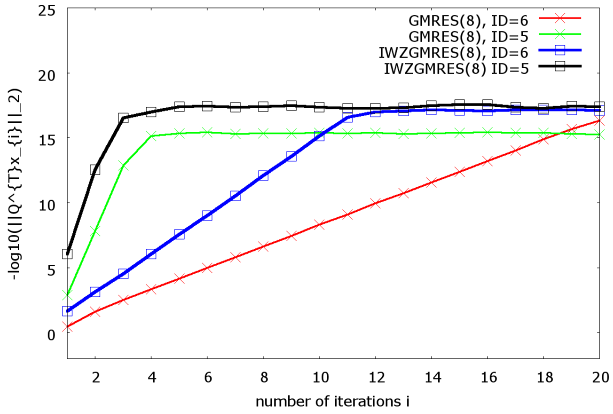

Fig. 13. Plot of the convergence curve $\log(||Q^T x_i||_2)$ as a function of i for the matrix 5 and 6

size.

Figure 14 shows relationship between number of iterations and the convergence $\log(||Q^T x_i||_2)$ for the GMRES(m) method and the IWZGMRES(m) method for parameter m with values $m = 25$, $m = 33$ i $m = 49$. Figure 14 and Table V present, that for certain values of m the method GMRES(m) had got a faster rate of convergence and for some the IWZGMRES(m) method had.

VII. Conclusion

Those numerical experiments helped us understand the effect of the nonzero structure and the size of the matrix on the convergence characteristics of preconditioned Krylov subspace methods like GMRES. The rate of convergence of the projection methods GMRES does not depend on the size of the matrix. Speed of convergence in terms of numbers of iterations of GMRES depends on the structure of the matrix. Tested matrices from two different models were characterized by the fact that the matrices of the model I have no structure, the matrix form the model II has got some structure.

Matrices from the first model was characterized by a parameter d. Namely, the set of matrices, which have a low value of the parameter d, ($d < 8$) are slowly convergent and require additional techniques to improve the rate of convergence. This technique was preconditioning.

The convergence, expressed in terms of p showed that we can identify the most optimal value of the parameter m, for which instead of the use of the GMRES(m) method we use the preconditioned GMRES(m) method, namely IWZGMRES(m).

On the basis of additional studies it may be concluded that irrespectively of the size and structure of the matrix GMRES($m + 1$) is faster convergent than the GMRES(m) for any matrix: similarly for the IWZGMRES(m) method the same dependence holds. With the increase parameter m, the rate of convergence of the method GMRES(m) increases, of course, up to some m_0, for which the rate is the largest, for all $m > m_0$ the rate is already the same.

The numerical example shows, that it is good to examine whether the matrix associated with a Markov chain is structured and has some properties, for example, the parameter d. If there is no structure you can use the preconditioning technique.

For the matrix of the model II it is not always the IWZGMRES(m) improves the convergence rate, because the matrices a structure. For this model we need to develop a separate algorithm to determine the vector of probabilities. These algorithms should take advantage of some properties of matrices associated with models.

On the Numerical Analysis of Stochastic Lotka-Volterra Models

Tuğrul Dayar[1], Linar Mikeev, and Verena Wolf
Department of Computer Science, Saarland University, Saarbrücken, Germany

***Abstract*—The stochastic Lotka-Volterra model is an infinite Markov population model that has applications in various life science domains. Its analysis is challenging since, besides an infinite state space with unbounded rates, it shows strongly fluctuating dynamics and becomes unstable in the long-run. Traditional numerical methods are therefore not appropriate to solve the system. Here, we suggest adaptations and combinations of traditional methods that yield fast and accurate solutions for certain parameter ranges of the stochastic Lotka-Volterra model. We substantiate our theoretical investigations with a comparison based on experimental results.**

I. Introduction

MORE than 80 years ago, Lotka and Volterra independently proposed the following three rules to describe the numerical evolution of two populations in interspecific competition [24, 30]:

1) The first population (prey) grows at rate αx, where x represents the population of prey.
2) The second population (predator) "eats" prey and grows at rate βxy, where y represents the population of predator.
3) The predator population decreases through natural death at rate γy.

The solution of the corresponding system of (non-linear) ordinary differential equations (ODEs)

$$\begin{aligned}\tfrac{dx}{dt} &= \alpha x - \beta xy\\ \tfrac{dy}{dt} &= \beta xy - \gamma y\end{aligned} \qquad (1)$$

shows sustained oscillations for positive constants α, β, γ along the closed curves

$$\beta x - \gamma \log x + \beta y - \alpha \log y = const$$

except if initially the system does start in the equilibrium point $x = \gamma/\beta, y = \alpha/\beta$. In Fig. 1(a), we plot the solution for $\alpha = \gamma = 1$ and $\beta = 0.01$ across time where we initially started with $x_0 = y_0 = 20$. Since its introduction, the Lotka-Volterra model became one of the most popular models in population dynamics, but it has also been successfully applied to neural networks [25] and game theoretic problems [16].

The stochastic Lotka-Volterra model assumes that x and y are represented by discrete random variables X and Y and that their evolution in time is given by a two-dimensional Markov process $\{(X(t), Y(t)), t \geq 0\}$ [11, 13, 20]. As opposed to the original Lotka-Volterra model, the stochastic variant takes into account the discreteness of the populations and their random fluctuations. In the stochastic model, extinction of species is possible and, depending on the initial conditions, the dynamics of the system can deviate drastically from the deterministic model. Recently, generalizations of the stochastic Lotka-Volterra model have been used to investigate the mechanisms that maintain biodiversity in Escherichia coli (E. coli) populations [18, 19, 26]. In such generalizations, the number of species is larger but the rules of interspecific competition remain the same.

Here, we are interested in the transient probability distribution of the stochastic Lotka-Volterra model (cf. Section II). It can be used to derive measures such as the distribution of the time until extinction, the probability of extinction until a certain time instant, the expected populations, etc. For a transient solution of the stochastic Lotka-Volterra model, the underlying Markov process has to be solved; this involves the solution of a system of ordinary differential equations known as the master equation [17]. Standard methods for the transient solution of Markov processes are based on the numerical integration of the differential equations, on uniformization of the process, or on approximations in the Krylov subspace (for an overview see [28]). An alternative approach, called method of moments, has recently been proposed by Engblom and is based on a deterministic approximation of the moments of the Markov process described by the master equation [10].

Already in the case of two species, the analysis of the stochastic Lotka-Volterra model using standard methods, such as numerical integration methods or approximations of the moments become inefficient or even infeasible for several reasons. The state space is infinite in two dimensions and it is non-trivial to truncate the state space in such a way that the number of states in the finite truncation remains tractable. Before one of the species becomes extinct, the expected populations oscillate in a similar way as in the deterministic model. Therefore the dynamics of the system change drastically. If the population of at least one of the two species is high, then a large number of events occur even in small time intervals. Moreover, the rates are unbounded; that is, the system is not uniformizable. In order to describe the strong non-linear dependence between the two populations, higher-order moments are necessary and a deterministic approximation of two or more moments yields poor results.

In this paper, we suggest several adaptations and combinations of standard methods that render an efficient solution of the stochastic Lotka-Volterra model possible. We concentrate on the numerical integration of the master equation (cf. Section III) as well as the method of moments (cf. Section IV).

Fig. 1. ODE solution and stochastic solution of the Lotka-Volterra model where $\alpha = \gamma = 1$, $\beta = 0.01$, and $x_0 = y_0 = 20$.

We extend these methods in such a way that the cheap but inaccurate method of moments becomes more accurate and the expensive but accurate numerical integration becomes faster. In Section V, we propose a stochastic hybrid approach that dynamically switches between a moment-based representation and a distribution-based representation as well as having the ability to simultaneously use a combination of both. We implemented all methods in C++ and performed extensive simulations of the stochastic Lotka-Volterra model in order to provide comparisons in terms of accuracy and run time. Numerical experiments on a number of problems indicate that the stochastic hybrid approach is overall the best method. It is at least an order faster than the numerical integration of the master equation and yields no more than a 5 % relative error in the first moment of the transient distribution.

II. Stochastic Lotka-Volterra model

We describe the transitions of the stochastic Lotka-Volterra model in a guarded command style [1, 23]. A guarded command has the form `guard |- rate -> update;` and it describes a set of transitions in the underlying Markov process. The `guard` is a Boolean predicate that determines in which states the transition is possible, the `rate` is the real-valued function that evaluated in the current state gives the positive transition rate in the Markov process, and `update` is the function that calculates the successor state of the transition. Let x and y be the positive integers that represent the populations of prey and predator, respectively. The three different possible transitions are given as follows:

$$\begin{array}{llll}
\mathtt{x} > 0 & \mathtt{|-} & \alpha \cdot \mathtt{x} & \mathtt{->} \quad \mathtt{x} := \mathtt{x} + 1; \\
\mathtt{x} > 0, \mathtt{y} > 0 & \mathtt{|-} & \beta \cdot \mathtt{x} \cdot \mathtt{y} & \mathtt{->} \quad \mathtt{x} := \mathtt{x} - 1, \mathtt{y} := \mathtt{y} + 1; \\
\mathtt{y} > 0 & \mathtt{|-} & \gamma \cdot \mathtt{y} & \mathtt{->} \quad \mathtt{y} := \mathtt{y} - 1;
\end{array}$$

The above guarded command model specifies the elements of the infinitesimal generator matrix Q of a Markov process $\{(X(t), Y(t)), t \geq 0\}$ which takes states (x, y) in $\mathbb{N}^2$. More precisely, if for a pair (x, y) the guard is true, then the element that belongs to (x, y) and the update of (x, y) is equal to the rate. E.g. the row of state $(2, 2)$ contains three positive entries. One for the transition to state $(3, 2)$ at rate 2α, one for the transition to state $(1, 3)$ at rate 4β, and one for the transition to state $(2, 1)$ at rate 2γ. The diagonal element is then given by the negative sum of the off-diagonal elements. It is easy to see that $\{(X(t), Y(t)), t \geq 0\}$ is a regular Markov process [8]. We remark that the outflow rate from state (x, y) with $x, y > 0$ is $(\alpha x + \gamma y + \beta xy)$, where $\alpha, \gamma, \beta > 0$, and this rate increases unboundedly with increasing values of x and y.

Let us fix the initial state of the system as (x_0, y_0). Then the transient probability distribution is given by the master equation

$$\tfrac{d}{dt} p^{(t)}(x, y) = \mathcal{M}(p^{(t)}(x, y)), \tag{2}$$

where $p^{(t)}(x, y) = P\{X(t) = x, Y(t) = y | X(0) = x_0, Y(0) = y_0\}$. The master operator $\mathcal{M}$ is defined for any real-valued function $g : \mathbb{N}^2 \to \mathbb{R}$ such that $\mathcal{M}(g)$ is the function that maps a state (x, y) to the value[1]

$$\begin{aligned}
\mathcal{M}(g(x, y)) = {} & \alpha(x-1)g(x-1, y) \\
& + \beta(x+1)(y-1)g(x+1, y-1) \\
& + \gamma(y+1)g(x, y+1) \\
& - (\alpha x + \beta xy + \gamma y)g(x, y),
\end{aligned} \tag{3}$$

where α, β, γ are the rate constants as defined before and $x, y > 0$. If $x = 0$ and/or $y = 0$, then the terms involving $g(x-1, y)$ and/or $g(x+1, y-1)$ are removed. The ordinary first-order differential equation in (2) is a direct consequence of the Kolmogorov forward equation and describes the change of the probability distribution as the difference between inflow of probability from direct predecessors (first three terms) and outflow of probability in state (x, y) (last term).

III. Direct numerical approximation

Since no analytical solution is known for Eq. (2) and the number of equations is infinite in two dimensions, a numerical solution is only possible if appropriate bounds for the variables x and y are found.

[1] We assume that all terms with a negative argument are zero (e.g. $\alpha(x-1)g(x-1, y) = 0$ if $x < 1$).

A. Dynamic numerical integration

Here, we suggest to construct the state space in a dynamic manner up to a certain bound. We discretize time and integrate over small time steps. In the first step, state (x_0, y_0) has probability 1 and, for a time step $h > 0$, we integrate Eq. (2) by considering only those states that have a non-zero probability during the next h time units. For the numerical integration, we use an explicit fourth-order Runge-Kutta method and thus in each step we add the states within a distance of four transitions from the current set of states.

The standard explicit fourth-order Runge-Kutta method applied to Eq. (2) yields the integration step [28]

$$\begin{aligned} p^{(t+h)}(x,y) = p^{(t)}(x,y) + \tfrac{h}{6}\Big(& k^{(1)}(x,y) \\ &+ 2k^{(2)}(x,y) + 2k^{(3)}(x,y) + k^{(4)}(x,y)\Big), \end{aligned} \tag{4}$$

where $h > 0$ is the time step of the method. For $i \in \{1, 2, 3, 4\}$ the values $k^{(i)}(x, y)$ are defined recursively as

$$\begin{aligned} k^{(1)} &= \mathcal{M}(p^{(t)}), \\ k^{(2)} &= k^{(1)} + \tfrac{h}{2}\mathcal{M}(k^{(1)}), \\ k^{(3)} &= k^{(1)} + \tfrac{h}{2}\mathcal{M}(k^{(2)}), \\ k^{(4)} &= k^{(1)} + h\mathcal{M}(k^{(3)}). \end{aligned} \tag{5}$$

Let $\tilde{p}^{(t)}$ be the approximation of $p^{(t)}$ at time t. Given $\tilde{p}^{(t)}$, we integrate Eq. (2) for h time units as follows. Let $S \subseteq \mathbb{N}^2$ be the set of states (x, y) with $\tilde{p}^{(t)}(x, y) > 0$. Each state $(x, y) \in S$ is represented as an array with entries $k^{(1)}(x, y), \ldots, k^{(4)}(x, y)$, $p(x, y)$. The former four entries are initialized with 0 while $p(x, y) = \tilde{p}^{(t)}(x, y)$ due to the previous integration step and, in the first integration step, $p(x, y) = 1$ if $x = x_0$, $y = y_0$ and $p(x, y) = 0$ otherwise. We have five substeps in which we go over all elements of S to compute for each state the four k-values as well as $\tilde{p}^{(t+h)}(x, y)$. In the first substep, each state (x, y) adds the three outflow probabilities $\alpha x p(x, y)$, $\beta x y p(x, y)$, and $\gamma y p(x, y)$ to the array element $k^{(1)}$ of the corresponding successor states $(x + 1, y)$, $(x - 1, y + 1)$, and $(x, y - 1)$ (see Eqs. (3) and (5)). Whenever a successor state is not in S, we add it to S. For $i \in \{2, 3\}$, in the i-th substep we first add $k^{(1)}(x, y)$ to the element for $k^{(i)}(x, y)$ and then add $\frac{h}{2}\alpha x k^{(i-1)}(x, y)$, $\frac{h}{2}\beta x y k^{(i-1)}(x, y)$, and $\frac{h}{2}\gamma y k^{(i-1)}(x, y)$ to the $k^{(i)}$-field of the corresponding successors $(x + 1, y)$, $(x - 1, y + 1)$, and $(x, y - 1)$ (again we add successors to S whenever they do not yet belong to S). The fourth substep is identical to the second and third except that $\frac{h}{2}$ is replaced by h (cf. Eq. (5)). In the fifth substep, we compute for each state (x, y) the probability $\tilde{p}^{(t+h)}(x, y)$ according to Eq. (4).

The dynamic numerical integration procedure described above yields accurate approximations of the transient probability distribution $p^{(t)}$ of the infinite Markov process $\{(X(t), Y(t)), t \geq 0\}$. Its drawback, however, is that the size of set S becomes very large since in each integration step states within a distance of four transitions are added. E.g. after a computer time of five hours and a time horizon of $t = 0.317$ we run out of memory on a 64-bit machine with 8 GB of main memory where we used the same parameters as in Fig. 1. At that time instant, the state space contained about 35 million states.

TABLE I
RESULTS OF AN APPROXIMATE DIRECT SOLUTION OF EQ. (2).

δ	run time	$\lvert S\rvert$	error
1e-15	51h 39min	9e5	2e-7
1e-14	40h 51min	7e5	2e-6
1e-12	22h 46min	4e5	9e-5
1e-10	10h 12min	2e5	6e-3

B. Inexact numerical integration

Similar to the approach in [9], we modify the numerical integration procedure described above as follows. During the first four substeps of the integration step, we only add new states to set S if their probability is greater than a small positive threshold δ. This has shown to lead to a significant reduction of the size of S while, for most systems, the approximation error is small. For instance, for $\delta = 10^{-15}$ the size of set S at time $t = 0.317$ is just 0.004% of the size of S for $\delta = 0$, while the total probability that got "lost", when states with probability smaller than δ were ignored, is only 7×10^{-12}.

In Table I we list our results of approximate direct solution of Eq. (2) for different values of δ. We analyzed the system for a time horizon of $t = 10$ and used the same parameters as in Fig. 1. For other parameters, such as those that we used for our experiments in Section VI, the results are similar (not shown). The column labeled $|S|$ lists the average size of set S, i.e. average number of states considered during one integration step. The last column gives the total probability that got "lost" due to the state space truncation. If the numerical integration were exact, the values in the last column would contain the total error of the approximation, i.e. the sum of all absolute errors of the state probabilities. Note that the resulting probability distributions provide full information about the system, i.e. arbitrary moments of the distribution as well as probability of certain events (such as extinction until time t) can be derived.

With the proposed numerical approach, we are able to solve the stochastic Lotka-Volterra model and accurate results are obtained. The method is, however, rather slow whenever the expected populations become large. This is because large populations are represented by a large number of discrete states, even though the relative variance is small. This problem gets worse when the populations oscillate in an even higher range as, for instance, in Fig. 2. On the other hand, a discrete stochastic representation is necessary whenever the populations become small.

Also, if the underlying system is stiff the explicit Runge-Kutta method will perform poorly and should be replaced by implicit finite difference methods. For instance, if the transition rates in the Markov process have very different orders of magnitude, the time step of explicit methods will be proportional to the fastest time scale. Besides implicit methods, it is possible to apply aggregation techniques that are designed for stiff systems [6, 7].

IV. Deterministic approximation of moments

Deterministic approximations are, besides Monte-Carlo simulation, the analysis techniques with most widespread use. The mathematical justification of the simplest deterministic approximation, mean-field analysis, has first been provided by Kurtz in the context of chemical kinetics [21] where it is applied extensively.

Mean-field analysis relies on the assumption that the expected populations can be approximated by variables that change continuously and deterministically in time. This idea can be generalized to higher moments where the accuracy of the approximation increases as higher moments are included [10].

A. Mean-field approximation

Let $Z(t) = (X(t), Y(t))$ denote the two-dimensional population vector at time t and, for $d \in \mathbb{N}$ let $f : \mathbb{N}^2 \to \mathbb{R}^d$ be a function that is independent of t. Assume that the expectation $E[f(Z(t))]$ exists. From Eq. (2), it is straightforward to derive the relationship[2]

$$\begin{aligned}\tfrac{d}{dt}E[f(Z)] &= \textstyle\sum_{(x,y)\in\mathbb{N}^2} f(x,y)\tfrac{d}{dt}p^{(t)}(x,y)\\ &= E[\alpha X(f(X+1,Y)-f(Z))\\ &\quad +\beta XY(f(X-1,Y+1)-f(Z))\\ &\quad +\gamma Y(f(X,Y+1)-f(Z))].\end{aligned} \tag{6}$$

If $f(x,y) = (x,y)$ we get as a special case that

$$\begin{aligned}\tfrac{d}{dt}E[X] &= \alpha E[X] - \beta E[XY]\\ \tfrac{d}{dt}E[Y] &= \beta E[XY] - \gamma E[Y].\end{aligned} \tag{7}$$

Thus, if $X(t)$ and $Y(t)$ were uncorrelated (which means that $E[XY] = E[X]E[Y]$), we could compute the expected number of individuals using Eq. (1). But if $X(t)$ and $Y(t)$ are highly correlated, the approximation of the mean in Eq. (1) is rather inaccurate. Fig. 1(a), for instance, shows the mean-field approximation of the Markov process whose true expectations are plotted in Fig. 1(b).

For finite time instants t, the mean-field approximation becomes exact for the scaled process $\{N^{-1}Z(t), t \geq 0\}$ as the scaling constant N approaches infinity under the assumption that the rate functions are density dependent [22]. In the context of the stochastic Lotka-Volterra model, the latter assumption means that the constant β depends on the scaling parameter N (which has a natural interpretation such as the total number of individuals) while α and γ are independent of N. Thus, the accuracy of the approximation increases if the populations become large. In Fig. 2 we plot the mean-field approximation versus the true expected populations for $\alpha = \gamma = 1$, $\beta = 0.003$ and initial state $(180, 200)$. For these parameters, both populations stay above 150 at all times in the deterministic model. Here, the mean-field approximation remains very accurate at least until time $t = 15$ (and the same holds for the expected number of preys).

B. Method of moments

Eq. (7) suggests that we would obtain a more accurate approximation of the expected number of individuals if we could accurately approximate the value $E[XY]$. The first idea, of course, is to set $f(x,y) = xy$ in Eq. (6) in order to extend the system of differential equations in Eq. (7) by additional equations for $E[XY]$. It is easy to see that with $f(x,y) = xy$ Eq. (6) yields a differential equation that involves $E[X^2Y]$, $E[X^2Y^2]$, and $E[XY^2]$. To approximate these quantities as well, additional equations are necessary that involve even higher moments. This argument repeats and yields an infinite set of differential equations. The idea of method of moments is to truncate this infinite set after a finite number of equations. Here, we improve the quality of the deterministic approximation by enriching the system in Eq. (7) with deterministic approximations of the second moments as proposed by Engblom for Markov population models [10]. Based on a Taylor series expansion of the rate function, the following deterministic approximation of second order can be shown:

$$\begin{aligned}\tfrac{d}{dt}E[X] &= \alpha E[X] - \beta E[X]E[Y] - \beta c_{XY}\\ \tfrac{d}{dt}E[Y] &= \beta E[X]E[Y] + \beta c_{XY} - \gamma E[Y]\\ \tfrac{d}{dt}c_{XX} &= 2\alpha c_{XX} + \alpha E[X] - 2\beta E[X]c_{XY}\\ &\quad -2\beta E[Y]c_{XY} + \beta E[X]E[Y] + \beta c_{XY}\\ \tfrac{d}{dt}c_{XY} &= \alpha c_{XY} - \beta E[Y]c_{XY} - \beta E[X]c_{YY}\\ &\quad +\beta E[Y]c_{XX} + \beta E[X]c_{XY}\\ &\quad -\beta E[X]E[Y] - \beta c_{XY} - \gamma c_{XY}\\ \tfrac{d}{dt}c_{YY} &= 2E[Y]c_{XY} + 2\beta E[X]c_{YY} + \beta E[X]E[Y]\\ &\quad +\beta c_{XY} - 2\gamma c_{YY} - \gamma E[Y],\end{aligned} \tag{8}$$

where c_{XX}, c_{XY}, c_{YY} approximate the covariances $COV[X,X]$, $COV[X,Y]$, $COV[Y,Y]$, respectively. Note that the first two equations are as in Eq. (7) if we use the relationship $COV[V,W] = E[VW] - E[V]E[W]$ for the two random variables V and W.

In Fig. 2 we plot the solution of Eq. (8) together with the mean-field solution as well as the true expectations. For these parameters both the mean-field approximation and the second-order method of moments become inaccurate after $t = 23$. The second-order method of moments predicts the dynamics of the expected predator population only slightly better. The situation is similar for the expected number of preys. Additional equations for higher moments give a more accurate approximation (not shown) but become very stiff once the prey population grows too fast. The main advantages of the method of moments are the low computational cost (the ODE can be solved in a few seconds) and the fact that for many models a second-order approximation is sufficient. If,

[2] To improve readability, we omit the dependence on t and write Z instead of $Z(t)$ and so on.

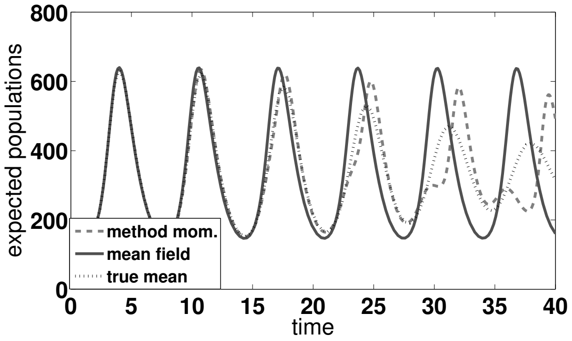

Fig. 2. The deterministic approximations of the expected number of predators remain accurate until $t = 23$. Here, we used the parameters $\alpha = \gamma = 1$, $\beta = 0.003$, and initial state $(180, 200)$.

however, besides the moments, certain probabilities are of interest (such as the probability of extinction) other solution techniques need to be chosen. Also, for the model under study higher order equations are necessary but lead to numerical instabilities. E.g. for the parameters considered in Fig. 1, the fourth-order approximation gives a matrix that is singular to working precision (while the second-order approximation yields poor accuracy). More advanced numerical techniques have to be considered in this case such as implicit finite difference methods and integration methods that are particularly designed for oscillatory systems [2–5, 29].

V. Stochastic hybrid method

In this section, we propose a hybrid solution technique for the stochastic Lotka-Volterra model that is motivated by two observations. First, the approximate direct numerical method presented in Section III-B is able to provide accurate results. However, if only one of the expected populations (say $E[Y(t)]$) is small and the other population is high, then it becomes inefficient because the number of "significant" states is large. It treats $X(t)$ and $Y(t)$ as discrete stochastic (DS) random variables and considers all possible values up to a predefined accuracy $\delta > 0$, i.e. the infinite ranges of $X(t)$ and $Y(t)$ are truncated with respect to δ. Second, the method of moments with a truncation of moments higher than order two provides a fast continuous deterministic (CD) approximation that is accurate whenever the expectations of $X(t)$ and $Y(t)$ are high.

A successful hybrid approach could therefore be based on the following two properties:

(a) It should be able to switch dynamically between a DS representation and a CD representation depending on population thresholds for $E[X(t)]$ and $E[Y(t)]$.

(b) Whenever $X(t)$ is represented as a DS variable and $Y(t)$ as a CD variable (or vice versa), a hybrid approach must be able to take into account the dependencies between $X(t)$ and $Y(t)$ in an appropriate way.

While requirement (a) is easy to realize, (b) turns out to be much more challenging. Assume that at a certain point in time, the predator population is represented by the DS variable $Y(t)$ and the prey population is represented by the CD variable $x(t) \approx E[X(t)]$; that is, we have a (truncated) probability distribution for $Y(t)$ and a single real value $x(t)$ as well as approximations of the covariances c_{XX} and c_{XY}. A straightforward idea is to consider the "global" ODE in Eq. (8) for the computation of $x(t+h) \approx E[X(t+h)]$ as well as the covariances at time $t+h$, where h is a small time step and $E[Y(t)]$ as well as c_{YY} are computed from the current approximation of the distribution of $Y(t)$. The equations for $E[Y(t)]$ and c_{YY} are removed in Eq (8) and the distribution of $Y(t+h)$ is computed by solving a "reduced" version of Eq. (2) given by

$$\begin{aligned}\tfrac{d}{dt}p^{(t)}(y) = &\ \beta(y-1)x(t)p^{(t)}(y-1)\\ &+ \gamma(y+1)p^{(t)}(y+1)\\ &- (\beta y x(t) + \gamma y)p^{(t)}(y),\end{aligned} \tag{9}$$

where $y > 0$. For state $y = 0$, we have $\frac{d}{dt}p^{(t)}(0) = \gamma p^{(t)}(1)$. Note that the transition that corresponds to the growth of prey is not included in Eq. (9) but is taken into account in Eq. (8). We can integrate Eq. (9) using the method described in Section III-B. In this way, the possible values for y and thus the number of equations would remain small (since we assumed that $E[Y(t)]$ and h are small) which makes the approach computationally cheap. For instance, the run time needed to approximate the probability distribution for the parameters used in Section I is only about 1 minute. However, it turns out that the approach yields bad accuracy. For instance, at the final time instant $t = 10$, the relative errors of the first moments of prey and predator are above 20%. In particular, the approach fails to detect the steep increase of the expected number of preys after $t = 6$ even though the results are accurate within $[0, 6]$. The reason is that when $E[Y(t)]$ is small, the (relative) variance of $Y(t)$ is important for the evolution of the CD variable $x(t)$ (and vice versa). For instance, if $Y(t) = 0$, then $X(t)$ grows exponentially at rate α. In this case, the total rate of change will therefore deviate largely from the rate $\frac{d}{dt}E[X]$ used in Eq. (8).

A more accurate approach is to consider "local" ODEs, i.e. if $X(t)$ has a CD representation and $Y(t)$ has a DS representation, then we consider the conditional expectation $E[X(t)|Y(t) = y]$ for each state y. Thus, in each integration step, we represent the current state of the system by the probabilities $p^{(t)}(y) \approx P\{Y(t) = y\}$ (but we still neglect probabilities smaller than or equal to δ) and real values $x_y(t)$ that approximate $E[X(t)|Y(t) = y]$. For a small time step h, we integrate the distribution $p^{(t)}$ and the values $x_y(t)$ in three substeps.

(1) We first integrate $p^{(t)}$ according to Eq. (9) to approximate the probabilities $P\{Y(t+h) = y\}$ by $p^{(t+h)}(y)$.

(2) For each state y with $p^{(t)}(y) > \delta$, we compute $\tilde{x}_y(t+h)$ by numerical integration of the ODE

$$\tfrac{d}{dt}\tilde{x}_y(t) = \alpha\tilde{x}_y(t) - \beta y\tilde{x}_y(t)$$

with initial condition $\tilde{x}_y(t) = x_y(t)$. Note that $\tilde{x}_y(t+h)$ is *not* an approximation of $E[X(t+h)|Y(t+h) = y]$ since the above

differential equation does not take into account that Y may leave state y within $[t, t{+}h]$. E.g. for newly discovered states with $p^{(t)}(y) < \delta$ and $p^{(t+h)}(y) > \delta$ the value $x_y(t)$ (and thus $\tilde{x}_y(t{+}h)$) does not exist. Thus, a third substep is necessary to approximate $E[X(t{+}h)|Y(t{+}h) = y]$.
(3) We compute $x_y(t{+}h)$ by "distributing" $\tilde{x}_y(t{+}h)$ according to the change in the distribution of Y as explained below. If we assume that $[t, t+h]$ is an infinitesimal time interval and, for $y \neq y'$, $q(y, y', h)$ is the probability to enter y from y' within $[t, t+h]$, then

$$\begin{aligned}P\{Y(t{+}h){=}y\} = &\sum_{y'\neq y} q(y,y',h)P\{Y(t){=}y'\}\\ &+(1-\sum_{y'\neq y} q(y',y,h))P\{Y(t){=}y\}.\end{aligned} \tag{10}$$

Thus, we approximate $E[X(t+h)|Y(t+h) = y]$ as

$$\begin{aligned}&\sum_{y'\neq y} \tilde{x}_{y'}(t{+}h)q(y,y',h)P\{Y(t){=}y'|Y(t{+}h){=}y\} \\ &+ \tilde{x}_y(t{+}h)(1{-}\sum_{y'\neq y} q(y',y,h))P\{Y(t){=}y|Y(t{+}h){=}y\}.\end{aligned} \tag{11}$$

The rationale behind this approximation is that, for $t' \in [t, t + h)$, the variance $VAR[X(t')|Y(t') = y]$ is small and the conditional distributions $P\{X(t') = \hat{x} \mid Y(t') = y\}$ can be approximated by a normal distribution with mean $E[X(t')|Y(t') = y]$.

Obviously, we make use of the current approximations $p^{(t)}$ and $p^{(t+h)}$ to compute the conditional probabilities $P\{Y(t){=} y'|Y(t{+}h) = y\}$. For a small time step h, $q(y, y+1, h) \approx h\beta y\tilde{x}_y(t)$ and $q(y, y{-}1, h) \approx h\gamma y$. Using Eq. (11), we define $x_y(t{+}h) \approx E[X(t{+}h)|Y(t{+}h) = y]$ as

$$\begin{aligned}x_y(t{+}h) = \Big(&h\beta(y{-}1)p^{(t)}(y{-}1)\tilde{x}_{y-1}(t{+}h)\tilde{x}_{y-1}(t)\\ &+h\gamma(y{+}1)p^{(t)}(y{+}1)\tilde{x}_{y+1}(t{+}h)\\ &+(1{-}hy(\beta\tilde{x}_y(t)+\gamma))p^{(t)}(y)\tilde{x}_y(t{+}h)\Big)/p^{(t+h)}(y).\end{aligned}$$

We illustrate the three substeps above by means of a simple example.

Assume that the distribution of $Y(t)$ is such that $p^{(t)}(0) = \frac{1}{3}$, $p^{(t)}(1) = \frac{2}{3}$ and all other states y have probability 0 at time t. Assume further that the CD variables $x_y(t)$ are such that $x_0(t) = 600$ and $x_1(t) = 500$. For the parameters $\alpha = \gamma = 1$, $\beta = 0.01$, $h = 0.1$ substep (1) yields $p^{(t+h)}(0) = \frac{2}{5}$, $p^{(t+h)}(1) = \frac{4}{15}$, $p^{(t)}(2) = \frac{1}{3}$ where, for simplicity, we integrate Eq. (9) with the Euler method. Substep (2) yields $\tilde{x}_0(t{+}h) = 660$ and $\tilde{x}_1(t{+}h) = 549.5$ and substep (3) gives $x_0(t{+}h) \approx 641.58$ and $x_1(t{+}h) = x_2(t{+}h) = 549.5$. Note that state $y = 2$ "inherits" the x-value of state $y = 1$ since its probability inflow of $\frac{1}{3}$ originated from $y = 2$.

The same strategy as explained above can be used for the case where $X(t)$ is a DS variable and $y(t)$ is a CD variable.

We performed experiments using different parameters to test the accuracy and run time if the representation is hybrid (coexistence of CD and DS variables) and also if switching occurs often. For the parameters used in Section I, for instance, we start with a purely stochastic representation and use a population threshold of 350 to switch the representation. At time $t \approx 3.3$ we switch the representation of $X(t)$ from DS to CD since the expectation reaches 350 (see also Fig. 1(b)). Around time $t = 4$, we switch back to a DS representation. Then, around $t = 4.3$ we switch the representation of $Y(t)$ from DS to CD because $E[Y(t)] > 350$, etc.

TABLE II
RESULTS OF THE STOCHASTIC HYBRID SOLUTION.

pop. thresh.	δ	run time	$\lvert S\rvert$	relative error of moments		
		time		1st	2nd	3rd
100	$1e$-15	12s	$9e2$	0.04	0.11	0.22
	$1e$-10	7s	$6e2$	0.04	0.11	0.22
200	$1e$-15	1h 43min	$5e4$	0.03	0.11	0.23
	$1e$-10	11min	$9e3$	0.03	0.11	0.23
400	$1e$-15	2h 35min	$1e5$	0.03	0.10	0.20
	$1e$-10	25min	$3e4$	0.03	0.11	0.21

We also performed experiments using different population thresholds and different values for δ. We summarize these results in Table II. We always compared our results with the full stochastic solution described in Section III-B to estimate the accuracy of the hybrid method. We list the relative errors of the first three moments when the hybrid method is compared to the full stochastic solution. For these parameters it turned out that the accuracy of the hybrid approach is less sensitive to population threshold than expected. In the range of $100 - 400$, the relative error of the first three moments is at most 23%. Similarly, the moments are accurately approximated even if δ is about 10^{-10}. It should, however, be noted that if a higher value is chosen for δ, then small event probabilities will be approximated as 0.

The accuracy of the hybrid approach becomes worse whenever both variables are represented deterministically. The reason is that the second-order method of moments relies heavily on an accurate prediction of the (co-)variances. But during a preceding hybrid phase where, say, X has CD representation and Y has DS representation, the variance of X is much smaller than the real variance $VAR[X(t)]$, i.e. the approximation

$$VAR[X(t)] \approx \textstyle\sum_{y:p^{(t)}(y)>\delta} p^{(t)}(y)(x_y(t) - E[X(t)])^2$$

is not accurate enough if it is used as an initial value for c_{xx} in Eq. (8) even though this has only a minor effect on accuracy during the hybrid phase. The hybrid method exploits the fact that, if X is large, then the *relative* variance is small and it is sufficient to record the evolution of $E[X(t) \mid Y(t) = y]$ for each value y that has a significant probability. This seems to contradict with the approximation in Eq. (8) that relies on a good estimate for the (co-)variances. For this reason, we suppressed the configuration CD, CD for our results in Table II and always kept at least one variable DS. We plan to extend the stochastic hybrid approach such that the distribution $P\{X(t) = x \mid Y(t) = y\}$ is approximated by a normal distribution which we represent by two values (mean and variance) instead of the single value $x_y(t)$. This, however, complicates the interdependencies between X and Y further and its study is beyond the scope of this paper.

VI. Experimental results

We performed experiments using five different parameter combinations for the stochastic Lotka-Volterra model and four different solution methods. In Table III we list our experimental results. Each row corresponds to one combination and is enumerated in the first column. We used the first and the second combination of parameters also in Section III and IV (see also Fig. 1 and Fig. 2). Note that for the latter combination, the expected populations oscillate in a much higher range. The remaining parameter combinations in rows 3 through 5 are taken from the literature [14] (third row), [15] (fourth row), [12] (fifth row). In columns two to four we list the rate constants, and the columns with labels x_0 and y_0 refer to the initial population sizes. In the column with label t_f, we list the final time instant at which we compute the transient distribution. We abbreviate the solutions methods as follows:

- IRK4(δ) refers to the inexact explicit fourth-order Runge-Kutta method as described in Subsection III-B using a significance threshold of δ. We list the run time, the average number of significant states and the error, i.e., the probability mass lost during the computation for the case $\delta = 10^{-15}$.
- MF refers to the mean field analysis discussed in Subsection IV-A. We list the run time and the relative error of the first moment (expected populations) at the final time instant where we compare to IRK4(10^{-15}). We took the average over the two species.
- MM refers to the method of moments that we discussed in Subsection IV-B. We list the run time and the relative error of the first and second moments where we again compare to IRK4(10^{-15}) and average over the two species.
- Finally, SH(δ,K) refers to the stochastic hybrid method where a significance threshold of δ and a population threshold of K is used. Here, we give results for $\delta = 10^{-15}$ and $K = 200$. The column with label $|S|$ lists the average number of significant states in each step and the last three columns list the relative error of the first, second, and third moments compared to those of IRK4(10^{-15}).

For the first combination of parameters the two deterministic approxmations MF and MM yield fast but poor results. The stochastic hybrid method gives a significant speed-up compared to IRK4(10^{-15}) (about 51 times faster) and the approximation is accurate. The parameters used in the second row yield a system where the expected populations oscillate in a high range (between 150 and 650, see also Fig. 2). Therefore, MF and MM give accurate solutions. The stochastic hybrid solution is fast since most of the time both populations are represented as continuous deterministic values. The third combination of parameters gives similar results as the first one. In the last two rows, only IRK4(10^{-15}) gives an accurate solution. The stochastic hybrid method accurately predicts the first moments of the species but for the second and third moments the approximation error is high. The reason is that, for both parameter combinations, at the final time instant $E[Y] \approx 0$ and $|S| = 1$ (fourth row) and $|S| = 3$ (fifth row). During the hybrid solution, Y is represented as a discrete stochastic variable and X becomes continuous deterministic. Only a small number of states y remain and the variance between their conditional expectations $E[X|Y = y]$ is small. Thus, the second moment $E[X^2]$ yields a relative error of around 90% whereas $E[Y^2] \approx 0$ is very accurately approximated. The average relative error is then around 50%.

VII. Conclusion

The popularity of the Lotka-Volterra model for the description of population dynamics relies on the fact that this model is able to reflect the strongly changing dynamics of interacting populations. Its stochastic variant includes the possibility of extinction, which is, for instance, important for modeling biodiversity and coevolution [18, 19, 26].

The analysis of the stochastic Lotka-Volterra model is challenging because events such as extinction of predator require a costly discrete representation of the predator population. This and other characteristics of the stochastic Lotka-Volterra model (change between small and large populations, highly correlated variables, infinite state space, unbounded rates) are prototypical for Markov population models. Therefore, its analysis is not only interesting from an application-oriented viewpoint but also from a methodological viewpoint.

We discussed different analysis approaches for the stochastic Lotka-Volterra model and modified them in order to improve accuracy and run time. It turned out that the stochastic hybrid approach with local ODEs performs best. It is at least an order faster than the numerical integration of the master equation and yields no more than a 5 % relative error in the first moment of the transient distribution. If high populations are approximated by continuous deterministic variables, then error estimates are hard to obtain. The benefits of an approximate numerical solution, however, are highly dependent on accurate error estimates. Here, we compared our hybrid solution with a full stochastic solution. In the future, we will try to estimate the accuracy of the hybrid approach without a comparison to a more accurate but costly solution. Moreover, we plan to additionally consider numerical analysis approaches based on a diffusion approximation of the stochastic Lotka-Volterra model such as the one suggested by Ferm et al. [27] and compare them with the methods discussed here.

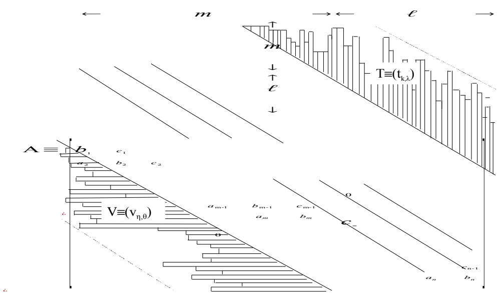
Abstract—**Explicit finite element approximate inverse preconditioning methods have been extensively used for solving efficiently sparse linear systems on multiprocessor and multicomputer systems. New parallel computational techniques are proposed for the parallelization of explicit preconditioned biconjugate conjugate gradient type methods, based on Portable Operating System Interface for UniX (POSIX) Threads, for multicore systems. Parallelization is achieved by assigning every loop of the parallel explicit preconditioned bi-conjugate conjugate gradient-STAB (PEPBiCG-STAB) to the desired number of threads, thus achieving for-loop parallelization. Theoretical estimates on speedups and efficiency are also presented. Finally, numerical results for the performance of the PEPBiCG-STAB method for solving characteristic two dimensional boundary value problems on multicore computer systems are presented, which are favorably compared to corresponding results from multiprocessor systems. The implementation issues of the proposed method are also discussed using POSIX Threads on a multicore system.**

I. Introduction

LET us consider the linear system derived by the finite element (FE) method for solving boundary value problems in two dimensions, [6] ,[8], [9], [10], i.e.

$$Au = s, \quad (1)$$



(2)

where the coefficient matrix A is a non-singular large, sparse, unsymmetric, positive definite, diagonally dominant (n×n) matrix of irregular structure (where all the off-center band terms are grouped in regular bands of width ℓ at semi-bandwidth m), [2], while u is the FE solution at the nodal points and s is a vector, with components resulting from a combination of source terms and imposed boundary conditions.

During the last decades, explicit approximate inverse preconditioning methods have been extensively used for efficiently solving sparse linear systems on multiprocessor systems, [3], [4], [9], [10]. In recent years many researchers have derived preconditioners based on various techniques, which are difficult to be implemented on parallel systems, [7], [11], [12]. The effectiveness of explicit approximate inverse preconditioning schemes relies on the use of suitable preconditioners that are close approximants to the inverse of the coefficient matrix and are fast to compute in parallel, [2], [5].

The approximate inverse $M_r^{\delta l}$ represents a class of generalized approximate inverses that includes various families of approximate inverses according to the requirements of accuracy, storage and computational work, as can be seen by the following diagrammatic relation:

$$A^{-1} \equiv \overset{\underline{\text{class I}}}{M} \leftarrow \overset{\underline{\text{class II}}}{M^{\delta l}_{r=m-1}} \leftarrow \overset{\underline{\text{class III}}}{M^{\delta l}_{r}} \leftarrow M_i \quad (3)$$

where M is the exact inverse resulting in a direct method, i.e. r=m-1 and δl=n with the disadvantage of high memory requirements and computational work for large order systems. The entries of the class I inverse have been retained after the computation of the exact inverse (r=m-1, δl=n) by retaining only δl and δl-1 elements in the lower and upper part of the exact inverse. The entries of the class II inverse have been computed and retained during the computational procedure of the (approximate) inverse (r≤m-1, δl<n), while the entries of the class III of the generalized approximate inverse retains only the diagonal elements, i.e. δl=1 while requires only the the diagonal entries of the sparse lower matrix L_r, [6], [10], resulting in a fast inverse algorithm.

978-83-60810-27-9/09/$25.00 © 2010 IEEE

Furthermore, we present the **E**xplicit **P**reconditioned **BI**-conjugate **C**onjugate **G**radient-**STAB** (**EPBI-CGSTAB**) method, which can be expressed by the following compact scheme:

Let u_0 be an arbitrary initial approximation to the solution vector u. Then,

compute $$r_0 = s - Au_0, \tag{4}$$

set $$r_0^{'} = r_0,\ \rho_0 = \alpha = \omega_0 = 1 \text{ and } v_0 = p_0 = 0 \tag{5}$$

Then, for i=1,….,n (until convergence) compute the vectors u_i, r_i and the scalar quantities α, β, ω_i as follows:

calculate $$\rho_i = \left(r_0^{'}, r_{i-1}\right) \text{ and } \beta = \frac{\left(\rho_i / \rho_{i-1}\right)}{\left(\alpha / \omega_{i-1}\right)} \tag{6}$$

compute $$p_i = r_{i-1} + \beta\left(p_{i-1} - \omega_{i-1} v_{i-1}\right), \tag{7}$$

form $$y_i = \mathbf{M}_r^{\delta l} p_i \text{ and } v_i = Ay_i, \tag{8}$$

compute $$\alpha = \rho_i / \left(r_0^{'}, v_i\right) \text{ and } x_i = r_{i-1} - \alpha v_i, \tag{9}$$

form $$z_i = M_r^{\delta l} x_i \text{ and } t_i = Az_i, \tag{10}$$

set $$\omega_i = \left(\mathbf{M}_r^{\delta l} t_i,\ \mathbf{M}_r^{\delta l} x_i\right) / \left(\mathbf{M}_r^{\delta l} t_i,\ \mathbf{M}_r^{\delta l} t_i\right) \tag{11}$$

compute $$u_i = u_{i-1} + \alpha y_i + \omega_i z_i \text{ and } r_i = x_i - \omega_i t_i \tag{12}$$

Assuming that the approximate inverse $M_r^{\delta l}$ can be compactly stored in n×(2δl-1) diagonal vectors, then the computational complexity of the **EPBICG-STAB** method is ≈O[(6δl+4 ℓ +16)n mults + 6n adds]*ν* operations, where ν is the number of iterations required for convergence to a certain level of accuracy, [6], [10].

In this article, new parallel computational techniques are proposed for the parallelization of explicit preconditioned conjugate gradient type methods, based on Portable Operating System Interface for UniX (POSIX) Threads, for multicore systems. The excessive overhead produced by the template-based parallel implementations was avoided by using POSIX Threads, maximizing the overall performance of the parallel implementation of the **PEPBICG-STAB** method and throttling it close to the corresponding theoretical estimate.

Finally, numerical results for the performance of the **PEPBICG-STAB** method for solving characteristic two dimensional boundary value problems on multicore computer systems are presented, which are favorably compared to corresponding results from multiprocessor systems. The implementation issues of the proposed method are also discussed using POSIX Threads on a multicore computer system.

II. Parallel Biconjugate Conjugate Gradient-Type Method

In this section, we demonstrate the parallel implementation of the **EPBICG-STAB** method designed for multicore computer systems using POSIX threads, [1], [13].

Specifically, kernel-level threads of the POSIX 1003.1c standard are used in a thread pool pattern, [1], originally designed by Sun Microsystems for Solaris Operating System, [13], and modified for the purposes of our computations. A thread pool manages a certain number of threads that perform tasks based on a job queue. Every time a thread finishes its task it switches to idle state, waiting for another task from the queue to be assigned to it. In this way, fork and join of threads is limited to just the active threads in the pool, rather than creating and detaching every thread that performs a task. Hence, due to the reduction of latencies an improvement is expected on the parallel performance of the proposed implementation.

This parallel implementation is based on the standard for-loop parallelization model. Let *nthreads* denote the number of threads used and *thread_id* be the "id" number of each thread (from 0 to *nthreads*). Then, every thread, denoted as *localthr,* deals only with the number of allocated elements, where *localthr*=n*/nthreads.*

Hence, the **P**arallel **E**xplicit **P**reconditioned **BI**conjugate **C**onjugate **G**radient-**STAB** (**PEPBICG-STAB**) method can be expressed by the following algorithmic scheme:

Let u_0 be an arbitrary initial approximation to the solution vector u. Then,

```
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(r_0)_j = s_j - A(u_0)_j$                                  (13)
end for
thread_pool_wait
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(r_0^{'})_j = (r_0)_j$                                     (14)
    $(p_i)_j = 0.0$                                             (15)
    $(v_i)_j = 0.0$                                             (16)
end for
thread_pool_wait
    $\rho_0 = \alpha = \omega_0 = 1.0$                          (17)
    $v_0 = p_0 = 0.0$                                           (18)
```

Then, **for i=1, ..., (until convergence)** compute in parallel the vectors u_i, r_i and the scalar quantities α, β, ω_i as follows:

```
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
do reduction + $\rho_i$
    $\rho_i = (r_0^{'})_j \cdot (r_{i-1})_j$                    (19)
end for
thread_pool_wait
    $\beta = (\rho_i / \rho_{i-1}) / (\alpha / \omega_{i-1})$   (20)
thread_pool_queue
```

```
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(p_i)_j = (r_{i-1})_j + \beta((p_{i-1})_j - \omega_{i-1}(v_{i-1})_j)$   (21)
end for
thread_pool_wait
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(y_i)_j = \left(\sum_{k=\max(1,j-\delta l+1)}^{\min(n,j+\delta l-1)} \mu_{j,k}(p_i)_k\right)$   (22)
end for
thread_pool_wait
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(v_i)_j = A(y_i)_j$   (23)
end for
thread_pool_wait
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
do reduction + $d_i$
    $d_i = (r'_0)_j \cdot (v_i)_j$   (24)
end for
thread_pool_wait
    $\alpha = \rho_i / d_i$   (25)
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(x_i)_j = (r_{i-1})_j - \alpha(v_i)_j$   (26)
end for
thread_pool_wait
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(z_i)_j = \left(\sum_{k=\max(1,j-\delta l+1)}^{\min(n,j+\delta l-1)} \mu_{j,k}(x_i)_k\right)$   (27)
end for
thread_pool_wait
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(t_i)_j = A(z_i)_j$   (28)
end for
thread_pool_wait
    $a_1 = 0.0$   (29)
    $a_2 = 0.0$   (30)
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
do reduction + $a_1$ , $a_2$
    $(tt_i)_j = \left(\sum_{k=\max(1,j-\delta l+1)}^{\min(n,j+\delta l-1)} \mu_{j,k}(t_i)_k\right)$   (31)
    $a_1 = (tt_i)_j \cdot (z_i)_j$   (32)
    $a_2 = (tt_i)_j \cdot (tt_i)_j$   (33)
end for
thread_pool_wait
    $\omega_i = a_1 / a_2$   (34)
thread_pool_queue
for j=(1+thread_id*localthr) to (thread_id+1)*localthr
    $(u_i)_j = (u_{i-1})_j + \alpha(y_i)_j + \omega_i(z_i)_j$   (35)
    $(r_i)_j = (x_i)_j - \omega_i(t_i)_j$   (36)
end for
thread_pool_wait
```

The computational complexity of the **PEPBICG-STAB** method is ≈O[(6δl+4 ℓ +16)*localthr* mults + 6*localthr* adds] ν operations, where ν denotes the number of iterations required for convergence to a certain level of accuracy and *localthr* is the number of rows of the matrices distributed onto each thread, [2], [3], [5].

Thus, the theoretical speedup and efficiency of the **PEPBICG-STAB** methods are respectively:

$$S_p^{\delta l} = \frac{1}{\dfrac{1}{\text{nthreads}} + \dfrac{12t_l}{O(6\delta l+4\ell+16)n\cdot t_m}} \qquad (37)$$

and

$$E_p^{\delta l} = \frac{1}{1 + \dfrac{12t_l\cdot \text{nthreads}}{O(6\delta l+4\ell+16)n\cdot t_m}} \qquad (38)$$

where t_m denotes the computational time of a multiplication, while t_l is the threads assignment latencies. It is obvious that for δl→ ∞ , then $S_p^{\delta l}$ →nthreads and $E_p^{\delta l}$ →1, (37)-(38).

The effectiveness of the parallel explicit preconditioned conjugate gradient type method is related to the fact that the approximate inverse × vector and vector × vector can be efficiently implemented on parallel systems, [1], [2], [5], [13].

III. Numerical Results

In this section we examine the effectiveness and applicability of the new proposed parallel schemes for solving characteristic two dimensional boundary value problems, on multicore computer systems, using POSIX threads, [1], [13]. The numerical test runs were performed on a Dual 2x Intel Xeon server at 2.0 GHz with 12MB cache memory, 8GB RAM and 1333MHz bus, running Debian GNU/Linux (University College at Cork, Ireland).

Let us consider the following 2D-boundary value problem:

$$\Delta u(x,y)+u(x,y) = f(x,y), \quad (x,y) \in R \qquad (39)$$

$$u(x,y)=0, \quad (x,y) \in \partial R, \qquad (39.a)$$

Table I

The convergence behavior of the **PEPBICG-STAB** method for several values of n, m, and δl with number of threads=1.

n	m	Number of iterations of PEPBICG-STAB method				
		“Retention” parameter δl

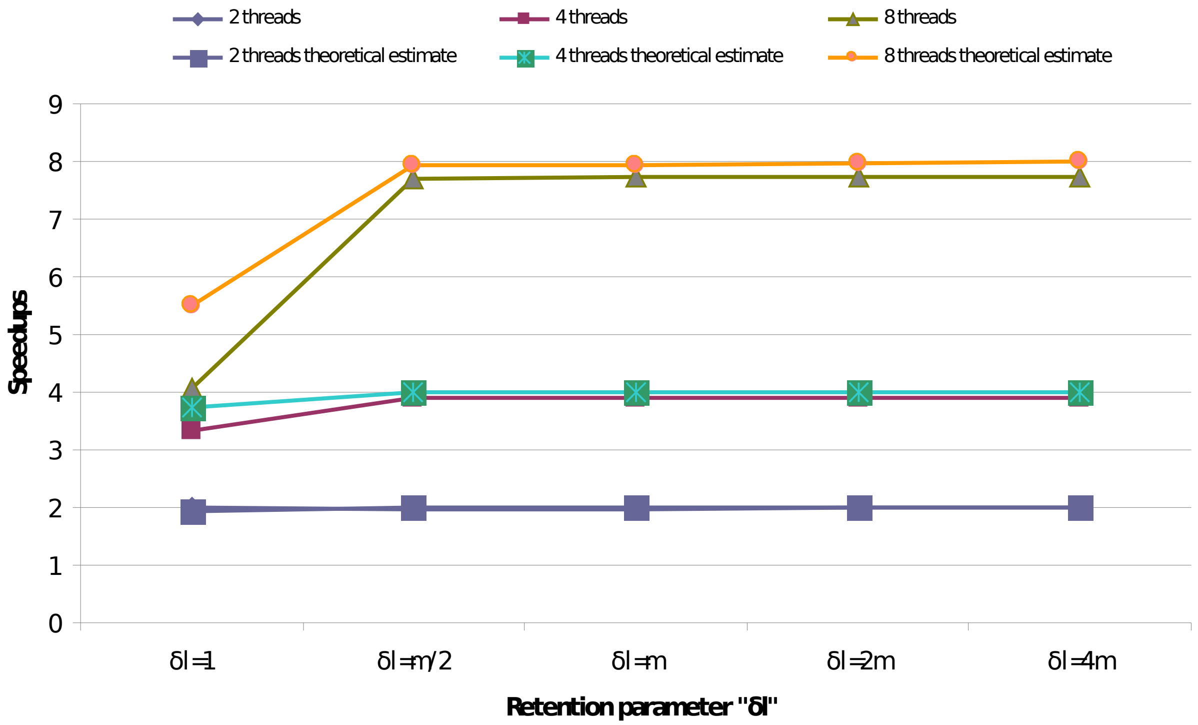

Fig 1. Speedups versus the retention parameter δl for the **PEPBICG-STAB** method, along with theoretical upper bounds, for n=202500.

where Δ is the Laplace operator, R is the unit square and ∂R denotes the boundary of R. The domain R∪∂R was covered by a non-overlapping triangular network resulting in a hexagonal mesh. The right hand side vector of the sparse linear system (1) was computed as the product of the coefficient matrix A by the solution vector, with its components equal to unity. The "width" parameter was set to $\ell=3$ and the "fill-in" parameter to r=2. The iterative process was terminated when $\|u_{i+1}-u_i\|_\infty < 10^{-5}$, [6], [8], [10].

The convergence behavior and the performance, given in "seconds.hundreds", of the **PEPBICG-STAB** method for several values of the order n, semi-bandwidth m and "retention" parameter δl is presented in Table I and Table II respectively. The speedups and number of threads allocated of the **PEPBICG-STAB** method for several values of the order n, semi-bandwidth m and "retention" parameter δl are given in Table III.

In Figure 1 the speedups and number of threads allocated for several values of δl along with theoretical estimates, are presented for the **PEPBICG-STAB** method.

It should be mentioned that the convergence behavior of the explicit preconditioned biconjugate conjugate gradient method was found to be in qualitative agreement with similar theoretical estimates obtained, [6], [10]. Additionally, when the "retention" parameter δl=1 the speedups and the efficiency are significantly improved, while for larger values of the "retention" parameter, i.e. multiples of the semi-bandwidth m, the speedups and the efficiency are slightly improved in comparison with results obtained on a multiprocessor system using OpenMP, [2].

Finally, it is pointed out that for large values of the "retention" parameter δl the speedups and the efficiency tend to the upper theoretical bound, for the parallel explicit preconditioned biconjugate conjugate gradient method, since the coarse granularity amortizes the parallelization overheads.

IV. Acknowledgment

The author would like to express his thanks to Dr. John Morrison of the Department of Computer Science, University College of Cork, for the provision of suitable computational facilities and support through the WebCom-G project funded by Science Foundation Ireland. The author wishes to acknowledge the SFI/HEA Boole Centre for Research in Informatics and the Centre for Unified Computing for the provision of computational facilities and support. Part of this work is partially funded by Science Foundation Ireland and the Higher Education Authority under the Cosmogrid project.

***Abstract*—We will consider** balanced **directed graphs, i.e., graphs of binary relations, for which the number of inputs and number of outputs are the same for each vertex. The commutative diagram is formed by two directed paths for which the same starting and ending points form the full list of common vertices. We refer to the length of the maximal path (the number of arrows) as the rank of the diagram. We will count a directed cycle of length m as a commutative diagram of rank m. We define the** girth indicator gi, gi ≥ 2 **of the directed graph as the minimal rank of its commutative diagram.**

We observe briefly the applications of finite automata related to balanced graphs of high girth in Cryptography. Finally, for each finite commutative ring K with more than two regular elements we consider the explicit construction of algebraic over K family of graphs of high girth and discuss the implementation of the public key algorithm based on finite automata corresponding to members of the family.

I. Introduction

CLASSICAL problems on Turan type problems on studies of the maximal size of simple graphs without prohibited cycles are attractive for mathematicians because they are beautiful and difficult (see [1], [9]). The concept of a family of simple graphs of large girth appears as an important tool to study such problems. Later the applications of these problems in Networking [2], Coding Theory and Cryptography were found (see [15 and further references]).

Section 2 is devoted to the concept of the girth indicator and the family of large girth for digraphs.

In Section 3 we consider the definition of a family of affine algebraic digraphs of large girth over commutative rings. Explicit constructions of such families of graphs can be used for the development of public keys and a key exchange protocol. We discuss the connection of these algorithms with the group theoretical discrete logarithm problem.

The known examples of families of simple algebraic graphs were constructed just in the case of finite fields (see [5]). In section 4 we consider an explicit construction of a family of affine algebraic digraphs of large girth over each finite commutative ring containing at least 3 regular elements. Different properties of this family are investigated in [14], [15], [17] [18] , [20], [7], [8].

Section 5 is devoted to the latest implementation of the public key algorithm based on one of the family described in section 4.

II. On the families of directed graphs of large girth

The missing theoretical definitions on directed graphs the reader can find in [6]. Let Φ be an irreflexive binary relation over the set V, i.e., $\Phi \in V \times V$ and for each v the pair (v, v) is not the element of Φ.

We say that u is the neighbour of v and write $v \rightarrow u$ if $(v, u) \in \Phi$. We use the term *balanced binary relation graph* for the graph Γ of irreflexive binary relation ϕ over a finite set V such that for each $v \in V$ the sets $\{x|(x, v) \in \phi\}$ and $\{x|(v, x) \in \phi\}$ have the same cardinality. It is a directed graph without loops and multiple edges. We say that a balanced graph Γ is k-regular if for each vertex $v \in \Gamma$ the cardinality of $\{x|(v, x) \in \phi\}$ is k.

Let Γ be the graph of binary relation. The *path* between vertices a and b is the sequence $a = x_0 \rightarrow x_1 \rightarrow \dots x_s = b$ of length s, where x_i, $i = 0, 1, \dots s$ are distinct vertices.

We say that the pair of paths $a = x_0 \rightarrow x_1 \rightarrow \cdots \rightarrow x_s = b$, $s \geq 1$ and $a = y_0 \rightarrow y_1 \rightarrow \cdots \rightarrow y_t = b$, $t \geq 1$ form an (s, t)- commutative diagram $O_{s,t}$ if $x_i \neq y_j$ for $0 < i < s$, $0 < j < t$. Without loss of generality we assume that $s \geq t$.

We refer to the number $\max(s, t)$ as the rank of $O_{s,t}$. It is ≥ 2, because the graph does not contain multiple edges.

Notice that the graph of antireflexive binary relation may have a directed cycle $O_s = O_{s,0}$: $v_0 \rightarrow v_1 \rightarrow \dots v_{s-1} \rightarrow v_0$, where v_i, $i = 0, 1, \dots, s-1$, $s \geq 2$ are distinct vertices.

We will count directed cycles as commutative diagrams.

For the investigation of commutative diagrams we introduce *girth indicator* gi, which is the minimal value for $\max(s, t)$ for parameters s, t of a ommutative diagram $O_{s,t}$, $s + t \geq 3$. The minimum is taken over all pairs of vertices (a, b) in the digraph. Notice that two vertices v and u at distance $<$ gi are connected by the unique path from u to v of length $<$ gi.

We assume that the *girth* $g(\Gamma)$ of a directed graph Γ with the girth indicator $d+1$ is $2d+1$ if it contains a commutative diagram $O_{d+1,d}$. If there are no such diagrams we assume that $g(\Gamma)$ is $2d+2$.

In case of a symmetric binary relation $\mathrm{gi} = d$ implies that the girth of the graph is $2d$ or $2d-1$. It does not contain an even cycle $2d-2$. In general case $\mathrm{gi} = d$ implies that $g \geq d+1$. So in the case of the family of graphs with unbounded girth indicator, the girth is also unbounded. We also have $\mathrm{gi} \geq g/2$.

In the case of symmetric irreflexive relations the above mentioned general definition of the girth agrees with the standard definition of the girth of simple graph, i.e., the length of its minimal cycle.

We will use the term *the family of graphs of large girth* for the family of balanced directed regular graphs Γ_i of degree k_i and order v_i such that $\mathrm{gi}(\Gamma_i)$ is $\geq c\log_{k_i} v_i$, where c' is a constant independent of i.

As it follows from the definition $g(\Gamma_i) \geq c'\log_{k_i}(v_i)$ for an appropriate constant c'. So, it agrees with the well known definition for the case of simple graphs.

The diameter of the strongly connected digraph [6] is the minimal length d of the shortest directed path $a = x_0 \to x_1 \to x_2 \cdots \to x_d$ between two vertices a and b. Recall that a graph is k-regular, if each vertex of G has exactly k outputs. Let F be the infinite family of k_i regular graphs G_i of order v_i and diameter d_i. We say, that F is a family of small world graphs if $d_i \leq C\log_{k_i}(v_i)$, $i = 1, \ldots$ for some constant C independent on i. The definition of small world simple graphs and related explicit constructions the reader can find in [3]. For the studies of small world simple graphs without small cycles see [9], [20] and [33].

III. On the K-theory of affine graphs of high girth and its cryptographical motivations

Let K be a commutative ring. A *directed algebraic graph* ϕ over K consists of two things, such as the *vertex set* Q being a quasiprojective variety over K of nonzero dimension and the *edge set* being a quasiprojective variety ϕ in $Q \times Q$. We assume that ($x\phi y$ means $(x, y) \in \phi$).

The graph ϕ is *balanced* if for each vertex $v \in Q$ the sets $\mathrm{Im}(v) = \{x \mid v\phi x\}$ and $\mathrm{Out}(v) = \{x \mid x\phi v\}$ are quasiprojective varieties over K of the same dimension.

The graph ϕ is *homogeneous* (or (r, s)-homogeneous) if for each vertex $v \in Q$ the sets $\mathrm{Im}(v) = \{x|v\phi x\}$ and $\mathrm{Out}(v) = \{x|x\phi v\}$ are quasiprojective varieties over F of fixed nonzero dimensions r and s, respectively.

In the case of *balanced homogeneous algebraic graphs* for which $r = s$ we will use the term r-homogeneous graph. Finally, *regular algebraic graph* is a balanced homogeneous algebraic graph over the ring K if each pair of vertices v_1 and v_2 is a pair of isomorphic algebraic varieties.

Let $\mathrm{Reg}(K)$ be the totality of regular elements (or nonzero divisors) of K, i.e., nonzero elements $x \in K$ such that for each nonzero $y \in K$ the product xy is different from 0. We assume that the $\mathrm{Reg}(K)$ contains at least 3 elements. We assume here that K is finite, thus the vertex set and the edge set are finite and we get a usual finite directed graph.

We apply the term *affine graph* for the regular algebraic graph such that its vertex set is an affine variety in Zarisski topology.

Let G be r-regular affine graph with the vertex $V(G)$, such that Out v, $v \in V(G)$ is isomorphic to the variety $R(K)$. Let the variety $E(G)$ be its arrow set (a binary relation in $V(G) \times V(G)$). We use the standard term *perfect algebraic colouring of edges* for the polynomial map ρ from $E(G)$ onto the set $R(K)$ (the set of colours) if for each vertex v different output arrows $e_1 \in \mathrm{Out}(v)$ and $e_2 \in \mathrm{Out}(v)$ have distinct colours $\rho(e_1)$ and $\rho(e_2)$ and the operator $N_\alpha(v)$ of taking the neighbour u of vertex v ($v \to u$) is a polynomial map of the variety $V(G)$ into itself.

We will use the term *rainbow-like colouring* in the case when the perfect algebraic colouring is a bijection. Let $\mathrm{dirg}(G)$ be a directed girth of the graph G, i.e., the minimal length of a directed cycle in the graph. Obviously $\mathrm{gi}(G) \leq \mathrm{dirg}(G)$.

Studies of infinite families of directed affine algebraic digraphs over commutative rings K of large girth with the rainbow-like colouring is a nice and a difficult mathematical problem. Good news is that such families do exist. In the next section we consider the example of such a family for each commutative ring with more than 2 regular elements.

Here, at the end of section, we consider cryptographical motivations for studies of such families.

1) Let G be a finite group and $g \in G$. The discrete logarithm problem for group G is about finding a solution for the equation $g^x = b$ where x is unknown positive number. If the order $|g| = n$ is known we can replace G on a cyclic group C_n. So we may assume that the order of g is sufficiently large to make unfeasible the computation of n. For many finite groups the discrete logarithm problem is NP complete.

Let K be a finite commutative ring and M be an affine variety over K. Then the Cremona group $C(M)$ of all polynomial automorphism of the variety M can be large. For example, if K is a finite prime field F_p and $M = {F_p}^n$ then $C(M)$ is a symmetric group S_{p^n}.

Let us consider the family of affine graphs $G_i(K)$, $i = 1, 2, \ldots$ with the rainbow-like algebraic colouring of edges such that $V(G_i(K)) = V_i(K)$, where K is a commutative ring, and the colour sets are algebraic varieties $R_i(K)$. Let us choose a constant k. The operator $N_\alpha(v)$ of taking the neighbour of a vertex v corresponding to the output arrow of colour α are elements of $C_i = C(V_i(K))$. We can chose a relatively small number k to generate $h = h_i = N_{\alpha_1} N_{\alpha_2} \ldots N_{\alpha_k}$ in each group C_i, $i = 1, 2, \ldots$

Let us assume that the family of graphs $G_i(K)$ is the family of graphs of large girth. It means that the girth indicator $\mathrm{gi}_i = \mathrm{gi}(G_i(K))$ and the parameter $\mathrm{dirg}_i = \mathrm{dirg}(G_i(K))$ are growing with the growth of i. Notice that $|h_i|$ is bounded below by dirg_i/k. So there is j such that for $i \geq j$ the computation of $|h_i|$ is impossible. Finally we can take the base $g = u^{-1}h_j u$ where u is a chosen element of C_j to hide the graph up to conjugation. We may use some package of symbolic computations to express the polynomial map g via the list of polynomials in many unknowns. For example, if $V_j(K)$ is a free module K^n then we can write g in a public mode fashion

$x_1 \rightarrow g_1(x_1, x_2, \ldots, x_n)$, $x_2 \rightarrow g_2(x_1, x_2, \ldots, x_n)$, ..., $x_n \rightarrow g_n(x_1, x_2, \ldots, x_n)$.

The symbolic map g can be used for Diffie - Hellman *key exchange protocol* (see [3] for the details). Let Alice and Bob be correspondents. Alice computes the symbolic map g and send it to Bob via open channel. So the variety and the map are known for the adversary (Cezar).

Let Alice and Bob choose natural numbers n_A and n_B, respectively.

Bob computes g^{n_B} and sends it to Alice, who computes $(g^{n_B})^{n_A}$, while Alice computes g^{n_A} and sends it to Bob, who is getting $(g^{n_A})^{n_B}$. The common information is $g^{n_A n_B}$ given in "public mode fashion".

Bob can be just a public user (no information on the way in which the map g were cooked) , so he and Cezar are making computations much slower than Alice who has the decomposition $g = u^{-1} N_{\alpha_1} N_{\alpha_2} \ldots N_{\alpha_k} u$.

We may modify slightly the Diffie - Hellman protocol using the action of the group on the variety. Alice chooses a rather short password $\alpha_1, \alpha_2, \ldots, \alpha_k$, computes the public rules for the encryption map g and sends them to Bob via an open channel together with some vertex $v \in V_j(K)$.

Then Alice and Bob choose natural numbers n_A and n_B, respectively.

Bob computes $v_B = g^{n_B}(v)$ and sends it openly to Alice, who computes $(g^{n_A})(v_B)$, while Alice computes $v_A = g^{n_A}(v)$ and sends it to Bob, who is getting $(g^{n_B})(v_A)$.

The common information is the vertex $g^{n_A \times n_B}(v)$.

In both cases Cezar has to solve one of the equations $E^{n_B}(u_A) = z$ or $E^{n_A}(u_B) = w$ for unknowns n_B or n_A, where z and w are known points of the variety.

2) We can construct the *public key* map in the following manner:

The key holder (Alice) chooses the variety $V_j(K)$ and the sequence $\alpha_1, \alpha_2, \ldots, \alpha_t$ of length $t = t(j)$ to determine the encryption map g as above. Let $\dim(V_j(K) = n = n(j)$ and each element of the variety be determined by independent parameters $x_1, x_2, \ldots, x_n$. Alice presents the map in the form of public rules, such as

$x_1 \rightarrow f_1(x_1, x_2, \ldots, x_n)$, $x_2 \rightarrow f_2(x_1, x_2, \ldots, x_n)$, ..., $x_n \rightarrow f_n(x_1, x_2, \ldots, x_n)$.

We can assume (at least theoretically) that the public rule depending on parameter j is applicable to encryption of potentially infinite text (parameter t is a linear function on j now).

For the computation she may use the Gröbner base technique or alternative methods, special packages for the symbolic computation (popular "Mathematica" or "Maple", package "Galois" for "Java" as well special fast symbolic software). So Alice can use the decomposition of the encryption map into u^{-1}, maps of kind N_α and u to encrypt fast. For the decryption she can use the inverse graph $G_j(K)^{-1}$ for which $VG_j(K)^{-1} = VG_j(K)$ and vertices w_1 and w_2 are connected by an arrow if and only if w_2 and w_1 are connected by an arrow in $G_j(K)$. Let us assume that colours of $w_1 \rightarrow w_2$ in $G_j(K)^{-1}$ and $w_2 \rightarrow w_1$ in $G_j(K)$ are of the same colour. Let $N'_\alpha(x)$ be the operator of taking the neighbour of vertex x in $G_j(K)^{-1}$ of colour α. Then Alice can decrypt applying consequently $u^{-1}, N'_{\alpha_t}, N'_{\alpha_{t-1}}, \ldots, N_{\alpha_1}$ and u to the ciphertext. So the decryption and the encryption for Alice take the same time. She can use a numerical program to implement her symmetric algorithm.

Bob can encrypt with the public rule but for a decryption he needs to invert the map. Let us consider the case $t_j = kl$, where k is a small number and the sequence $\alpha_1, \alpha_2, \ldots, \alpha_{t_j}$ has the period k and the transformation $h = u^{-1} N_{\alpha_1} N_{\alpha_2} \ldots N_{\alpha_k} u$ is known for Bob in the form of public key mode. In such a case a problem to find the inverse for g is equivalent to a discrete logarithm problem with the base h in related Cremona group of all polynomial bijective transformations.

Of course for further cryptoanalysis we need to study the information on possible divisors of order of the base of related discrete logarithm problem, alternative methods to break the encryption. In the next section the family of digraphs $RE_n(K)$ will be described.

3) We may study security of the private key algorithm used by Alice in the algorithm of the previous paragraph but with a parameter t bounded by the girth indicator of graph $G_j(K)$. In that case different keys produce distinct ciphertexts from the chosen plaintext. In that case we prove that if the adversary has no access to plaintexts then he can break the encryption via the brut-force search via all keys from the key space. The encryption map has no fixed points.

IV. On the family of affine digraph of large girth over commutative rings

E. Moore used term *tactical configuration* of order (s, t) for biregular bipartite simple graphs with bidegrees $s + 1$ and $r + 1$. It corresponds to the incidence structure with the point set P, the line set L and the symmetric incidence relation I. Its size can be computed as $|P|(s + 1)$ or $|L|(t + 1)$.

Let $F = \{(p, l)|p \in P, l \in L, pIl\}$ be the totality of flags for the tactical configuration with partition sets P (point set) and L (line set) and an incidence relation I. We define the following irreflexive binary relation ϕ on the set F:

Let (P, L, I) be the incidence structure corresponding to regular tactical configuration of order t.

Let $F_1 = \{(l, p)|l \in L, p \in P, lIp\}$ and $F_2 = \{[l, p]|l \in L, p \in P, lIp\}$ be two copies of the totality of flags for (P, L, I). Brackets and parenthesis allow us to distinguish elements from F_1 and F_2. Let $DF(I)$ be the directed graph (double directed flag graph) on the disjoint union of F_1 with F_2 defined by the following rules

$(l_1, p_1) \rightarrow [l_2, p_2]$ if and only if $p_1 = p_2$ and $l_1 \neq l_2$,

$[l_2, p_2] \rightarrow (l_1, p_1)$ if and only if $l_1 = l_2$ and $p_1 \neq p_2$.

Below we consider the family of graphs $D(k, K)$, where $k > 5$ is a positive integer and K is a commutative ring. Such graphs are disconnected and their connected components were investigated in [17] (for the case when K is a finite field F_q see [5]).

Let P and L be two copies of Cartesian power K^N, where K is the commutative ring and N is the set of positive integer numbers. Elements of P will be called *points* and those of L *lines*.

To distinguish points from lines we use parentheses and brackets. If $x \in V$, then $(x) \in P$ and $[x] \in L$. It will also be advantageous to adopt the notation for co-ordinates of points and lines introduced in [16] for the case of general commutative ring K:

$$\begin{aligned}(p) &= (p_{0,1}, p_{1,1}, p_{1,2}, p_{2,1}, p_{2,2}, p'_{2,2}, p_{2,3}, \ldots, \\ &\quad p_{i,i}, p'_{i,i}, p_{i,i+1}, p_{i+1,i}, \ldots), \\ [l] &= [l_{1,0}, l_{1,1}, l_{1,2}, l_{2,1}, l_{2,2}, l'_{2,2}, l_{2,3}, \ldots, \\ &\quad l_{i,i}, l'_{i,i}, l_{i,i+1}, l_{i+1,i}, \ldots].\end{aligned}$$

The elements of P and L can be thought as infinite ordered tuples of elements from K, such that only a finite number of components are different from zero.

We now define an incidence structure (P, L, I) as follows. We say that the point (p) is incident with the line $[l]$, and we write $(p)I[l]$, if the following relations between their coordinates hold:

$$\begin{aligned}l_{i,i} - p_{i,i} &= l_{1,0}p_{i-1,i} \\ l'_{i,i} - p'_{i,i} &= l_{i,i-1}p_{0,1} \\ l_{i,i+1} - p_{i,i+1} &= l_{i,i}p_{0,1} \\ l_{i+1,i} - p_{i+1,i} &= l_{1,0}p'_{i,i}\end{aligned}$$

(These four relations are defined for $i \geq 1$, $p'_{1,1} = p_{1,1}$, $l'_{1,1} = l_{1,1}$). This incidence structure (P, L, I) we denote as $D(K)$. We identify it with the bipartite *incidence graph* of (P, L, I), which has the vertex set $P \cup L$ and the edge set consisting of all pairs $\{(p), [l]\}$ for which $(p)I[l]$.

For each positive integer $k \geq 2$ we obtain an incidence structure (P_k, L_k, I_k) as follows. First, P_k and L_k are obtained from P and L, respectively, by simply projecting each vector onto its k initial coordinates with respect to the above order. The incidence I_k is then defined by imposing the first $k-1$ incidence equations and ignoring all others. The incidence graph corresponding to the structure (P_k, L_k, I_k) is denoted by $D(k, K)$.

For each positive integer $k \geq 2$ we consider the *standard* graph homomorphism ϕ_k of (P_k, L_k, I_k) onto $(P_{k-1}, L_{k-1}, I_{k-1})$ defined L_k by simply projection of each vector from P_k and L_k onto its $k-1$ initial coordinates with respect to the above order.

Let $DE_n(K)$ $(DE(K))$ be the double directed graph of the bipartite graph $D(n, K)$ $(D(K)$, respectively). Remember, that we have the arc e of kind $(l^1, p^1) \rightarrow [l^2, p^2]$ if and only if $p^1 = p^2$ and $l^1 \neq l^2$. Let us assume that the colour $\rho(e)$ of the arc e is $l^1_{1,0} - l^2_{1,0}$.

Recall, that we have the arc e' of kind $[l^2, p^2] \rightarrow (l^1, p^1)$ if and only if $l^1 = l^2$ and $p^1 \neq p^2$. Let us assume that the colour $\rho(e')$ of arc e' is $p^1_{1,0} - p^2_{1,0}$. It is easy to see that ρ is a perfect algebraic colouring.

If K is finite, then the cardinality of the colour set is $(|K| - 1)$. Let Reg$K$ be the totality of regular elements, i.e., not zero divisors. Let us delete all arrows with colour, which is a zero divisor. We will show that a new graph $RE_n(K)$ $(RE(K))$ with the induced colouring into colours from the alphabet $\mathrm{Reg}(K)$ is vertex transitive. Really, according to [31] graph $D(n, K)$ is an edge transitive. This fact had been established via the description of regular on the edge set subgroup $U(n, K)$ of the automorphisms group $\mathrm{Aut}(G)$. The vertex set for the graph $DE_n(K)$ consists of two copies F_1 and F_2 of the edge set for $D(n, K)$. It means that Group $U(n, K)$ acts regularly on each set F_i, $i = 1, 2$. An explicit description of generators for $U(n, K)$ implicates that this group is a colour preserving group for the graph $DE_n(K)$ with the above colouring.

If K is finite, then the cardinality of the colour set is $(|K| - 1)$. Let Reg$K$ be the totality of regular elements, i.e., nonzero divisors. Let us delete all arrows with colour, which is a zero divisor. We can show that a new affine graph $RE_n(K)$ $(RE(K))$ with the induced colouring into colours from the alphabet $\mathrm{Reg}(K)$ is vertex transitive (see [18]).

V. On the implementation of the public key algorithm based on $RE(t, K)$

The graphs $CRE_n(K)$ have the best known speed of growth of the girth indicator evaluated in the previous section. It turns out that for the computer implementation of the public key algorithm described in the section 4 the family $RE_n(K)$ of "enveloping" for $CRE_n(K)$ graphs were chosen first. It is also a family of digraphs of large girth but the speed of the growth of girth indicator for the family is less of those for $RE_n(K)$. Graphs $RE_n(K)$ were defined via the family of graphs $D(n, K)$ in the way described in the previous section. So, in some publications the description of the algorithm was done in terms of $D(n, K)$. We introduced here a speed evaluation of the algorithm for its latest implementation.

The set of vertices of the graph $RE_n(K)$ is a union of two copies free module K^{n+1}. So the Cremona group of the variety is the direct product of $C(K^{n+1})$ with itself, expanded by polarity π. In the simplest case of a finite field F_p, where p is a prime number $C(F_p)$ is a symmetric group $S_{p^{n+1}}$. The Cremona group $C(K^{n+1})$ contains the group of all affine invertible transformations, i.e., transformation of kind $\mathrm{x} \rightarrow \mathrm{x}A + \mathrm{b}$, where $\mathrm{x} = (x_1, x_2, \ldots, x_{n+1}) \in C(K^{n+1})$, $\mathrm{b} = (b_1, b_2, \ldots, b_{n+1})$ is a chosen vector from $C(K^{n+1})$ and A is a matrix of a linear invertible transformation of K^{n+1}.

Graph $RE_n(K)$ is a bipartite directed graph. We assume that the plaintext K^{n+1} is a point $(p_1, p_2, \ldots, p_{n+1})$. We choose two affine transformations T_1 and T_2 and a linear transformation u will be of kind $p_1 \rightarrow p_1 + a_1p_2 + a_3p_3 + \cdots + a_{n+1}$. We slightly modify a general scheme, so Alice computes symbolically of chosen T_1 and T_2, chooses a string $(\beta_1, \beta_2, \ldots, \beta_l)$ of colours for $RE_n(K)$, such that $\beta_i \neq -\beta_{i+1}$ for $i = 1, 2, \ldots, l-1$. She computes $N_l = N_{\beta_1} \times N_{\beta_2} \cdots \times N_{\beta_l}$.

Recall that N_α, $\alpha \in \mathrm{Reg}(K)$ is the operator of taking the neighbour of the vertex v alongside the arrow with the colour α in the graph $RE_n(K)$.

Alice keeps chosen parameters secret and computes the public rule g as the symbolic composition of T_1, N and T_2. The case $uT_2 = {T_1}^{-1}$ is a special form of the general algorithm considered in chapter 4.

In case $K = F_q$, $q = 2^n$ this public key rule has a certain similarity to the Imai-Matsomoto public rule, which is computed as a composition T_1ET_2 of two linear transformations T_1 and T_2 of the vector space $F_{2^n F_{2^s}}$, where F_{2^s} is a special subfield, and E is a special Frobenius automorphism of F_{2^n}. The public rule corresponding to T_1ET_2 is a quadratic polynomial map (see [3] for the detailed description of the algorithm, its cryptoanalisis and generalisations by J. Patarin)

In the case of $RE_n(K)$ the degree of transformation N_l is 3, independently on the choice of length l [21]. So the public rule is a cubical polynomial map of the free module K^{n+1} onto itself. In case of a finite field the algorithm is equivalent to the public rule considered in [19.]

In our computer implementations we used T_1 and T_2 of kind $p_1 \to p_1 + a_1p_2 + a_3p_3 + \cdots + a_{n+1}p_{n+1}$.

A. Time evaluation of the private key algorithm for Alice

Alice can use numerical algorithms for the encryption. The decryption ${T_2}^{-1}N_{-\alpha_l}N_{-\alpha_{l-1}}\dots N_{-\alpha_1}{T_1}^{-1}$ takes the same time as the encryption.

In [4] we have implemented a computer application, which uses the family of graphs $RDE(n, K)$ for *private key* cryptography. To achieve high speed, we will use commutative rings $K = Z_{2^k}$, $k \in \{8, 16, 32\}$, with operations $+, \times$ modulo 2^k. The parameter n stands for the length of a plaintext (input data) and the length of a ciphertext. Later on we use a loaded multiplication tables for finite fields and implement cases of finite fields $K = F_{2^k}$, $k \in \{8, 16, 32\}$. We denote by $G1$ the algorithm with $k = 8$, by $G2$ the algorithm with $k = 16$, and by $G4$ the algorithm with $k = 32$. So $Gi, i \in 1, 2, 4$ denotes the number of bytes used in the alphabet (and the size of 1 character in the string).

All the tests were run on a computer with parameters:

- AMD Athlon 1.46 GHz processor
- 1 GB RAM memory
- Windows XP operating system.

The program is written in Java language. Well known algorithms RC4 which is used for comparison is taken from Java standard library for cryptography purposes - *javax.crypto*.

RC4 is a well known and widely used stream cipher algorithm. Protocols SSL (to protect Internet traffic) and WEP (to secure wireless networks) use RC4 as an option. Nowadays RC4 is not secure enough. Anyway we chose it for comparison, because of its popularity and high speed.

RC4 is not dependent on the password length in terms of complexity, and our algorithm is. Longer password makes us do more steps between vertices of graph. So for fair comparison we have used a fixed password length equal suggested upper bound for RC4 (16 Bytes).

TABLE II
TIME OF ENCRYPTION

	$w = 1$ ($\mathbb{Z}_{2^8}$)	$w = 2$ ($\mathbb{Z}_{2^{16}}$)	$w = 4$ ($\mathbb{Z}_{2^{32}}$)
$n = 20$	16	0	0
$n = 40$	265	47	15
$n = 60$	1375	188	15
$n = 80$	3985	578	47
$n = 100$	10078	1360	125

The speed of execution of the above implementation compares well with implementations of other graph based symmetric encryption algorithms [10], [12], [16].

B. On the time evaluation for the public rule

Recall, that we combine a graph transformation N_l with two affine transformation T_1 and T_2. Alice can use $T_1N_lT_2$ for the construction of the following public map of

$$y = (F_1(x_1, \dots, x_n), \dots, F_n(x_1, \dots, x_n))$$

$F_i(x_1, \dots, x_n)$ are polynomials of n variables written as the sums of monomials of kind $x_{i+1} \dots x_{i_3}$, where $i_1, i_2, i_3 \in 1, 2, \dots, n_1$ with the coefficients from $K = F_q$. As we mention before the polynomial equations $y_i = F_i(x_1, x_2, \dots, x_n)$, which are made public, have the degree 3. Hence the process of an encryption and a decryption can be done in polynomial time $O(n^4)$ (in one y_i, $i = 1, 2 \dots, n$ there are $2(n^3 - 1)$ additions and multiplications). But the cryptoanalyst Cezar, having only a formula for y, has a very hard task to solve the system of n equations of n variables of degree 3. It is solvable in exponential time $O(3^{n^4})$ by the general algorithm based on Gröbner basis method. Anyway studies of specific features of our polynomials could lead to effective cryptoanalysis. This is an open problem for specialists.

We have written a program for generating a public key and for encrypting text using the generated public key. The program is written in C++ and compiled with the Borland bcc 5.5.1 compiler.

We use a matrix in which all diagonal elements equal 1, elements in the first row are non-zero and all other elements are zero as A, identity matrix as B and null vectors as c and d. In such a case the cost of executing affine transformations is linear.

The table **??** presents the time (in milliseconds) of the generation of the public key depending on the number of variables (n) and the password length (p).

The table **??** presents the time (in milliseconds) of encryption process depending on the number of bytes in plaintext (n) and the number of bytes in a character (w).

***Abstract*—We consider two nonlinear methods for generating uniform pseudo-random numbers in [0, 1), namely quadratic congruential generator and inversive congruential generator. The combinations of the Van der Corput sequence with the considered nonlinear generators are proposed. We simplify the mixed sequences by a restriction of the b-adic representation of the points.**

We study numerically the b-adic diaphony of the nets obtained through quadratic congruential generator, inversive congruential generator, their combinations with the Van der Corput sequence, and the simplification of the mixed sequences. The value of the b-adic diaphony decreases with the increase of the number of the points of the simplified sequences which proves that the points of the simplified sequences are pseudo-random numbers. The analysis of the results shows that the combinations of the Van der Corput sequence with these nonlinear generators have good pseudo-random properties as well as the generators.

I. Introduction

Many branches of the contemporary science research as stochastic simulation, stochastic optimization techniques, computational statistics, Monte Carlo simulation, molecular dynamics, cryptography, computer graphics, etc., depend on the random numbers [3], [4], [16], [19]–[21], [29]. In practice, random numbers are generated by deterministic recursive rules, formulated in terms of simple arithmetic operations. Obviously the emerging numbers can at best be pseudo-random. To design random number generators that approximate "true randomness" as closely as possible, is a great challenge. Except this obvious requirement, pseudo-random number generators should possess reproducible results, they should be portable between different computer architectures, and since in most applications millions of random numbers are needed, generators should be as efficient as possible.

The fields of probability and statistics are built over the abstract concepts of probability space and random variable. This has given rise to elegant and powerful mathematical theory, but exact implementation of these concepts on conventional computers seems impossible. Random variables and other random objects are simulated by deterministic algorithms. The purpose of these algorithms is to produce sequences of numbers or objects whose behavior is almost undistinguishable from that of their "truly random" counterparts, at least for the application of interest. Depending on the context, pseudo-random number generators must satisfy different requirements.

For Monte Carlo methods, the main aim is to reproduce the statistical properties on which these methods are based, so that the Monte Carlo estimators have a behavior as expected. On the other hand, for gambling machines and cryptology, observing the sequence of output values for some time should provide no practical advantage for predicting the forthcoming numbers better than by just guessing at random. In computational statistics, random variate generation is usually made in two steps. The first step is generating imitate ions of independent and identically distributed (i.i.d.) random variables having the uniform distribution over the interval (0, 1). And the second step is applying transformations to these i.i.d. $U(0,1)$ random variates in order to generate (or imitate) random variates and random vectors from arbitrary distributions. The expression (pseudo-)random number generator (RNG) usually refers to an algorithm used for first step. In principle, the simplest way of generating a random variate X with distribution function F from a $U(0,1)$ random variate U is to apply the inverse of F to $U : X = F^{-1}(U) \overset{\mathrm{def}}{=} \min\{x|F(x) \geq U\}$. This is the inversion method. It is easily seen that X has the desired distribution: $P[X \leq x] = P[F^{-1}(U) \leq x] = P[U \leq F(x)] = F(x)$. Other methods are sometimes preferable when F^{-1} is too difficult or expensive to compute.

The basic ingredients of any stochastic simulation are uniform pseudo-random numbers in the interval $[0,1)$. The outcome of a typical stochastic simulation strongly depends on the structural and statistical properties of the underlying pseudo-random number generators. That is why their quality is of fundamental importance for the success of the simulation. The classical and most frequently used method for the generation of pseudo-random numbers is still the linear congruential

978-83-60810-27-9/09/$25.00 © 2010 IEEE

method. However, its simple linear nature implies several undesirable regularities. Mainly for this reason, a variety of nonlinear methods for the generation of pseudo-random numbers has been introduced and studied as alternatives to the linear congruential method. These nonlinear congruential generators provide a very attractive alternative to linear congruential generators and have been extensively studied in the literature [1], [5], [7]–[10], [15], [16], [23], [25]–[28]. Two special cases: the quadratic congruential generator and the inversive congruential generator, are of special interest. A good survey of this important research area is given in [4], [17], [19]–[21], [29]. Many authors study pseudo-random properties of the sequences, generated by quadratic and inversive congruential generators by using the bounds of the discrepancy [2], [6], [11]–[13], [22], [24].

We use the $b-$adic diaphony to study pseudo-random numbers, generated by quadratic and inversive congruential generators. We will recall some known notions and definitions.

Let $\xi = (\mathbf{x}_j)_{j\geq 0}$ be a sequence in $[0,1)^s$ and $J = [\boldsymbol{\alpha}, \boldsymbol{\beta}) \subseteq [0,1)^s$, where $\boldsymbol{\alpha} = (\alpha_1, \dots, \alpha_s)$ and $\boldsymbol{\beta} = (\beta_1, \dots, \beta_s)$. For arbitrary integer M $A_M(\xi; J)$ is the number of belonging to J points of ξ. The sequence $\xi = (\mathbf{x}_j)_{j\geq 0}$ is uniformly distributed mod 1 in $[0,1)^s$ if for every $J = [\boldsymbol{\alpha}, \boldsymbol{\beta}) \subseteq [0,1)^s$ the equality

$$\lim_{M\to\infty} \frac{A_M(\xi; J)}{M} = \prod_{i=1}^{s} (\beta_i - \alpha_i)$$

is hold, see [30].

The above equality shows when a sequence of points in $[0,1)^s$ is uniformly distributed but it does not allow to compare the distributions of two sequences. For that purpose various measures of the distribution of the sequences are used. Such measure is the $b-$adic diaphony [14].

Let $b \geq 2$ be a fixed integer and b denotes the base of the number system everywhere in this paper. Also, let an arbitrary $x \in [0,1)$ have a $b-$adic representation $x = \sum_{l=0}^{\infty} x_l b^{-l-1}$, where for $l \geq 0$, $x_l \in \{0, 1. \dots, b-1\}$ and for infinitely many values of l, $x_l \neq b-1$. The integer part of $b-$adic logarithm of x is $\lfloor \log_b x \rfloor = -g-1$, if $x_l = 0$ for $l < g$ and $x_g \neq 0$. We denote the operation $x \dot{-} y = \sum_{l=0}^{\infty} [(x_l - y_l) (\mathrm{mod}\ b)] b^{-1-l}$ and for vectors $\mathbf{x}, \mathbf{y} \in [0,1)^s$ we note $\mathbf{x} \dot{-} \mathbf{y} = (x_1 \dot{-} y_1, x_2 \dot{-} y_2, \dots, x_s \dot{-} y_s)$, where $\mathbf{x} = (x_1, x_2, \dots, x_s), \mathbf{y} = (y_1, y_2, \dots, y_s)$.

We define the functions $\gamma : [0,1) \to \mathbb{R}$ and $\Gamma : [0,1)^s \to \mathbb{R}$ as

$$\gamma(x) = \begin{cases} b+1-(b+1)b^{1+\lfloor \log_b x \rfloor}, & \text{if } x \in (0,1) \\ b+1, & \text{if } x = 0 \end{cases}$$

and

$$\Gamma(\mathbf{x}) = -1 + \prod_{d=1}^{s} \gamma(x_d), \mathbf{x} = (x_1, x_2, \dots, x_s).$$

The $b-$adic diaphony $F_N(\xi)$ of the first N elements of the sequence $\xi = (\mathbf{x}_i)_{i\geq 0}$ in $[0,1)^s$ is defined as

$$F_N(\xi) = \left(\frac{1}{(b+1)^s - 1} \frac{1}{N^2} \sum_{i=0}^{N-1} \sum_{j=0}^{N-1} \Gamma(\mathbf{x}_i \dot{-} \mathbf{x}_j) \right)^{\frac{1}{2}},$$

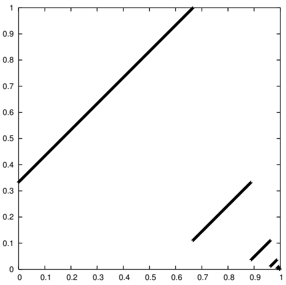

Fig. 1. The distribution of points of the Van der Corput sequence with $N = 1024$, $b = 3$.

where the coordinates of all points of the sequence ξ are $b-$adic rational.

Let $i = \sum_{l=0}^{\infty} i_l b^l$ be the $b-$adic representation of the non-negative integer i. Then the i-th element of the Van der Corput sequence is defined as

$$\zeta_b(i) = \sum_{l=0}^{\infty} i_l b^{-l-1}.$$

The Van der Corput sequence is deterministic sequence and does not have pseudo-random properties. The distribution of 1024 points of the net

$$(\zeta_b(i), \zeta_b(i+1))$$

is seen on Fig. 1.

II. Nonlinear Congruential Generators

Let $M \geq 2$ be modulus of a nonlinear congruential generator. The sequence of pseudo-random numbers $\left\{ x_i = \frac{y_i}{M} \right\}$ is produced by nonlinear congruential generator $y_{i+1} = f_M(y_i), \quad y_i \in [0, M), \quad \forall i = 0, 1, \dots$, where $y_0 \in [0, M)$ is the initial starting point. The study of the pseudo-randomness of the sequence $x_i, i = 0, 1, \dots$ is connected with the estimation of the distribution of the two-dimensional net

$$(x_i, x_{i+1}) = \left(\frac{y_i}{M}, \frac{y_{i+1}}{M} \right). \qquad (1)$$

Our aim is a numerical computing of the $b-$adic diaphony F_N of these two-dimensional nets. For the function f_M we use two nonlinear congruential generators: quadratic generator and inversive generator.

The quadratic congruential generator (QCG) is introduced by Knuth [17] and studied by [2], [11], [12]. This generator is defined as

$$f_M^{QCG}(y_i) \equiv q_2 y_i^2 + q_1 y_i + q_0 (\mathrm{mod}\ M),$$
$$y_{i+1} = f_M^{QCG}(y_i), \quad y_i \in [0, M), \qquad (2)$$

where q_2, q_1, q_0 are three integer parameters.

The inversive congruential generator (ICG) is defined as

$$f_M^{ICG}(y_i) \equiv \begin{cases} r_{-1} y_i^{-1} + r_0 (\mathrm{mod}\ M), & \text{if } y_i \geq 1, \\ r_0, & \text{if } y_i = 0, \end{cases}$$

where r_{-1}, r_0 are integer parameters and y_i^{-1} denotes the inversive element of y_i, i.e. $y_i^{-1} y_i \equiv 1 (\bmod\ M)$,

$$y_{i+1} = f_M^{ICG}(y_i), \quad y_i \in [0, M). \tag{3}$$

In this paper we consider generators with modulus $M = 2^\mu$, $\mu \geq 4$. In this case the quadratic congruential generator (2) is purely periodic with maximum possible period length $M = 2^\mu$ if and only if

$$q_0 \equiv 1 (\bmod\ 2), \quad q_2 \equiv 0 (\bmod\ 2), \quad q_2 \equiv q_1 - 1 (\bmod\ 4).$$

In [10] it is proved that for $M = 2^\mu$ the inversive congruential generator (3) has maximal period length $2^{\mu-1}$ if and only if

$$r_{-1} \equiv 1 (\bmod\ 4) \quad \text{and} \quad r_0 \equiv 2 (\bmod\ 4).$$

Further in this paper we will denote the period of the generators by N.

III. PSEUDO-RANDOMNESS OF THE SEQUENCES PRODUCED BY QUADRATIC AND INVERSIVE CONGRUENTIAL GENERATORS

In this section the $b-$adic diaphony of two-dimensional nets (1), obtained by quadratic and inversive congruential generators, is numerically computed. We used PRNG library [31] created by Otmar Lendl to obtain the sequences. The parameters used in the numerical experiments in this work are: $q_2 = 8, q_1 = 5, q_0 = 3, r_{-1} = 9, r_0 = 6, y_0 = 1$, i. e.

$$y_{i+1} = f_M^{QCG}(y_i) \equiv 8y_i^2 + 5y_i + 3 (\bmod\ M),$$

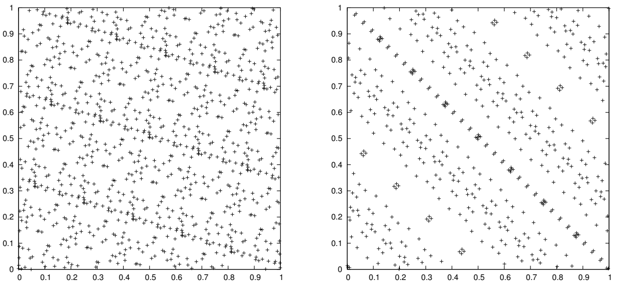
$$y_{i+1} = f_M^{ICG}(y_i) \equiv 9y_i^{-1} + 6 (\bmod\ M).$$

The distribution of the points of two-dimensional nets (1) with $M = 1024$ can be seen at Fig. 2. Table I contains the results for the $b-$adic diaphony of such two-dimensional nets.

IV. PSEUDO-RANDOMNESS OF THE COMBINATION OF THE VAN DER CORPUT SEQUENCE WITH QUADRATIC AND INVERSIVE CONGRUENTIAL GENERATORS

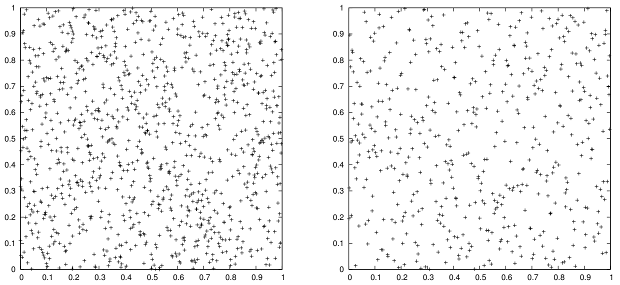
We consider the net

$$(\zeta_b(y_i), \zeta_b(y_{i+1})), i = 0, 1, \ldots, N-1. \tag{4}$$



QCG, $N = 1024$ ICG, $N = 512$

Fig. 2. The distribution of points of quadratic and inversive generators, $M = 1024$.



QCG, $N = 1024$ ICG, $N = 512$

Fig. 3. The distribution of points of the combination $\zeta_b(y_i)$ of quadratic and inversive generators with Van der Corput sequence with $M = 1024$, $b = 3$.

We compute the $b-$adic diaphony of the combination of the Van der Corput sequence ζ_b with quadratic and inversive generators, i.e. $y_{i+1} = f_M^{QCG}(y_i)$ and $y_{i+1} = f_M^{ICG}(y_i)$. The combination of the Van der Corput sequence with quadratic generator is proposed by Oto Strauch. We consider the combination of the Van der Corput sequence with inversive generator, too. In such way, the obtained nets have a better pseudo-random property than original sequences. The distribution of such nets for $M = 1024$ can be seen at Fig. 3. The obtained results for the $b-$adic diaphony of these combinations are presented in Table II. Fig. 4 shows a comparison between the computed $b-$adic diaphony of the nets (1) and (4) using two nonlinear generators.

V. SIMPLIFICATION

Let $m \geq 1$ be an arbitrary integer and $x \in [0,1)$ then for the $b-$adic expression

$$x = 0.x_1 x_2 \dots x_{m-1} x_m x_{m+1} \dots$$

we define

$$\zeta^*_{b^m}(x) = 0.x_m x_{m-1} \dots x_2 x_1.$$

In fact we truncate the $b-$adic expression of the number x to the m digits and we reverse the digits. O. Strauch proposed the net

$$\zeta^*_{b^m}\left(\frac{y_i}{M}\right), i = 0, 1, \dots, N-1. \tag{5}$$

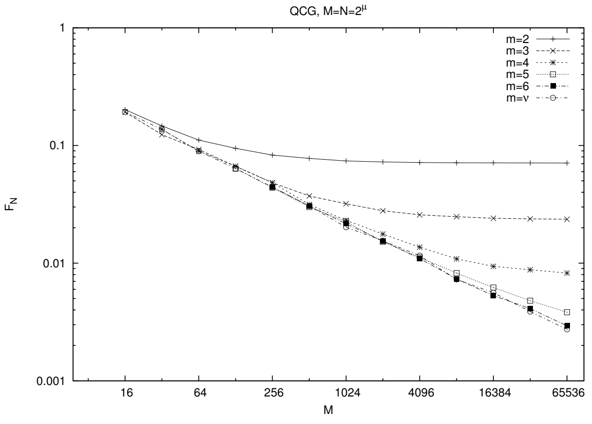

Fig. 7. The Diaphony F_N of the nets (6) with a quadratic generator.

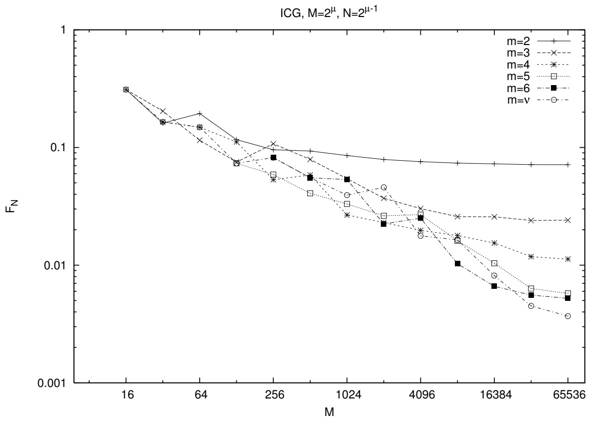

Fig. 8. The Diaphony F_N of the nets (6) with an inversive generator.

For pseudo-randomness of (5) we study the $b-$adic diaphony F_N of the two-dimensional net

$$\left(\zeta^*_{b^m}\left(\frac{y_i}{M}\right), \zeta^*_{b^m}\left(\frac{y_{i+1}}{M}\right)\right), i = 0, 1, \ldots, N-1. \qquad (6)$$

Let ν be an integer such that $b^{\nu-1} < N \leq b^{\nu}$. For two-dimensional net with N points we choose $m = 2, \ldots, \nu$. The distribution of the points of the nets (6) for $M = 1024$ for six values of the number m is shown in Figs. 5 and 6. Tables III and IV as well as Figs. 7 and 8 show the computed $b-$adic diaphony of such nets using two nonlinear generators.

VI. Analysis of the Results

The results in Table I show that the $b-$adic diaphony of the two-dimensional net (1) tends to zero with the increase of the number of the points for both considered nonlinear generators. The $b-$adic diaphony has the same order for both generators. We will note a fact that for one and the same modulus the number of the points produced by an inversive generator is twice less than the number of the points from a quadratic generator. The fast convergence of the $b-$adic diaphony of the quadratic generator shows that it has better pseudo-random properties. In other words, this deterministic algorithm simulates better random number. The same conclusion can be made for the $b-$adic diaphony of the combination of the Van der Corput sequence with considered nonlinear generators. The comparison between Fig. 1 and Fig. 3 shows that the combination of the deterministic Van der Corput sequence with the nonlinear generators improves the distribution of two-dimensional net. Hence, the pseudo-random properties of the sequence $\zeta_b(y_i)$ are similar to the properties of the generators. Although the values of the $b-$adic diaphony of the combination are greater than the values of the $b-$adic diaphony of the generators, from the comparison between Tables I and II it is seen that the $b-$adic diaphony of the combination has a faster convergence to zero. The two-dimensional net (4) with the used nonlinear generators have better uniform distribution than (1), therefore, the combination $\zeta_b(y_i)$ has better pseudo-random properties than original sequences. Fig. 4 illustrates this fact.

The usage of the proposed simplification leads to a restriction of the number of the sequence points. This simplification maps the points produced by the generators to uniformly distributed nets with b^{2m} points in $[0, 1)^2$. Under too strong restriction, i.e. $m = 2$ or $m = 3$, the value of the $b-$adic diaphony of the net (6) for quadratic generator stays big independently of the increase of points number. It is true for inversive generator, too. However, for big m the behavior of the $b-$adic diaphony using both generators is different. This behavior for different restrictions $m = 2, 3, \ldots, 11$ can be seen in the last two tables and the last two figures. Comparing Fig. 7 and 8 we conclude that F_N of the simplification of the quadratic generator has faster convergence to zero. The diaphony F_N of the simplification of the inversive generator also tends to zero but for $N < b^{2m}$ there are some intervals where the distribution worsen and F_N increases.

VII. Conclusions and Future Work

In practice, different pseudo-random number generators are used depending on the application. A generator is good, if it has some properties as large period length, good uniform distribution qualities, lattice structure, efficiency, fast generation algorithm, repeatability, portability, unpredictability.

The combination of the Van der Corput sequence with nonlinear generators, in fact, is a new generator. This combination saves the properties of the generators. The obtained generators have the same period length as the original generators. The good uniform distribution qualities are shown on Fig. 3. Obviously, the new generators have lattice structure, efficiency, fast generation algorithm, reproduce exactly the same sequence on different computers and we can not predict the next generated value by the algorithm from the previous ones. In this way the combination of the Van der Corput sequence with quadratic and inversive generators is a good pseudo-random number generator.

The comparison between the combinations of the Van der Corput sequences with quadratic generator and inversive generator shows that the $b-$adic diaphony of the first combination tends to zero faster than $b-$adic diaphony of the second combination. It means that the first combination has better simulation of the pseudo-random numbers. On the other hand, the second combination has less points than the first combination, but the behavior of the $b-$adic diaphony for this combination is similar. The proposed simplification of quadratic and inversive generators can also be considered as a generator. Depending on the purpose of the application, the combination of the Van der Corput sequence with quadratic and inversive generators or proposed simplification can be used. The results show that the $b-$adic diaphony is a good tool to study pseudo-randomness of the sequences.

These research can be continued in several directions: from theoretical point of view — to find estimations of the $b-$adic diaphony of all considered generators; from the viewpoint of Monte Carlo and quasi-Monte Carlo applications — to find connection between the error of the numerical integration and the $b-$adic diaphony and to study applications of the considered generators in the area of the computer graphics for uniform sampling.

Acknowledgments

We would like to thank Prof. Oto Strauch for the wonderful ideas about the combination of the Van der Corput sequence with quadratic generator and the simplification of this combination. The study of pseudo-randomness of the proposed by Prof. Oto Strauch sequences is very interesting and useful for us. This work is supported by the project Bg-Sk-207, Bulgarian NSF.

***Abstract*—Recently, we have introduced an approach to multi-core computations on sparse matrices using recursive partitioning, called *Recursive Sparse Blocks* (*RSB*). In this document, we discuss issues involved in assembling matrices in the RSB format. Since the main expected application area is iterative methods, we compare the performance of matrix assembly to that of matrix-vector multiply (*SpMV*), outlining both scalability of the method and execution times ratio.**

I. Introduction

IN RECENT papers, we have introduced a recursive data structure for performing Sparse BLAS ([1]) operations on cache based multi-core architectures. Initial performance results for the proposed format and its modifications/improvements, for both matrix-vector multiplication and triangular solve have been very encouraging (see, [2], [3], [4], [5]). We call our hybrid format *Recursive Sparse Blocks* (*RSB*), as it features the recursive subdivision of a matrix, with sparse submatrices in the leaves of a quad-tree.

Our efforts are targeted primarily towards *iterative methods*, appearing in the solution of either linear or eigenvalue problems ([6]). Here, the usual case for the user, is to select a specific iterative method (and preconditioner) for a given computational problem. For instance, the choice of a method over another could be influenced by the available computer hardware. With different sparse matrix storage formats, different operations could have different performance patterns on variously configured core/processor hardware. An important motivation for our work (as well as that of others, e.g.: CSB [7]) is the need for a format capable of performing thread-parallel Sparse Matrix-Vector Multiply (*SpMV*) with the same ease and comparable performance to the *Transposed SpMV* (*SpMV_T*). Since many iterative methods require both *SpMV* and *SpMV_T* (e.g. CGS or BiCGSTAB; see [8, section 2.4]), the development of a unified parallel approach to both operations is needed. Here, the common matrix formats, as *Compressed Sparse Rows* (*CSR*), and the plain *COOrdinate* (*COO*) formats do not support efficiently parallel *SpMV_T*.

At the problem level, the use of iterative methods often occurs in the solution of partial differential equations (PDEs), e.g. arising from simulating some physical phenomenon. Here, different usage patterns could arise; for instance: i) a sparse matrix could be instantiated and solved once; ii) a sparse matrix could be instantiated once and solved against a number of (updated/not known *a priori*) right hand sides. In choosing the best solution method for a given problem, the developer should take into account the overall (wall-clock) computation time; that is, the time to assembly a sparse matrix (and for updating it, if needed), as well as solving the problem. Additionally, the time for computing a preconditioner (See [6, Ch.10]) should be taken into account, but this issue is outside the scope of this paper.

The assembly of a sparse matrix could proceed in a number of ways. The author of [9, Ch.4] presents some common cases for the assembly of symmetric and unsymmetric matrices—from *usual* Finite Element Methods (FEM) data arrays as input, into COO and CSR formats. Overall, the most general routine for assembling a sparse matrix should be able to process as input the full list of coordinates of the matrix elements (*structural nonzeroes*), defining the *nonzeroes pattern* of the matrix. The numerical values of the matrix elements could be specified or updated in a later moment. The RSB matrix "*constructor*" we discuss here, works by converting the original array specifying the matrix as row-major sorted COO (now on, we will refer to COO assuming it as row-major sorted) into the RSB layout. Note that, from the assembly routines we present, it would be easy to derive routines for the extraction/conversion of rows or block-rows of RSB matrices.

We start by reviewing related works, in Sec. II. Next, we outline selected properties of RSB's quad-trees (in Sec. III). We follow by a presentation of our algorithm for converting a row-major sorted COO matrix to RSB, in Sec. IV. Then, in Sec. VI we report, for a representative set of matrices, how many *SpMV*'s are time-equivalent to a single matrix assembly. While we do not claim optimality of either of our techniques (the assembly and the *SpMV*), presented results illustrate the relevant relation between performance of these two operations. We have selected this particular comparison since, as stated above, *SpMV* is the basic operation for most standard iterative methods. Experiments were performed on machines and matrices described in Sec. V.

II. Related Work

The use of recursion in numerical linear algebra is a *recurring* theme (e.g., see [10]). We found proposals for *hypermatrix* (multilevel indexed matrices) based approaches to the solution of linear systems dating back to 1972 [11] (usage of hypermatrices with dense submatrices), and 1969 [12] (out-of-core dense matrix computations). Further, with regards to sparse matrices, Herrero and Navarro [13] investigated a hypermatrix-based Cholesky solver, but without discussing

978-83-60810-27-9/09/$25.00 © 2010 IEEE

performance of hypermatrix assembly. In [14] authors used asymmetrical *recursive bipartitioning* of sparse matrices in a distributed computing context. Sparse hypermatrix techniques were reportedly used for distributed-memory operations in the PERMAS proprietary package for FEM analysis [15]. The techniques most similar to the ones investigated here, reported in [16], deal with the optimal balancing of sparse matrix computations across distributed processors. Interestingly enough, while hypermatrix-based approaches have been applied to sparse matrix computations, almost no research has been reported as to what concerns assembly of such matrices. However, we found research in a similar spirit to ours in [17]. It documents algorithms and discusses patterns of usage in the assembly of sparse matrices in the context of their *serial* "MTL" package. Our discussion is more limited but in-depth than that, as we are concerned with a single pattern of construction: the conversion of COO input arrays to RSB, to be used on multi-core computers.

III. Some Properties of the Quad Trees Used in RSB Matrices

We described our rules for the construction of a quad tree-based recursive matrix representation in [2]. Given an $m \times k$ matrix A, we build a graph structure (*quad-tree*) q with nodes corresponding to *quadrant submatrices*. The four quadrants are sized respectively (in clockwise order, from the upper left) $\lceil \frac{m}{2} \rceil \times \lceil \frac{k}{2} \rceil$, $\lceil \frac{m}{2} \rceil \times \lfloor \frac{k}{2} \rfloor$, $\lfloor \frac{m}{2} \rfloor \times \lceil \frac{k}{2} \rceil$, and $\lfloor \frac{m}{2} \rfloor \times \lfloor \frac{k}{2} \rfloor$. This subdivision (or *bipartition*) is applied recursively to the quadrants; quadrants with no nonzero are not represented. Only leaf nodes are associated with actual data arrays, while inner ones contain only pointers. A simple *cutoff* function is used to balance the tree in order to obtain *leaf submatrices* with neither too many, nor too few nonzeroes. Fig. 23 depicts a matrix subdivided into RSB.

Let us now review some properties of our quad-trees, which will be useful during the discussion of matrix assembly.

Let us call q_h the *complete* quad-tree of height h; that is, the quad-tree having $N_i(q_h) \stackrel{def}{=} \sum_{i=0}^{h-1} 4^i$ intermediate nodes and $N_l(q_h) \stackrel{def}{=} 4^h$ leaf nodes, We indicate with $H(q)$ the height of quad-tree q. We assume that any quad-tree could be constructed by adding nodes to the singleton quad-tree q_0 (the one which is associated to the entire matrix). Let Q be the set of quad-trees with height ≥ 1. We call q' a $k-$*derivation* (or *derivation*, for short, if we ignore k) of quad-tree q, if q' can be built from q, by making one leaf an intermediate node, and adding $1 \leq k \leq 4$ leaves. We call q' an *indirect derivation* of quad-tree q, if q' can be built from q after a sequence of derivations. Observe that if q' is a $k-$derivation of q, then $N_i(q') = N_i(q) + 1$, and $N_l(q') = N_l(q) + k - 1$.

Property 1. *For any q among the possible quad-trees with height 1, we have $\frac{N_i(q)}{N_l(q)} \geq \frac{1}{4}$, and $\frac{N_i(q_1)}{N_l(q_1)} = \frac{1}{4}$.*

Proof: By explicit enumeration of possible cases. ■

Property 2. *For any $q \in Q$ with $H(q) > 1$,we have $\frac{N_i(q)}{N_l(q)} \geq \frac{1}{4}$*

```
/*Matrix $A$ is expressed using arrays $I, J, V$*/
Instantiate the root matrix node $s_A$, marked RSB and "open"
$[P, s_A] \leftarrow COO\_to\_RSB\_s(s_A, I, J)$/*symbolic subdivision*/
/*Now $s_A$ is the root of a quad-tree for A, with empty leaves*/
/*P is a rows pointer array for $I, J, V$*/
$COO\_to\_RSB\_V(s_A, P, V)$   /*numerical arrays shuffling*/
$COO\_to\_RSB\_J(s_A, P, J)$ /*indices shuffling/displacement*/
/*P is no longer needed and $I, J, V$ are in RSB order*/
$RSB\_Leaf\_Switch(s_A)$    /*indices switch*/
/*A number of leaf matrices has halfword indices, now.*/
return $s_A$ /*return $s_A$, now quad-tree for $A$*/
```

Fig. 1. $COO\_to\_RSB(I, J, V)$

Proof: Let q be a quad-tree having $\frac{N_i(q)}{N_l(q)} < \frac{1}{4}$, necessarily a derivation of a quad-tree q' having $\frac{N_i(q')}{N_l(q')} \geq \frac{1}{4}$. In the case q is a $k-$derivation of q', indicating $i = N_i(q'), l = N_l(q')$, we have $\frac{i}{l} \geq \frac{1}{4}$ and $\frac{i+1}{l-1+k} < \frac{1}{4}$. But this implies $4i - l \geq 0$ and $4i - l < k - 5$, which is impossible, for $1 \leq k \leq 4$. In the case q is an indirect derivation of q', it must be a derivation of some quad-tree q" having $\frac{N_i(q")}{N_l(q")} < \frac{1}{4} \leq \frac{N_i(q')}{N_l(q')}$, but existence of such q" is impossible, as we have seen. ■

If some internal node of q has one child only, we call q *degenerate* (with some terminology abuse;see [18, Sec. 2.3.4.5]).

Property 3. *For any sparse matrix M with no empty rows, if its corresponding quad-tree q is not degenerate, we have $\frac{N_i(q)}{N_l(q)} \leq 1$.*

Proof: Since M has no missing rows, it has some leaf node of q covering each row interval. Since q is not degenerate, at each level > 1, there are at least two nodes, or no node at all. Therefore, quad-tree q can be built by inserting additional $k \geq 0$ leaves to some binary tree q'. A non degenerate binary tree q' has $N_l(q') = N_i(q') + 1$, So we have $\frac{N_i(q)}{N_l(q)} = \frac{N_i(q')}{N_i(q')+k+1}$, whose upper limit is 1, for $k = 0$, and $N_i(q) \to \infty$. ■

Property 3 guarantees that for *non degenerate* quad-trees, there will be no more internal nodes than leaves. Please note that, for the time being, for simplicity of implementation, degenerate quad-trees are allowed in RSB.

IV. Building RSB From COO

Let us now describe in detail our approach for the conversion of an $m \times k$ matrix A with nnz nonzeros, expressed in (row-major sorted) COO (I, J coordinate arrays and the V numerical values array) into RSB order. The proposed procedure builds a quad-tree structure for A, allocating a *small* number of auxiliary structures (see the previous section) for the submatrix nodes, and reusing I, J, V. Unless otherwise stated, in the following, by *matrix* we will refer to A only, and denote as a *submatrix* any of the *quadrant submatrices* obtained by recursive bipartitioning (defined in Sec. III). Here, we assume no duplicates in the input (which happen in publicly available matrices; e.g.: ones from [19]).

There are three stages of assembly: first the *subdivision* of A in *COO_to_RSB_s*, where the input is repeatedly scanned, and a quad-tree structure is built; then the *shuffling* of rows laid in COO order to the rows of RSB sub-

```
1  $N \leftarrow [0,0,0,0]$ /*nonzeroes count for quadrants */
2  Allocate four $(s.m+1)$-sized arrays $L, M, R, P$
3  /*CS: Cache(s) Size, ES(= 8 for double): Element Size*/
4  $s_A.N_S \leftarrow 0$; $s_A.MAX_S \leftarrow (s_A.nnz \cdot ES)/(CS/N_{threads})$
5  $COO\_RowP(I, J, P, s_A.nnz, s_A.m)$ /*fill row pointers in P*/
6  $s_A.L \overset{p}{\leftarrow} P$; $s_A.R \overset{p}{\leftarrow} P+1$
7  /*$s_A.L$ points to row beginnings, $s_A.R$ points to row endings
   (aliasing the second element of P)*/
8  while Some leaf submatrix is still "open" do
9      $s_A.N_S \leftarrow s_A.N_s + 1$;
10     $s \leftarrow$ "largest" open submatrix
11     if $\delta_r(s.m, s.k, s.nnz, CS, ES, WS)$ then
12         /*copy subrow pointers stored in $s.I, s.J$ */
13         $L \leftarrow s.I$; $R \leftarrow s.J$;
14         /*get quadrants info $N$, fill middle pointers array $M$*/
15         $N \leftarrow Subrow\_Split(s, L, R, M, J)$
16         /*split s, appending up to four quadrant submatrices*/
17         $RSB\_Split\_Node(s, N, L, M, R, I, J)$
18     else
19         /*closing (marking as terminal)*/
20         if $s$ is $s_A$ && $s.nnz \geq s.m+1$ then $s.I \leftarrow L$
21         /*For $s_A$, a copy is necessary.*/
22         if $s.nnz \geq s.m+1$ then Mark as CSR
23         else Mark as COO
24     end
25 end
26 return $[P, s_A]$/*Arrays $L, M, R$ can be freed.*/
```

Fig. 2. $COO\_to\_RSB\_s(s_A, I, J)$

matrices (Fig. 8,9), and finally *compression of indices* in RSB_Leaf_Switch (Fig.10). Accordingly, we break down the RSB assembly pseudo code into three listings, called from procedure COO_to_RSB, in Fig. 1.

Procedure $COO\_to\_RSB\_s$ (Fig. 2), performs a cycle, identifying bounds for candidate submatrices. This information is stored in auxiliary arrays L, M, R. A *row pointers* array P is constructed (line 5), kept and returned for later usage. At each iteration, the *largest open submatrix s* (in terms of number of nonzeroes) is selected; then it is analyzed, and either subdivided in quadrants (and marked as *closed node*) or marked as a *closed leaf*. In either case, each cycle *closes* submatrix s and *opens* up to four submatrices. Therefore, the loop iterates a number of times equal to the number of the nodes (both inner and leaf) in the produced quad-tree. In Fig. 3 we present the cutoff function δ_r which decides if subdivision of s should proceed.

Since the input COO arrays are row-major sorted, in order to identify quadrants of s in them, we need to mark, for each row, indices for: the leftmost element of the two left quadrants, the leftmost of the two right quadrants, and the first one after the rightmost of the two right quadrants; that is, pin-point *subrows* in each quadrant. To this end, I and J are scanned in $Subrow\_Split$, and subrows information is stored in the three *row pointers arrays* L, M, R. Row pointers data will be reused when assembling submatrices in CSR. The first invocation of $Subrow\_Split$ requires L, R for the whole A in order to compute the first *middle row pointers* array M. Notice that for any row i of A, $L[i+1] \equiv R[i]$. For this reason, before entering the loop, we pre-compute a single row pointers array P, and set the initial L, R as *pointer aliases* of P. That is, P can serve as L, and aliased after its first element, as R does; in Fig. 2 and 7, we have used "$\overset{p}{\leftarrow}$" to signify pointer aliasing. P is computed by COO_RowP, listed in Fig. 4.

```
/*$WS(=4)$: Word Size of index element, $\mu = 3$ */
if $s_A.N_S \geq s_A.MAX_S$ then return False
if $n \cdot ES \ > 2 \cdot CS$ && $m < 2^{16}$ && $k < 2^{16}$ then return
True
if $(ES\ (2 \cdot n + m) + WS \cdot (m+n)) > \alpha\ CS$ &&$n/m > \mu$
then return True
return False
```

Fig. 3. $\delta_r(m, k, n, CS, ES, WS)$

```
$P[:] \leftarrow$ 0/* fill with zeros*/
for $n \leftarrow 0$ to $nnz-1$ do  $P[I[n]+1] \leftarrow P[I[n]+1]+1$
for $i \leftarrow 0$ to $m-1$ do  $P[i+1] \leftarrow P[i+1]+P[i]$
/*for each $i$, $P[i]$ now has the offset of row $i$ in $I, J$*/
```

Fig. 4. $COO\_RowP(I, J, P, nnz, m)$

After boundaries are identified, and nonzeroes counts are known for each quadrant, at line 17, we invoke the RSB_Split_Node. It will add an *open* leaf submatrix for each non-empty quadrant, and copy the L, M, R arrays in appropriate offsets of the I array. In this way, I is used for storing submatrices rows information, and subsequent invocations of $Subrow\_Split$ will use the L, R arrays recovered from there.

In the case the δ_r does not make s a candidate for subdivision, s gets *closed* as a leaf matrix, and marked to contain data in the CSR or COO format (depending on the available index space; lines 18-23). In the case s is the root node for A (s_A), and fitting CSR arrays ($nnz > m$), L (aliasing P) is copied at the appropriate offset of I, overwriting original row indices (not needed anymore).

After assembling the quad-tree for the s_A, the original J, V arrays storing column indices and values of the matrix coefficients are still unmodified, and ready for being displaced

Fig. 7. $RSB\_Split\_Node(s, N, L, M, R, I, J)$

to their destination location. The I array, instead, has been overwritten. For submatrices marked for CSR storage, I already stores a *row pointers array*, which a CSR representation requires. For submatrices marked for COO storage, the relevant subarrays for I could have been overwritten during parent node subdivision, and therefore they should be reinitialized to their original values. Actually, each submatrix node has information on the count of nonzero elements in its own quadrants. Recall, that in RSB_Split_Node, the *nonzero offset* of each submatrix in the quad-tree representation was computed. Now, each submatrix s could be extracted to a temporary storage, row by row, from the original matrix specified in subsequent rows, at the submatrix offset $s.nzoff$ (computed by RSB_Split_Node, in Fig. 7). To keep the shuffling algorithm simple, we have chosen to allocate two temporary J_t and V_t arrays; gather there the displaced rows for coefficients and indices, and copy back to J, V. Since different submatrices should be laid in separate intervals of J and V, the shuffling algorithm can be parallelized on a submatrix basis in a parallel cycle. Once shuffled, the temporary arrays are copied back using a simple OpenMP-parallel wrapper around the standard memcpy ([20]) function .

The shuffling procedures for J (Fig.9) and V (Fig.8) are similar. For V ($COO\_to\_RSB\_V$), only rows shuffling is needed, but for J ($COO\_to\_RSB\_J$), besides shuffling, we need also to adjust indices relative to the submatrix location, and restore indices of I. After the shuffling phase, submatrices are either stored as *fullword* (by default, 32 bit) COO or CSR. RSB (see [5]) allows smaller leaves to have 16 bit coordinate (for COO) or column (for CSR) indices. For this, we use a separate procedure, RSB_Leaf_Switch, operating an *in place* conversion on the arrays of the candidate submatrices.

```
Allocate a temporary vector $V_t$, fitting $V$.
parallel foreach $s \in S$ do
    $V_s \overset{p}{\leftarrow} V_t[s.nzoff]$
    if $s.nnz \geq 2 \cdot s.m + 2$ then
        for $i \leftarrow 0$ to $s.m - 1$ do
            Append subrow $V[s.L[i] : s.R[i]]$ to $V_s$
        end
    else
        for $i \leftarrow 0$ to $s.m - 1$ do
            $l \leftarrow P[s.moff + i]$;$r \leftarrow P[s.moff + i + 1]$
            $l \leftarrow Search(J, l, r, s.koff)$
            $r \leftarrow Search(J, l, r, s.koff + s.k)$
            Append subrow $V[l : r]$ to $V_s$
        end
    end
end
$MEMCPY\_Parallel(V, V_t)$/*$V \leftarrow V_t$*/
```

Fig. 8. $COO\_to\_RSB\_V(s_A, P, V)$

```
Allocate a temporary vector $J_t$, fitting $J$.
parallel foreach $s \in S$ do
    $J_s \overset{p}{\leftarrow} J_t[s.nzoff]$
    if $s.nnz > 2 \cdot s.m + 2$ then
        for $i \leftarrow 0$ to $s.m - 1$ do
            Append subrow $J[s.L[i] : s.R[i]]$ to $J_s$
            Make a CSR row pointer in I, using L, R
        end
    else
        for $i \leftarrow 0$ to $s.m - 1$ do
            $l \leftarrow P[i]$;$r \leftarrow P[i + 1]$
            $l \leftarrow Search(J, l, r, s.koff)$
            $r \leftarrow Search(J, l, r, s.koff + s.k)$
            Append subrow $J[l : r]$ to $J_s$
            if $s.nnz < s.m + 1$/*COO case*/ then
                Set array $s.I$ with value $i$
            else
                Make a CSR row pointer in I, using L, R
            end
        end
    end
    Adjust $s.J$ indices, by subtracting the offset $s.koff$.
end
$MEMCPY\_Parallel(J, J_t)$/*$J \leftarrow J_t$*/
```

Fig. 9. $COO\_to\_RSB\_J(s_A, P, J)$

Note that interleaving shuffling and conversion could save a substantial fraction of memory accesses; however the constructor logic would be much more involved. After this (last) step, the matrix is assembled as RSB and ready for use.

The presented assembly procedure consists of a *serial* stage (*subdivision*), followed by two stages exploiting parallelism (*shuffling* and *conversion*). Initially, we considered to propose a parallel subdivision step. However, we observed that this would require us to use more complicated techniques, and would also entail differences in the computed partitions. For instance, we could have let threads subdivide the matrix concurrently, but non-determinism in the order of subdivision could lead to non-deterministic quad-tree shape/matrix partitioning. In such case, we would have either to accept the

```
parallel foreach leaf node $s$ of quad-tree $s_A$ do
    if Marked for halfword indices then
        if CSR format then
            Convert J to use 16 bit indices, in place
        end
        if COO format then
            Convert I, J to use 16 bit indices, in place
        end
    end
end
```

Fig. 10. $RSB\_Leaf\_Switch(s_A)$

algorithm as non-deterministic (which we did not want), or use complicated *backtracking* techniques to revert unnecessarily subdivided submatrices and an equivalent tree. On the other hand, we have found strategies for the parallelization of the current subdivision algorithm routines (based on fine-grained parallelism) to be problematic regarding synchronization, and therefore shortsighted, in the perspective of many-core computations, expected in the forthcoming computers. Therefore, for the time being, we have chosen a simple serial strategy, and left other enhancements for future developments. Indeed, besides being serial, the subdivision stage faces a growing amount of work, as more subdivisions are performed on a matrix; and thus, it will slow down further, the more threads will participate in the *SpMV* computation (recall line 1 in Fig. 2). Each subdivision of a submatrix s requires (a) the copy of two arrays, (b) $s.m$ binary searches during split, and (c) one array write per search. In the worst case, this involves about $s.m$ random accesses in the binary searches, (which perform non-linear accesses), but the remaining accesses are linear, and could be performed taking advantage of the available prefetching engine on the CPU. Analysis of the complexity of subdivision is beyond the scope of this paper; a gross, pessimistic estimate we could provide for the memory traffic would be up to $o(h \cdot nnz)$ memory writes (where h is the height of the quad-tree). This would be the case where all of the submatrices would fit exactly as CSR: if some were COO, binary searches would be performed on their parent matrices, but with no subsequent row pointers copy (matrices are assigned as COO if they don't fit CSR, with no further subdivision). If some submatrices had rows denser ($s.nnz > s.m + 1$), it would mean that only $O(s.m + 1)$ elements would be moved (out of $s.nnz$).

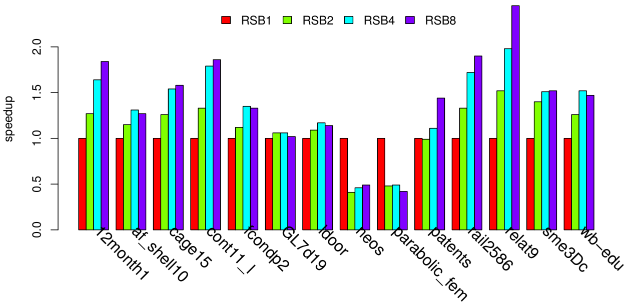

Fig. 11. RSB matrix assembly scaling on **M1**.

The shuffle stage is different: it involves two transfers of contents of arrays V and J; and between m and nnz element moves for I. If not coupled to the copy operation, the index adjustment for J accounts for further, up to $O(nnz)$, accesses; similarly for restoring the I arrays of COO leaves. Similarly, the complexity of the compression stage involves modifications of up to $2nnz$ memory locations (once). Besides the `memcpy`-like operations, when shuffling the COO submatrices, the J array would be *binary-searched* repeatedly for the identification of subrows bounds (after determining bounds for search using P). The same binary-search based algorithm is needed for the CSR submatrices having $s.nnz \le m$ (since the corresponding I subarray would not contain both right and left subrows pointer arrays). For CSR leaves having $s.nnz > s.m$, right and left subrow pointers are recovered from I, subrows in J and V are located, and no search is needed at all. Notice the independence from the quad-tree height (and thus, from the matrix size).

V. Experimental Setup and Methodology

Our experimental setup is similar to that of [5]: same machines, same compilers, same methodology, but for space reasons, we selected only an *essential* subset of the matrices used there (see Table I). We compiled and ran our codes on machines **M1** (AMD Opteron 2354; 2×4-core CPU; caches: 2×2MB L3, 4× 512KB L2 and 64KB L1) and **M2** (Intel Xeon 5670; 2×6-core CPU; caches: 2×12MB L3, 4× 256KB L2 and 32KB L1), using `-O3` as the only optimization flag, with `icc` v.11 on **M1**, and `gcc` v.4.3 on **M2**. The time samples employed are the *best ones*, after 100 runs for the *SpMV* operation, and 10 runs for the constructor. **M2** is a lightly loaded network server.

VI. Results

For space reasons, we won't be able to present a comprehensive analysis of the constructor performance, and thus we will focus on the most important topics. Our exposition is

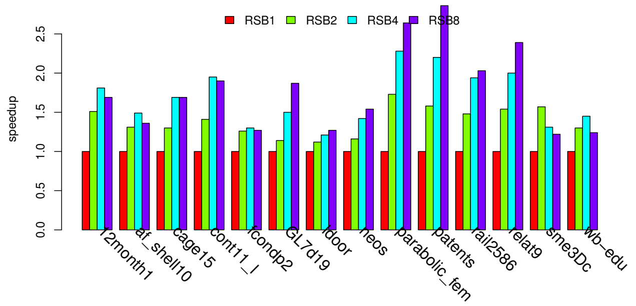

Fig. 12. RSB matrix assembly scaling on **M2**.

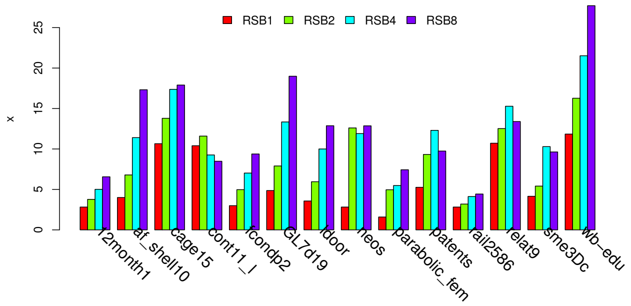

Fig. 13. RSB matrix assembly to *SpMV* time ratio on **M1**.

geared towards iterative methods; here, the affordability of the constructor code is inversely proportional to the number of *SpMV*'s that are expected to be performed after matrix instantiation. Thus, performance profiles for both *SpMV* and construction operations are needed. We will thus present the constructor performance considering two metrics: the number of *SpMV* that are time-equivalent to a constructor run on the given matrix, and the scalability of the constructor with respect to the single core case.

In our previous work (See [5],[4]), using 8 cores on **M1** and **M2**, we have encountered a *SpMV* speedup of up to 5×. In Sec. IV, we have motivated the reasons for keeping a part of our constructor code serial. Therefore, the observed scalability is indeed weak, as depicted in Fig. 11,12. We see that the maximum speedup on both machines is 2.45× on **M1** and 2.86× on **M2**; this is approximately half than observed for the *SpMV*. We notice the best speedup for matrices *relat9* and *rail2586* on **M1**; *patents* and *parabolic_fem* on **M2**. In two cases (*neos* and *parabolic_fem* on **M1**) we notice a slow-down. Due to the increasingly loaded serial stage; in both cases, this happens after a no-subdivisions instantiation, for 1-core (for space reasons, we omit graphs with submatrix counts).

Relating constructor and *SpMV* times, we notice the constructor dominating the *SpMV*, in Fig. 13,14. We observe the maximal ratio for matrix *wb-edu* (up to 52.8× on **M1**, up to 27.7× on **M2**); a minimal one for matrix *rail2586* (from 2.8× to 4.4×, on **M1**). In two cases (matrices *cont11_l*, *patents*), it happens that the constructor and *SpMV* times keep a similar pace (around 10×, on both machines). Indeed, the *SpMV* performance of matrix *cont11_l* does not increase with more cores, and matrix *patents* gets partitioned in the same number of leaf matrices, regardless the cores count. We notice worse ratios for bigger matrices: *cage15*, *wb-edu*, and *GL7d19*. Here, *patents* is big, but it performs *SpMV* exceptionally slow (see [5]).

Let us break down the constructor performance in the serial (*subdivision*) and parallel (*shuffle* and *conversion*–we will include this last one in the shuffle results, for convenience) stages. As discussed in Sec.IV, the subdivision code is expected to perform a number of passes on the input growing with the number of threads available for *SpMV*. In Fig. 15 and 16, we see the *scaling-down* of subdivision performance; we encounter a near-to 5-fold slow-down for matrices *parabolic_fem* and *neos*. It is due to no subdivision being performed in the 1-core case, on them. In the remaining cases, we do not notice more than a 2-fold slow-down.

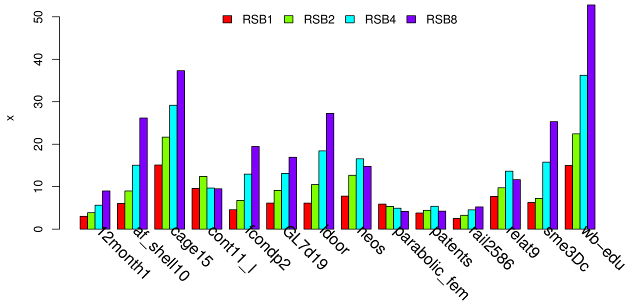

Fig. 14. RSB matrix assembly to *SpMV* time ratio on **M2**.

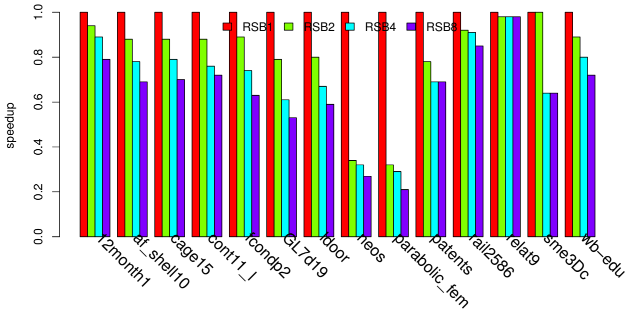

Fig. 15. Subdivision scaling on **M1**.

In Fig. 17,18, we can see the growing gap between the subdivision and *SpMV*. For 1 or 2 cores, this ratio is always lower than 7.0, but for more, it can grow much: for matrix *wb-edu* on **M2**, the subdivision takes 5.1× for 1 core, and up to 42.4 times *SpMV* time, for 8 cores.

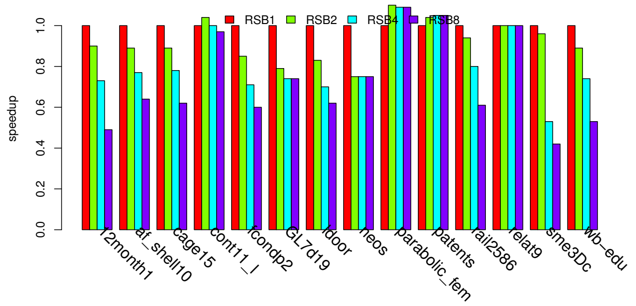

Fig. 16. Subdivision scaling on **M2**.

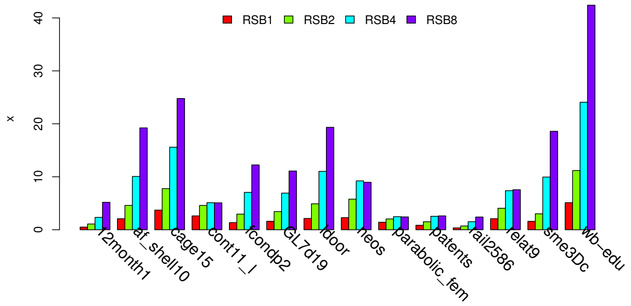

Fig. 18. Subdivision to *SpMV* time ratio on **M2**.

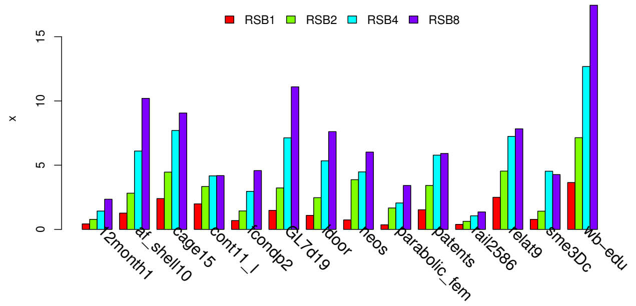

Fig. 17. Subdivision to *SpMV* time ratio on **M1**.

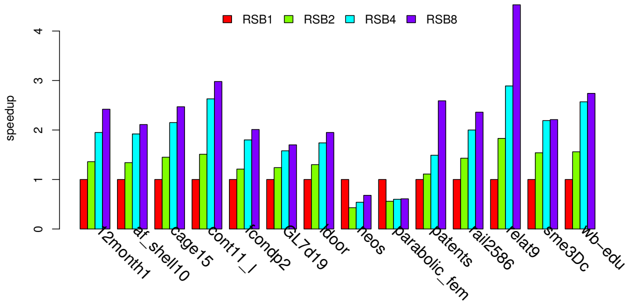

Fig. 19. Shuffle scaling on **M1**.

On the other hand, the *shuffle* stage scales quite regularly on all matrices in the test set; see Fig. 19, 20. Recall that, with higher cores counts, notwithstanding the growing number of submatrices to handle, the shuffle operation moves approximately the same amount of memory locations (see [5] for a discussion on indexing space). As noted in Sec. IV, in the shuffle (comprehensive of index compression) phase, the amount of involved traffic depends on the leaves format; prevalence of COO leaves will trigger more traffic; since compression happens after the copy operations, it contributes to additional traffic.

We also notice that the ratio of shuffle-to-*SpMV* times remains very close, regardless active cores count. This is satisfactory, because it indicates that both the operations scale similarly: see Fig. 21,22. Indeed, both operations seems to be memory bound; shuffle more than *SpMV*, as it doesn't involve floating point operations, which could be slower than integer operations. During stand-alone benchmarking our naive parallel `memcpy` wrapper (MEMCPY_Parallel, used in Sec. IV), we experienced at most $8.4GB/s$ on **M1**, $6.4GB/s$ on **M2**, and speedups respectively up to 3.1 and 2.2. We expect this limit to contribute with a relevant fraction to the shuffle stage.

By comparing, respectively, Fig. 17 to Fig. 21 and Fig. 18 to Fig. 22, we notice that on both machines, the subdivision (serial) stage becomes dominant over the shuffle (parallel) at around 4 active threads. Clearly, this situation is not desirable in the perspective of more computing cores, so we recognize the need for a scaling parallel subdivision stage. Also, by allowing degenerate subtrees (see Sec. IV) input could be scanned repeatedly and generating no new subdivision; this case should also be dealt with.

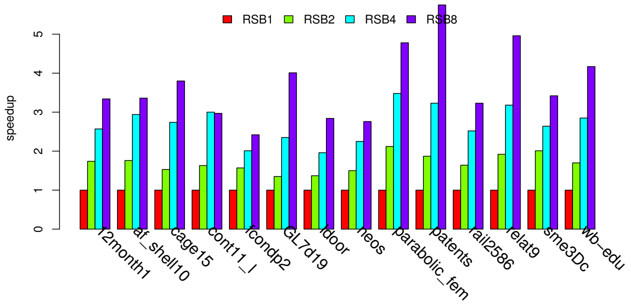

Fig. 20. Shuffle scaling on **M2**.

VII. Concluding Remarks

We have shown a multi-threaded algorithm for the instantiation of RSB matrices out of row major sorted COO arrays.

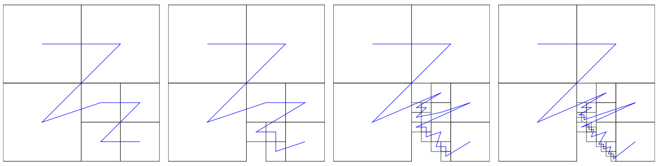

Fig. 23. Recursive subdivisions of matrix *cont11_l* for respectively 1,2,4,8 threads on **M1**. Notice the blue line joining (nonempty) leaf submatrices in the order they are stored in the RSB arrays. Notice that the more threads are active, the finer is the partitioning.

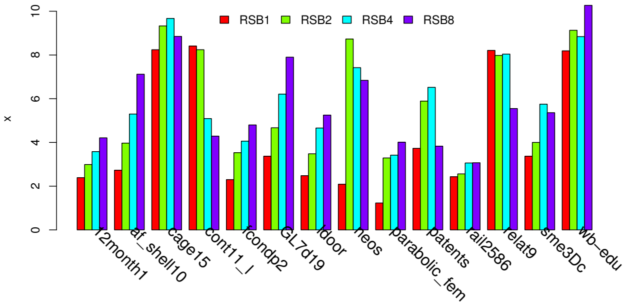

Fig. 21. Shuffle to *SpMV* time ratio on **M1**.

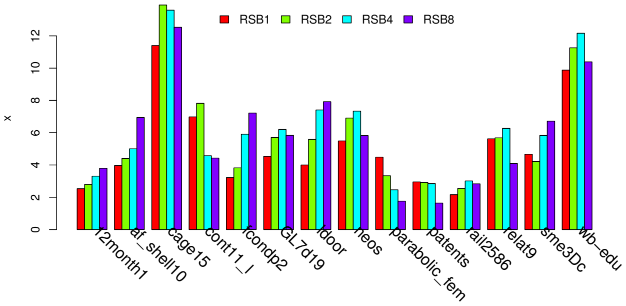

Fig. 22. Shuffle to *SpMV* time ratio on **M2**.

Experimentally, we established that its execution speed seems tightly bound to the peak memory bandwidth; even more than *SpMV*. Our procedure features a serial *subdivision* stage, where binary search and arrays copy operations are predominant, followed by a parallel *shuffle* stage, where arrays are displaced and indices adjusted. The shuffle stage scales smoothly; its performance seems strictly memory bandwidth-bound. While shaping the subdivision stage, we observed that an efficient parallel reformulation of it would require us to modify the definition of our format. We did not want to proceed this way as we wanted it to remain comparable with our earlier work, and so we have decided to leave the subdivision serial, for now. In practice, we observed the constructor-to-*SpMV* time ratio to be 1.6..15.1 times for 1 core, 2.5..22.4/2 cores, and 4.2..52.8/8 cores. Indeed, we have observed that the serial phase begins to dominate the constructor time as soon as at about 4 threads. For this reason, we recognize need of further research to develop a scalable, parallel algorithm to perform the initial subdivision, as this is the key to a scalable RSB matrix constructor. We deem also interesting to study parallel conversion/extraction mechanisms for interfacing to other formats, and consider the performance impact of building preconditioners, while solving linear systems. Of course, a number of trivial but effective optimizations (see Sec. IV) may also be applied.

***Abstract*—Recently, we have introduced an approach to basic sparse matrix computations on multicore cache based machines using recursive partitioning. Here, the memory representation of a sparse matrix consists of a set of *submatrices*, which are used as leaves of a *quad-tree* structure. In this paper, we evaluate the performance impact, on the Sparse Matrix-Vector Multiplication (*SpMV*), of a modification to our *Recursive CSR* implementation, allowing the use of multiple data structures in leaf matrices (CSR/COO, with either 16/32 bit indices).**

I. Introduction

It IS known that computations with sparse matrices incur very poor memory performance: indirect addressing causes unpredictable run-time dependencies in memory read/write access; memory access has poor data locality (just to name a two key aspects; see also [1], [2], [3]). To address these issues, recently, we have proposed a *recursive* approach to sparse matrix representation. In [4] we have outlined the proposed method and reported initial experiments with the *SpMV* operation. In the follow-up [5], we have evaluated its performance for the triangular solve and *SpMV* for symmetric matrices. Experimental results lead us to modify the storage scheme in order to reduce the indexing overhead. Encouraging results of an approach employing 16-bit indices have been reported in [6]. Here, we continue investigations leading to the development of methods that can reduce impact of indirect addressing, by reducing the memory traffic incurred in accessing index data. Specifically, we employ *index compression*, and *diversify* the representation of *leaf submatrices* with the intent of raising the floating point performance of the *SpMV* by saving memory bandwidth.

Proceeding, we outline the RCSR storage format with index compression in Section II. Next, we describe modifications to the sparse matrix representations in Section III. Setup for performed experiments can be found in Section IV, while in Section V we analyze the obtained results.

II. The recursive storage format and index compression

We (logically) organize a sparse matrix as a *quad-tree* structure, with nodes consisting of submatrices arising from a recursive partitioning into quadrants. While intermediate nodes are used only as a pointer structure, leaf nodes hold actual subarrays with index and numerical values. The *SpMV* algorithm described in [5] is independent from the actual format of leaf matrices. It only assumes a *coarse* recursive partitioning in leaf submatrices. Similarly to blocking used in dense matrix computations, submatrices at leaf level should be *sized* (in terms of their *memory footprint* during the *SpMV*) in relation to the *cache sizes of the machine*.

In this context, we have investigated a variation to the leaf matrices format, obtained by converting some of the *Compressed Sparse Rows* (CSR) leaves of a matrix to use 16 bit column indices (and thus, reducing the memory traffic). As motivated in Section I (and in the literature; e.g.: [1]), index compression techniques are particularly effective with many active cores. Here, techniques which may not be optimal on a single core (because of a slight memory-bandwidth-to-computation trade-off, in the form of pointer arithmetics), may show their potential when working with multiple cores (where the memory traffic is heavier). As a motivation of our "16-bit" approach, we observe that after partitioning a large sparse matrix (in the RCSR format), it is likely to have many of the leaf submatrices *dimensioned* less than 2^{16}. Thus, using a 16 bit (*halfword*) index type in their CSR *column indices* arrays is possible, and could lead to savings in memory traffic. We name this variant RCSRH. Obviously, for matrices dimensioned less than 2^{16}, the conversion to RCSRH is possible for all submatrices. The outcome of our experiments (documented in [6]) was encouraging: using halfword indices by itself yielded up to a 25% floating point speedup (with a saving in memory usage up to a 16%) on unsymmetric matrices, and 30% on symmetric ones. However, in a number of cases, the RCSRH variant was not helpful. One of the perceived reasons was that CSR itself does not always fit into leaf submatrices, and thus we have decided to convert some leaf matrices to the *COOrdinate* (COO) format. Let us discuss this change with more detail.

III. Recursive storage format with CSR and COO leaves

In this section, we motivate quantitatively why and when storing some submatrices as COO instead of CSR could reduce index overhead, and the way we have chosen to use COO to enhance RCSR.

A matrix is stored in the RCSR format as a quad-tree structure with CSR ([7, Section. 4.3.1]) submatrices at the leaf level of a *recursive bipartitioning* (see [4]). To store an $r \times c$ matrix with n nonzeroes in CSR, we use an array JA (of size n) with *column indices*, and a *row pointers* array PA (of size $r+1$), referencing *rows* in the JA array. Array JA stores column indices for nonzeroes in a *row-major* order. The array of coefficients (VA) is laid in the same order as JA. To store a matrix in a plain COO format, two n-sized arrays for (row,column) indices (IA,JA) are required. By denoting as $I(r,n)$ the index space requirements for an $r \times c$ matrix (with n nonzeroes) instance we have $I_{CSR}(r,n) \doteq 4(r+1)+4n$ and $I_{COO}(r,n) \doteq 4n+4n$ bytes. Let us call CSRH the CSR format implementation with 16 bit JA indices, and COOH, a COO format implementation with 16 bit IA and JA indices. For these variants, we have $I_{CSRH}(r,n) \doteq 4(r+1)+2n$ and $I_{COOH}(r,n) \doteq 2n+2n$ bytes. This means that for some values of (r,n), COO/COOH would use less indexing space than CSR/CSRH; specifically, $I_{COO}(r,n) < I_{CSR}(r,n)$ when $n < r+1$, and $I_{COOH}(r,n) < I_{CSRH}(r,n)$ when $n < 2r+2$. For this paper, we modified the matrix constructor code to use CSRH whenever a CSR submatrix is dimensioned less than 2^{16}. Similarly, we use COOH whenever a COO submatrix is dimensioned less than 2^{16}; we choose to use COO when $n < r+1$. We adopt COO/COOH as row-major sorted (so we have the same memory access pattern of CSR for JA and VA arrays). In [4] and [6], we have described the *cutoff* function δ as our heuristic regulating subdivision into submatrices; in this paper, we use slightly differing matrix assembly criteria. While we still use the δ_h function from [6], we limit subdivisions by forcing each submatrix not to use more indexing space than a *fullword* COO storage of it would require. The other rules for subdivision are still the same as imposed by δ_h. Please refer to [8] for a full discussion on the new constructor layout. We call the hybrid format resulting from these modifications *Recursive Sparse Blocks* (*RSB*).

IV. Experimental Setup and Methodology

In order to compare the new approach with previously documented experiments using RCSR format (see [6]), we measured performance on the same test set of 36 matrices: 12 of them are symmetric (See Table I), 12 are square unsymmetric (See Table II), and 12 are non square (See Table III). For readability reasons, in Sec. V we left matrices with less significant results (marked with an asterisk (*), in the tables) out of the plots; so the commentary of them is indirect. Furthermore, we have used the same two machines (summarized in table IV). Recall, that **M2** is a lightly loaded network server, while **M1** is a dedicated machine.

For each *matrix/cores* sample, we ran our RSB code, performing 100 times the *SpMV* operation and report the best result. However, timing variation was below 5%, so our results were consistent. We measured timings using the POSIX ([9]) `gettimeofday()` function. Figures in section V depict results, expressed in MFlops (millions of floating point operations per second). Conventionally, we counted 2 Flops per nonzero element for non-symmetric matrices, and 4 for symmetric. We use double precision arithmetic (C's `double` type). Our measurements were performed with *hot caches*; that is, we did not flush deliberately cache contents between subsequent *SpMV*'s; therefore, to avoid artificially high results, all measurements were performed on matrices not fitting entirely in the caches.

Our codes were compiled with the Intel `icc` version 11 on **M1**, and `gcc`, version 4.3 on **M2**. In Section V-C we compare our results to that obtained with a publicly available CSB prototype ([2]). On both machines we compiled it using the Cilk++ compiler; version (“`Cilk Arts build 8503`”), based on the `gcc` (*GNU C Compiler*), v.4.2.4. To unify the

test environment, all codes were compiled using the `-O3` flag only (besides the OpenMP enabling flags).

V. RESULTS

We structure the analysis of results as in [6]. Note that, for brevity, we sometimes reference as RSB-k the k-threaded RSB. In most cases we start by commenting the 8 threaded performance, and proceed from discussing the particularly problematic cases to the best performing ones.

A. Results, Unsymmetric Matrices

For the unsymmetric matrices on **M1**, we observe an improvement when switching from RCSR to RSB in nearly all of the test set matrices; up to 67% on square ones, and up to 33% on non square ones (Fig. 1,2).

The only matrices "suffering" from the switch are: square *av41092* and *raefsky3* (Fig. 1), non square *c8_mat11_I* and *diego-smtxMM-573x230k*, and two borderline cases: *rail2586* and *sme3Dc*.

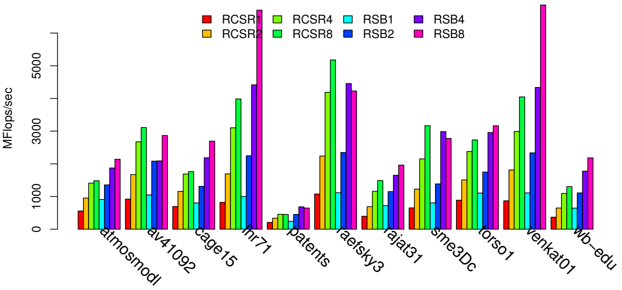

Fig. 1. Unsymmetric *SpMV* on **M1**, square matrices.

On machine **M2** (Fig. 3,4), we see improvements up to 128% for square matrices, and 65% for non square ones, and a single case of a performance drop: a 3% fall for the non square matrix *cont11_l*.

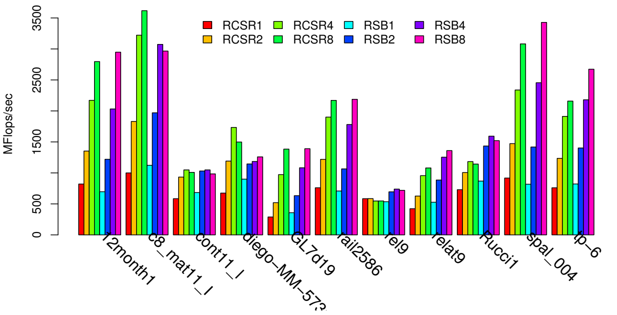

Fig. 2. Unsymmetric *SpMV* on **M1**, non square matrices.

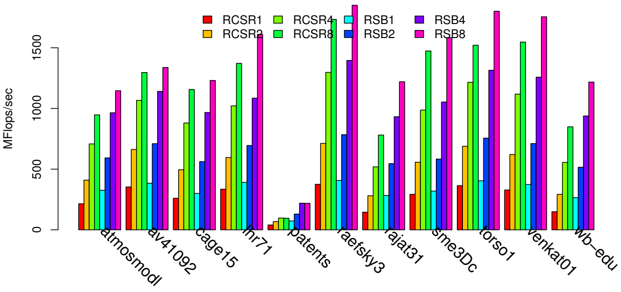

Fig. 3. Unsymmetric *SpMV* on **M2**, square matrices.

In Fig. 6,7,8,9 we observe index usage saving almost always. Out of 24 non-symmetric matrices, we experience three cases where index usage raises: square matrix *patents* (Fig. 6,8) and non square matrices, *rel9*, *relat9* (Fig. 7,9). We note, however, that the effect of RSB is actually an improvement of the performance on these matrices, notwithstanding the increased index usage. Among these matrices, problematic cases remain: *patents* performs better, but continues scaling poorly, (remaining the "slowest" of our entire test set); *relat9* suffers from poor scaling, too (especially on 8 cores **M2**); *rel9* continue not scaling at all.

These matrices have a feature in common: a very low nonzeroes/row elements ratio: 2.39 for *rel9*, 3.15 for *relat9* (see Table III) 3.97 for *patents* (see Table II). Although for such matrices one cannot expect high efficiency for either CSR or COO formats, we have realized why this is also the case for our recursive format (see [6], [5]), so now we present only the particular case for RSB.

Although very poorly performing, *patents*, actually scales up to 4 threads. In facts, *patents* is assembled in 37 COO leaves, regardless the thread count. When working with 8 threads, we observe that scaling is inhibited: this means that particular partitioning leaves a number of threads starving, while most of row intervals are *locked* by other threads. This is a situation occurring when the thread count approaches the number of submatrices in disjoint row intervals (see Fig. 5); and thus threads contend for available row intervals to operate on. In the current formulation of RSB, further partitioning of this matrix is not allowed, for it does not have enough

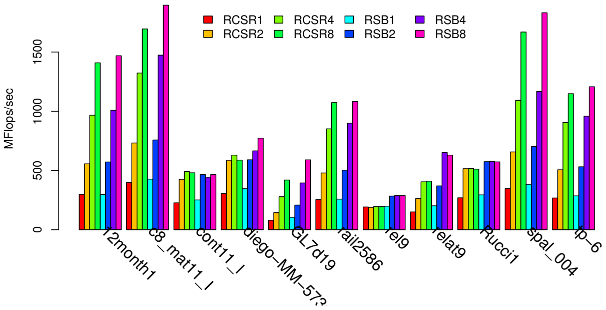

Fig. 4. Unsymmetric *SpMV* on **M2**, non square matrices.

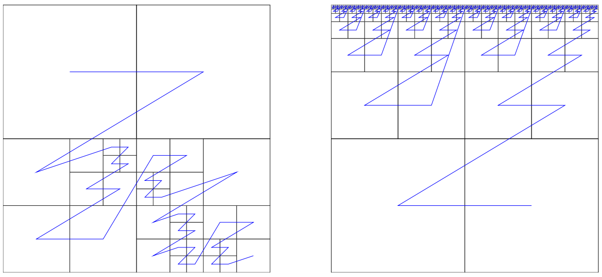

Fig. 5. On the left, matrix *patents* as partitioned on **M1**. On the right (widened, for viewing convenience) *diego-smtxMM-573x230k* on **M1**. Both in RSB format.

nonzeroes per row. On **M2**, the case for *patents* is similar: while on 1,2,4,8 threads, the matrix is partitioned respectively into 13,25,37,37 COO leaves.

The cases of *rel9* and *relat9* (Fig. 2,4) are similar. Since *relat9* has a little higher nonzeroes/row count than *rel9*, it succeeds in scaling in a limited way (up to 30 COO leaves, on both machines), but *rel9* gets partitioned in 7 leaves only, in all cases. Therefore, for *rel9*, more than 2 threads contend for row locking on 7 submatrices, with no possible scaling. Notice, however, that RSB is capable of allowing dual threaded parallelism in these *very sparse* cases, whereas RCSR was not.

The cases we have just discussed are worst/limit cases, and as such are not the primary target of our modifications, so we tolerate them here, and use them for comparison means.

Although quite different, two matrices (*sme3Dc*, *raefsky3*) suffer similar problems, when instantiated as RSB on **M1**. That is, while they are well-performing on RCSR and loosing index overhead from the RSB switch, they also get partitioned into less leaves, giving rise to the same *SpMV* scalability problem. In facts, while RCSR-8 partitions these matrices respectively into 115 (113 CSRH, 2 COOH) and 94 (CSRH) leaves, RSB-8 produces 16 (all CSRH) and 13 (11 CSRH, 2 COOH) leaves.

Given the lock-based nature of our *SpMV* algorithm, and the distribution of submatrices, RSB-8 suffers from contention problems on both matrices. It is interesting to note that on **M2**, these matrices get subdivided respectively in 115 and 94 leaves, and we observe in Fig. 3 that this suffices to scale and experience, respectively, a 7% and a 6.7% improvement. Index overhead shifts from 4.44. to 2.55 bytes/nonzero for *sme3Dc*, and from 4.28 to 2.34 bytes/nonzero for *raefsky3*.

Matrix *av41092* on **M1** experiences the same problem *sme3Dc* and *raefsky3* did: insufficient partitioning. While **M1** partitions this matrix in 10 (9 CSRH, 1 COOH) submatrices only, **M2**, due to its smaller caches, partitions it in 72 leaves (64 CSRH, 8 COOH). So, the halving in index overhead experienced on **M1** (from 4.65 to 2.27 bytes/nonzero) could not bring advantage to RSB-8, while on **M2**, the 42% index saving (from 4.5 to 2.61 bytes/nnz) allows for scaling and a modest 3% performance increase.

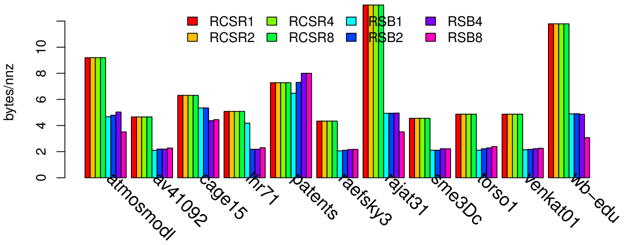

Fig. 6. Index storage requirement (in bytes) per nonzero on **M1** (square matrices).

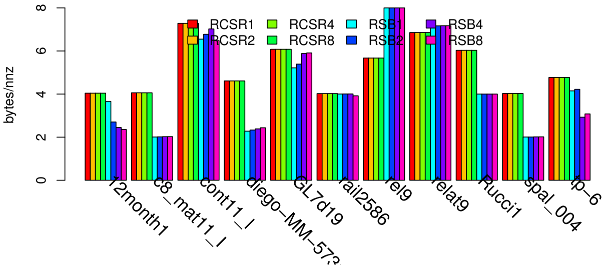

Fig. 7. Index storage requirement (in bytes) per nonzero on **M1** (non square matrices).

The remaining three cases with a missing improvement are non square matrices *c8_mat11_I*, *diego-smtxMM-573x230k*, and *rail2586* (Fig. 2). Matrix *c8_mat11_I*, alike to the matrices we have seen before on **M1**, suffers from poor partitioning, here: RSB partitions it in respectively 1,4,10,13 leaves for 1,2,4,8 threads. On 8 threads, the 13 leaves are not enough to ensure the parallel operation of all the threads, thus leaving some of them *starving*. Similarly to the previous cases, **M2**

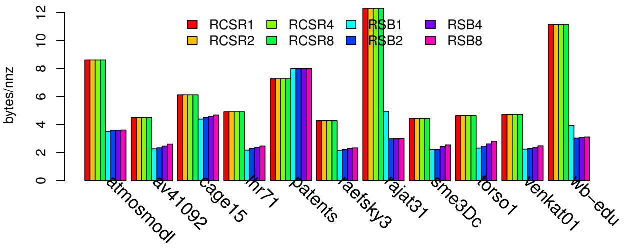

Fig. 8. Index storage requirement (in bytes) per nonzero on **M2** (square matrices).

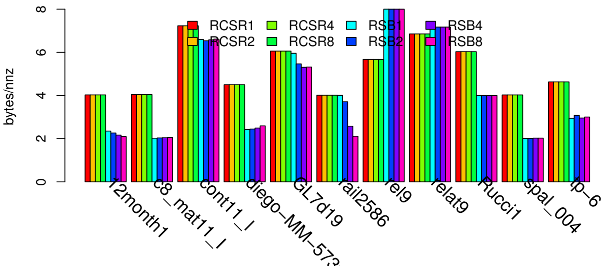

Fig. 9. Index storage requirement (in bytes) per nonzero on **M2** (non square matrices).

divides the matrix in much more leaves, thus avoiding the scaling problem.

The case for matrix *diego-smtxMM-573x230k* is different (and interesting). On **M1**, this matrix performs best as RSCR, while on **M2**, best as RSB. On both machines, though, while not scaling up to 8 threaded RCSR, it scales (although very *slightly*) for RSB, up to 8, but poorly. Poor scaling is evident: RSB-8 on **M1** is only 88% faster than RSB-1; on **M2**, only 123%. By looking at the number of submatrices, we could not say their number is too low. It is only after inspecting the distribution of submatrices (see Fig. 5), that we notice a big unbalance: actually, most of the submatrices are located on the top of the matrix, and it seems that RSB arranged submatrices in "block rows". Given the row-lock-based nature of our *SpMV* algorithm, such a distribution is enough to destroy the parallelism of the computation on this matrix. Here, after completing the bigger-dimensioned submatrices across various row intervals of the matrix, threads will try to acquire a lock on the intervals located on the upper border, with no success for most of them: only a few of them will be able to work at a time, on the upper submatrices. Contention will last during the whole computation for most of the threads, then, because our current *SpMV* algorithm has no mechanism for concurrent update of a single subvector.

Matrix *rail2586* constitutes another special case. For being *wide*, it fits particularly well when stored in a row-oriented storage as CSR. However, for having its nonzeroes scattered quite uniformly around the matrix, it would end up having very sparse submatrices, if it had not as much as 3097 nonzeroes per row, globally. But it happens that for being so wide, the proper introduction of CSRH leaves is only possible after a certain number of subdivisions. On **M1** (Fig. 12), it happens that there are not enough subdivisions for switching much of the submatrices to CSRH. So, the use of RSB for *rail2586* on **M1** does not lighten the index overhead significantly (it remains at about 4 bytes per nonzero), and the performance remains the same (notwithstanding the submatrices reduction: from RCSR's 352, to RSB-8's 55). For architectural reasons, RSB on **M2** ends up partitioning the matrix more finely, and thus falling to switch to CSRH in 335, out of the 352 leaves of RSB-8. The matrix is thus partitioned in number of matrices which is the double of RCSR's. However, in this case, the performance gain expected from RSB is negligible: less than 1%. We conjecture that the *flat* distribution of submatrices in the matrix, and its considerable width, cause a considerable overhead to the memory subsystem, which in turn is forced to continuously load elements from the right hand side vector, which would barely fit in the cache.

We notice that some matrices gain a considerable speedup from the RSB representation: *rajat31* (56%), *lhr71* (17%), *torso1* (18%) on **M2** (Fig. 4), *venkat01* (67%), *cage15* (50%) on **M1** (Fig. 2), *wb-edu* on both (68% on **M1**, 43% on **M2**). The assembled instances of these matrices as RSB differs from RCSR, for the relevant number of COO/COOH submatrices. On **M2**, *rajat31* gets partitioned in 1534 leaves, of which 896 COOH, and 126 COO; *wb-edu* in 4336 leaves, of which 2511 COOH, 254 COO; *torso1* in 357 leaves, of which 39 COOH; *lhr71* in 87 leaves, of which 34 COOH. In all these cases, index overhead is cut down approximately in a half. On matrices *rajat31* and *wb-edu*, index overhead falls down respectively from 12.3 to 3 bytes/nnz and from 11.15 to 3.12 bytes/nnz. This means that RSB *cures* cases where RCSR alone produced subdivisions abusing from CSR leaves; that is, producing CSR leaves with less nonzeroes than rows. The case for matrix *cage15* on **M1** is alike, in that it gets partitioned in 751 leaves, 132 of which are COO, 316 COOH, 6 CSR, 297 CSRH. With RSB, this configuration of *cage15* saves approximately 30% index overhead (from 6.3 bytes/nonzero), which is not much compared to other cases. So probably, the gain is due to the *fuller* submatrices (RSB-8 assembles 751 of them; RCSR as much as 4457). Performance gain on *torso1* is probably due only to index overhead saving: in RSB-8 on **M1**, it gets partitioned in 59 CSRH leaves only, (from 176 CSR), saving 64% of indexing overhead (from 4.6 bytes/nonzero, Fig. 6), which is quite good.

B. Results, Symmetric Matrices

Bar plots in Fig. 10 and 11 present the comparative performance results of RCSR and RSB for symmetric matrices. We observe performance enhancements nearly in all cases. There are three exceptions, though: *crankseg_1*, *ct20stif*, *F1* on **M1**.

We comment these exceptions first, and the remaining cases next.

On **M1**, matrix *F1* in RSB (Fig. 10) does not scale from 4 to 8 threads. On less than 8 threads, *F1* is processed faster with RCSR; e.g.: with 1 thread, *F1* gets partitioned by RSB in 10 submatrices only, all fullword CSR. But with 8 threads, RSB partitions *F1* in 72 leaves, of which 70 are CSRH and 2 COOH. With RCSR, a number of 573 leaves were obtained, which is much more. Given the higher number of subdivisions, load balancing in RCSR ran for sure smoother, while RSB did fall in a lock contention problem here, it seems. Please recall (See [5]) that our symmetric *SpMV* implementation variant incurs in a higher locking overhead than unsymmetric. On **M2**, the situation is almost reversed: for 8 cores, it is RSB that partitions *F1* in more leaves (573: 504 CSRH and 69 COOH), while RCSR divides the matrix in 278 leaves *only*. The index overhead of RCSR is quite high on *F1*: 5.08 bytes/nnz on **M2**, 5.4 on **M1**; on RSB it is always less than this, on both machines. However, the RSB index overhead depends on the threads count: on **M2** (Fig. 13) with more threads, the overhead tends to grow too, from 2.6 to 3.3 bytes/nnz, suggesting that further subdivisions could degrade performance. On the other hand, on **M1**, when going from 1 to 8 threads, this overhead decreases from 4.25 to 2.52 bytes/nnz (Fig. 12). These observations suggest us that the performance improvement over 1-core RCSR (on both **M1** and **M2**) is due to less index overhead, which itself is a consequence of less submatrices fragmentation. We believe that some *optimum partitioning* for 8 cores *F1* is between all of these four instances of RCSR/RSB on **M2**/**M1**; that is, the algorithm should have partitioned *F1* less coarsely on RSB/**M1**, more coarsely on RCSR/**M1**, and so on.

The cases for matrices *ct20stif* and *crankseg_1* (still on **M1**) are different. With *ct20stif* we observe that 2-threaded RSB fails from partitioning, thus cutting off two-cores parallelism completely (Fig. 10). On more cores the heuristic succeeds partitioning the matrix, but too coarsely to gain a sufficient workload balance. Please note that this matrix is among the smallest in our test set ($1.3 \cdot 10^6$ nonzeroes), stressing the limit of our rule of thumb (*sizing* matrices around the cache sizes). On both **M1** and **M2** machines, index usage for *ct20stif* keeps very low: for RSB it ranges from 2.27 to 2.52 bytes per nonzero, coming from RCSR's approximate 4.5. With an analogy to the previous case, on machine **M2**, partitioning is finer than on **M1**, from the single thread case on (1-threaded RSB partitions *ct20stif* to 7 submatrices), and an adequate workload balancing follows. Thus with *ct20stif* on **M2**, we do not loose the 8 threaded case, and RSB's performance is higher than RCSR's. Here, the sparser leaf submatrices are assembled as COOH (2 out of 7 on 8 cores **M1**, 2 out of 60 on **M2**), the remaining ones in CSRH. Notice that both *F1* and *ct20stif* matrices had more than 25 nonzeroes/row, which is quite sufficient to achieve good results with RCSR/RSB. Matrix *crankseg_1* is a little bit sparser (10 nnz/row). It suffers from the same *poor partitioning* problem on **M1**, having respectively 3,10,16,39 leaves for 1,2,4,8 threads, and loosing 30% of performance on 8 threads. On the other hand, on **M2**, matrix *crankseg_1* performs quite well, achieving an improvement to RCSR. The improvement itself is about 21% on 8 cores, when the matrix is partitioned in 37 COOH and 202 CSRH submatrices.

After having discussed the problematic cases, let's look at the remaining ones.

In one case there is almost no change: *nd24k* on **M1** (Fig. 10). Here, RCSR partitions the matrix in 503 CSR leaves, RSB in 87 CSRH leaves. The index overhead (Fig. 12) gets almost halved (from 4 bytes bytes/nonzero). We are not aware of the reason for the missing performance increase, here, but note that this is our symmetric matrix with the higher nnz/row count (199, see table I). On **M2** (Fig. 11), the same matrix witnesses a slight (5%) speedup, while being partitioned by RSB in 503 (all CSRH, except 5 COOH ones) pieces, and 278 ones by RCSR. The index overhead (Fig. 13) similarly to that of **M1**, halves from RCSR (4.2 bytes/nnz) to RSB (2.1 bytes/nnz). We conjecture that the 87 leaves on **M1** somehow limited parallelism, but we would need to investigate further to confirm this.

In one case, on **M1**, RSB performance boosts up as high as 66%, when compared to RCSR: it is for matrix *s3dkq4m2* (Fig. 10). Here, RCSR partitions in 127 leaves, while RSB in 15 only (8 CSRH, 7 COOH). We observe the index overhead (Fig. 12) is almost halved, switching from RCSR to RSB (for > 1 threads). We deem that this speedup is due to a case in which the matrix offers caching potential (the whole result vector and a matrix portion): on **M2**, where the L3 cache is considerably smaller than on **M1**, the performance of *s3dkq4m2* improves by only 2%, passing from 63 leaves of RCSR to 120 CSRH and 7 COOH leaves of RSB. Performing a run with *cold caches* (that is, making sure that any location caching the matrix or the involved vectors gets overwritten between each *SpMV*), on **M1** the performance of RSB is approximately 7% lower, while on **M2** it made no difference (and the boost becomes 55%, rather than 66%). Please note that the smallest symmetric matrix in the test set is not *s3dkq4m2* but *ct20stif*, which we have commented before.

When switching from RCSR to RSB on **M2** (Fig. 11), we observe speedups in all cases. Probably, L3 cache on **M2**, smaller than on **M1**, induced too coarse partitionings, thus limiting the scalability of our symmetric *SpMV*.

We can now comment the cases where the biggest improvement was observed: *af_shell10* (30%), *BenElechi1* (29%), *bone010* (24%), *fcondp2* (20%), *ldoor* (19%) on **M1** (Fig. 12), and *fcondp2* (28%), *crankseg_1* (21%), *ldoor* (16%), *F1* (12%) on **M2** (Fig. 13). For *af_shell10* on **M1**, we observe that RSB instantiates 255 submatrices (192 CSRH, 48 COOH, 15 COO), while RCSR used to instantiate 1534 CSR leaves. This matrix is also the one to experience the higher saving in index overhead: from 5.22 to 2.5 bytes per nonzero (more than 50%, Fig. 12). Matrix *BenElechi1* gets partitioned by RSB in 63 leaves: 32 CSRH, 30 COOH, 1 COO; by RCSR in 382 CSR matrices. Index usage (Fig. 12) halves: from 4.66 to 2.25 bytes per non zero. Similarly to the *af_shell10* case, we experience a smaller number of leaf matrices, a more appropriate leaf matrix selection, and a consequent reduction in indexing overhead. On **M2** (Fig. 11), the same matrix improves only by 1.6%. By looking at its partitioning, we notice that it is partitioned in 127 leaves by RCSR, which is much less than RSB's 255 leaves (238 CSRH, 16 COOH, 1 COO). For *bone010*, RCSR assembles 1316 CSR matrices; RSB assembles 170 CSRH, 2 CSR, and 5 COO. Index usage is reduced down from 4.6 to 2.5 bytes/nnz (Fig. 13). On **M2**, RSB assembles 1054 CSRH, 279 COOH, and 5 COO submatrices, while RCSR allocates 630 CSR leaves (index overhead shifting from 4.53 to 2.55 bytes/nonzero). Again, it seems the partitioning proceeded too deeply. Matrix *fcondp2* is partitioned in 31 leaves (19 CSRH, 1 CSR, 11 COOH) with RSB, and with RCSR in 255 leaves. Index overheads falls from 4.63 to 2.42 bytes/nnz. On the same matrix, on **M2** the improvement is even higher, this time. Here, RSB partitions in 257 leaves (182 CSRH, 75 COOH), while RCSR in 127 leaves only. Index overhead falls from 4.56 to 2.5 bytes/nonzero. So, in contrast to the preceding cases, matrix *fcondp2* benefits from increased subdivision, on **M2**. Matrix *ldoor* is partitioned in 157 leaves (122 CSRH, 5 CSR, 26 COOH, 4 COO, 3.14 bytes/nnz) by RSB, and 789 leaves by RCSR (5.47 bytes/nnz, Fig. 12). On **M2**, the performance gain is smaller than on **M1** (16%, rather than 19%). Partitioning of *ldoor*, here, produces 804 (471 CSRH, 329 COOH, 4 COO) submatrices, while RCSR produces 431 leaves. Also index overhead falls more gently: from 5.30 to 3.36 bytes/nnz.

We conclude by observing that there is a strong correlation between the index saving and performance gain: milder index savings on **M2** showed milder performance improvements, while bigger index savings on **M1** were accompanied by higher improvements.

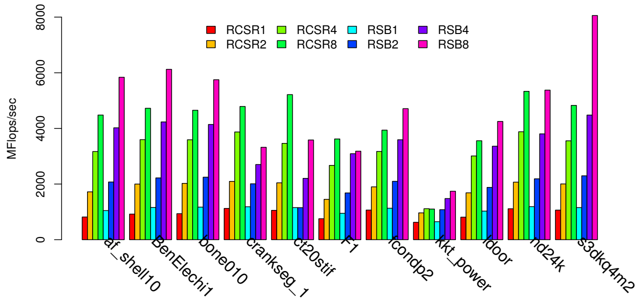

Fig. 10. Symmetric *SpMV* on **M1**.

C. Comparative analysis

Let us now look at the performance of all matrices as RCSR, RCSRH, and RSB, using 8 threads. For unsymmetric matrices, we also give performance results for the CSB prototype. Unfortunately, we had to skip matrix *cage15* (the one with the highest nonzeroes count), because CSB was unable to instantiate it (the CSB implementation needed more memory than the 24 GB available on **M1**).

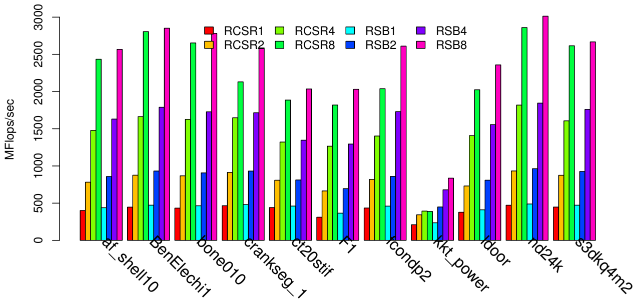

Fig. 11. Symmetric *SpMV* on **M2**.

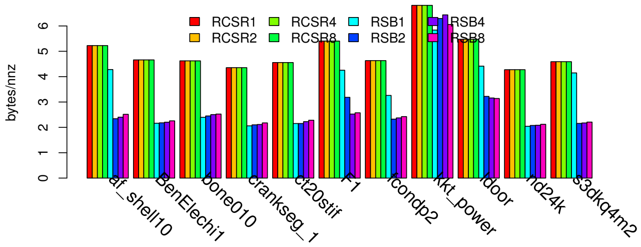

Fig. 12. Index storage requirement (in bytes) per nonzero on **M1** (symmetric matrices).

We observe that for **M2** (Fig. 15): matrices which favor RSB most (over CSB) are *c8_mat11_I*,*spal_004*,*wb-edu*; one matrix looses against RCSR (*cont11_l*); the majority of RSB cases is faster than RCSR (19 matrices out of 20). Summarizing, RSB performs faster than CSB (and is also the fastest among the four cases) in 7 cases out of 20. CSB is the fastest in 12 cases; in one case it is faster than RSB, but not the fastest one.

On **M1** (Fig. 14) we observe that: RSB is much faster than CSB on *wb-edu* and *venkat01*; 6 matrices seem to perform very similarly in both CSB or RSB; the remaining ones perform better in one of the two formats. Some matrices loose performance in RSB, over RCSR: matrices *av41092*,*c8_mat11_I*,*cont11_l*; (slightly) *diego-smtxMM-573x230k*,*sme3Dc*; other matrices favor RSB over RCSR: about 15, out of 20.

For space reasons, we omit figures showing comparative performance for symmetric matrices on RCSR, RCSRH, RSB formats, but include some general comments.

On **M2**, we notice RSB as the fastest format 5 times out of 12; on **M1**, 4 times. Here, RCSRH is the fastest in 7 cases; in all cases, very near to RSB. On **M1**, we see a similar situation, but notice a performance degradation in some additional cases: they are due to the poor partitioning problem discussed in Section V-B. In no case RCSR was the fastest format for

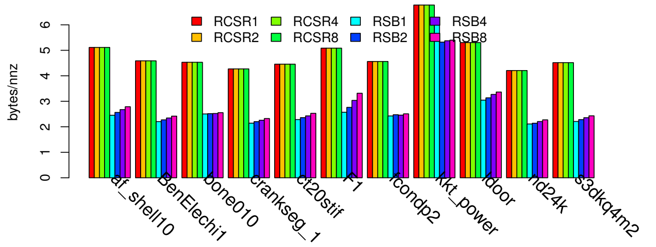

Fig. 13. Index storage requirement (in bytes) per nonzero on **M2** (symmetric matrices).

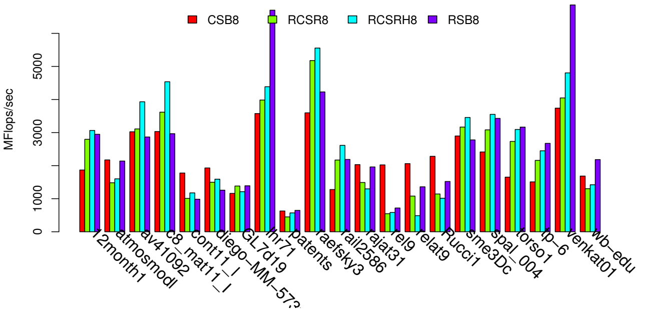

Fig. 14. Results for 8 cores on **M1**, comparing CSB, RCSR, RCSRH, and RSB (unsymmetric matrices).

symmetric matrices (exception made for the poorly scaling three matrices) on **M1**: (*crankseg_1*, *ct20stif*, *F1*).

VI. Conclusions and Future Work

In this paper, we have shown a possible improvement of our BLAS-oriented recursive storage for sparse matrices. We have found that, by using index compression and format diversification techniques, we can improve the floating point performance of *SpMV*. We have also found that, for unsymmetric matrices, the performance of our modified format (RSB) is comparable to that of a scalable sparse matrix format (CSB: currently for unsymmetric only). During comparison with RCSR and CSB, we noticed some particular cases that expose *weak points* of both RSB and RCSR; consequently allowing us to identify room for further improvement: (i) To redefine our format in order to obtain some estimate on the parallelism expected from a given partitioning (in Section V-B, we noticed that, despite the apparently adequate partitioning, some instances of matrices (e.g.: smaller symmetric) did not scale on 8-threaded *SpMV*). (ii) To modify the *SpMV* algorithm to be more parallel, by working around the need for row locking (e.g.: by using temporary vectors, as CSB does [2, Sec.4], although this may be challenging in our case). (iii) While our primary interest is focused on bigger matrices, tuning the partitioning algorithm for small matrices could prove useful to ensure parallelism in these cases, too. (iv) Properly subdividing matrices which are big, but with an extremely low nonzeroes/row ratio would be challenging (and fruitful), as well.

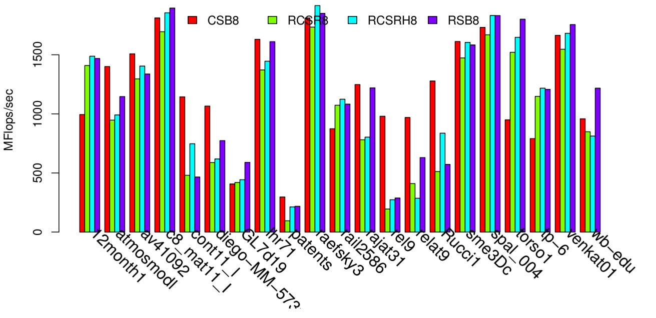

Fig. 15. Results for 8 cores on **M2**, comparing CSB, RCSR, RCSRH, and RSB (unsymmetric matrices).

Some ideas we have introduced should be developed further. For instance, a more aggressive form of tuning could diversify index types at the *leaf level* and continue using traditional CSR or COO layouts, if profitable. Probably future architectures (with much higher number of cores, and even higher risks for stall due to higher memory latencies and longer instruction pipelines) would render such approaches advantageous.

In summary, we can state that our work illustrates that combinations of hierarchical indexing and index compression techniques can be useful to achieve high efficiency of computing on sparse matrices (on general purpose hardware). In this light, we see the RSB format as a candidate format for a complete multicore sparse BLAS implementation (that is, support for symmetric storage, solve operations, parallel transposed *SpMV*, etc.).

Finally, we would like to thank Jamie Wilcox and Victor Gamayunov from Intel EMEA Technical Marketing HPC Lab for their technical support during experiments.

***Abstract*—Paper presents results obtained when porting FEM 2D linear elastostatic local stiffness matrix calculations to Tesla architecture with OpenCL framework. Comparison with native NVIDIA CUDA implementations has been provided.**

I. Motivation

IN FINITE element simulations usually two computation stages most significantly impact performance of the whole process:

- obtaining global stiffness matrix
- solving system of linear equations

In case of non-linear, higher order element geometry, higher order approximations and p and hp-adaptations, process of obtaining global stiffness matrix requires computationally intensive separate calculations of local (element) stiffness matrices. For some problems it can be most time consuming stage of FEM calculations.

Aim of our work is parallelizing this stage utilizing modern graphics processor units (GPUs) and OpenCL platform.

The paper is organized as follows. The first two sections are devoted to the definition of the problem of FEM numerical integration. In the third section we summarize the problem in terms of requirements for numerical algorithms. Then we show how to design parallel algorithms that solve the formulated computational problem on modern GPUs. The results of experiments close the paper.

II. Finite element numerical integration

The standard procedure in FEM computations consist in obtaining weak formulation of a problem, discretizing problem domain Ω into finite elements and utilizing appropriate basis functions—constructed from element shape functions—to create a system of linear equations, with the global stiffness matrix as the system matrix, that is then solved to provide approximate solution.

Generation of global stiffness matrix is usually performed by calculating integrals over finite elements, then assembling obtained that way local matrices into global one. Since integrals evaluation over multiple different element geometries (possibly curved) would pose a problem, elements are mapped to a reference element with simple geometry and integrals are calculated over its area. Every element is processed independent of the others thus many can be calculated in parallel.

III. Model problem

We chose 2D linear elastostatics problem. As a model finite element we use quadrilateral with curved, second order, geometry. Solution is approximated with hierarchical shape functions up to order $p = 7$, constructed from tensor products of 1D Lobato hierarchical functions [2]. Reduced space was used with number of shape functions equal to

$$n = 4 + 4(p-1)_+ + (p-2)(p-3)_+/2$$

where q_+ denotes $max(q, 0)$. Local stiffness matrix dimension is equal to $2n$, where n is number of shape functions for a particular order p. Matrix entries are results of calculating the integral [1]

$$k^{(e)}_{IJ} = \iint_{\Omega_{ref}} (([D^*]\{\varphi_I\})^T [E][D^*]\{\varphi_J\}) \mid J \mid d\xi d\eta \quad (1)$$
$$I, J = 1, 2, ..., 2n$$

where $k^{(e)}_{IJ}$ is (I, J) matrix entry, Ω_{ref} is $[-1,1] \times [-1,1]$ reference quadrilateral, $[E]$ is 3×3 material matrix, $\mid J \mid$ is the determinant of the Jacobian matrix of geometry transformation, $\{\varphi_I\}$ and $\{\varphi_J\}$ are columns of $2n \times 2$ matrix of shape functions. $[D^*]$ is the matrix differential operator

$$[D^*] = \begin{bmatrix} \frac{\partial}{\partial x} & 0 \\ 0 & \frac{\partial}{\partial y} \\ \frac{\partial}{\partial y} & \frac{\partial}{\partial x} \end{bmatrix}$$

where

$$\begin{aligned} \frac{\partial}{\partial x} &= J^*_{11}\frac{\partial}{\partial \xi} + J^*_{12}\frac{\partial}{\partial \eta} \\ \frac{\partial}{\partial y} &= J^*_{21}\frac{\partial}{\partial \xi} + J^*_{22}\frac{\partial}{\partial \eta} \end{aligned}$$

and $[J^*]$ is inverse Jacobian matrix.

Integration over reference quadrilateral is done using Gauss quadratures where the double integral is replaced by double sum

$$\int_{-1}^{1}\int_{-1}^{1} f(\xi,\eta) d\xi d\eta \approx \sum_{i=1}^{n_g}\sum_{j=1}^{n_g} f(\xi_i,\eta_j) W_i W_j$$

978-83-60810-27-9/09/$25.00 © 2010 IEEE

In case of bilinear mapping, integration is accurate when number of gauss points n_g in both dimensions is not less than $(p+1)^2$ where p is order of approximation (i.e. highest polynomial order in shape functions set).

IV. Computation overview

Evaluating the double integral boils down to calculating double sum, which can be achieved with single loop over gauss points in two dimensions. In every iteration, for every entry in a matrix, the result of calculating (1) is multiplied by Gauss weights and added to the (first zeroed) element stiffness matrix matrix.

The integrated formula differs for different matrix entries only in shape functions used—for every entry a distinct pair of shape functions is evaluated (taking into account the symmetry of a matrix).

Jacobian determinant and the inverse of Jacobian matrix (which appears in $[D^*]$ operator) are the same for all matrix entries thus can be calculated once per iteration.

Assuming constant Young modulus and Poisson ratio over a single finite element, material matrix $[E]$ can be calculated once per element.

Calculation of single local stiffness matrix requires:

- single calculation of material matrix $[E]$
- n_g calculations of Jacobian determinant and inverse of the Jacobian matrix, where n_g is number of gauss points
- $n_g\frac{n(n+1)}{2}$ calculations of entries (1), where n is matrix dimension (symmetric matrix case)

V. Parallel numerical integration in OpenCL

Finite element local stiffness matrices are calculated independent of each other therefore can be carried out concurrently. The process of calculating a single local stiffness matrix can also be parallelized by simultaneous computations of its entries. Therefore we can identify two possible parallelization levels:

- processing finite element matrices
- processing matrix entries

This naturally fits to OpenCL parallelization model [4] of:

- work-groups executed concurrently, independent of each other
- work-items executed concurrently, cooperating inside each work-group

Our implementation takes advantage of above similarities and divides computations as follows:

- each work-group is responsible for processing single finite element
- work-item is responsible for calculating one or more matrix entries

Despite the fact that the OpenCL platform aims to provide unified execution environment for broad range of hardware solutions like multi-core CPUs, graphics processors and accelerators like IBM Cell, programmer still needs to realize differences between them and optimize his code accordingly. Our implementation targets Nvidia Tesla architecture.

Calculations on device, in our case GPU, are directed by host CPU. Its role is to upload elements data into device global memory, execute kernel and download output matrices when kernel finishes. If not all elements can be processed in single kernel launch—for example due to limited amount of global device memory—whole computations can be divided across multiple sequences of:

- uploading data to device memory
- executing kernel
- downloading data

Kernel launch is non-blocking therefore host can process remaining batches of elements while waiting for GPU to finish, thus increasing overall performance.

Parallel calculations overview is presented on Fig.1.

Each work-group reads the data representing particular finite element from global device memory. Then work-items in cooperation evaluate matrix entries and store them in local memory—shared by all items in a work-group. When done, matrix is copied from local to global device memory accessible by host.

Data that are common for all finite elements i.e. gauss points and weights is calculated once on CPU, stored in constant memory and available for all work-groups. Constant memory is cached on a GPU and well serves the purpose of supplying the multiprocessors with the data that are the same for all elements of a given order p.

During the execution work-groups are queued and successively consumed by device computation units. Each computation unit—in our case a GPU multiprocessor—can execute more than one work-group at a time, however splitting single work-group across many computation units is not allowed.

The number of simultaneously processed work-groups on single computation unit (resident work-groups) depends on factors like consumption of registers, consumption of multiprocessor local memory and size of a work-group. GPU scheduling hardware will send as much work-groups as possible for concurrent execution on single multiprocessor until there are no resources left. In situation when number of consumed registers, shared memory or number of work-items exceeds the half of maximum available for particular hardware, only one work-group at a time will be resident on single multiprocessor.

Optimal use of multiprocessor resources is important to achieve high occupancy i.e. high number of work-items from one or more work-groups executed concurrently on multiprocessor. In our case resource consumption depends on approximation order—the higher is the order p the bigger is the local stiffness matrix and more local memory is needed by work-group during the computations.

Resource limits for Nvidia GPU devices of compute capability 1.3 (all cards we tested) are:

- Multiprocessor registers: 16384
- Local memory per multiprocessor: 16KiB
- Maximum number of work-items in work-group: 512
- Maximum number of resident work-items on multiprocessor: 1024

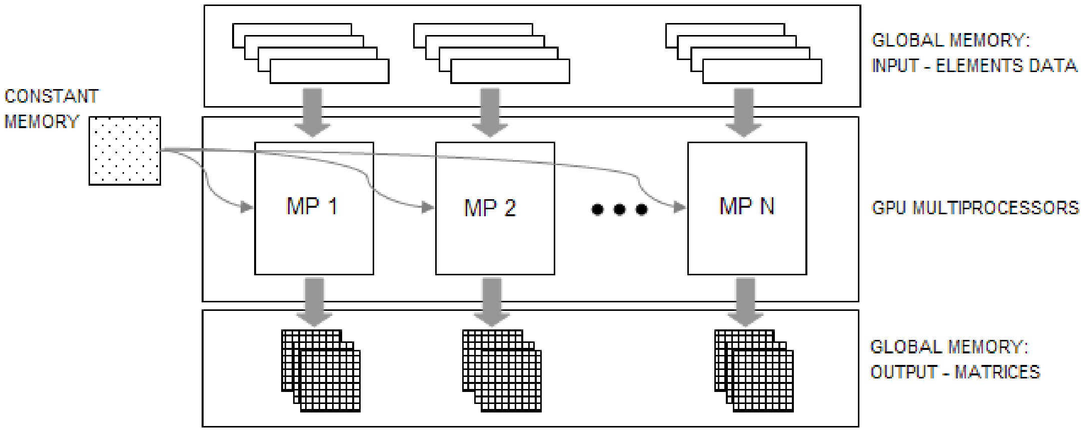

Fig. 1. Parallel calculations on GPU.

Available registers are uniformly distributed among resident work-items executed on multiprocessor and local memory is divided across resident work-groups.

In order to generate local stiffness matrix for single finite element, following information needs to be supplied (23 float values in total):

- geometry of quadrilateral (coordinates of its vertices and second order geometry mapping nodes)
- edge orientations
- material information (Young modulus, Poisson ratio)

We have padded each element data to 32 and placed all elements data in contiguous region of global memory in order to achieve specific coalesced access pattern [3] by every work-group. For the same reason we also used padding for output matrices.

Every work-group (i.e. all its work-items executing in parallel) performs single coalesced read from input global memory region in the beginning of computations to get element data and coalesced writes at the end of execution to store generated matrix.

Total size of input data is

$$32 * sizeof(float) * numelems$$

Total size of output matrices is

$$matpaddedsize(p) * sizeof(float) * numelems$$

where $matpaddedsize(p)$ is matrix size with padding and depends on order of approximation p. Due to symmetry we are only calculating and storing upper-half matrices, thus reducing both local and global memory usage. Sizes of matrices for different approximation orders are presented in table I.

Depending on the order p different kernel is being executed on the device. Flow of computation for every kernel is similar. The differences come from different number of gauss points, different set of hierarchical shape functions and different sizes of matrices and manifest themselves in:

- amount of local memory needed to compute stiffness matrix
- number of iterations over gauss points
- amount of local memory needed to compute derivatives of shape functions in every Gauss point
- number of matrix entries per work-item
- number of work-item engaged in calculations of stiffness matrix (which is less-or-equal to the work-group size)

For every kernel we configured computations in such way not to exceed the available computation unit resources (registers and local memory), maximize global memory throughput with coalesced reads and writes, maximize computation unit occupancy and minimize divergent branches inside groups of 32 consecutive work-items called warps.

Execution configuration included proper sizing of work-groups and defining number of matrix entries calculated by single work-item. We experimented with broad range of configurations for every kernel in order to chose optimal ones—those are presented in table I.

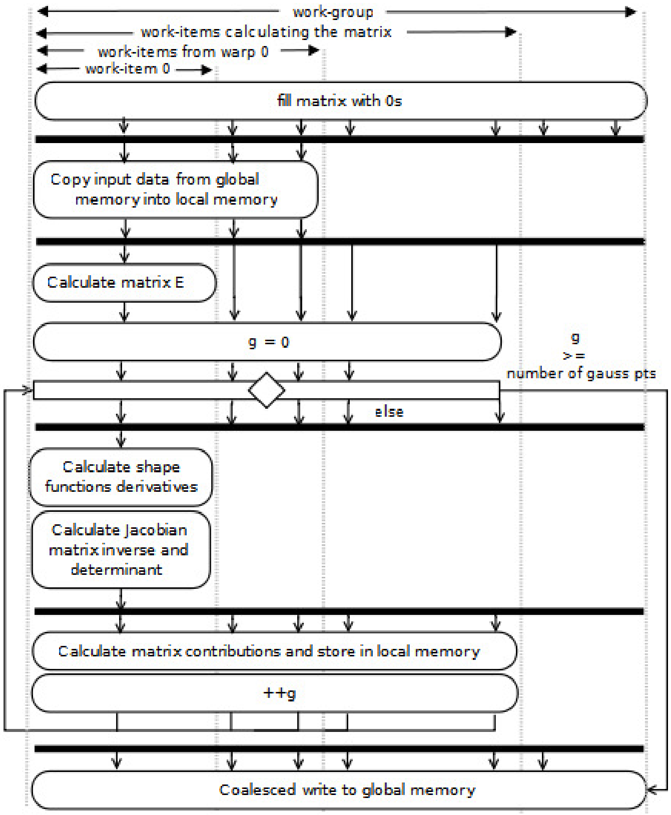
In case of higher p orders, limited multiprocessor resources—especially local memory size of only 16KiB on Tesla architecture—prevented simultaneous execution of more than one work-group thus reducing multiprocessor occupancy.

We implemented kernels for orders of approximation up to 7—for higher orders half-matrix size is bigger than amount of local memory available on Tesla architecture and different approach to computations would be needed.

VI. Kernel computations

Main steps of kernel execution are:

1) Zero matrix in local memory (all work-items)
2) Load element data from global memory (first warp)
3) Calculate 3×3 material matrix $[E]$ (single work-item)
4) Loop over gauss points:
   a) Calculate values of shape functions derivatives (single work-item)



work-group
work-items calculating the matrix
work-items from warp 0
work-item 0
fill matrix with 0s
Copy input data from global memory into local memory
Calculate matrix E
g = 0
g >= number of gauss pts
else
Calculate shape functions derivatives
Calculate Jacobian matrix inverse and determinant
Calculate matrix contributions and store in local memory
++g
Coalesced write to global memory

Fig. 2. Work-group execution.

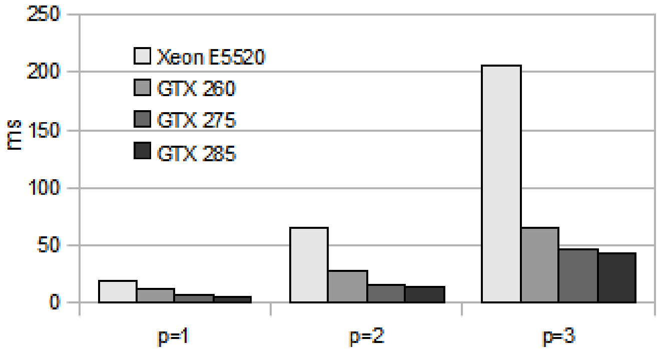


Fig. 4. Execution times for 10000 elements.

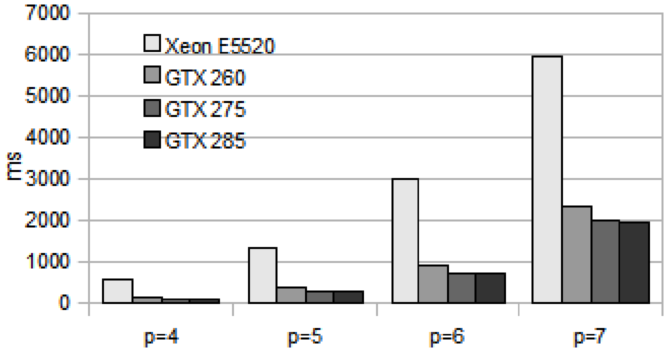

Fig. 5. Execution times for 10000 elements (continued).

b) Calculate Jacobian determinant and the inverse of Jacobian matrix (single work-item)
c) Calculate stiffness matrix contributions (in parallel—number of work items depends on kernel—see table I)

5) Upload matrix to global memory (all work-items)

Fig. 2 presents the calculation flow for a work-group. Black horizontal bars indicate OpenCL $CLK\_LOCAL\_MEM\_FENCE$ synchronization barriers. Those are needed to ensure that all calculations from previous steps are done before utilizing their results in steps that follows. We experimented with disabling synchronizations in order to observe their influence on overall algorithm performance—execution times dropped by not more than 5%.

Material matrix $[E]$, Jacobian determinant, inverse of Jacobian matrix and shape function calculations never took more than 10% of total execution time. Attempts to spread shape functions calculations across more work-items and perform them in parallel resulted in higher register consumption per work-item thus reducing occupancy and decreasing performance for most kernels.

In order to effectively utilize limited local memory, local stiffness half-matrix is stored in linear contiguous fashion row by row, every consecutive row being one shorter than previous. Every work-item in a work-group is identified by its local id obtained with get_local_id device function. Assignment of matrix entries to distinct work-items relies on mapping formula involving square root operation. Fig. 3 presents work-items assignments for kernel $p = 3$. For example work-item with id 44 is responsible for calculating five matrix entries at positions (22,11), (23,11), (12,12), (13,12) and (14,12). Work-items with numbers from 60 to 63 are left idle during matrix calculations, but do participate in writing padded matrix to global memory when done.

Matrices in every kernel are padded to the nearest multiply of 32 and their size is multiply of work-group size to achieve coalesced writes.

VII. Results

Figures 4 and 5 show results we obtained while calculating 10^4 matrices on 3 NVDIA GTX series graphics cards. For comparison we performed tests of cache optimized sequential code run on single Nehalem core of Intel Xeon E5520 processor.

Best performing kernel ($p = 4$) achieved 5.3 speedup over sequential implementation. Lowest speedups of 3.3 and 3 were observed with kernels for $p = 1$ and $p = 7$ respectively.

For GPU implementation timings include transfers of data between host and device through PCI-Express bus ($clEnqueuReadBuffer$ and $clEnqueueWriteBuffer$ host functions). Data transfer is amortized—especially for lower order kernels—only when number of processed elements is high enough—for example for $p = 1$ and 1000 elements transfers take 25% of total execution time while for $p = 5$ only 4%.

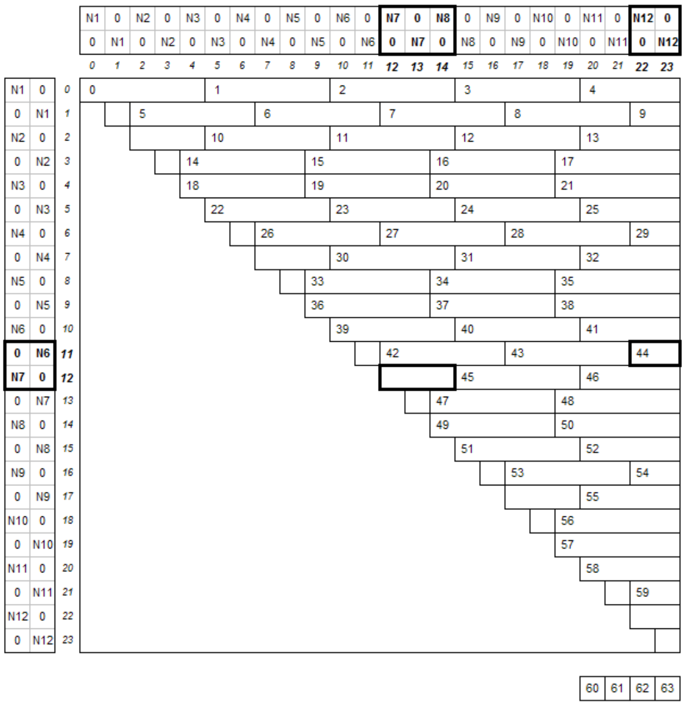

Fig. 3. Work-items to matrix entries assignment for $p = 3$.

TABLE I
KERNEL PARAMETERS

	p=1	p=2	p=3	p=4	p=5	p=6	p=7
Work-group size	64	192	64	128	192	384	448
Work-items involved in matrix generation	36	136	60	119	181	366	418
Matrix dimension	8	16	24	34	46	60	76
Padded matrix entries number	64	192	320	640	1152	1920	3136
Register consumption per work-item	12	13	18	19	20	19	18
Local memory consumption per work-group (bytes)	568	1208	1848	3288	5528	8824	13944

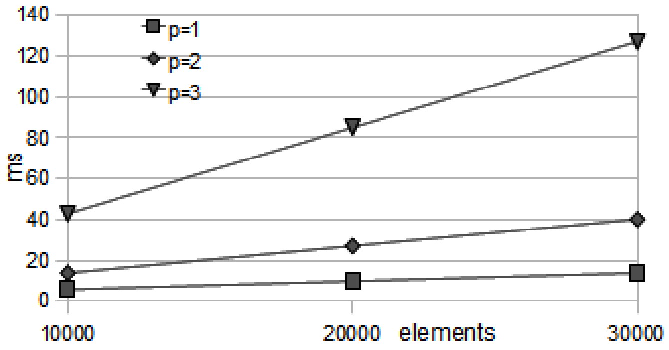

Fig. 6. Execution times for different elements number on GTX 285.

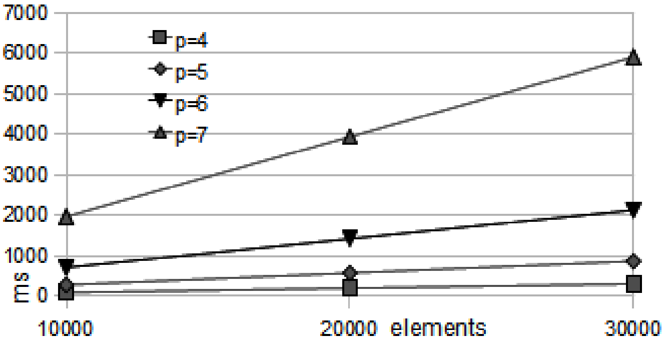

Fig. 7. Execution times for different elements number on GTX 285 (continued).

Figures 6 and 7 present execution times with varying number of elements processed. As expected execution time scales in linear fashion with elements number—as every element is represented on device by work-group and work-groups are queued for execution on multiprocessors.

Of 3 cards tested 2 (GTX 275 and GTX 285) have the same number of multiprocessor (32) and differ in global memory bus bandwidth—448 bit and 512 bit respectively. Performance difference between those two cards is minimal as compared to

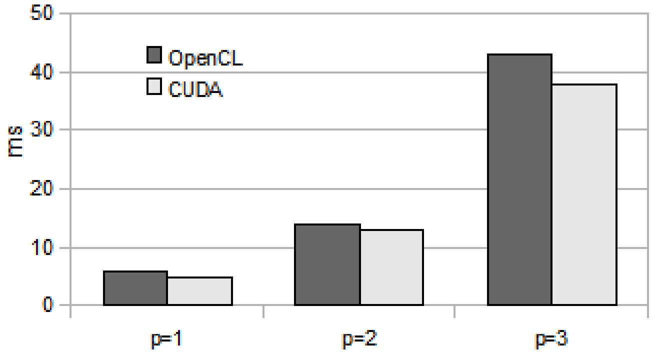

Fig. 8. Performance comparision of OpenCL and CUDA with 10000 elements on GTX 285.

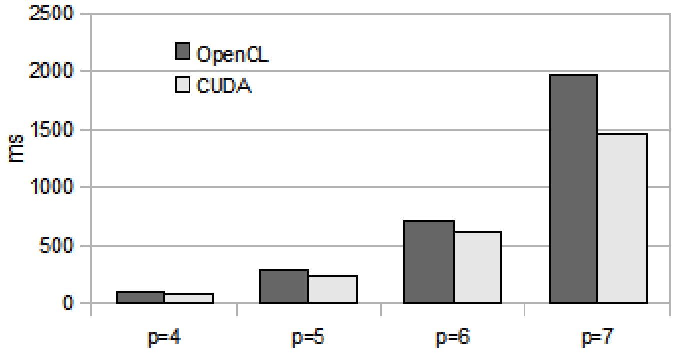

Fig. 9. Performance comparision of OpenCL and CUDA with 10000 elements on GTX 285 (continued).

the difference between cards with different number of multiprocessors (GTX 260 with 27 and GTX 275 and GTX 285 both having 30). Our implementation isn't memory constrained since all operations except single input and output coalesced writes are performed on local multiprocessor memory and the biggest size of transferred batch is only 13KiB for matrix of $p = 7$.

One can expect linear performance scaling with increasing number of GPU multiprocessors. Number of simultaneously processed work-groups on all multiprocessors is given as:

$$R_{wg} \times M$$

where R_{wg} is number of resident work-groups per multiprocessor and M number of multiprocessors. Let t_1 be the time that takes to process $R_{wg} \times M_1$ work-groups on GPU G_1 having M_1 multiprocessors. Similarly t_2, M_2 for GPU G_2. Assuming identical performance (i.e same clock rate and architecture) of multiprocessors in both GPUs $t_1 = t_2 = t$. Total time of processing N work-groups on GPU G_1 is:

$$T(G_1, N) = \frac{N}{M_1 \times R_{wg}} t$$

and on G_2:

$$T(G_2, N) = \frac{N}{M_2 \times R_{wg}} t$$

Speedup calculated as a ratio of those two times:

$$\frac{T(G_1, N)}{T(G_2, N)} = \frac{\frac{N}{M_1 \times R_{wg}} t}{\frac{N}{M_2 \times R_{wg}} t} = \frac{M_2}{M_1}$$

indicates linear scaling with number of multiprocessors.

According to the above statement observed speedup should be not less than 11% between GTX 260 and GTX 275 processors. Our benchmarks demonstrate speedup in fact being higher—especially for lower orders of approximation—due to increased GPU clock-rate and better system components (i.e. CPU, motherboard) on machine equipped with GTX 275 card.

We compared OpenCL performance with native NVIDIA CUDA 3.0 implementations (see Figures 8 and 9) of our kernels. For $p = 1$ and $p = 2$ kernels were compiled with same register consumptions on both platforms and results are close. Initial compilation of other kernels resulted in increased register usage of OpenCL kernels as compared to CUDA.

Since higher register consumption resulted in much lower occupancy and significantly decreased performance we forced OpenCL compiler to use the same number of registers as in the CUDA build. Consumption decreased, but unfortunately OpenCL compiler was unable to achieve this without spills to slow private memory thus slightly decreasing performance (however not that much as with increased register consumption).

Overall performance of OpenCL in our case is comparable to CUDA, except when compiler is not able to optimize its output the way more mature CUDA tools do.

Abstract—**In this paper we investigate the parallelization of Hestenes-Jacobi method for computing the SVD of an mxn matrix using systolic arrays. In the case of real matrix an array of R^2 processors is proposed, such that each row contains n columns. In order to extend this idea we have presented three transformations which are used for transforming the complex into the real matrix. After the additional computations, we show how the same array may be used for the SVD of a complex matrix.**

I. Introduction

THE Singular Value Decomposition (SVD) is a matrix decomposition of a great importance in different engineering applications. It is particularly useful in the areas of signal and image processing, robotics, pattern recognition etc. This decomposition can be used for determining the rank of a matrix in numerically reliable manner [2,7]. Different approaches are known in the literature for the parallel computation of the SVD of a matrix where the elements are meanly real numbers. In [5], an expandable array for parallel computing of SVD of large matrices is proposed. In [11], the use of CORDIC method for SVD is demonstrated. In [14] is given a fast Jacobi-like algorithm for the parallel solution of the SVD not focusing in CORDIC form, but by applying approximate rotations. In some applications one needs to use complex matrices as well (like in beam-forming algorithms in the signal processing [8]). In this paper we propose an approach which offers parallelization using systolic arrays. First we give the method of constructing the corresponding systolic array where the matrix is real, and then we analyze how the corresponding systolic array for the SVD can be designed if the elements of the matrix are complex numbers. This differs from the case of real matrix, because of the fact that complex arithmetic and matrix transformations in this arithmetic require greater number of computational steps. In [9] it is proposed the SVD of a matrix with complex elements where the matrix is with special structure. On the other hand in [10] this idea is extended for an arbitrary complex 2x2 matrix. In [12] is presented a systolic design concept for iterative algorithms when the VLSI design keeps evolving into nanoscale. In [15] is designed the parallelism of the so called Hestenes-Jacobi method for the SVD using the ring array. A systolic array for the computation of the SVD is presented in [5]. The array uses $(n/2)^2$ processors and is capable of processing the SVD of a square matrix. The time complexity is $O(n\log n)$, which is to be compared with the best serial algorithms, which have a $O(n^3)$ time complexity. In [13,16] the efficiency of this array is improved. In this paper it is given a model of systolic array for the SVD of an mxn matrix which can be found with the Hestenes-Jacobi method. Then, in the case of a complex matrix, there are given some transformations which transform the complex into the real matrix. Using these transformations the same systolic array can be used for the SVD of complex matrix.

II. The SVD of A Matrix

The SVD of an $m\times n$ matrix A is given by:

$$A = U\Sigma V^T =$$

$$\begin{bmatrix} u_1 & u_2 & \dots & u_{m-1} & u_m \end{bmatrix}_{m\times m} \begin{bmatrix} \sigma_1 & 0 & 0 & \dots & 0 \\ 0 & \dots & & & \\ 0 & 0 & \sigma_r & \dots & 0 \\ 0 & 0 & 0 & \dots & 0 \\ 0 & 0 & 0 & \dots & 0 \end{bmatrix}_{m\times n} \begin{bmatrix} v_1^T \\ v_2^T \\ : \\ v_{n-1}^T \\ v_n^T \end{bmatrix}_{n\times n} \quad (1)$$

where U and V are orthogonal $m\times m$ and $n\times n$ matrices respectively, (i.e., $U^T U=I_m$ and $VV^T=I_n$) and Σ is a diagonal $m\times n$ matrix such that $\Sigma=diag(\sigma_1,\sigma_2,\dots)$; $\sigma_1\geq\sigma_2\geq\dots\geq\sigma_r\geq\sigma_{r+1}=\dots=\sigma_k=0$ where $r=rankA$. In the case $m=n,\ \Sigma$ is square diagonal matrix of order n . In the definition given above the σ_i -s are the singular values of A .

The SVD decomposition is often based on diagonalizing rotations which are orthogonal transformations which preserve Eigenvalues and Eigenvectors as well as singular values and singular vectors. The sequence of rotations A_k , such that $\lim_{k\to\infty} A_k=\Sigma$, is applied during the process.

III. Jacobi Rotations

The classical Jacobi rotation [1] has been used by Jacobi in 19th century as a tool for solving the least square problem. This rotation is also called Given's rotation. This method uses a sequence of plane rotations to diagonalize a symmetric $n \times n$ real matrix A. We denote the Jacobi rotation of an angle θ in the (i, j) plane by $J(i, j, \theta)$. This is a square matrix equal to the identity matrix except the four additional elements in the intersection of i-th and j-th rows and columns:

$$\begin{array}{r|ccccccc|}
 & & & i & & j & & \\
 & 1 & & & & & & \\
 & & \cdots & & & & & \\
i & & & c & \cdots & s & & \\
J(i,j,\theta)= & & & & \cdots & & & \\
j & & & -s & \cdots & c & & \\
 & & & & & & \cdots & \\
 & & & & & & & 1
\end{array}$$

where $c = \cos\theta$ and $s = \sin\theta$. It's not difficult to verify that this is an orthogonal transformation because of the fact that $J(i,j,\theta)^T J(i,j,\theta) = I$ for each θ. The rotation angle θ is chosen such that to annihilate the $n(n-1)$ off-diagonal elements of the given matrix. Each Jacobi transformation brings the matrix A closer to the diagonal form [2].

In the two sided Jacobi method for the SVD decomposition of a nonsymmetric matrix, the annihilation of the off-diagonal elements is done using a pair of rotations [3], such that:

$$\begin{bmatrix} a_{ii}^{k+1} & 0 \\ 0 & a_{jj}^{k+1} \end{bmatrix} = \begin{bmatrix} c_1 & -s_1 \\ s_1 & c_1 \end{bmatrix}^T \cdot \begin{bmatrix} a_{ii}^k & a_{ij}^k \\ a_{ji}^k & a_{jj}^k \end{bmatrix} \cdot \begin{bmatrix} c_2 & s_2 \\ -s_2 & c_2 \end{bmatrix} \qquad (2)$$

If θ_1 and θ_2 are the angles generating the pairs (s_1, c_1) and (s_2, c_2) then the solution given in [3] is:

$$tg(\theta_1 + \theta_2) = \frac{a_{ji}^k + a_{ij}^k}{a_{jj}^k - a_{ii}^k}, \quad tg(\theta_2 - \theta_1) = \frac{a_{ji}^k - a_{ij}^k}{a_{jj}^k + a_{ii}^k} \qquad (3)$$

IV. HESTENES-JACOBI METHOD

Computationally better results offers the so called Hestenes-Jacobi method [4]. This method works with a smaller unit of computation (only with the rows of the matrix) compared with the first explained Jacobi method (which modifies both the rows and columns). Since Hestenes-Jacobi transformations are orthogonal transformations which leave singular values unchanged, it is not important how many such transformations are applied. For a given $m \times n$ matrix A the Hestenes-Jacobi method produces an orthogonal matrix U as a product of plane rotations and a matrix N which rows are orthogonal.

$$UA = N = [\eta_1 \quad \eta_2 \quad \ldots \quad \eta_n];\ \eta_i^T \eta_j = 0 \text{ for } i \neq j \qquad (4)$$

The matrix N can be normalized by computing the square of the row norms $\sigma_i = \eta_i^T \eta_i$ and writing: $N = \Sigma\Sigma^{-1}N = \Sigma V$ (in this case the computation of V is done by dividing the element η_i of N by $\sigma_i = \eta_i^T \eta_i$. Because of $\eta_i^T \eta_j = 0$ for $i \neq j$, the matrix Σ is a diagonal matrix). The matrix V is orthogonal and the σ_i are the non-negative squares of the singular values. Because U is orthogonal we have:

$$UA = \Sigma V \Rightarrow A = U^T \Sigma V \qquad (5)$$

This equation is the same as the equation of the SVD of the matrix A. Multiplying both sides of (5) by A^T we have:

$$A^T A = (U^T \Sigma V)^T U^T \Sigma V = V^T \Sigma^T U U^T \Sigma V = V^T \Sigma^T \Sigma V$$

This means that Hestenes computation mathematically is equivalent to the Jacobi method applied to $A^T A$ where singular values are equal to the squares of σ_i.

The orthogonal matrix U may be taken as a plane rotation matrix $J(i, j, \theta)$. If $A_1 = A$, then $A_{k+1} = A_k J$. The iterations result in the matrix N defined by (4). Working with a submatrix of order 2×2 we have:

$$\begin{aligned} \begin{bmatrix} a_i^{k+1} & a_j^{k+1} \end{bmatrix} &= \begin{bmatrix} a_i^k & a_j^k \end{bmatrix} \cdot \begin{bmatrix} c & -s \\ s & c \end{bmatrix} = \\ &= \begin{bmatrix} a_i^k \cdot c + a_j^k \cdot s & -a_i^k \cdot s + a_j^k \cdot c \end{bmatrix} \end{aligned} \qquad (6)$$

From the condition of orthogonality we have:

$$(a_i^k \cdot c + a_j^k \cdot s)^T \cdot (-a_i^k \cdot s + a_j^k \cdot c) = 0 \qquad (7)$$

From these relations the iteration formulae for updating the value of an inner product is given by the relation bellow:

$$\begin{aligned} &(a_i^{k+1})^T \cdot a_j^{k+1} = (c^2 - s^2)(a_i^k)^T \cdot a_j^k + cs\left[(a_i^k)^T a_i^k - (a_j^k)^T a_j^k\right] \\ &\Leftrightarrow (a_i^{k+1})^T \cdot a_j^{k+1} = (c^2 - s^2)(a_i^k)^T \cdot a_j^k + cs\left[\left\|a_i^k\right\|^2 - \left\|a_j^k\right\|^2\right] \end{aligned} \qquad (8)$$

Writing $g_{ij}=\left(a_i\right)^T \cdot a_j$, the following equality will be fulfilled:

$$\left(c^2-s^2\right)g_{ij}+cs\left[\|a_i^k\|^2-\|a_j^k\|^2\right]=0 \qquad (9)$$

From the equality (9) we can obtain the relation:

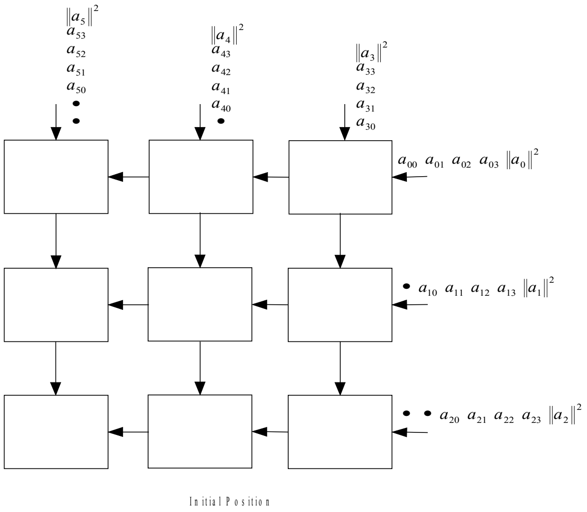
$$\lambda=ctg\,2\theta=\frac{\cos 2\theta}{\sin 2\theta}=\frac{\|a_j^k\|^2-\|a_i^k\|^2}{2g_{ij}} \qquad (10)$$

Putting $t=tg\,\theta$, to the relation $tg\,2\theta=\frac{2tg\,\theta}{1-tg^2\theta}$ there will be obtained the new relation $\frac{1}{\lambda}=\frac{2t}{1-t^2}$ which is equivalent to the quadratic equation $t^2+2\lambda t-1=0$. One solution for t and then for c and s is given by the relation below:

$$t=-\mathrm{sgn}\,\lambda\left(|\lambda|+\sqrt{1+\lambda^2}\right) \text{ and } c=\frac{1}{\sqrt{1+t^2}}\ ;\ s=ct \qquad (11)$$

V. Systolic Array for the SVD of a Matrix

We present a systolic array consisting of 9 processors (generally the number of processors is RxR). The systolic array first computes the values $g_{ij}=\left(a_i\right)^T \cdot a_j$. After receiving the row norms $\|a_i\|^2$ and $\|a_j\|^2$, each processor computes the rotation values s_{ij} and c_{ij} according to the formulas (8) and (10). The initial position of the corresponding systolic array is given in the figure below:



$\|a_5\|^2$ a_{53} a_{52} a_{51} a_{50}
$\|a_4\|^2$ a_{43} a_{42} a_{41} a_{40}
$\|a_3\|^2$ a_{33} a_{32} a_{31} a_{30}
a_{00} a_{01} a_{02} a_{03} $\|a_0\|^2$
a_{10} a_{11} a_{12} a_{13} $\|a_1\|^2$
a_{20} a_{21} a_{22} a_{23} $\|a_2\|^2$
Initial Position

Fig. 1 Systolic computation of rotation angles according (11) for R=3 and n=4

In Fig. 1 it is shown the first step of the systolic array for computing the SVD of a matrix of order mxn $(m=6,\ n=4)$. After 13 steps (the data movement proceeds systolically such that the first three rows move horizontally from right to left and the last three rows move vertically from top to bottom) the values c_{ij} and s_{ij} are computed. The processor that receives row i from the right and row j from the top computes c_{ij} and s_{ij} . Then, the same array may be used for obtaining the correspondent values of the matrix A_{k+1} according to the relation (6). This is the second part of the systolic array. In the same way as in the previous case, the processor receives values from right and top. Then it uses the calculated values for c_{ij} and s_{ij} , and the generalized form of the relation (6) to compute the values of a^{k+1} . The initial form of this array is given in the Fig. 2.

Fig. 2 Obtaining the values of A_{k+1} using the values c_{ij} and s_{ij} computed in fig. 1

In the presented cases there are required 13 time steps for computing the values of c_{ij} and s_{ij} (Fig.1), as well as 15 time steps in the calculation of the values of A_{k+1} (Fig. 2). In general, in the case of Fig.1 there are required $n+1$ time steps for the computation of the values of inner product $g_{ij}=\left(a_i\right)^T \cdot a_j$. According to (11) there are used 4 time steps for the computation (one step for each of factors λ, c, t, s). We have to take into the consideration that this computation will start 2(R-1) time steps later. So the total number of time steps in the case of fig. 1 is n +2R+3. In the case of Fig. 2 there are used more number of steps because of the use of two multiplicative and additive operations. The total number is 2(n +R)+1. In the case presented in Fig. 2 these operations are merged together.

Therefore the exact number of time steps will be twice bigger. So, the total number of time steps will be n +2R+3+4(n +R)+1=5 n +6R+4.

VI. SVD OF A COMPLEX MATRIX

The polar representation of each complex number $z = a + ib$ may be written in the form $z = R_z e^{i\theta_z}$, where

$$e^{i\theta} = \cos\theta + i\sin\theta, \; R_z = \sqrt{a^2 + b^2},$$
$$\theta_z = \tan^{-1}\left(\frac{b}{a}\right) \text{ and } 0 \le \theta_z \le 2\pi$$

Let

$$\mathrm{M} = \begin{bmatrix} a_{11} + ib_{11} & a_{12} + ib_{12} \\ a_{21} + ib_{21} & a_{22} + ib_{22} \end{bmatrix} = \begin{bmatrix} Ae^{i\theta_a} & Be^{i\theta_b} \\ Ce^{i\theta_c} & De^{i\theta_d} \end{bmatrix} \tag{12}$$

be a 2x2 complex matrix. There are proposed several unitary transformations for the diagonalization of a complex 2x2 matrix. The two-sided unitary transformation proposed in [3] is:

$$\begin{bmatrix} c_\phi e^{i\theta_\alpha} & -s_\phi e^{i\theta_\beta} \\ s_\phi e^{i\theta_\gamma} & c_\phi e^{i\theta_\delta} \end{bmatrix} \begin{bmatrix} Ae^{i\theta_a} & Be^{i\theta_b} \\ Ce^{i\theta_c} & De^{i\theta_d} \end{bmatrix} \begin{bmatrix} c_\psi e^{i\theta_\xi} & -s_\psi e^{i\theta_\eta} \\ s_\psi e^{i\theta_\mu} & c_\psi e^{i\theta_\omega} \end{bmatrix} \tag{13}$$
$$= \begin{bmatrix} We^{i\theta_\omega} & 0 \\ 0 & Ze^{i\theta_z} \end{bmatrix}$$

where

$$\tan(\theta_\alpha - \theta_\beta) = -\frac{AC\sin(\theta_a - \theta_c) + BD(\theta_b - \theta_d)}{AC\cos(\theta_\alpha - \theta_\beta) + BD\cos(\theta_b - \theta_d)}$$
$$\tan(\theta_\eta - \theta_\omega) = -\frac{AB\sin(\theta_a - \theta_b) + CD(\theta_c - \theta_d)}{AB\cos(\theta_a - \theta_b) + CD\cos(\theta_c - \theta_d)} \tag{14}$$
$$\tan(\theta_\phi - \theta_\psi) = -\frac{Be^{i(\theta_\alpha + \theta_\omega + \theta_b)} - Ce^{i(\theta_\beta + \theta_\eta + \theta_c)}}{De^{i(\theta_\beta + \theta_\omega + \theta_d)} - Ce^{i(\theta_\alpha + \theta_\eta + \theta_a)}}$$
$$\tan(\theta_\phi + \theta_\psi) = -\frac{Be^{i(\theta_\alpha + \theta_\omega + \theta_b)} - Ce^{i(\theta_\beta + \theta_\eta + \theta_c)}}{De^{i(\theta_\beta + \theta_\omega + \theta_d)} - Ce^{i(\theta_\alpha + \theta_\eta + \theta_a)}}$$

If M is a real matrix then conditions given above can be simplified taking:

$$\theta_\alpha = \theta_\beta = \theta_\gamma = \theta_\delta = 0$$

The obtained result is identical to the two by two transformation given in (3).

Another method is proposed in [6]. This method is given by the two-sided unitary transformation:

$$\begin{bmatrix} \chi^{\frac{1}{2}} c_\xi & -\chi^{\frac{1}{2}} s_\xi \\ -\chi^{\frac{1}{2}} s_{\xi'} & \chi^{\frac{1}{2}} c_{\xi'} \end{bmatrix} \begin{bmatrix} Ae^{i\theta_a} & Be^{i\theta_b} \\ Ce^{i\theta_c} & De^{i\theta_d} \end{bmatrix} \begin{bmatrix} \chi^{\frac{1}{2}} c_z & -\chi^{\frac{1}{2}} s_{z'} \\ \chi^{\frac{1}{2}} s_z & \chi^{\frac{1}{2}} c_{z'} \end{bmatrix} \tag{15}$$
$$= \begin{bmatrix} We^{i\theta_\omega} & 0 \\ 0 & Ze^{i\theta_z} \end{bmatrix}$$

where

$$z = \psi + i\phi, \; z' = \psi - i\phi,$$
$$\xi = \varepsilon + i\eta, \; \xi' = \varepsilon - i\eta,$$
$$\chi = \sec h2\phi$$

Transformations in (15) are unitary because the fact that $\chi(c^2 + s^2) = 1$.

The main objective in the ordering the SVD of a complex matrix is transforming that into the real form. For that purpose some special forms of transformations are given which will help in that contest.

Transformation 1: The transformation that converts two elements of a complex 2x2 matrix into real values (two elements of a second row) is given by:

$$\begin{bmatrix} e^{i\theta_\alpha} & 0 \\ 0 & e^{i\theta_\alpha} \end{bmatrix} \begin{bmatrix} Ae^{i\theta_a} & Be^{i\theta_b} \\ Ce^{i\theta_c} & De^{i\theta_d} \end{bmatrix} \begin{bmatrix} e^{i\theta_\beta} & 0 \\ 0 & e^{-i\theta_\beta} \end{bmatrix}$$
$$= \begin{bmatrix} Ae^{i\theta_\omega} & Be^{i\theta_x} \\ C & D \end{bmatrix} \tag{16}$$

where

$$\theta_\alpha = -\frac{\theta_d + \theta_c}{2} \text{ and } \theta_\beta = \frac{\theta_d - \theta_c}{2}$$

Proof: The left side of (16) is equal with:

$$\begin{bmatrix} A \cdot e^{i(\theta_\alpha + \theta_a + \theta_\beta)} & B \cdot e^{i(\theta_\alpha + \theta_b - \theta_\beta)} \\ C \cdot e^{i(\theta_\alpha + \theta_c + \theta_\beta)} & D \cdot e^{i(\theta_\alpha + \theta_d - \theta_\beta)} \end{bmatrix}$$

Summing and subtracting the equalities $2\theta_\alpha = -\theta_d - \theta_c$ and $2\theta_\beta = \theta_d - \theta_c$ we have: $\theta_\alpha + \theta_\beta + \theta_c = 0$ and $\theta_\alpha + \theta_d - \theta_\beta = 0$. Hence, the two elements of the second row will be real numbers.

Similarly there can be obtained two other transformations given below:

Transformation 2: The transformation that converts two elements of a complex 2x2 matrix into real values (two elements of a second column) is given by:

$$\begin{bmatrix} e^{i\theta_\alpha} & 0 \\ 0 & e^{-i\theta_\alpha}\end{bmatrix}\begin{bmatrix} Ae^{i\theta_a} & Be^{i\theta_b} \\ Ce^{i\theta_c} & De^{i\theta_d}\end{bmatrix}\begin{bmatrix} e^{i\theta_\beta} & 0 \\ 0 & e^{i\theta_\beta}\end{bmatrix} = \begin{bmatrix} Ae^{i\theta_\omega} & B \\ Ce^{i\theta_y} & D\end{bmatrix} \qquad (17)$$

where

$$\theta_\alpha = \frac{\theta_d - \theta_b}{2} \text{ and } \theta_\beta = -\frac{\theta_d + \theta_b}{2}$$

Transformation 3: The transformation that converts two diagonal elements (main diagonal) of a complex 2x2 matrix into real values is given by:

$$\begin{bmatrix} e^{i\theta_\alpha} & 0 \\ 0 & e^{i\theta_\alpha}\end{bmatrix}\begin{bmatrix} Ae^{i\theta_a} & Be^{i\theta_b} \\ Ce^{i\theta_c} & De^{i\theta_d}\end{bmatrix}\begin{bmatrix} e^{i\theta_\beta} & 0 \\ 0 & e^{-i\theta_\beta}\end{bmatrix} = \begin{bmatrix} A & Be^{i\theta_x} \\ Ce^{i\theta_y} & D\end{bmatrix} \qquad (18)$$

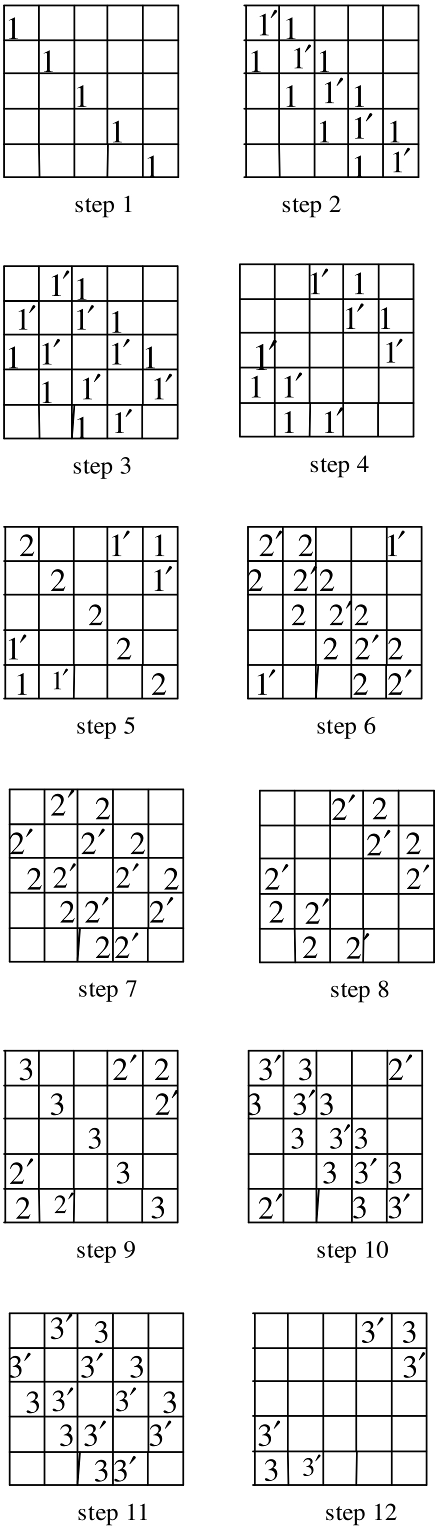
where

$$\theta_\alpha = -\frac{\theta_d + \theta_a}{2} \text{ and } \theta_\beta = \frac{\theta_d - \theta_a}{2}$$

Now, considering the transformations given above, it is possible to give general explanation of this procedure. For a complex matrix given as in (12), the first step is applying the transformation 1. After applying the transformation 2 and the transformation 3 the result will be a real matrix. Then the procedure is the same as in equations (2) and (3).

What about the systolic array of the SVD for a complex matrix? Each of the three transformations requires the generation and use of six angles, four unitary (a,b,c,d) and two rotational (α,β). These six angles must be propagated along both the rows and columns of processors on the main diagonal. The angles are generated by these processors and then are used for the diagonalization of a 2x2 complex matrices.

To improve the systolic array in the aspect of computation steps which are used, the performance will be as follows: during the computation by the diagonal processors using transformation 2, at the same time the nearest off diagonal processors may be used for computing using transformation 3. Similarly, the computations according transformation 3, may be performed before finishing the computations according transformation 1 and transformation 2. Thus, while the main diagonal are still computing the values according transformation 2, the nearest off diagonal processors are applying the transformation 1 etc. This pipelining of transformations by formulas (16), (17) and (18) is given in the following figure:



step 1 step 2

step 3 step 4

step 5 step 6

step 7 step 8

step 9 step 10

step 11 step 12

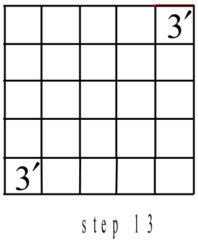


Fig. 3 Steps of computations on systolic array for the transforming the complex into the real matrix

After this procedure, the obtained matrix will be a real matrix, so the same systolic array as in figures 1 and 2 may be used for calculations.

***Abstract*—The aim of this paper is to show that a special kind of boundary value problem for second-order ordinary differential equations which reduces to the problem of solving a tridiagonal system of linear equations with almost Toeplitz structure can be efficiently solved on modern heterogeneous computer architectures based on CPU and GPU processors using an algorithm based on the *divide and conquer* method for solving linear recurrence systems with constant coefficients.**

I. Introduction

SEVERAL problems in scientific computing can be reduced to the following boundary value problem [8]:

$$-\frac{d^2u}{dx^2} = f(x) \quad \forall x \in [0,1], \tag{1}$$

where

$$u'(0) = 0 \text{ and } u(1) = 0. \tag{2}$$

Numerical solution to the problem (1)–(2) reduces to the problem of solving a tridiagonal system of linear equations. Simple algorithms based on Gaussian elimination achieve poor performance, since they do not fully utilize the underlying hardware, i.e. memory hierarchies, vector extensions and multiple (or many) processors (cores). The matrix of such systems have a special (almost Toeplitz) form and it clear that it should also be exploit. The problem can be solved in parallel using the *divide and conquer* approach [10] and novel data formats for dense matrices with the square blocked full column major order [2]. The performance of the algorithm can also be improved by using non-square tiles [11] which can better fit into L1 cache [1].

Graphical processing units (GPUs [5]) have recently been widely used for scientific computing due to their large number of parallel processors which can be exploit using the Compute Unified Device Architecture (CUDA) programming language [4]. GPUs offer very high performance at low costs for data-parallel computational tasks, when computations are carried out in single precision [3], [7]. Thus it is a good idea to develop algorithms for hybrid (heterogeneous) computer architectures where large parallelizable tasks are scheduled for execution on GPUs, while small non-parallelizable tasks should be run on CPUs (possibly using double precision to improve numerical properties of algorithms).

The aim of this paper is to show that the divide and conquer method for solving (1) can be efficiently implemented on such heterogeneous systems including a multicore CPU and CUDA-enabled GPU.

II. The method

We want to find an approximation of the solution to the problem (1) in the grid points

$$0 = x_1 < x_2 < \ldots < x_{n+1} = 1,$$

where $x_i = (i-1)h$, $h = 1/n$, $i = 1, \ldots, n+1$. Let $f_i = f(x_i)$ and $u_i = u(x_i)$. Using the approximation for the second derivative

$$u''(x_i) \approx \frac{u_{i+1} - 2u_i + u_{i-1}}{h^2}$$

and the boundary conditions

$$u''(0) \approx \frac{u(0-h) - 2u_1 + u_2}{h^2}, \quad u'(0) \approx \frac{u_2 - u(0-h)}{2h}$$

we get the following equations

$$\begin{array}{rcl} 2(u_1 - u_2) & = & h^2 f_1, \\ -u_{i-1} + 2u_i - u_{i+1} & = & h^2 f_i, \ i = 2, \ldots, n-1, \\ -u_{n-1} + 2u_n & = & h^2 f_n. \end{array} \tag{3}$$

Thus, we can rewrite (3) as the problem of solving the system of linear equations [8]:

$$A\mathbf{u} = \mathbf{d}, \tag{4}$$

where the matrix A is of the following form

$$A = \begin{pmatrix} 1 & -1 & & & \\ -1 & 2 & -1 & & \\ & \ddots & \ddots & \ddots & \\ & & -1 & 2 & -1 \\ & & & -1 & 2 \end{pmatrix} \in \mathbb{R}^{n \times n},$$

and the vectors satisfy $\mathbf{u} = (u_1, \ldots, u_n)^T$, $\mathbf{d} = (d_1, \ldots, d_n)^T$ and $d_1 = \frac{1}{2}h^2 f_1$, $d_i = h^2 f_i$ for $i = 2, \ldots, n$. The matrix A

can be factorized as $A = LR$, where L and R are bidiagonal Toeplitz matrices

$$L = \begin{pmatrix} 1 & & & & \\ -1 & 1 & & & \\ & \ddots & \ddots & & \\ & & -1 & 1 & \\ & & & -1 & 1 \end{pmatrix} \tag{5}$$

and

$$R = \begin{pmatrix} 1 & -1 & & & \\ & 1 & -1 & & \\ & & \ddots & \ddots & \\ & & & 1 & -1 \\ & & & & 1 \end{pmatrix}. \tag{6}$$

The solution to the system (4) can be found using Gaussian elimination without pivoting. A simple algorithm for solving (4) based on such a factorization can comprise two sequential stages, namely solving the systems $L\mathbf{y} = \mathbf{d}$ (forward reduction) and $R\mathbf{u} = \mathbf{y}$ (back substitution). The first stage can be done using

$$\begin{cases} y_1 = d_1 \\ y_i = d_i + y_{i-1} \qquad \text{for } i = 2, \ldots, n. \end{cases} \tag{7}$$

Then (second stage) we find the final solution to the system (4) using

$$\begin{cases} u_n = y_n \\ u_i = y_i + u_{i+1} \qquad \text{for } i = n-1, n-2, \ldots, 1. \end{cases} \tag{8}$$

More sophisticated approach can be based on the *divide-and-conquer* algorithm for solving linear recurrence systems [9]. The main idea of the algorithm is to rewrite the considered systems as block-bidiagonal systems of linear equations [9], [12]. Without loss of generality, let us assume that there exist two positive integers r and s such that $rs \le n$ and $s > 1$. The method can be used for finding $y_1, \ldots, y_{rs}$. To find $y_{rs+1}, \ldots, y_n$, we use (7) directly. For $j = 1, \ldots, r$, we define vectors

$$\mathbf{d}_j = \left(d_{(j-1)s+1}, \ldots, d_{js}\right)^T \in \mathbb{R}^s$$

and

$$\mathbf{y}_j = \left(y_{(j-1)s+1}, \ldots, y_{js}\right)^T \in \mathbb{R}^s.$$

Then we find all $\mathbf{y}_j$ using the following formula

$$\begin{cases} \mathbf{y}_1 = L_s^{-1}\mathbf{d}_1 \\ \mathbf{y}_j = L_s^{-1}\mathbf{d}_j + y_{(j-1)s}\mathbf{e} \qquad \text{for } j = 2, \ldots, r, \end{cases} \tag{9}$$

where $\mathbf{e} = (1, \ldots, 1)^T$ and the matrix $L_s \in \mathbb{R}^{s \times s}$ is of the same form as L given by (5). Analogously, we can perform the second stage using

$$\begin{cases} \mathbf{u}_r = R_s^{-1}\mathbf{y}_r \\ \mathbf{u}_j = R_s^{-1}\mathbf{y}_j + u_{js+1}\mathbf{e} \qquad \text{for } j = r-1, \ldots, 1, \end{cases} \tag{10}$$

where $\mathbf{u}_j = \left(u_{(j-1)s+1}, \ldots, u_{js}\right)^T \in \mathbb{R}^s$ and $R_s \in \mathbb{R}^{s \times s}$ is of the same form as R given by (6). However, it is better to find the following matrix

$$U = (\mathbf{u}_1, \ldots, \mathbf{u}_r) \in \mathbb{R}^{s \times r} \tag{11}$$

instead of individual vectors $\mathbf{u}_j$. Also, there is no need to use temporary vectors $\mathbf{y}_j$. It is clear that we have to allocate only one $s \times r$ array U and initially store vectors $\mathbf{d}_j$ in its columns. Then (Step 1A) we use a previously updated row to update the next row of the array. During Step 1B we update the bottom row of the table. Finally (Step 1C) we update $s-1$ first entries of each column (except for the first one). Similarly we proceed during the second stage of the algorithm (Figure 1). During Step 2A we update rows of the table *bottom-up*. Then (Step 2B) we update the first row of the table from right to left. Finally (Step 2C) using elements from the first row, we update the remaining entries of each column (except for the last one).

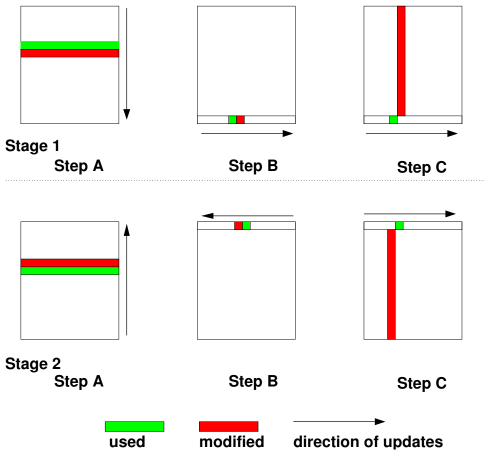

Fig. 1. *Divide and conquer* algorithm using a 2-D array

Both stages can be easily vectorized and parallelized. The array can be divided into blocks of columns and each processor can be responsible for computing one block. Steps A and C can be performed in parallel but steps B (in both stages) are sequential.

III. CUDA-BASED IMPLEMENTATION OF THE ALGORITHM

The detailed description of nVIDIA CUDA architecture can be found in [6]. Such a *computing device* (usually GPU) comprises a number of streaming multiprocessors (SM). Each SM consists of eight scalar cores (streaming processors, SP). SMs are responsible for executing blocks of threads. Threads in a block are grouped into so-called *warps*, each consisting of 32, that are managed and executed together. A device has its own memory system including the *global memory* (large but slow), *constant* and *texture* read-only memories providing reduction of memory latency. Each SM has also a 16 kB of fast *shared memory* that can be used for sharing data among threads within a block. The global memory access can be improved by coalesced access by all threads of a half-warp. Threads must access either 4-byte words in one 64-byte memory transaction, or 8-byte words in one 128-byte memory transaction. All 16 words must lie in the same memory segment and threads must access words in a sequence, namely k-th thread in a half-warp must access the k-th word in a segment [6]. CUDA programs consist of a number of C functions called *kernels* that are to be executed on devices as

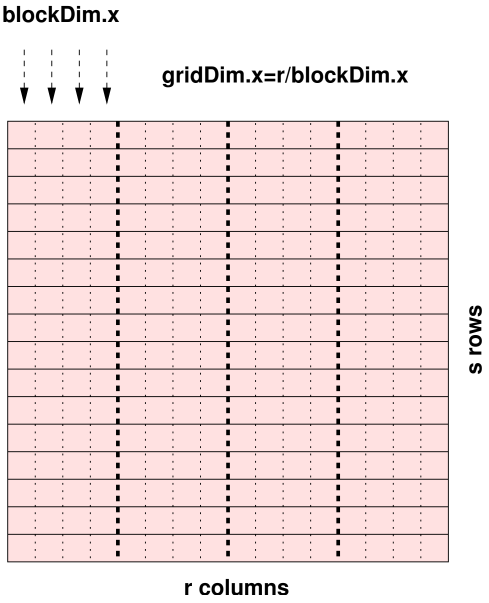

Fig. 2. Storage for the *divide and conquer* algorithm on GPUs

threads. Kernels are called from programs executed on CPUs. Host programs are also responsible for allocation of variables in the device global memory. The are also some CUDA API-functions used to copy data between host and device global memories. Each thread can identify its number, the number of its block and the block size using built-in variables `threadIdx`, `blockIdx` and `blockDim`, respectively.

Now let us consider the implementation of the *divide and conquer* algorithm. The basic idea is depicted in Figure 2. To allow coalesced memory access, elements of the $s \times r$ array U should be stored row-wise in the global memory of a device. Each thread is responsible for computing one column of the array. The number of its column can be computed as follows:

```
m =blockIdx.x*blockDim.x+threadIdx.x;
```

Each block of threads is responsible for computing one *panel* – a group of adjacent columns. For simplicity, we assume that

$$r = (\#blocks) \times (\#threads\ in\ block).$$

The source code of the host function is shown in Figure 3. Just after the array in the global memory of a device and auxiliary arrays in the host memory are allocated, the first kernel is executed to initialize the array (Figure 4). Note that the parallelized steps, namely 1A, 1C, 2A and 2C, are executed as kernels (see Figures 5–7), while sequential steps 1B and 2B are executed on CPU using double precision. In case of Step 1B, the bottom row of the array is copied from the device global memory, then it is updated using (9) and finally it is sent back to the device global memory. Analogously during Step 2B, the top row of the array is copied and updated using (10).

IV. Results of experiments

```
void cuda_bvp(int r, s, bsize, float *u_h){
/*
  s,r   - the number of rows and columns in the array
  bsize - the number of CUDA threads in a block
  u_h   - the array for the solution
*/

  int j,n=r*s;
  size_t size = N * sizeof(float);

// allocate arrays on host & device
  cudaMalloc((void **) &u_d, size);
  float  vf_tmp = (float *)malloc(r*sizeof(float));
  double vd_tmp = (double *)malloc(r*sizeof(double));

// initialize the s x r array on the device
  cuda_bvp_set <<< r/bsize, bsize >>> (u_d, s, r);

// perform Step 1A on the device
  cuda_bvp_1a <<< r/bsize, bsize >>> (u_d, s, r);

// perform Step 1B on CPU using double precision
  cudaMemcpy(vs_tmp, &u_d[(s-1)*r], sizeof(float)*r,
                                 cudaMemcpyDeviceToHost);
  vd_tmp[0]=vs_tmp[0];
  for(j=1;j<r;j++){
    vd_tmp[j] = (double)vs_tmp[j]+ vd_tmp[j-1];
    vs_tmp[j] = (float)vd_tmp[j];
  }
  cudaMemcpy(&u_d[(s-1)*r], vs_tmp, sizeof(float)*r,
                                 cudaMemcpyHostToDevice);

// perform step 1C and 2A on the device
  cuda_bvp_1c2a <<< r/bsize, bsize >>> (u_d, s, r);

// perform Step 2B on CPU using double precision
  cudaMemcpy(vs_tmp, u_d, sizeof(float)*r,
                                 cudaMemcpyDeviceToHost);
  vd_tmp[r-1]=vs_tmp[r-1];
  for(j=r-2;j>=0;j--){
    vd_tmp[j] = (double)vs_tmp[j]+vd_tmp[j+1];
    vs_tmp[j]=(float)vd_tmp[j];
  }
  cudaMemcpy(u_d, vs_tmp, sizeof(float)*r,
                                cudaMemcpyHostToDevice);

// perform Step 2C on the device
  cuda_bvp_2c <<< r/bsize, bsize >>> (u_d, s, r);

// copy results to the host array
  cudaMemcpy(u_h, u_d, sizeof(float)*N,
                                cudaMemcpyDeviceToHost);
}
```

Fig. 3. The source code of the *divide and conquer* algorithm

Both considered algorithms: **A1** – sequential based on (7) and (8), and **A2** – described in the previous section, have been tested on a computer with Intel Core2 Duo (2.66 MHz, 4GB RAM) and nVidia GeForce GTX 260 (216 cores, 1792MB RAM) running under Linux with `gcc` and nVidia `nvcc` compilers for various equations of the form (1) and problem sizes (Table I, II and III, IV). To observe the accuracy of the algorithms, we have considered the following special cases:

- **A1S** – sequential algorithm based on (7) and (8) using single precision, executed on CPU,
- **A1D** – sequential algorithm based on (7) and (8) using double precision, executed on CPU,
- **A2S** – parallel algorithm, steps 1A, 1C, 2A, 2C executed on GPU, steps 1B, 2B executed on CPU, all compu-

```

  int m,k;

  m=blockIdx.x*blockDim.x+threadIdx.x;

  if(m!=r-1) {
    float a=u[m+1];
    for (k=1;k<s;k++)
        u[m+k*r]+=a;
  }
}
```

Fig. 7. CUDA kernel for Step 2C

tations in single precision,

A2D – the same as **A2S**, but all computations in double precision,

A2SD – parallel algorithm, steps 1A, 1C, 2A, 2C executed on GPU (using single precision), steps 1B, 2B executed on CPU (double precision).

As exemplary test problems, let us consider the following.

P1: Solve

$$-\frac{d^2u}{dx^2} = \frac{\pi^2}{4}\cos(\frac{\pi}{2}x) \quad \forall x \in [0,1], \tag{12}$$

with boundary conditions (2). The exact solution to (12) is as follows

$$u(x) = \cos(\frac{\pi}{2}x).$$

P2: Solve

$$-\frac{d^2u}{dx^2} = 20000e^{-100x^2}(1-200x^2) \quad \forall x \in [0,1], \tag{13}$$

with boundary conditions (2). The exact solution to (13) is as follows

$$u(x) = 100e^{-100x^2} - 100e^{-100}.$$

Tables I and II show the accuracy of the considered algorithms for both problems. The relative error of the computed solution is calculated due to

$$error = \frac{\|\mathbf{u}-\bar{\mathbf{u}}\|_2}{\|\mathbf{u}\|_2} \tag{14}$$

where $\mathbf{u}$ and $\bar{\mathbf{u}}$ are the exact and computed solutions respectively, and $\|\cdot\|_2$ is the Euclidean norm. Tables III and IV show execution time (in seconds) of **A1D**, **A2D** and **A2SD**, and speedup of **A2D** over **A1D**. Note that it is impossible to run **A2D** on our GPU for $n = 268435456$ (2048MB of RAM required, but only 1792MB available), thus tables III and IV do not contain results for **A2D** and $n = 268435456$. Moreover, for this case, tables I and II show the results obtained on CPU using the nVidia compiler simulation feature (the option `-deviceemu`). We can observe that

- the algorithm **A1S** (single precision) achieves very poor accuracy, the use of double precision (Algorithm **A1D**) gives much better results,
- the algorithm **A2S** (single precision) achieves reasonable accuracy; the use of double precision during the steps 1B and 2B (Algorithm **A2SD**) improves the accuracy of the results,
- the algorithm **A2D** (double precision) gives better accuracy than **A1D**,
- parallel algorithms **A2D** and **A2SD** are much faster than the sequential algorithm **A1D**; the speedup grows when the problem size (value of n) grows,
- **A2SD** is about 2-3 times than **A2D** and up to 95 times faster than **A1D**, thus if someone can accept results produced by **A2SD**, the use of **A2SD** can be profitable,
- CUDA-enabled GPUs are much slower when computations are carried out using double precision, however

the next generation GPU architecture called Fermi is pretty much faster when double precision is used (visit `http://www.nvidia.com/` for more details), thus the use of **A2D** seems to be very attractive for such new devices.

V. CONCLUSIONS AND FUTURE WORK

We have showed that the kind of boundary value problem for second-order ordinary differential equations which reduces to the problem of solving a tridiagonal system of linear equations with almost Toeplitz structure can be efficiently solved on modern heterogeneous computer architectures based on CPU and GPU processors using the *divide and conquer* algorithm for solving linear recurrence systems with constant coefficients. The algorithm achieves reasonable accuracy and excellent speedup. We have showed that the use of double precision in sequential parts of the algorithm can improve its accuracy. In the future we will consider the problem of the numerical stability of our algorithm.

Computational Linguistics—Applications

The CLA Workshop is located within the framework of the IMCSIT conference to create a dialog between researchers and practitioners involved in Computational Linguistics and related areas of Information Technology.

IMSCIT is a multi-disciplinary conference gathering scientists form the different fields of IT & Computer Science together with representatives of industry and end-users. IMSCIT with its motto: "new ideas are born not inside peoples' heads but in the space between them", quickly became a unique place to share thoughts and ideas.

Workshop Goals

The Computational Linguistics – Applications Workshop was established in 2008 in response to the fast-paced progress in the area.

Traditionally, computational linguistics was limited to the scientists specialized in the processing of a natural language by computers. Scientific approaches and practical techniques come from linguistics, computer science, psychology, and mathematics. Nowadays, there is a number of practical applications available. These applications are sometimes developed by smart yet NLP-untrained developers who solve the problems using sophisticated heuristics. CLA aims to be a meeting place for both parties in order to share views and ideas. It will help scientist to better understand real world needs and practitioners not to reinvent the wheel.

Computational Linguistics needs to be applied to make the full use of the Internet. There is a definite need for software that can handle unstructured text and information to allow search for information on the web. The priority aim of the research in this area is to enable users to communicate with the computer in their native language.

CLA'10 Workshop is a place where the parties meet to exchange views and ideas with a benefit to all involved. The Workshop will focus on practical outcome of modeling human language use and the applications needed to improve human-machine interaction.

Paper Topics

This call is for papers that present research and practical developments on all aspects of Natural Language Processing used in real-life applications, such as (this list is not exhaustive):

- ambiguity resolution
- anaphora resolution
- applied CL software and systems
- computational morphology
- computational phonology
- corpus annotation and corpus-based language modeling
- creation of lexical resources
- dialogue systems
- entity recognition
- extraction of linguistic knowledge from text corpora
- information retrieval and information extraction
- machine learning methods applied to language processing
- machine translation and translation aids
- multi-lingual dialogue systems
- ontology and taxonomy evaluation
- opinion mining and sentiment classification
- paraphrasing and entailment
- parsing issues
- parts-of-speech tagging
- proofing tools
- prosody in dialogues
- question answering
- semantic networks and ontologies
- semantic role labeling
- semantic web
- speech recognition and generation
- summarization
- text classification
- text summarization
- word sense disambiguation

***Abstract*—This paper presents a system that combines two text mining techniques; information extraction and clustering. A rule-based approach is used to perform the information extraction task, based on the dependency relation between some intransitive verbs and prepositions. This relationship helps in extracting types of crime from documents within the crime domain. With regard to the clustering task, the Self Organizing Map (SOM) is used to cluster Arabic crime documents based on crime types. This work is then validated through experiments, the results of which show that the techniques developed here are promising.**

I. Introduction

ONE OF the most important motivations for creating this system is because of the lack of Arabic systems in general, and the crime domain in particular. Furthermore, the crime domain has been chosen as an application area because of its social importance. Information extraction aims to extract specific, predefined entities from text. In this current research, one of our aims is to develop a system that is able to recognize crime phrases in a given document in order to extract types of crime. Feldman and Sanger [1] have stated that entities, such as peoples names, organizations names, locations, attributes (e.g. age of a person), and crime type can all be extracted. According to Toral and Munoz [2] and Collins and Singer [3], there are two types of evidence that help in identifying entities. Internal evidence can be deduced from the sentence that contains the entity by noticing a particular sequence of words. On the other hand, external evidence is gained from the context. In the first stage, the rule based approach (based on syntactical analysis) is adopted. In the second stage, the extracted types of crime are then used to by Self Organizing Map (SOM) in order to perform clustering. So instead of processing the whole content of each document, the rule based approach is used to guide the SOM to cluster the data by extracting important or meaningful patterns. According to Flexer [4] SOM is a very common tool for clustering and visualizing high dimensional data spaces. More details about SOM will be presented in one of the following sections.

The rest of the paper is organized as follows. In section II, a background and a review of the related work are given. The crime domain is described in section III. Domain analysis is presented in section IV. Section V presents the proposed clustering system. Section VI provides the results of the experiments and an evaluation of their performance. Finally, the conclusion of this work is presented in section VII.

II. Background

According to Michailidis [5], the Message Understanding Conference (MUC-6) introduced Named Entity Recognition (NER) in 1995, and it has been used in many different text-based applications, such as information extraction, question and answering, information retrieval and text classification [5], [6]. The approaches that are used to identify named entities are as follows [5]:

- Hand-craft rules, known as linguistic approaches.
- Machine learning approaches.
- Hybrid, which combines hand-craft recognition grammar with machine learning methods.

Alruily et al. [7] have developed a software package to extract crime information from texts. Their approach is based on a dictionary that is created manually. On the other hand, the task of automatically constructing lists of entities has been studied by many researchers. Riloff [8] has developed a program called AutoSlog that automatically constructs a domain-specific dictionary for information extraction. Nadeau et al. [9] used an approach that has two aspects: retrieve pages with seed, and a web page wrapper in order to build or generate gazetteers. Toral and Munoz [2] have proposed an approach to automatically build and maintain dictionaries of proper nouns using a noun hierarchy and a POS tagger. Also, Chau et al. [10] used named entity extraction techniques to identify meaningful entities from police narrative reports. To the authors' knowledge, there is no work available regarding the SOM technique applied to Arabic texts within the crime context for crime analysis. On the other hand, in the English language, Chen et al. [11] have developed a system based on SOM to cluster and visualize crime-related data.

III. Crime Domain

As far as we know, no information systems have been applied to the crime domain in the Arabic language. Therefore, the major problem we faced was the lack of data. This issue has been solved by compiling news articles on crime incidents, published by some Arabic newspapers. The reason for exploiting newspapers is that it is difficult to obtain official reports or narrative reports from police stations, especially in

978-83-60810-27-9/09/$25.00 © 2010 IEEE

Arab countries. The news articles contain the information that the police reports would normally include. So, collecting these data was an important step in gaining a better understanding of the crime domain and the nature of the data that our system will deal with.

A. Types of Crime

The crime domain includes several types of crime, starting from civic crimes, such as drinking and driving, to international crimes, for instance, homicide by terrorists [12]. In this research, types of crime have been categorized into six main types, as in Table I.

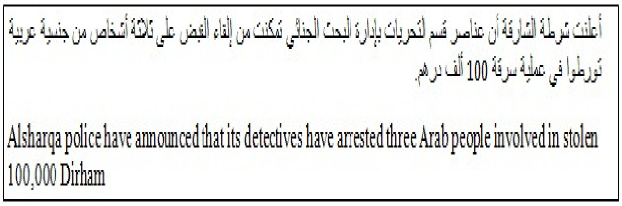
TABLE I
TYPES OF CRIME.

English	Arabic	Pronunciation
Theft	السرقة	Alsareqah
Fraud	الاَحتيَال	alehtial
Drug and alcohol smuggling	تهريب المخدرَات	Tahreeb almokhdrat
Magic and sorcery	السحر وَالشعوذه	Alseher walshaawathah
Sex crime	الجنس	Aljens
Violent crime	العنف	Alonf

As previously mentioned, the aim is to extract crime types from Arabic news articles for work that will be presented later. This extracted information is considered as ”keywords”; which are significant words that are able to give clues about the main idea of the document or article. Consequently, keywords play an important role in many text mining tasks, such as clustering, summarization and document retrieval. In this research, the extracted words will be treated as keywords to guide the Self Organizing Map (SOM) in order to perform clustering. So, the previous task of keyword extraction is an important process that must be considered carefully. Accordingly, the crime domain must be studied and its characteristics explored in order to find the appropriate extraction algorithm.

B. Event Description

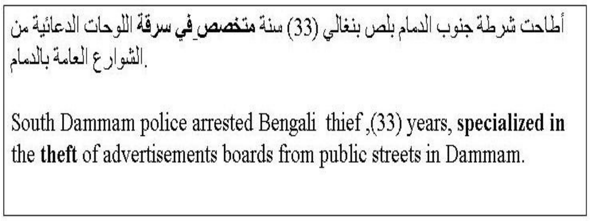
Most Arabic newspaper reports have the same structure, with respect to writing style, in the crime domain. Most journalists or reporters start with a sentence containing the name of the police station that has investigated the crime, followed by a description of that crime. The crime description is about the type of crime committed and the type of criminal. Following these, details of any victims and other information are described. The reason for this formulaic approach is because they are dealing with a specialist domain that has its own language, and which can be called here the language of crime. According to Almas and Ahmad [13], each special language has a limited vocabulary and idiosyncratic syntactic structures. The journalists who work with these restricted languages seem to share the same words and same sentence structures. In other words, the usage of their words has the same behaviour. Fig. 1 shows a description for a theft crime published by Alriyadh newspaper [14]. The location of the committed crime can be deduced from the following pattern: ”شرطة الشَارقة / shurtat alsharqa / Alsharga police” . Furthermore, other related crime information can be extracted from the text, such as the nationalities of the people involved in the crime, e.g. ”جنسية عربية / jnsyt arabiat / Arabic nationality”. The type of crime can also be extracted from this pattern: ”تورطوَا في سرقة / tawaratwo fi sareekat / involved in stealing”. Also, the following is another example that has been taken from Aljazirah newspaper articles [15]:



أعلنت شرطة الشارقة أن عناصر قسم التحريات بإدارة البحث الجنائي تمكنت من إلقاء القبض على ثلاثة أشخاص من جنسية عربية
تورطوا في عملية سرقة 100 ألف درهم.

Alsharqa police have announced that its detectives have arrested three Arab people involved in stolen 100,000 Dirham

Fig. 1. Article Excerpt from Alriyadh Newspaper.



أطاحت شرطة جنوب الدمام بلص بنغالي (33) سنة **متخصص_في سرقة** اللوحات الدعائية من
الشوارع العامة بالدمام.

South Dammam police arrested Bengali thief ,(33) years, **specialized in** the **theft** of advertisements boards from public streets in Dammam.

Fig. 2. Article Excerpt from Aljazirah Newspaper.

It can be seen from the above example in Fig. 2 that the same writing style is followed. The name of the police station, which carries the name of the location, is stated first. The nationality of the criminal is also mentioned, and the type of offense is described. However, the crime type information is what we want to concentrate on in this research.

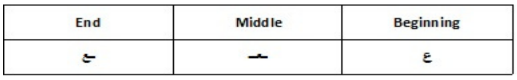
IV. DOMAIN ANALYSIS

A. Arabic Language

In this research, the Arabic language is studied; it is one of the Semitic languages and it is used in over 21 Arab countries. This language consists of 29 letters that can be used to form a word. Moreover, other languages, such as Farsi and Urdu use mostly Arabic characters [16]. From the sentence construction point of view, Arabic words can be divided into three classes: nouns, verbs and particles [17], [18], [19]. When working with the Arabic language, some other important characteristics need to be taken into account [20]:

1) A character may have up to three different forms, each form corresponds to the position of that character in the word (beginning, middle or end), such as letter ”ع / Ayn ” in Table II.

TABLE II
POSITION OF THE CHARACTER IN THE WORD.



End	Middle	Beginning
ـع	ـعـ	عـ

2) Arabic does not have capital letters; this characteristic represents a considerable obstacle to the NER task because in other languages capital letters represent a very important feature.
3) Finally, it is a language with a very complex morphology because it is highly inflectional.

A linguistic study of Arabic words and grammatical structures will be required before extracting the most appropriate structures for common Arabic sentence forms within the crime domain. Hence, the use of the linguistic internal structures of Arabic sentences will allow us to identify logical sequences of words. As previously mentioned, the structure of Arabic can comprise of three categories : noun (اسم), verb (فعل) and particle (حرف).

- Noun
  This category in Arabic comprehends any word that describes a thing, idea or person. It can be divided into two types: primitive and derivative. Primitive nouns are nouns that are not derived. Derivative nouns are nouns that are derived from verbs, other nouns, and particles. The Arabic nouns are inflected for gender (masculine and feminine) and number (singular, dual and plural). Also Nouns are either definite, which starts with the article ”ال / al” or indefinite, which has no ”ال” article at the beginning of the noun. Moreover affixes and clitics, such as some prepositions, conjunctions and possessive pronouns, can be attached to them. The clitic is subdivided into proclitic (located at the beginning of a stem) and enclitics (located at the end of a stem). For example, Table III shows the different morphological segments for the word ”وبدرجَاتهم” which means ”and by their grades”.

TABLE III
EXAMPLE FOR MORPHOLOGICAL SEGMENTS.

	enclitic	affix	stem	proclitic	proclitic
Arabic	هم	ات	درج	ب	و
pronunciation	hm	at	drg	be	wa
Gloss	their	s	grade	by	and

- Verb
  This word type points out an event or action. Verbs are also inflected in terms of number (singular, plural, dual), gender (masculine, feminine), person (1st, 2nd, 3rd), voice (active and passive) and mood (subjunctive, indicative and jussive). Furthermore, from the tense point of view, the verb can be in the past, present or future.
- Particle
  This class includes prepositions, conjunctions, interrogative particles, exceptions, and interjections. In other words, it includes the words that are not nouns or verbs, and sometimes these words are called function words.

In the Arabic language, sentences are divided into two types, as follows:

- A nominal sentence, according to Hadj et al [19], a nominal sentence can start with a noun or a particle.
- A verbal sentence
  A verbal sentence can start with a verb or a particle. The verb is divided into two types: transitive and intransitive. With respect to transitive verbs, a sentence, e.g., ”قطفت التفَاحة / qtft altfaht / I picked up the apple” contains one object or more as well as the subject. In other words, it takes more than one argument. On the other hand, a sentence that contains an intransitive verb has no object, and is composed of a verb and only one argument, e.g., ”مرض خَالد / mrd Khaled / Khaled became ill”. In some cases, some intransitive verbs can be converted into transitive verbs, for example, ”ذهبت إِلَى دبي / thhbt ela dubai / I went to Dubai”. In this example, the verb has a subject and a quasi sentence (the prepositional phrase) ”إِلَى دبي / ela dubai / to Dubai” which is the complement of the sentence ”ذهبت / thhbt / I went”; this help in determining the meaning of the whole sentence. Most Arab linguists state that most of the intransitive verbs can not refer to the object of the sentence but they can be strengthened by some prepositions, which are called transitive prepositions, such as ”البَاء / bi / because”, ”الَّام / allam / for”, ”من / mn / from”, ”علَى / ala / on”, ”في / fi / in”, ”إِلَى / ela / to”, in order to refer to the object. These verbs are called ”transitive verbs by preposition” [21], and they play an important role in achieving our goal.

B. Intransitive Verbs and Prepositions in the Crime Domain

As shown in the above section, our study of the crime domain corpus has led us to identify the characteristics of the language used. The first feature is that the past tense is used when describing crime incidents, whether the verbs describe the action of the crime itself or indicate a phrase that carries information about the crime type. Moreover, the modifier, sometimes called the qualifier, such as prepositional phrases and adjectives, are used for describing the type of offence. However, in this research, we concentrate on using the characteristics of some intransitive verbs and their propositions in order to recognize the type of crime. In other words, the correlation or dependency relationship between some intransitive verbs and some prepositions will be exploited. The Arabic language has approximately fourteen prepositions, most of which are short. Most of them are formed from three letters, such as ”علَى / ala” or from two, such as ”في / fi”, but they can be formed with only one Arabic letter, such as ”ل / li” or ”ب / bi”. The structure of a prepositional phrase is usually composed of two parts: preposition and noun-phrase [22]. For example, ”الولد في البيت / alwalad fi albyt” means ”the boy in the house”. In this example, the preposition is ”في / fi” and the noun is ”البيت / albyt”. Table IV shows a list of Arabic prepositions with their English translations. Only the most frequently used prepositions in crime domain texts are presented but more illustration regarding the listed prepositions is given in order to clarify them semantically.

TABLE IV
LIST OF PREPOSITION IN ARABIC LANGUAGE.

Arabic Preposition	Pronunciation	English Translation
علَى	Ala	on
في	Fi	in
إِلَى	Ela	to
ب	Bi	because
ل	Li	for

The preposition ”ب / bi” has different meanings, so based on a whole sentence, its meaning can be inferred. In this research context, the preposition ”ب / bi” means ”because”. In other words, it answers the question ”why”. Also, the preposition ”في / fi” represents the preposition ”in” in the English language, for example, ”تورط في قتل / twrat fi qtl / involved in killing” and ”متخصّص في قتل / motakasys fi qtl / specialized in killing”. With regard to the preposition ”ل / li”, it has many meanings but in the current domain being studied it again means ’because’; put simply, it justifies the reason, for example, ” هو ابلغ الشرطة لتعرضه للّسرقة / howa ablqa alshortat lita’arrudh lilsareekat / he reported to the police because he was robbed”. Thus, in this context ”ب / bi” and ”ل / li” carry very similar meanings. Sometimes the preposition ”إِلَى / ela” takes the place of the preposition ”ل” (e.g. ”تعرض إِلَى السرقة / ta’arrada ela lilsareekat / s/he was exposed to theft”). Thus, these prepositions can be utilized in many different ways. Additionally, they can work as a link between some verbs and nouns, whether they are adjacent or not. Moreover, the meanings of sentences that contain some specific verbs cannot be identified without prepositional phrases. Based on this, the main forms where a type of crime is located in the text can be identified. Fig. 3 depicts this case. Thus, in order to mark the crime phrases in the text, the system looks for the verbs in the text and (their prepositions), and the type of crime should not be more than three words away from the preposition. Therefore, only three words are extracted after the preposition. As a result, in order to recognize and extract types of crime, the list of these intransitive verbs and their prepositions (that indicate the patterns of crime type) must be defined beforehand.

From the above illustrations, it can be seen that there are strong correlations between some verbs and prepositions. These relationships are considered as key elements, and form an important part in accomplishing this work. Accordingly, these can lead to discovering a local grammar for crime type patterns, which will help in their extraction. Fig. 4 shows the various frequent patterns used in news articles for describing the type of crime committed.

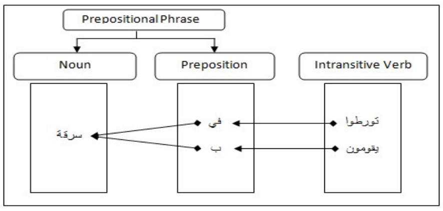


Fig. 3. Types of crime in Prepositional Phrases.

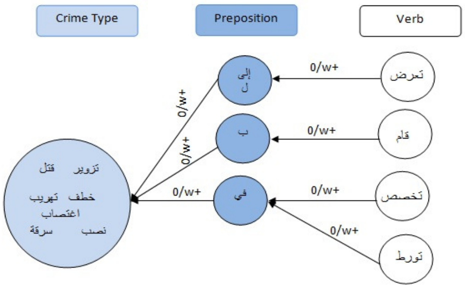

Fig. 4. Crime types Local Grammar.

V. CLUSTERING SYSTEM

Fig. 5 shows the proposed framework, which consists of stages, divided as follows:

- Normalization
  In this stage, some letters that perform the same function, and that can be written in different forms in a word, are normalized. For example, the letters ”أ” , ”إ” and ”آ” are converted into the letter ا.
- Information Extraction
  The system here is focused on prepositional phrases. Hence, the dependency relationship between prepositions and intransitive verbs is exploited. The advantage of this method is that there is no need for an annotated corpus, whether manual or automatic. In other words, the system has no linguistic components, such as PoS taggers or shallow parsers. Instead, lists of intransitive verbs and their prepositions are provided to the system in order to extract the desired patterns. Fig. 4 shows the list of verbs, with their appropriate prepositions, that are used in this research. In other words, it describes the local grammar for extracting types of crime. To sum up, in the processing phase, the system looks for words in a text that match the words in the verb list. When a match occurs, the next step is to search for a preposition that always comes with the verb. After that, the three words

that immediately follow the preposition are extracted to represent the whole content of the document. Moreover, the crime type should appear within these three words.

- Stemming
  Through this process, the stem of a word can be obtained by eliminating the word's affixes. After stemming, the content of file is automatically converted into numbers by giving each word of interest a unique number. Also, during this process the stopwords are removed.
- Clustering and Visualization
  For the clustering process, the Self Organizing Map (SOM) has been chosen to cluster documents that were generated by the information extraction process, based on their similarity. The SOM technique is popular and widely used for clustering and visualizing high dimensional data spaces. According to Eyassu and Gamback [23] SOM has many different structures but the most popular architecture is composed of two layers of processing units; the input layer and the output layer. These two layers are fully interconnected. The idea behind SOM is that it performs mapping for similar input vectors to similar areas on the output grid. The following is the SOM algorithm:
  1) Initialize weight randomly
  2) Initialize neighbourhood ratio
  3) Set input pattern
  4) Calculate Euclidean distance
  5) Find the winner neuron (smaller distance)
  6) Update winner and neighbour weight neurons
  7) Repeat Steps 3 to 7 until the convergence criterion is satisfied

  As can be seen, this algorithm is iterative. The first step is to randomly initialize the weight vectors of the output map. At each iteration (training), a sample vector is randomly chosen from the input data. This phase is called the learning process or competitive learning. Through competitive learning, the Euclidean distance is calculated for choosing the Best Matching Unit (BMU). The wining neuron or BMU is the one most similar to the input pattern. That is, its weight is close to the input pattern. As a result, all neurons on the output layer enter into a competition with each other. The neuron on the output layer that has the smallest distance to the input pattern is the winner. Once the winning neuron has been selected, its weight and the weights of its neighbour are both updated in order to make them more similar to the input pattern. This process is repeated with other documents until accurate results are found or the maximum number of iterations (epochs) are reached.

VI. Experimental Result and Evaluation

A. Corpus

Text mining research relies on the availability of a suitable corpus. As a result, many corpora have been created for specific purposes. For this research, two corpora have been collected from different Arabic newspapers published in different Arabic countries, such as Alriyadh, Aljazeera and Okaz from Saudi Arabia, Elkhabar newspaper issues from Algeria, Addustour from Jordan and Ahram from Egypt. The first corpus contains 26 documents and the other includes 24 documents. The reason for compiling corpora from different resources is to avoid the problem of bias, which could occur if the system is tested on documents that were collected from only one country.

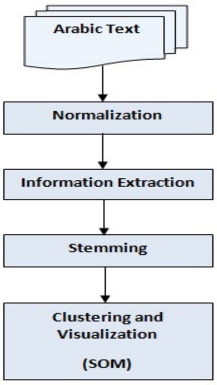

Fig. 5. System Architecture.

B. Experiments

Two experiments have been carried out on 26 documents in order to show how the information extraction process guides the Self Organizing Map (SOM) to gain accurate results. The size of this corpus is 25.3 KB. The SOM has been trained on the same documents, obtaining good results; the best learning rate, radius and iteration are 0.5, 8 and 1000, respectively.

- First Experiment
  In the first experiment, the information extraction process is used. So, instead of processing the whole of each document's content, the extracted patterns from each document are used by SOM to perform clustering. As a result, the size of the corpus has become 1.56 KB. Only 21 unique words represent the 26 text documents and they comprise 57 tokens. Fig. 6 shows the results of the first experiment after achieving the clustering process.

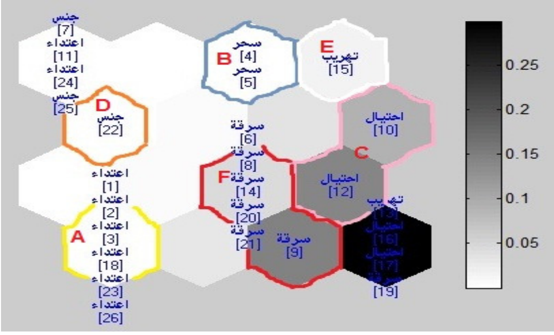

Fig. 6. Clustering Result for First Experiment (A: Violante, B: Magic, C: Fraud, D: Sex, E: Smuggling, F: Theft).

- Second Experiment
  This experiment does not rely on the information extraction process. So the whole content of each file is stemmed and used for the clustering process. The 26 textual files are represented by 32 unique words. These 32 words form 228 tokens. Also, the results of this experiment can be seen in Fig. 7.

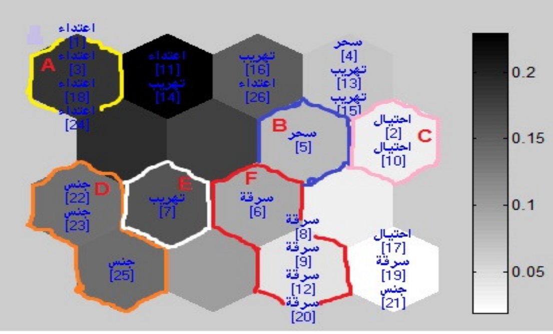

Fig. 7. Clustering Result for Second Experiment (A: Violante, B: Magic, C: Fraud, D: Sex, E: Smuggling, F: Theft).

In order to examine the proposed system and the SOM (at the same learning rate, radius and iteration value) on a new and untouched corpus other experiments have been also carried out. This new corpus contains 24 documents, and its size is 28.5 KB. The third and fourth experiments are as follows:

- Third experiment
  This is exactly like the first experiment because the information extraction process is used. The size of the whole corpus after the extraction became 1.83 KB. The number of unique words is 13 which, form 44 tokens. These 44 tokens are then used by SOM to cluster the documents. The clustering results can be seen in Fig. 8.

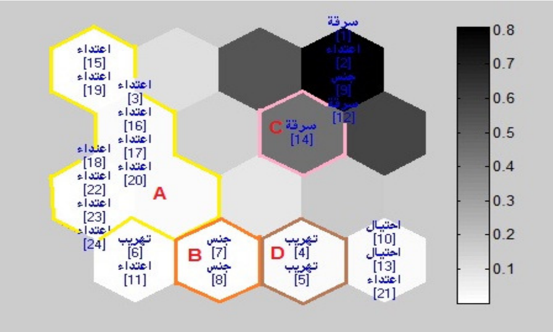

Fig. 8. Clustering Result for Third Experiment (A: Violante, B: Sex, C: Theft, D: Smuggling).

- Fourth experiment
  This experiment is as the second experiment. It uses the whole content of each document because no information extraction technique is used. 23 unique words represent the tested documents, and they form 235 tokens. As a result, 235 tokens are used by SOM to cluster the documents in this experiment. Fig. 9 shows the clustering outcome of SOM.

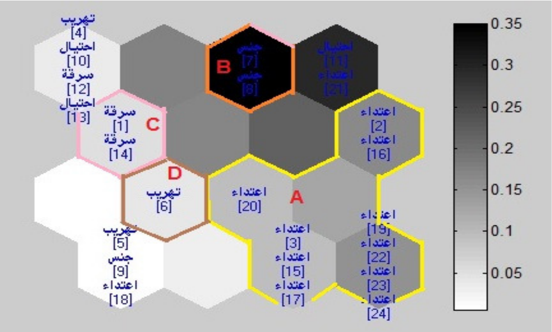

Fig. 9. Clustering Result for Fourth Experiment (A: Violante, B: Sex, C: Theft, D: Smuggling).

C. Result Analysis

The average distance between each data vector and its BMU (quantization error) in the first experiment is 0.686, and in the second experiment it is 0.949. So the performance of the SOM is better when using the information extraction process. As is well-known, SOM clusters documents based on their similarity. Moreover, each document is treated as a vector of words. So the number of a word's frequency that occurs in a file affects its clustering and sometimes this leads to a wrong cluster. For example, File 23 from Group A in Fig. 6 is clustered as a violent crime, which is true, but in Fig. 7 it is clustered as a sex crime. The reason for this clustering mistake in Experiment 2 is because of the phrase ”سعودي الجنسية / saudi aljensyat”, which means ”Saudi nationality”, occurred many times when talking about the criminal. So the word ”الجنسية / aljensyat” means ”nationality” in English, but after stemming this word by removing its affixes (the article ”ال” and the letter ”ة”) the word becomes ”جنس / jens”, which means ”sex”; this affected its clustering in the second experiment. Also, another clustering mistake occurred in Experiment 2 for File 14. This file belongs to Group F in the first experiment; i.e. it is clustered as a theft crime, but in the second experiment it has been labelled as ”smuggling”, and is far from its Group (F) in Fig. 7. The reason for this being wrongly clustered is because of the word ”هرب / hrb”, which appears many times in the file; it has two meanings in the Arabic language, and it means ”flee” or ”smuggle” in English. The file is totally about a theft crime but in the crime description the phrase ”thieves fled / هرب الّصوص ” is stated many times in different ways, and ”هرب / hrb” in our context means ”smuggle”. As a result, Group F in Experiment 2 does not contain the file number 14. Also, Fig. 10 shows that the letters attached to the vertical axis represent categories of crime types, as in Table V, and the numbers that are underneath the horizontal axis refer to the files. This graph clarifies how our system labels files with the right category names using the extracted patterns, and it worked better than when using the full content. In Experiment 1, the file numbers 12, 16 and 17 have incorrect crime type category names. On the other hand, in Experiment 2 file numbers 2, 7, 14, 17, 21 and 23 also have the wrong category names. With regards to Experiments 3 and 4, the quantization errors are 0.6 and 0.888, respectively.

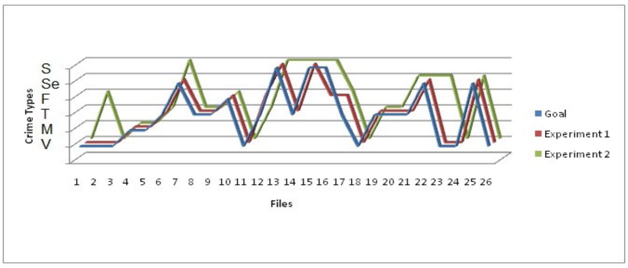

Fig. 10. Result of Labeling Crime Documents.

TABLE V
MEANING OF VERTICAL AXIS

Letter	V	M	T	F	Se	S
Crime Type	Violent	Magic	Theft	Fraud	Sex	Smuggling

VII. CONCLUSION

In this paper, we have developed a system for clustering textual documents containing information about different types of crimes. The Self Organizing Map (SOM) technique was chosen to perform the clustering. Moreover, the rule-based approach, based on intransitive verbs and propositions, was used to help in obtaining good clustering results. Also, a comparison study was carried out through four experiments in order to show the effects of the rule-based method on the Self Organizing Map. The results show that although SOM used fewer tokens in Experiments 1 and 3, it was able to achieve clustering that was as good as or better than in Experiments 2 and 4. Therefore, it can be confirmed that the SOM technique has been improved in terms of its performance. The reason behind this remarkable achievement is because of the system's ability to extract keywords based on syntactic principles, and this led directly to the improved clustering results.

***Abstract*—The present work covers a comparison of the text retrieval qualities of open source relational databases and Lucene, which is a full text search engine library, over English documents. TREC-4 adhoc task is completed to compare both search effectiveness and search efficiency. Two relational database management systems and four different well-known English stemming algorithms have been tried. It has been found that language specific preprocessing improves retrieval quality for all systems. The results of the English text retrieval experiments by using Lucene are at par with top six results presented at TREC-4 automatic adhoc. Although open source relational databases integrated full text retrieval technology, their relevancy ranking mechanisms are not as good as Lucene's.**

I. Introduction

RELATIONAL database management systems (RDBMS) have been the preferred way of managing data for the past two decades. In recent years, data that many applications manage are moving more from structured to unstructured (free form text). Although relational databases are designed to handle structured data, many web applications use databases to manage and query unstructured data. With the increase in unstructured text, development of search engine libraries - which are specifically designed to quickly and effectively search large volumes of unstructured text - has been gaining momentum. There are several open source search engine libraries available with different features [1]. Many database vendors (IBM DB2[1], Microsoft SQL Server[2], MySQL[3], Oracle[4], PostgreSQL[5]) have recognized the need for free form text search and started implementing features that would support full-text search capabilities. Search engine libraries and relational databases each have unique advantages but also they have overlapping capabilities in common. In our previous work [2], we compared the full text search capabilities of different open source relational databases and Lucene on Turkish text documents. In this work we are extending our experiments by using English data set and deeply exploring full text search configuration parameters of relational databases.

The paper is organized as follows. Section II briefly summarizes the related work, Section III explains the retrieval systems and stemming algorithms that we used, Section IV shows experimental results and our analysis on them, Section V gives summary of our observations about relational databases' full text search, and Section VI provides concluding remarks.

II. Related Work

There are many studies which evaluated the performance of search engine libraries over Text REtrieval Conference (TREC) test collections. TREC[6] is an annual conference aiming to encourage research in information retrieval (IR) based on large test collections. Database vendors also have evaluated their full-text search capabilities by participating in TREC competitions [3], [4]. Earlier papers [5], [6], [7] have described full text search capabilities and features of different relational databases, focusing specifically on the integration of free form text and structured data. The studies on comparison of IR systems are common, but there are no studies on Relational Database Management Systems' information retrieval qualities. The other studies have focused on hybrid IR-DB system solutions and integration of IR and databases.

Some unpublished articles discuss and compare different aspects of relational databases and search engines libraries. In [8], Marc Krellenstein explores the benefits of a full text search engine in comparison to a database. The article by David Smiley [9], addresses a scenario in which a web application needs to have a full text search capability. It discusses using the text search features of relational database versus using Apache Solr[7] - an open source search platform built on top of Lucene.

In a recent paper Yinan Jing and Chunwang Zhang [10] compared Lucene and a relational database in terms of query time. The data set used in their work was composed of auto-generated numeric and alphanumeric fields. They performed their test on these structured fields which are not tokenized therefore they didn't use full-text search but rather structured queries. A systematic comparison of text retrieval quality of relational databases and search engine libraries has not been done.

III. Experimental Setup

In this study TREC-4 adhoc task was completed by querying forty nine topics (numbers 202-250) over 567,529 documents. Topic 201 was ignored since it retrieved no relevant documents and wasn't used in the actual evaluation of TREC-4 adhoc competition. DOCNO field - which is common for all documents - used as unique identifier in our experiments and the rest of the document - except DOCNO and DOCID fields - is taken as single textual field named contents. Topics are queried over this single field. The details of the document set and topics used in TREC-4 can be found here [11].

We used one open source information retrieval library (Apache Lucene 3.0.1) and two open source Relational Database Management Systems with full-text search capabilities (MySQL 5.5.3, PostgreSQL 8.4.4) for retrieval experiments. The latest versions of each system were used in our study in order to take account into latest features and improvements. We would like to experiment with other popular relational databases such as IBM DB2, Microsoft SQL Server and Oracle; however they do not permit disclosure results of any program benchmark tests without their prior consent.

All of the experiments were completed on Apple Mac Pro with two 2.8 GHz Quad-Core Intel Xeon processors and 6 GB 800 MHz DDR2 memory running Mac OS X Version 10.5.7. All test programs were implemented with the Java programming language, running on JDK 1.6.

A. Stemming Algorithms for English

Stemming is the most employed technique in IR to enhance retrieval quality in terms of recall. We investigated publicly available stemmers for the English language in our experiments. Probably the two most well-known stemming algorithms for English language are the Porter [12] stemming algorithm and the Lovins [13] stemming algorithm. Lovins is the first ever published stemming algorithm and removes 297 different endings using longest-match algorithm. Porter stemming algorithm created and maintained by Dr. Martin Porter. The algorithm can be best defined by its author's own words:

"The Porter stemming algorithm (or 'Porter stemmer') is a process for removing the commoner morphological and inflectional endings from words in English. Its main use is as part of a term normalisation process that is usually done when setting up Information Retrieval systems."[8]

English (Porter2)[9] stemming algorithm is a result of Dr. Martins attempt to improve the structure of the original Porter algorithm.

These algorithms are rule based and do not use dictionary or lexicon and preferred for their linear running time complexity since dictionary based stemmers can be sometimes slow for real-world web applications.

TABLE I
Analyzer Building Blocks

ootb	**Porter**	**Lovins, English**	**KStem**
LetterTokenizer	LetterTokenizer	LetterTokenizer	LetterTokenizer
LowerCaseFilter	LowerCaseFilter	LowerCaseFilter	LowerCaseFilter
StopFilter	StopFilter	StopFilter	StopFilter
	PorterStemFilter	SnowballFilter	KStemFilter

KStem [14] stemming algorithm is a dictionary based inflectional stemming algorithm which uses human readable dictionary. It is a less aggressive stemmer than the standard Porter stemmer. It was written by Bob Krovetz, ported to Lucene by Sergio Guzman-Lara (UMASS Amherst).

We used these four different stemming algorithms for English to improve text retrieval performances of each system. To measure this improvement we included out-of-the-box settings of each system. In out-of-the-box option no preprocessing is done on the documents and queries. Built-in English support and stop-word list of each system is used.

B. Lucene

Lucene[10] is a powerful, free, open source IR library written entirely in Java. It is suitable for nearly any application that requires full-text search and its popularity is increasing because of simplicity, high performance, maturity and scalability.

Analysis, in Lucene, is the process where free form text is converted into tokens by tokenization, lowercasing, stemming and etc. Analysis process begins with a Tokenizer which breaks free form text into tokens. And then, the created token stream is fed into nested TokenFilters. TokenFilters can add, modify or delete its input token stream. For example lowercasing, removing common words, reducing words to a common base form or injecting synonyms occurs in TokenFilters. Lucene has several Tokenizer and TokenFilter implementations. An analyzer is an encapsulation of the analysis process which is an essential part of Lucene. Custom Analyzers can be built from a Tokenizer and a TokenFilter chaining pattern.

Five different analyzers are used in our runs and Table I shows the Analyzer building blocks used to create them. First column of Table I represents StopAnalyzer that comes with out-of-the-box Lucene. StopAnalyzer's default English stopword set contains 33 common words.

LetterTokenizer divides text at non-letters by capturing tokens as maximal strings of adjacent letters, as defined by `java.lang.Character.isLetter()` method. We have used this tokenizer because TREC-4 topics do not have any alphanumeric or numeric words. All tokens are composed of letters. (Except three acronyms U.S., U.K. and e.g. which are taken as stop words in our runs) Therefore we didn't index any numeric or alphanumeric tokens.

LowercaseFilter normalizes the token by lowercasing its text.

[8] http://tartarus.org/\textasciitildemartin/PorterStemmer/

[9] http://snowball.tartarus.org/algorithms/english/stemmer.html

[10] http://lucene.apache.org

StopFilter removes tokens that exist in a provided list of stop words. In custom analyzers, we used 70 stopwords which are superset of StopAnalyzer's default stopword list.

SnowballFilter - that comes in contrib package of Lucene -, stems words using a Snowball-generated stemmer. Snowball[11], which is created by Dr. Martin, is a small string manipulation language specifically designed for creating stemming algorithms for use in Information Retrieval. A range of non-English stemmers are implemented by using snowball script, including Danish, Dutch, Finnish, French, German, Hungarian, Italian, Norwegian, Portuguese, Romanian, Russian, Spanish, Swedish and Turkish [15]. There exists three English-specific stemmers (named English, Lovins, and Porter) implemented by using snowball script and available at Dr. Martins web site. These exact names can be passed as parameter to constructor of SnowballFilter to initialize a stem filter for that language in Lucene. In our experiments we used English and Lovins.

PorterStemFilter is java implementation of Porter algorithm and has the same behavior as SnowballFilter when Porter is used for the name argument to the SnowballFilter constructor. PorterStemFilter is much faster since it does not use Snowball Program.

KStemFilter stems words according to Bob Krovetz's kstem algorithm. Lucene does not have KStemmer implementation with the out-of-the-box settings. Source code of the stemmer is downloaded from web site of Center for Intelligent Information Retrieval - University of Massachusetts Amherst[12].

StopAnalyzer and four different custom Lucene analyzers—representing each stemming option—are used to create five Lucene indices. The same analyzers are used to search topics over each index.

C. MySQL

MySQL has support for full-text indexing and searching based on a space-vector model. Full-text indices can be created only on CHAR, VARCHAR, or TEXT columns of MyISAM tables. Full-text searching is performed using MATCH()...AGAINST() syntax which is introduced on June 2000. However MySQL has no linguistic support (stemming) for English or any other language. MySQL has a default stopword list for English[13] and removes them during indexing and searching. Like words included in the built-in stop word list, also words that are less than four or greater than 84 characters are also ignored by default in full-text searches. Table II shows MySQL's user-overridable full-text search parameters including their default values and descriptions. These parameters are defined by the system variables and can be obtained by executing

```
SHOW VARIABLES LIKE 'ft_%';
```

SQL statement. The other modifications such as disabling 50% threshold and changing tokenization behavior are non-trivial tasks that require source code modification and recompilation of MySQL.

1) Indexing: Five different MySQL tables with two columns (docno, contents) are created. For out-of-the-box option documents are inserted directly into the table. For the remaining stemming options, first they passed through respective Lucene Analyzer and then inserted into their tables. Full-text indices are built on tables thus:

```
ALTER TABLE docs ADD FULLTEXT (contents);
```

The indices are created after loading all data to tables because for large data sets, it is much faster than loading data into tables that have an existing FULLTEXT index.

2) Searching: MySQL full text search have basically three modes: natural language mode, Boolean mode and with query expansion.

Natural Language Full-Text Search[14] performs a natural language search for a query against a text collection. There are no operators in this mode and the stop-word list applies. Another interesting property of this mode is the elimination of query words that occur in more than or equal to half of the collection. In another words if a query word is present in at least 50% of the documents, it is treated as a stop-word. This mode is the default mode in MySQL and automatically sorts search results in order of decreasing relevance. Run using this mode is executed as follows:

```
SELECT docno, MATCH (contents) AGAINST ('<topic>')
AS score FROM docs WHERE MATCH (contents)
AGAINST ('<topic>') LIMIT 1000;
```

Relevance ranking algorithm of Natural Language mode uses Vector Space Model where rows and queries are represented as weighted vectors. MySQL uses a variant of the classic tf-idf (term frequency-inverse document frequency) weighting scheme along with pivoted document length normalization. Details of the ranking algorithm can be found here [16].

Boolean Full-Text Search[15] allows usage of implied Boolean operators ([no operator], +, -) and various advanced search methods like wildcard (*) and phrase search. A leading plus sign means required or mandatory operator. The word after the plus sign must exist in every row returned. A leading minus sign means prohibited operator. The word after the minus sign must not exist in any row returned. When no operator is specified, it means that this word is optional and should exist in returned rows. Rows that contain optional words will get higher scores. Complete list of supported operators are shown at the first row of Table II. Stop-word list applies but 50% threshold limitation does not apply with this mode. This mode does not automatically sort search results in order of decreasing relevance therefore 'ORDER BY score DESC' clause is added to SQL sentence in two runs using this mode:

[15] http://dev.mysql.com/doc/refman/5.5/en/fulltext-boolean.html

TABLE II
MYSQL VARIABLES ASSOCIATED WITH FULLTEXT SEARCHING

Variable Name	Default Value	Description
ft_boolean_syntax	+ - >< () ˜ * : ”” & |	List of operators supported by boolean full-text searches performed using IN BOOLEAN MODE.
ft_max_word_len	84	Maximum length of the word to be included in a FULLTEXT index.
ft_min_word_len	4	Minimum length of the word to be included in a FULLTEXT index.
ft_query_expansion_limit	20	Number of top matches to use for full-text searches performed using WITH QUERY EXPANSION
ft_stopword_file	(built-in)	File from which to read the list of stopwords for full-text searches.

SELECT docno, MATCH (contents) AGAINST ('<topic>' IN BOOLEAN MODE) AS score FROM docs WHERE MATCH (contents) AGAINST ('<topic>' IN BOOLEAN MODE) ORDER BY score DESC LIMIT 1000;

Relevance ranking algorithm of Boolean Mode is quite different from Natural Language Mode. This mode provides only simplistic relevance ranking [17]. It is defined as the sum of weights of matched words in query string. Weights are defined by boolean operators. This ranking mechanism produces always 1 when + operator is used before query terms. For example in the pure required type query '+term1 +term2 +term3 +term4' weights of each term will be 1/4. When no operator is used, score is equal to count of matching query terms. For example in the pure optional type query 'term1 term2 term3 term4' weights of each term will be 1. If a document contains three of these terms, it will get score of three. This ranking algorithm does not use collection-wide statistics (inverse document frequency) therefore Boolean Mode full text searches does not require FULLTEXT indices. Other interesting property of this ranking is that calculated scores are always greater than or equal to one.

Full-Text Searches with Query Expansion[16] applies classic blind relevance feedback which is also known as Pseudo relevance feedback. It performs natural language mode search twice and assumes top few (controlled by ft_query_expansion_limit variable which has a default value of 20) results of first search are relevant. And then, it appends these documents to the original query to perform second search. This mode can be activated by adding WITH QUERY EXPANSION or IN NATURAL LANGUAGE MODE WITH QUERY EXPANSION modifiers to the query. Functions of these two modifiers are exactly the same and they yield same results. Since this mode is modified version of a natural language search, it automatically sorts search results in order of decreasing relevance. Runs using this mode are executed as follows:

SELECT docno, MATCH (contents) AGAINST ('<topic>' WITH QUERY EXPANSION) AS score FROM docs WHERE MATCH (contents) AGAINST ('<topic>' WITH QUERY EXPANSION) LIMIT 1000;

D. PostgreSQL

PostgreSQL supports full text indexing of textual documents and relevance ranking for full text database searching.

In PostgreSQL, dictionaries[17] allow fine-grained control over how tokens are normalized. PostgreSQL provides several predefined dictionaries for linguistic support, available for many languages, and English is one of them.

PostgreSQL have two special data type tsvector and tsquery representing preprocessed documents and processed queries with support of boolean operators respectively. These data types are vector representation of documents and queries like in vector space model. There are some functions to convert documents or queries into these data types. to_tsvector is used to transform a document to tsvector data type while to_tsquery and plainto_tsquery are used for converting a query to the proper tsquery data type. All of these transformation functions take a language specific configuration parameter. Full text searching is done using the match operator @@, which returns true if a tsvector (document) matches a tsquery (query).

1) Indexing: Five different PostgreSQL tables with two columns (docno, contents) are created. An additional tsvector type column named ts_col is added to the table.

ALTER TABLE docs ADD COLUMN ts_col tsvector;

For out-of-the-box option, documents are inserted into the tables without any preprocessing. Then ts_col column is populated from contents column by invoking to_tsvector function with the configuration parameter for the English language that comes with out-of-the-box settings of PostgreSQL.

UPDATE docs SET ts_col = to_tsvector('english', contents);

For the remaining stemming options, documents are first analyzed by respective Lucene Analyzer and then inserted into their tables. The ts_col column is populated with the output of to_tsvector function, but this time using the simple template parameter which behaves like no language is specified because data in the table are already preprocessed.

UPDATE docs SET ts_col = to_tsvector ('pg_catalog.simple', contents);

PostgreSQL offers two kinds of indices that can be used to speed up full text searches.

- GiST (Generalized Search Tree) based index
- GIN (Generalized Inverted Index) based index

[16] http://dev.mysql.com/doc/refman/5.5/en/fulltext-query-expansion.html

[17] http://www.postgresql.org/docs/8.4/static/textsearch-dictionaries.html

TABLE III
POSTGRESQL DOCUMENT LENGTH NORMALIZATION OPTIONS

Mode	Meaning
0	(the default) ignores the document length
1	divides the rank by 1 + the logarithm of the document length
2	divides the rank by the document length
4	divides the rank by the mean harmonic distance between extents (this is implemented only by ts_rank_cd)
8	divides the rank by the number of unique words in document
16	divides the rank by 1 + the logarithm of the number of unique words in document
32	divides the rank by itself + 1

Since GIN index is best for static data and searches are about three times faster than GiST, GIN index was created to speed up the search as follows:

CREATE INDEX text_index ON docs USING gin (ts_col);

2) Searching: PostgreSQL provides two functions to_tsquery and plainto_tsquery for converting a query to the tsquery data type. plainto_tsquery transforms unformatted text querytext to tsquery by parsing and normalizing text, then inserting the & (AND) Boolean operator between surviving words. to_tsquery creates a tsquery value from querytext, which must consist of single tokens separated by the Boolean operators & (AND), | (OR) and ! (NOT). Note that to_tsquery with AND operator is identical to plainto_tsquery.

To rank search results, PostgreSQL provides two predefined ranking functions to calculate similarity between a tsvector (document) and a tsquery (query). These are standard ranking function (ts_rank) and cover density ranking function (ts_rank_cd) [18]. While the ts_rank does not consider term position proximity, the ts_rand_cd ranking function punishes documents where the search terms are further apart. PostgreSQL's both ranking functions do not use any global information (inverse document frequency); therefore indices are not mandatory but can be used to speed up full text searching.

Both ranking functions take an integer normalization option[18] that specifies whether and how document length normalization will be done. Table III shows the document length normalization options and their effect on ranking mechanism that PosgreSQL supports with the out-of-the-box settings.

Note that mode 32 is used just to scale ranks between zero and one. The ordering of search results does not change in this mode.

In out-of-the-box option to obtain pure OR queries, description parts of topics are tokenized at white spaces and then OR operator ("|") is inserted between each token. English language configuration is used in this mode. SQL queries are submitted as follows:

SELECT docno, *ranking_function*(ts_col, query,
normalization) AS rank FROM docs,
to_tsquery('english','<topic>') query WHERE query @@
ts_col ORDER BY rank DESC LIMIT 1000;

In remaining stemming options to obtain pure OR queries, description parts of topics are first passed through respective Lucene Analyzer and then OR operator ("|") is inserted between surviving words. Simple template configuration is used because queries are already analyzed. SQL queries are submitted as follows:

SELECT docno, *ranking_function*(ts_col, query,
normalization) AS rank FROM docs,
to_tsquery('pg_catalog.simple','<topic>') query WHERE
query @@ ts_col ORDER BY rank DESC LIMIT 1000;

IV. EXPERIMENTAL RESULTS

Since the overview of TREC-4 paper presents the precision/recall curves for the groups with the highest non-interpolated average precision (**MAP**) and the runs are ranked by the average precision, in this work the same metric is used in global evaluation. While evaluating each system in itself we also presented precision at 5 (**P@5**) and precision at 10 (**P@10**) values as well as search time (**sec/q**) per query. Additionally results of citri2 run of Royal Melbourne Institute of Technology [19] (one of the best TREC-4 automatic adhoc) were included in experimental result for comparison.

The evaluation measures presented in this paper are calculated by using Chris Buckley's `trec_eval`[19] package (version 8.1) which is the standard tool used by the TREC community for evaluating an adhoc retrieval run, given the results file and a standard set of judged results.

In our calculations a cut-off level of 1000 is used, which defines the retrieved set as the top 1000 documents in the ranked list which is similar to official TREC usage:

trec_eval -c -M1000 official_qrels submitted_results

All retrieval systems are designed in a similar fashion to standard TREC-type adhoc runs that retrieve maximum 1000 documents per topic.

Topics created for the TREC-4 adhoc task consist of only one field (description). Therefore we ran retrieval experiments over each index, by using description-only queries. In this work completely automatic query construction is used. Description only queries had on average 16 terms with stop words, 9 terms without stop words.

A. Lucene

Lucene's scoring[20] mechanism uses both the Vector Space Model and the Boolean Model. The Boolean model is used to first filter the documents to be used in score calculation. Lucene's scoring algorithm implements cosine similarity between tf-idf weighted documents and queries. It adds several factors to cosine similarity including document length normalization. Default length normalization function divides the score by square root of the number of words in the document.

with query expansion limit 20	0.0331	0.1265	0.0898	20.6530

Details of the Lucene scoring can be found in chapter 3.3 of [15].

Lucene allows selecting between two Boolean operators (AND, OR) when performing search. Search quality results of these two operators are given in Table IV. Result set of OR operator is superset of the result set of AND operator. In other words, result set of OR operator already contains result set of AND operator. Moreover Lucene gives higher scores to the documents that contain more query terms. This fact implies that highest ranked documents will usually have the most ORed query terms among documents returned. OR operator used in remaining Lucene runs since it yields better results than AND operator.

B. MySQL

Total eight runs performed (with the out-of-the-box settings) to determine which type of MySQL full-text search is superior. Search quality results of our MySQL runs are given in Table V. It includes different boolean operators and search options described in section III-C2.

Boolean mode with pure required and pure optional queries performed badly due to its simplistic ranking mechanism which is described in section III-C2.

Blind relevance feedback (BRF) is used in TREC competitions and usually improves performance in TREC adhoc tasks. For example Cornell SMART system [20] at TREC 4 applied BRF (with good success) by adding the most frequently occurring 50 single terms and 10 phrases from the top 20 documents to initial query. However in MySQL it didn't perform as expected. To investigate this behavior we ran experiments with query expansion with five different ft_query_expansion_limit values. However results were still lower than natural language mode. We compared individual MAP values of natural language mode run and best with query expansion mode (limit 5) run and found that in 4 topics query expansion performed better. MySQL Reference Manual does not explain details of the query expansion mechanism but we suspect that this is due to appending whole document text to the initial query. Appending whole document to the initial query increases noise significantly and returns nonrelevant documents.

It is easy to understand TREC-like runs; natural language mode is more suitable due to its sophisticated ranking algorithm and the 50% threshold limitation. Query terms that occur in half of the documents in the collection have no distinctive property. Such words alone would return at least half of the documents in the collection. Natural language mode that yields best results in terms of retrieval quality is selected as best representative of MySQL.

C. PostgreSQL

In PostgreSQL, both matching operator (@@) and ranking functions takes same two parameters, tsquery and tsvector. We observed that when AND is used as matching operator, some topics did not return any documents while the others returned a few documents. Pure AND queries returned 13 documents per topic on the average. This behavior of AND operator yield very poor retrieval quality. Therefore - as described in section III-D2 - initially we used OR for both matching operator and ranking functions in our runs. By doing so, we obtained better results than AND operator.

When we examined our submitted qrels file, we observed that many documents ranked exactly with the same float value for a particular topic. Further investigations revealed that one of the ranking functions (ts_rank) does not play well with OR operator. As it can be understood from first two rows of Table VI ts_rank does not take account into how many ORed terms match when all query terms occur in a document. When it is used with AND operator, this behavior reverses and score increases with the number of matched terms. Interestingly ts_rank with AND operator (last row), does not yield zero for the document that does not contain all of the query terms. On the other hand ts_rank_cd function yields zero in this scenario. Also score produced by ts_rank_cd with OR operator increases as the number of the query terms found in the specified document increases.

After these observations we concluded that it is more convenient to use ts_rank_cd with OR operator while rank_cd with AND operator in our score calculations. We keep using OR operator for matching function in our remaining runs. Note that if we were to use ts_rank_cd with AND operator, the documents that do not contain all of the query terms would get a rank of zero. To obtain pure AND tsquery for use with ts_rank function, topics are fed into plainto_tsquery function. SQL sentence of runs using ts_rank is modified as follows:

SELECT docno, ts_rank(ts_col,
plainto_tsquery('english','<topic>'), *normalization*) AS
rank FROM docs WHERE to_tsquery('english','<topic>')
@@ ts_col ORDER BY rank DESC LIMIT 1000;

Total eleven different runs performed (with the out-of-the-box settings) to determine which ranking function and doc-

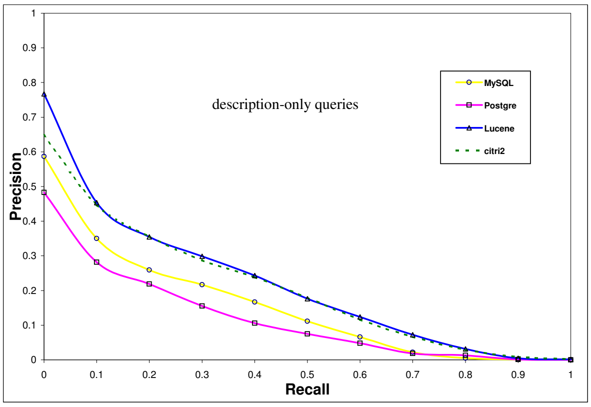

Fig. 1. Interpolated precision - recall graph

ument length normalization combination yields best results. Search quality results of PostgreSQL runs are given in Table VII. It includes six different document length normalization options and two ranking functions described in section III-D2. Note that option 4 is supported only by ts_rank_cd and option 32 is just a cosmetic change so that it is not included in our runs.

In all of runs ts_rank performed better than ts_rank_cd in terms of both search quality and search time. ts_rank_cd yielded highest MAP value with mode 4 which is implemented just for it. Among two predefined ranking functions and six length normalization options, standard ranking (ts_rank) function with the normalization option 1, yielded highest MAP value. Therefore this combination is selected as best representative of PostgreSQL.

D. Global Evaluation

In this section we compare best representative of each system. In Table VIII, the retrieval qualities (in terms of mean average precision) of each system are compared. Each system performed its best with KStemmer while overall best performing one is Lucene (with KStemmer). It is observed that among four different stemming methods, best performing is the KStemmer for the English language. Also English (porter2) stemming algorithm performed slightly better than the original porter stemming algorithm in all systems. KStemmer with Lucene performed slightly (2.8%) better than citri2 [19] which was at the seventh seat at TREC-4 automatic adhoc competition with the MAP value of 0.1956. PosgreSQL's poor performance can be explained by lack of inverse document frequency component in its ranking mechanism.

Among the several metrics eleven point precision recall curves of each system are presented in the TREC-4 overview paper [11]. Therefore the curves of each system (with KStemmer) and citri2 are plotted on Figure 1 to compare information retrieval systems visually. Lucene whose curve is the closest to the upper right-hand corner of the graph (where recall and precision are maximized) indicates the best performance.

Although main focus of this study is text retrieval quality benchmarking, as a side note, indexing times of each system are presented on Figure 2. In our experiments relational database settings are optimized for static data. Note that in PostgreSQL, GIN index is recommended[21] for static data since lookups are about three times faster than GiST, on the other hand GIN index takes about three times longer to build than GiST.

Average searching times of each system's different runs are depicted separately in **sec/q** column of tables in previous subsections. Relational Databases' searching and indexing speed are much slower than Lucene. With the response time under 50 milliseconds per query, Lucene would perfectly satisfy online web users.

V. OBSERVATIONS

Many Relational Databases have full text search functionalities but all have different syntax so there is no real standard between different vendors. Details of their inner algorithms are not well-documented.

All three systems use document length normalization in order to prevent long documents taking over. Lucene and

[21] http://www.postgresql.org/docs/8.4/static/textsearch-indexes.html

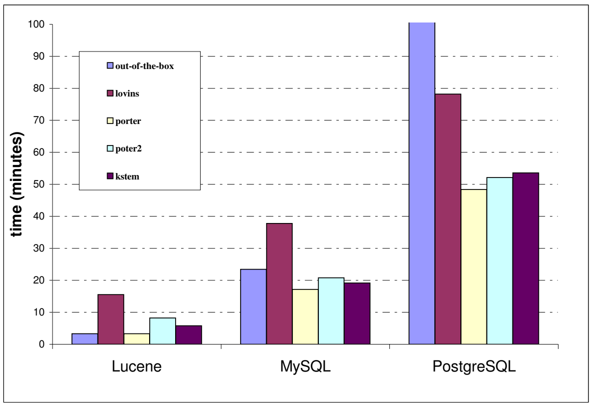

Fig. 2. Average Indexing Times

MySQL uses idf component in their score calculation while PostgreSQL does not. MySQL's full text search is limited to only MyISAM tables and has a few tuning parameters. PostgreSQL has more configurable parameters through dictionaries that provide stemming, synonym expansion, stop word removal etc. Available PosrgreSQL dictionaries are Stop Words, Simple, Synonym, Thesaurus, Ispell and Snowball. PosgreSQL's full text search, similar to Boolean mode in MySQL, does not require full text indices. In PostgreSQL, it is possible to immediately see the output of full text related functions and debug this way. For example executing SELECT to_tsvector('english', 'Testing the English configuration'); displays `'configur':4 'english':3 'test':1`

PostgreSQL and Lucene have highlighting feature that can generate snippets where query terms are highlighted. Generally users like to see which part of the document matches their queries.

VI. Conclusion

Our work in comparing the performances of relational databases and information retrieval libraries showed that; for TREC-4 adhoc collection, Lucene produced the best results in terms of efficiency and effectiveness. Lucene's out-of-the-box search quality reached to top six for TREC-4 adhoc evaluation. Although relational databases provide easy to use full text search capabilities that do not require an additional system installation and maintenance, without linguistic preprocessing their search quality is quite low. Due to the impractical response and indexing times, open source relational databases are unsuitable to be installed as a full text search solution for high traffic web applications.

Parallel, Massive Processing in SuperMatrix—a General Tool for Distributional Semantic Analysis of Corpus

Bartosz Broda, Damian Jaworski, Maciej Piasecki
Institute of Informatics, Wrocław University of Technology, Poland
Email: {bartosz.broda, maciej.piasecki}@pwr.wroc.pl

***Abstract*—The paper presents an extended version of the SuperMatrix system — a general tool supporting automatic acquisition of lexical semantic relations from corpora. Extensions focus mainly on parallel processing of massive amounts of data. The construction of the system is discussed. Three distributed parts of the system are presented, i.e., distributed construction of co-incidence matrices from corpora, computation of similarity matrix and parallel solving of synonymy tests. An evaluation of a proposed approach to parallel processing is shown. Parallelization of similarity matrix computation demonstrates almost linear speedup. The smallest improvements were achieved for construction of matrices, as this process is mostly bound by reading huge amounts of data. Also, a few areas in which functionality of SuperMatrix was improved are described.**

I. Introduction

HUGE text corpora are now relatively easy to be collected, e.g., on the basis of the Web. They can be a valuable, direct source of linguistic data, e.g., use examples, but also a basis for the automated extraction of linguistic knowledge. Such applications as automatic induction of morphological descriptions or extraction of syntactic subcategorisation frames are well known. However, recently we can also observe applications of automated extraction methods in the lexical semantics, too. Construction of a large scale language resource describing lexical semantics, e.g. a wordnet[1], is a very laborious process, in which skilled lexicographers must be involved. Such a process can be supported by the automatic extraction of semantic relations among words, or multi-word units in general, as well, as semantic restrictions imposed by particular words on their occurrence contexts. The extracted knowledge can be consulted by linguists during the construction of a resource or can be used for suggesting to the lexicographers some new elements of a semantic lexicon, e.g., lexical semantic relations between lexical units or groups of lexical units (i.e., wordnet synsets) in a wordnet, cf [2].

There are two main paradigms of automatic extraction of instances of lexical semantic relations, e.g., [3]:

- *pattern-based*,
- and *clustering-based*.

The clustering-based paradigm is also called *distributional paradigm*, as it originates directly from the *Distributional Hypothesis* formulated by Harris [4].

According to the pattern based approaches there are some lexico-syntactic patterns, which combine two words and mark the word pair as an instance of some lexical semantic relation, e.g., hypernymy [5]. So every single occurrence of a precise pattern is treated as evidence for the semantic association of the given words. The pattern-based methods can utilise individual occurrences of word pairs in a corpus, but are error prone in the same time, as they depend on individual occurrences. This drawback can be corrected by taking into account statistics of word co-occurrences with different patterns across the whole corpus, cf Espresso [3] and Estratto [6] methods.

Statistical analysis of co-occurrences can lead to the automatic construction of a Measure of Semantic Relatedness (MSR) (also called Measure of Semantic Similarity) which is modelled as a function:

$$MSR : W \times W \to R \tag{1}$$

where W is a set of words and R is the set of real numbers.

MSR construction is based on the analysis of the similarity of distributions of some words across different lexico-syntactic or even semantic contexts as evidence for their close semantic relation.

There are plenty of methods of the automatic extraction of MSRs. Most of them start with processing a corpus and constructing a co-incidence matrix describing co-occurrences of LUs (rows) and lexico-syntactic contexts (columns). They differ in three aspects: definitions of contexts, transformations of the raw frequencies and calculation of the final measure value. A context can be a whole document, but much better results can be obtained using a more precise description of the context. So, a word occurrence is mostly described by other words occurring in its context and, possibly, syntactic relations linking them to it, e.g., a particular noun can be characterised by adjectives such that they occur in its context and syntactically modify it. A *feature* is a particular type of co-occurrence describing the context, and a lexico-syntactic feature is a pair: a word and a syntactic relation, e.g., ⟨*fast*, `modifier`⟩. The initial value of the features are the frequencies of their co-occurrence with the words that are described. However, these raw values are mostly transformed later in order to emphasise the semantic information they express in relation to words being described.

[1] By wordnet we mean here an electronic thesaurus of a structure following the main lines of the Princeton WordNet thesaurus [1].

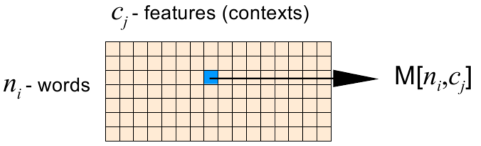

Fig. 1. Schematic view of co-occurrence matrix.

Several algorithms for collecting corpus frequencies, transforming feature value and calculating semantic relatedness of words on the basis of their feature vectors were implemented in the *SuperMatrix* system [7] – a general tool for the extraction of lexical semantic knowledge on the basis of distributional analysis of corpora. The increasing size of corpora processed by SuperMatrix and the resulting huge amount of the extracted data resulted in very long processing time in practical applications of SuperMatrix. From the very beginning a typical practice was to divide manually huge processing tasks into several parts processed independently: several copies of SuperMatrix were run in parallel, on different computers, and next the partial results were merged using manually controlled functions of SuperMatrix. The general requirement for the computing time is unavoidable, if one wants to work with huge corpora, but the total time of task completion can be reduced by extending SuperMatrix with elements of the parallel architecture.

The goal of the paper is to present a version of SuperMatrix, which is extended with elements of the parallel processing architecture, that is aimed towards better support for efficient distributional analysis of massive corpora. Moreover, several extensions and improvements concerning extraction and clustering algorithms of SuperMatrix are also presented.

In the following sections, first we will briefly describe the SuperMatrix system as a tool supporting semantic analysis, i.e., its basic algorithms and functionality. Next we will identify these algorithms that can be successfully transformed into their parallel versions. We will present the distributed, parallel architecture of the new version of SuperMatrix. Finally, we will report on the experiments performed, practical applications and plans for further extensions.

II. SuperMatrix

SuperMatrix is a collection of libraries for programmers and end-user tools for creating, storing and manipulating co-incidence matrices that describe distributional patterns of words. A co-incidence matrix is a matrix, in which rows correspond to words being described and columns to features, see Fig. 1. Initial values of cells are set to frequencies with which features occurred in the contexts of the subsequent words. The system consists of the four main modules,[2] namely:

- *Matrices* – a library for storing and accessing matrices. SuperMatrix supports a few formats of storing matrices, but the most important one are sparse matrices.
- *Comparator* – a library enabling computation of similarity between rows of matrices (i.e., between one word and multi-word lexical units) using different MSRs. Comparator was also designed in a modular manner. The computation of a similarity matrix was decomposed into a few steps, i.e., global filtering of features, local selection of features, weighting of features and comparing feature vectors. For every stage there are several algorithms implemented in SuperMatrix.
- *Matrix tools*, including (but not limited to) tools for: constructing co-incidence matrices (collecting raw frequencies and transforming feature values), MSRs, joining matrices and analysing matrix content, e.g., manually browsing selected rows and columns from any matrix – including transformed and weighted matrices.
- Clustering – a package consisting of several clustering algorithms, e.g., implementation of Clustering by Committee [8] (modified and extended [9]), RObust Clustering using linKs [10] and Growing Hierarchical Self-Organising Maps [11], and also an interface to the CLUTO package [12].

III. Distributed SuperMatrix

There are two main problems of processing huge corpora: long processing time and huge amount of memory required. Fortunately, corpus processing has in general a parallel nature and the majority of matrix operations can be easily decomposed into operations performed on matrix parts. In the following subsection we will discuss parallel algorithms introduced into extended SuperMatrix, and in the next subsection we will present the contemporary, improved functionality of the system.

A. Parallel Algorithms

We have identified three main areas of the SuperMatrix functionality, in which parallel algorithms can introduce improvements:

- co-incidence matrix construction,
- similarity matrix calculation,
- MSR evaluation by WordNet-based Synonymy Test (WBST)[3] [16].

Corpus processing is the fourth possible area, which is suitable for parallel processing, but SuperMatrix is mostly applied to text previously tagged morphosyntactically and text processing is reduced to the application of morphosyntactic constraints or reading annotation – both these elements are included in the matrix construction.

A natural way of task distribution among processing nodes during matrix construction seemed to be assignment of the subsequent parts of the corpus to the different nodes. However, this solution encounters several problems. First, the applied binary corpus format of Poliqarp is best suited for sequential corpus processing in our wrapping library. Secondly, definition of the matrix columns in the form of lexicalised morpho-syntactic constraints can consume huge amount of operating

[2] We present a brief description of a system, for detailed discussion see [7].

[3] The task in WBST test is to determine which word among a few choices given is synonymous to the given question word. There is a long tradition of evaluation of MSRs using synonymy tests, e.g., [13]–[15].

memory, as the constraints are kept in the compiled form due to efficiency reasons. Thus, a large constraint-based matrix of around 500 thousands of columns is too large to be kept in the memory[4], but we face the necessity to build such a matrix as a tool in the analysis of a huge Polish corpus of 930 million of words. Construction of a matrix including features based on the morpho-syntactic constraints requires huge amounts of memory, but it is also the most valuable type of a matrix in terms of the accuracy of the results generated and possible applications of SuperMatrix.

Instead of distributing data across processing nodes, we distribute processing. Each processing node is assigned a matrix with a subset of the original set of columns. The sub-matrices (column slices) are defined by the specification of the features sent by the central managing node. All nodes are run on the corpus in parallel. A corpus is stored on the shared resource, as this is the usual approach in computing clusters. Also, a corpus can be huge so keeping it copied in multiply places is not practical. Nevertheless, this is a potential bottleneck of the system. However, as our experiments with corpus copies placed on the processing nodes showed, the data transfer influences the system efficiency to a minor extent. At the end, the data stored in the sub-matrices are read sequentially by the central node and merged into the resulting matrix of possible huge dimensions, but typically very sparse. Constraints are kept in memory only for processing in the nodes, columns in the resulting matrix are described by labels.

The big advantage of the above model is the ability to construct word descriptions unlimited in the number of features used distributed across processing nodes. Scheduling is also simple in the case of a limited set of nodes – the central manager can gradually sent the subsequent sub-matrices to nodes which just finished their task.

In the case of the similarity matrix calculation, the smallest unit of processing which can be distributed independently of specifics of measure of semantic relatedness is the calculation of the similarity of two rows. As a typical task is computation of the k most semantically related words to the given one, the central manager assigns identifiers of rows to be processed to the processing nodes. The central node collects the computed values or ranking lists for the subsequent words.

In the parallel implementation of WBST-based evaluation of MSR, all processing nodes store the full list of question-answer (QA) pairs, the similarity matrix and the central manager assigns subsequent <test, MSR, matrix> tuples to free nodes. Testing results (the number of correct and incorrect answers, as well, as omitted QA pairs when one of the words was not described by a given matrix) are sent to the central node which calculates the final aggregated test statistics.

B. Improved Functionality

The functionality of SuperMatrix has been improved in a few areas. Aside from bugfixes and general code clean-up we have added a few new algorithms for construction of MSR or extended existing ones. We have added simple quantization of weighted values to mutual information based measures (Mutual Information of Lin's [17] measure and Pointwise Mutual Information [8]). Several different methods of weighting inside RWF function have been implemented using contingency table based definitions proposed by [18]. We have added RWF based on: mutual information, log likelihood and χ^2 measures of associations. Rank weight functions were also extended with a possibility of building non-linear rankings of features (e.g., exponential).

Treating co-occurrence data gathered using different lexico-semantic constraints (or different grammatical relations acquired from parser) in an uniform way may be sometimes inappropriate. Thus, we have added simple *ensemble-like* MSRs that works on different parts of matrices independently. This is one of the ongoing area of research within our team.

As it was mentioned above, SuperMatrix does data clustering via either using built-in algorithms (e.g., GHSOM or CBC) or interfacing with CLUTO. Both of these ways expose pretty advanced clustering algorithms for the user. However, there was no easy way to use some very simple algorithms. Thus we have implemented two baseline clustering algorithms: k-means and k-medoids. The latter uses classical *partition around medoids* approach. The implementation of those algorithms is a little bit different then classical ones, i.e., we perform clustering on the basis of similarity (any weighting scheme in SuperMatrix can be used, but similarity is restricted to cosine in current version). In terms of clustering we have improved our integration with CLUTO, i.e., for internal algorithms we use output format of CLUTO and we added tools for evaluation of clustering based on this format. We have implemented only a few evaluation measures, namely: purity, Rand Index, normalised mutual information and precision, recall and f-measure [19]. Having this tight integration with CLUTO enables us to use also SenseCluster [20] method of evaluation, which uses a little bit different definition for computing precision and recall.

We also work on the web service base access to SuperMatrix and part of the targeted functionality is already available[5]. This work is done as a part of the CLARIN project. Currently we have most of the technical bits of SOA-based communication with SuperMatrix worked out and a user can query a few pre-build matrices for similarity between words.

We have added an interface to work with Doug Rohde's SVDLIBC library[6] — a cleaned up version of Berry's SVDPACKC [21].

Also a few technical improvements have been made in SuperMatrix. The performance of (sequential) parts of MSR computation have been greatly improved (by a factor of 2-10 depending on complexity of MSR, the more complex the higher the speedup) by allowing user to weight whole matrix, before computations (which can be undesirable in a few cases,

[4] On the processing node with 4 GB of RAM only construction of a matrix with 76,000 columns could be started, but was not completed.

[5] http://nlp.pwr.wroc.pl/clarin/ws/supermatrix/

[6] http://tedlab.mit.edu/ dr/SVDLIBC/

e.g., some MSRs use unweighted data in the later stages of processing, or raw frequencies are required in different part of user's application). We have improved a parser of MSR request in a way that every part of MSR can be now specified via a character string without resorting to assembling MSR inside the code. In previous version of SuperMatrix only predefined combinations of parameters were available in this way.

IV. Experiments

All experiments were aimed at comparing the processing time of the single-node version of SuperMatrix with the new parallel version run in the distributed network of processing nodes. For the needs of semi-automated development of plWordNet (a wordnet for Polish) [2] a corpus of the size 900 million words[7] is processed, around 350,000 lexicalised constraints (based on adjectives, nouns and verbs) were identified as delivering statistically meaningful information and the description is built for around 25,000 nouns (some of them are multiword expressions)[8]. Concerning these numbers, performing the repeated tests on the corpus of this size would consume the power of our computing cluster to the very large extent, while the cluster is being extensively used in everyday practice of the works on preparing semantic resources for plWordNet. Also, it is not possible to fit a matrix of this size in the memory which is needed for comparison with performance of a run on a single node – only up to 40–60 thousands of column constraints, depending on the complexity of the constraints, can be stored in 4GB RAM. Thus all experiments were performed on smaller matrices or on partially completed tasks.

All experiments were performed on the computing cluster consisting of 6 computing nodes. Each node is equipped with two dual core processors Intel(R) Xeon(R) CPU 5160 3GHz. 4 processes can be run in parallel on each node that gives maximally 24 virtual processing nodes. Three of the nodes have 5 GB RAM, three 6 GB RAM – this is a strong limitation for SuperMatrix, concerning a single processing node. The nodes are connected by the InfiniBand network of 96Gbit/s bandwidth. The cluster runs under CentOs 5.3. All parallel algorithms of the extended SuperMatrix were written in C++ and the inter-process communication using Message Passing Interface (MPI) library.

Aside from time of execution we mention also *speedup* $S(p) = \frac{T_s}{T_p(p)}$, where p is a number of processors, Ts is a time of execution of best sequential algorithm solving the problem and $T_p(p)$ is time of execution of parallel algorithm using p processors. In practice $T_s = T_p(1)$ for convenience [24].

TABLE I
Matrix construction on the different number of processing nodes.

No of nodes	1	2	4	6	8	10	12	14
Time (min)	90.5	71.5	64.25	62	61.75	54.5	51.5	53
Speedup		1.27	1.41	1.46	1.47	1.66	1.76	1.71

A. Co-incidence Matrix Construction

A matrix was constructed on the basis of the IPI PAN Corpus (around 250 millions of words). Description of 25,000 nouns was based on constraints based only on adjectives that resulted in around 35,000 lexical constraints (columns). A constraint of this type recognises occurrence of the given adjective in text as modifying the given noun which is being described.

During the first experiment constraints were uniformly assigned to the processing nodes. The results for different number of nodes used are presented in Tab. I. The processing time decreases with the increasing number of nodes. However, the process saturates with 10 processing nodes, and starting with 12 nodes the speed of processing starts to increase. It is caused by the communication overhead: adding new nodes brings a relatively small increase of processing speed but increases the complexity of communication. The reason for this is that a significant part of the process has a sequential character, i.e., mainly reading the corpus.

In the second experiment, we compared the behaviour of the system in the environment of the limited memory capacity. The maximal number of the constraints stored was limited to 7800 only. A sequential non-parallel version was run 4 times and was compared with the parallel version run on the 4 nodes simultaneously. The results are, respectively: 169.5 minutes and 64.25 minutes. The total cost of processing 257 min. (4 times 64.25 min.) is much higher in the case of the parallel version, however we get the result 2.64 times faster.

B. Similarity Matrix Calculation

Experiments in this subsection were based on the co-incidence matrix of 25,000 rows (describing nouns) and 240,000 columns representing lexicalised constraints. Cosine measure was applied as row similarity measure, so no transformation took place during the similarity calculation.

In the first experiment, computations was repeated for several different numbers of words, in each case the goal was to find $k = 20$ most semantically related words to the given one. Experiment was repeated for the different numbers of processing nodes used. As complete would require a lot of processing time, the final results were estimated on the basis of the first hour of processing in each case. The results are presented in Tab. II.

The achieved speedup is almost linear – with the increasing number of nodes the speedup of the processing is increasing (see Fig. 2). The sequential part is performed on each node and encompasses reading the co-incidence matrix (from the shared hard drive) and calculating the similarity function. So

[7] A joint corpus consisting of 10 smaller, including the IPI PAN Corpus [22], the corpus of *Rzeczpospolita* [23] and several corpora built on the basis of the Web content.

[8] The set includes words already included in plWordNet and new ones, as the aim of the process is to extract from the corpus information concerning semantic associations among words and next use this information in generating suggestions concerning the placement of the new words in the plWordNet structure.

TABLE II
TIME (MIN) REQUIRED FOR THE SIMILARITY MATRIX CALCULATION ON THE DIFFERENT NUMBER OF PROCESSING NODE – "ND." AND FOR DIFFERENT SIZE OF THE PROBLEM.

	No of words

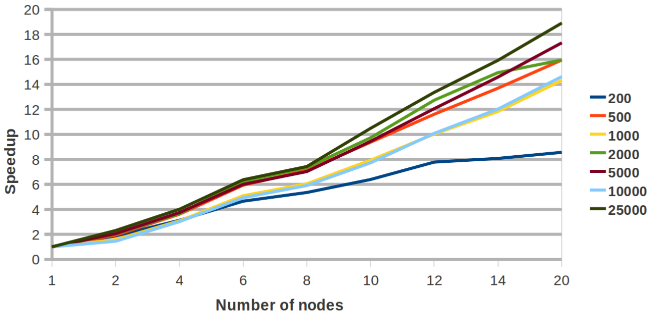

Fig. 2. Speedup of similarity matrix calculation in relation for different size of the problem

the parallel part of the process increases with the increasing number of words.

A typical task is calculation of a list of the k most semantically related words to each described word. Such a list is used next, e.g., as a knowledge source in a *WordNet Weaver* system that supports extension of a Polish wordnet in a semiautomatic way.

During the second experiment, we tested the influence on the speedup of the number of k most semantically related words calculated for each word and sent to the central manager. Our aim was to analyse consequence of the expected increasing communication complexity with the increasing length of lists returned to the central manager. The results for the two values of k: 20 – a typical one, and 25,000 – the full list, are presented in Tab. III. The lists were computed for a sample of 500 words (nouns).

In the case of 1 and 2 nodes, the processing time was estimated on the basis of part of the process. If size of the results had had an influence on the communication, the time required for computing a list for $k = 25000$ would have been larger than for $k20$, but it is much smaller in fact! It is caused by the lack of sorting in the case the whole list of 25,000 similarity values is returned. According to the assumed algorithm, if k is smaller than the number of words a list must be sorted and only the k top are returned.

Both experiments showed that with the increasing complexity of the problem, but also with increasing number of processing time the system expresses very positive efficiency.

TABLE IV
TIME (MIN) USED REQUIRED FOR PERFORMING WBST TESTS FOR DIFFERENT CO-INCIDENCE MATRICES AND MEASURES OF SEMANTIC RELATEDNESS. THE VALUE OF SPEEDUP IS GIVEN IN THE BRACKETS.

MSRs	5		10	
Matrices	1	2	1	2
Nodes				
1	21	51	66.5	157.5
2	13 (1.61)	26 (1.96)	35 (1.9)	82.5 (1.91)
3	10.2 (2.05)	22 (2.32)	28 (2.37)	65 (2.42)
4	10 (2.1)	19.5 (2.61)	24.2 (2.74)	55.5 (2.84)
5	6 (3.5)	15 (3.4)	18 (3.69)	42.2 (3.73)
8	6 (3.5)	11.2 (4.53)	16.2 (4.09)	28.5 (5.53)
10	6 (3.5)	8 (6.35)	16.2 (4.09)	22.5 (7)

These results have a very practical meaning, as row similarity matrices are comptuted very often in practice, and in the case of a non-parallel version of SuperMatrix their calculation was a serious bottleneck for more complex process of the extraction of lexico-semantic relations.

C. *Measure of Semantic Relatedness Evaluation*

For the needs of the experiment a WBST test was randomly generated from plWordNet. The test consisted of around 15,000 of question-answers (QA) pairs. Two large co-incidence matrices were collected. For the experiment we selected also 10 MSRs based on different algorithms of different complexity. All MSRs were calculated during experiment for the pairs of words from the test. Matrices were stored on the processing nodes.

Two versions of the WBST-based evaluation were compared. The old one, which is parallel (thread-based parallelism) but not distributed. It can assign different <test, MSR, matrix> tuples to different cores of the single machine. The second one of extended SuperMatrix is capable of distributing subsets of <test, MSR, matrix> tuples across processing nodes.

The parallel version was tested for 5 and 10 different MSRs to be tested and 1 and 2 co-incidence matrices on up to 10 processing nodes. The old non-distributed version was tested for the same combinations of MSRs and matrices but only up to 4 cores – the maximal number in the PC used for the test. The results of the experiment are presented in Tab. IV.

We expected that the WBST performance would be increasing with the increasing number of processing but the speed will not rise linearly in relation to the size of the problem. In our expectations we took into account different complexity of the used MSR algorithm and different properties of the two co-incidence matrices applied. WBST parts, i.e., subsets of QA pairs are different from the computation point of view – they differ only in their size. In order to solve one QA pair, the system has to compare four row vectors. The achieved results are generally compatible with our initial expectations. The only difference is that in the case of two matrices processed the speedup grows almost linearly, while in the case of one matrix saturates around 5 nodes.

TABLE III
TIME (MIN) REQUIRED FOR COMPUTING LIST OF THE k MOST SEMANTICALLY RELATED WORDS TO THE GIVEN ONE.

	Number of Nodes								
	1	2	4	6	8	10	12	14	20
k=20	267	138	74	45	37.5	28.5	23	19.5	16.75
k=25000	215.5	117.25	75.5	45.25	37.75	29.25	23.25	19.75	16.75

V. RELATED WORKS

There are a few systems that are similar in functionality to SuperMatrix, but process data in a sequential manner. Reimplementation of LSA [13] is possible with the combination of *MC Toolkit* [25] and SVDPACKC [21]. There are a few problem with this approach, e.g., MC Toolkit supported only ASCII encoding and could only create a words by documents matrix. *Infomap NLP* package [26] supports similar functionality to MC Toolkit with SVD, but it was especially created for the extraction of word meanings from free text corpora. Infomap NLP package has been abandoned in favour of a new system called *Semantic Vectors* (SV) [27]. Main differences with Infomap NLP are: usage of random projection instead of SVD for dimensionality reduction and the implementation, which was written completely in Java, using Apache Lucene as a document-indexing engine.

Distribution of computation in natural language processing has a long tradition in domain of Information Retrieval (IR). However, in IR the main approaches focuses on reducing volumes of fetching, sending and processing of (inverted) index, cf [28], [29].

Pantel et al. present work similar to subset of ours — scaling similarity calculation to very large datasets [30]. However, the focus in [30] was put on distribution of only the similarity function, like cosine or Dice. In our approach we parallelized all the computations (matrix construction, feature selection and filtering, weighting and similarity calculation). Pantel et al. use a approach based on MapReduce framework which is popular in many application in NLP, e.g., clustering [31].

VI. CONCLUSIONS

SuperMatrix appeared to be a very valuable system during the semi-automated construction of plWordNet, see the detailed report on techniques applied in [2]. However, the growing size of both: corpus and plWordNet, caused that the further usage of a single-machine version of SuperMatrix started to be difficult. Work on transforming the system into a system based on the parallel architecture have been initiated.

In SuperMatrix, the basic data structure is a matrix, the majority of operations have a sequential character in relation to processing rows or columns of the matrix. Thus, the main concern was in which areas the effort on introducing parallel and distributed processing will be most effective in terms of the reduced time of processing or the increased scale of problems processed. The latter was even a more severe limitation than the former.

Three main areas were identified for transformation into parallel computation, namely: co-incidence matrix construction, similarity matrix calculation and MSR evaluation by WBST. The first two are the most costly processes in terms of computation complexity and both were bottlenecks for larger problems: the former because of the memory usage, and the latter due to time complexity. Less attention was given so far to the feature-oriented transformations of the matrix, as they are applied to the already collected frequencies and sparse matrices. Matrix-oriented transformations, like SVD, form a separate class of problems, SuperMatrix depends in this area on the third-party solutions, so this important issue was left for further development. Corpus preprocessing, e.g., by a morpho-syntactic tagger, is also an area suitable for parallel processing. However there is an ongoing work on some solutions in this phase in another project, cf. [32], so it was not solved here – SuperMatrix is able to co-operate with some language tools, e.g., the TaKIPI tagger, but from the point of view of parallel SuperMatrix architecture we assume that the input corpus is already pre-processed. Moreover, the morpho-syntactic constraints, which are heavily applied during matrix construction are in fact a language tool similar to a chunker (a kind of a parser).

All introduced solutions appeared to be effective in performed tests and in practice. In the case of the matrix construction the decrease of processing time saturates with the increasing number of processors, but even more important profit is that parallel architecture enables construction of matrices of practically unlimited size in a convenient way, i.e., without human guiding the system through the process. This is important feature, because the construction of large amount of submatrices independently and summing them in correct order is long, laborious and error prone process when done manually. The use of 500,000 features and even more is justified as distribution of words in the natural language is very sparse and different subsets of lexicon can be described by different subsets of lexico-syntactic features, e.g., by different specific adjectives. The present version of SuperMatrix is prepared for this.

The applied technical solution based on the MPI, makes possible to use the system not only on a specialised computing cluster by also on a network of computers or even utilise multi-core architecture of a modern PC.

We plan to make SuperMatrix more flexible with respect to the application to different languages and different corpus annotation schemes. The present version works for Polish and English, but some elements are tightened to some specific language tools.

Possible application areas for SuperMatrix include extraction of MSRs from corpora and semantic correction of handwritten text. This system can be also used to perform unsupervised word sense disambiguation, named entity disambiguation, sentiment analysis, document indexing, clustering and retrieval and search engine construction. Last but not least, we suspect that SuperMatrix can be used outside the domain of natural language processing, i.e., everywhere were an object can be represented as a sparse feature vector (especially in high dimensional space).

***Abstract*—In this paper the development of a prototypic mobile voice control for navigating autonomous robots within a multi robot system is described. As basis for the voice control a hidden markov model based speech recognizer with a very low vocabulary of 30 words is utilized. It is investigated how many training samples for a markov model are required for a normal operation of speaker-dependent speech recognition. Therefore, hidden markov models were developed successively in parallel with an own training data corpus containing finally 2290 utterances from 12 speakers. Within the successive development of acoustical models and training corpus, the work revealed details about how many speakers are necessary to achieve an acceptable degree of speaker independence. We focused on an evaluation of the speech recognizer in adverse outdoor environments. The evaluation ranges from almost calm conditions of about 39 dB up to very adverse noise conditions of 120 dB. It is investigated whether a small vocabulary attenuates the noise vulnerability and in how far an increase of speaking volume can compensate noises of different intensity. The voice control was tested in outdoor environments and aspects of its usage are described.**

I. Introduction

IN HUMAN-MACHINE scenarios, e.g., where the user does not have his hands free to type in commands, or where the user is handicapped, the ability to control a system by voice can be considered. For those purposes usually small vocabularies are sufficient. In calm acoustical environments, e.g., in flats, low vocabulary speech recognition performs almost perfectly. Unfortunately in outside-scenarios or in in-vehicle-scenarios the acoustical environment can be very adverse.

It is not clear in how far a small vocabulary can compensate such bad acoustical conditions in order to maintain an acceptable word recognition rate (WRR) of 95%. Furthermore, it is an open question in which noise scenarios an increase of the speaking volume can maintain this recognition rate.

To this end, a low vocabulary speech recognizer was developed and evaluated under several adverse conditions. The evaluation ranged from almost calm conditions of about 39 dB up to very adverse noise conditions of 120 dB. For the training of models we constructed an acoustic corpus containing 2290 hand labeled German utterances from 12 people with different accents and relevant issues in corpus construction are described. For the unit of speech that has to be acoustically modeled by hidden markov models (HMMs), the word was chosen. Suitable numbers of gaussian mixture components were specified for speaker-dependent and speaker-independent training. The successive development of the acoustic models revealed insights in how many training samples are required per model and how many speakers are needed for speaker independent speech recognition. The core speech recognizer was connected to the software framework of the robots by means of suitable software libraries as will be explained in Section II. Finally, the speech recognizer was integrated into a voice control application for navigating robots within a multi robot system and issues in operating the voice control in outside environments are described.

A. Related work and Goals

In various studies experimental speech communication with robots has already been developed and successfully used (see, e.g., [1], [2]). However, in these works no studies were conducted regarding the performance of speech recognition when used in different noise scenarios. Therefore, we developed the voice control application with the aim to give answers to the following questions:

1) How strong is the effect of street noise, crowd noise, and in-vehicle noise of different degrees on the performance of speech recognition? Can an increase of speaking volume improve recognition rate and can a vocabulary with less than 50 words compensate such noise?
2) How many speakers are necessary to achieve an acceptable level of small-vocabulary speaker independence?
3) Does direct voice input suit to perform spatial navigation tasks?

The rest of the paper is structured as follows. Next, Section II describes groundwork and conceptual considerations for the voice control. The successive development of the application is illustrated in Section III. The speech recognizers performance is evaluated in Section IV and Section V concludes with a discussion.

II. Conception

This section describes basic conditions and conceptual considerations on which basis the voice control was developed.

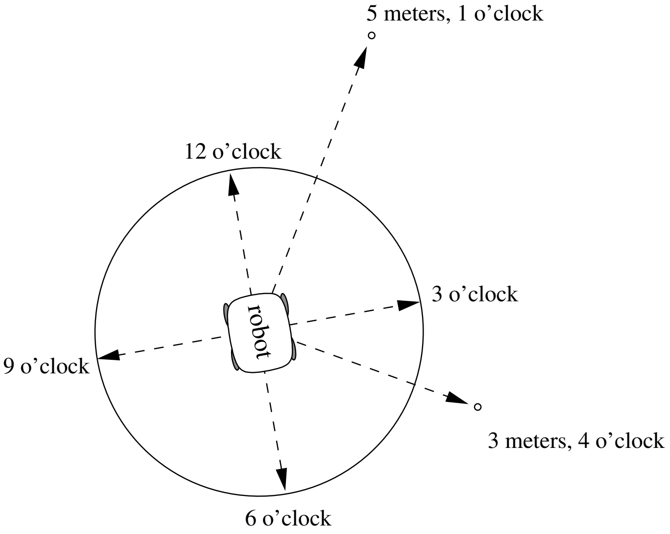

Fig. 1. Specifying target coordinates in a robot-centered 2-dimensional area

A. Navigation by the use of voice

The goal was to enable a navigation of robots onto a two-dimensional arbitrary ground, i.e., to move the robots backwards and forwards, and to rotate and stop. To allow for such a control, one single command was defined to consist of the specification of a direction and a distance. The values of distance and direction are given in *meters*[1] and *o'clock*. For instance, if the user commands robot 1 to go five meters forwards, the command to be uttered is formed as *"robot 1: 5 meters, 12 o'clock"*. If robot 1 should drive five meters to the right, the command is *"robot 1: 5 meters, 3 o'clock"*. The values for the parameters distance and direction are always specified relative to the robot (see also Figure 1).

B. Reused tools, software and platforms

In the following, toolkits and robot platforms utilized for the implementation of the voice control application are described.

Robots software and hardware: For the operation of the voice control we used robots of ATRV series from Real World Interface[2]. An ATRV-robot is a four-wheeled mobile platform equipped with sonar sensors and wireless ethernet communications. The ATRV-robots employ the software robot framework *RoSe* [3], [4], which serves as framework for control and communication among roboters. A C++ application is embedded in this framework and is called a *RoSe service*. The framework provides methods that allow RoSe services to communicate with each other via wireless link. A relevant service for the voice control is the *collision avoidance service* [5]. To this service a target coordinate in a two-dimensional robot-centered coordinate system can be passed. The service computes a path to the target coordinate which prevents to collide with obstacles. In order to put the robot in motion the collision avoidance service instructs a further RoSe service which is responsible for control of the robot's motor.

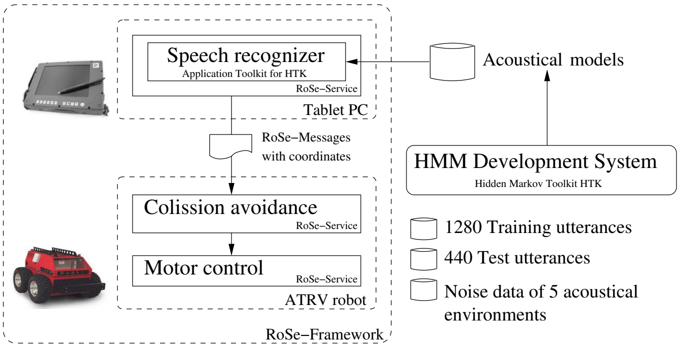

Fig. 2. Several software components arranged into an overall system for development, evaluation, and tests in outdoor environments

Toolkits for speech recognition: For development of acoustic models and evaluation under noise, the hidden markov Toolkit (HTK, [6]) was used. For embedding the developed acoustic models into a C++-application of the robots framework the *Application Toolkit for HTK* (ATK, [7]) was used. ATK is designed to create experimental applications based on HTK. It consists of a C++ layer which directly accesses the HTK library modules. ATK enables acoustic models that have been developed by HTK to be reused and integrate them into arbitrary C++-applications wrapped by ATK.

Composition of the voice control application: A combination of the software tools and hardware platforms described above composed the voice control application as follows. Acoustic models were trained with a development system based on HTK. These models were loaded into ATK. A RoSe service was written which utilizes the ATK libraries and, in particular, markov recognition algorithms and thus represents a RoSe service for voice control. Since the voice control appears as RoSe service, it is able to send messages with target coordinates to the collision avoidance service (see Figure 2).

C. Determining the speech recognizers application scope

This section describes the determination of adequate parameters for defining the speech recognizers application scope.

Vocabulary size: A small vocabulary of around 30 words was chosen to cover the required words for navigating the robot like, e.g., "robot", "meter", "o'clock" and several numbers ranging from "one" to "twelve".

Degree of speaker independence: Investigations dealing with speaker independence indicate different numbers of speakers required to achieve an acceptable degree of speaker independence [8], [9], [10]. According to *Lee* [9], at least 100 male speakers are in the training set as a minimum requirement for speaker independence. Furthermore, *Kubala* [10] shows that with 12 carefully selected speakers the same degree of speaker independence as a reference system can be obtained which was trained with 100 speakers. Thus, in this work utterances of 12 speakers of our research group were used as data basis. According to the statement of *Kubala* [10], it

[1] All commands have to be uttered in German. But for better readability they are written in English throughout the paper.

[2] formerly RWI, now iRobot, http://www.irobot.com

is assumed that even with this little number of speakers an approximately similar degree of speaker independence can be achieved as with a system that is trained with great speaker numbers.

D. Conception of Acoustic Modeling

The parameters that define the structure of the hidden markov models and the feature extraction are as follows.

Unit of speech: As unit of speech that has to be modeled by hidden markov models the word was chosen.

Number of states: The number of states per word-model was chosen dependent from words number of phonems but an extra state was added for the closure phase of plosives to model their non-stationarity more adequately. The number of states of the HMM was chosen to be linear to the number of phonemes in the corresponding word. This was intended to ensure that the phonetic structure of words is identical with the states of the HMMs. Furthermore, Bakis models [11] were used in which each of the next state may be skipped. This was intended, to take care of articulatory phenomena like vowel reduction.

Number of gaussian mixture densities: In literature there is no way known how to calculate the correct number of gaussian mixture densities. Accordingly, the number of gaussian mixture densities was kept variable. In development of acoustic models various numbers of gaussian mixture densities were tested in order to determine a suitable value.

Feature extraction: Mel Frequency Cepstral Coefficients (MFCC) were used to simulate a frequency sensitivity that is similar to that of the human ear.

E. Conception of the Acoustic Corpus

The overall speech corpus was recorded with a *Sennheiser PC 30* microphone.

Utterances to be spoken: It was determined to use speech samples out of continuously spoken utterances. Phenomena of coarticulation as they will occur in the operation of the speech are aimed to be included into the models. For instance, a sentence that had to be recorded looked like the following.

```
robot one drive ten meters twelve o'clock
```

Amount of utterances to be spoken: As requirement for HMM training for each model that should be trained at least 10, but better 50 or 100 samples should be available [8]. With a vocabulary of about 30 words, it should be sufficient to take 60 training utterances as basis to achieve a set of 20 references per word. Thus, in this work 60 training utterances were specified as minimum.

Manual annotation of utterances: Training procedures for hidden markov models require model specific pre-annotated audio data. For good results, at least an initial annotation for the models should be provided [12], [8]. For that reason parts of the corpus were manually segmented on word level. For the utterances for which no segmentation has taken place, a complete orthographic annotation was required instead.

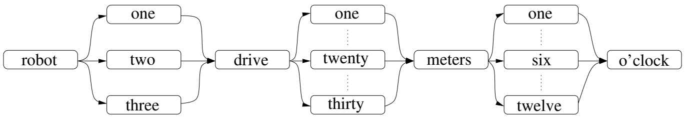

Fig. 3. Grammar network to cover navigation commands

III. Development and Implementation

In this section the development of the speech recognizer, its connection to the robots framework, and its integration onto a Tablet PC is described.

A. Realization of the Grammar

To allow for the requested operation the following grammar has been constructed. A command basically consists of a citation of the robot which is to execute a command, e.g., "robot two", and the actual statement, e.g., "drive ten meters towards twelve o'clock". Figure 3 depicts the grammar where silence models are omitted for better clarity.

B. Development of the Acoustic Corpus

In order to create the corpus, speaker utterances for training and for testing were recorded, afterwords post-processed, and finally partly annotated on word level with *Praat* [13].

Recording: The recordings have taken place in a carpeted large room with curtains. In total 220 training and 50 test utterances were recorded from the author. From each of the 12 speakers, 72 training and 50 test utterances were recorded. The whole corpus consists of 2290 utterances which includes the training part of 1850 utterances and the test part of 440 utterances. Issues related to the recording procedure were as follows. In order to maintain an adequate recording level and to avoid overmodulation, the distance to the mouth was readjusted for each speaker. For very loud or very soft voices the recording volume of the sound device had to be adjusted. Increasing the recording volume had to be done carefully in order to avoid too much inclusion of ambient noise into the signal. Sometimes it was difficult to maintain the same mean energy due to a movement of the microphone or a change of speaking volume. To ensure a flawless corpus, it was necessary to review the recorded utterances and, if some utterances were faulty, to capture those again.

Post-processing: The recorded utterances had needed to be post-processed such that only those audio data was included in the speech signals that were specified by our orthographic annotation. Thus, the utterances were freed from previous and following silence with standard sound-editing software. Random reviewing of temporal and spectral variation has taken place at approximately one third of the statements. Attention in inspecting the utterances was paid to modulation issues like insufficient modulation or overmodulation.

Manual annotation: All 240 utterances of the author were entirely manually annotated considering to use them for speaker-depended training. 10 of the 70 utterances of remaining speakers have been annotated manually aiming to use them for speaker-independent training. An automatic conversion

of annotations from the Praat format into HTK format has been realized with linux scripts. Naturally appearing speaking sounds like those of smacking and exhalation were separately annotated intending to train particular models for them later on. When smacking sounds merged with subsequent verbal sounds those were included into the annotation boundaries of the whole word. Small pauses between words were handled such that the word boundary was set in the middle of the pause. Regarding the annotation of silence, it had to be ensured that the duration of the intervals was consistently the same. Therefore, we chose an interval of 110 to 130 ms for silence annotations.

C. Development of acoustic models

In literature there was no precise information found about how much data is necessary for training of acoustic models. For this reason, the development of acoustic models was keeping pace with the creation of the acoustic body. In each development step, a model version was created. Below the structure and development of acoustic models is described.

Creating the HMM structure: The number of model states N_s was initially selected for each model by $N_s = N \cdot (P + 3)$ with the word's number of phonemes P, and a weight factor N. A small number of 3 states were provided for the word's beginning and the word's end. After the results for $N > 1$ were significantly worse, N was set to 1. In determining the number of phonemes of a word an extra state was provided for closure phases of plosives. For instance, for the German word 'roboter' 11 states were provided where two states are considered to model the closure phases of /b/ and /t/.

Training of HMMs: The training of models was carried out in two main steps. First, a speaker-dependent model was developed and optimized for high detection rates. Second, the speaker-dependent model was gradually extended to other speakers to achieve a high degree of speaker independence. To keep the development cycle as small as possible, the entire exercise was automated with linux scripts for which HMM parameters could be specified. The varied parameters of the training were *number of gaussian mixture components* and *number of training reestimations*. Tables II and III show the development of the speaker-dependent and speaker-independent models. As expected, it was observed that the degree of speaker independence increased for each additional speaker in the training set.

D. Creating the link to the robot framework

After development of the acoustic models was finished, a RoSe service has been written in C++ in which ATK connects the acoustic models with the RoSe-framework (see Fig. 2). ATK provides methods for starting the speech recognition process and returns the word chain that is assumed to be uttered. From the recognized word chain values for distance and direction are extracted by regular expressions. If the distance r in meters and the angle α is given in clock the target coordinate (x, y) was determined by $x = r \cdot sin(\frac{\alpha \cdot \pi}{6})$ and $y = r \cdot cos(\frac{\alpha \cdot \pi}{6})$. The target coordinate is then sent via a RoSe-message to the RoSe service for collision avoidance which is responsible for further activation of the robot's motor.

E. Integration onto a Tablet PC and outdoor tests

In the integration and test of the speech recognizer on a Tablet PC, it was observed that the sensitivity of the microphone had to be adjusted such that less ambient noise was included in the signal. If the recording level was set too high, the detection rate fell off dramatically. This was noted especially for operation in a outdoor environments when the microphone was adjusted too sensitive because even little noise was included in the signal.

IV. EVALUATION

The overall development of the voice control described above has already revealed some details about the degree of

speaking very loudly	78 dB	108 dB
screaming	84 dB	114 dB
screaming maximally	90 dB	120 dB
screaming maximally (single cases)	96 dB	126 dB

speaker independence and vulnerability to noise. In this section these features are examined in more detail.

A. Speaker independent recognition

The speaker-independent training has shown that the degree of speaker independence increased with the number of speakers in the training set. For evaluation of the degree of speaker independence, only those speakers had to be used who were not in the training set of acoustic models. By repeatedly leaving out a speaker in the respective training set and testing only this specific speaker, i.e., performing a *leave-one-out test*, one measurement of the degree of speaker independence for this specific speaker could be achieved. Since a total number of 11 speakers were available, the exhaust test was repeated several times for each available speaker. Depending on the mean value of the results, the general degree of speaker independence was estimated. The test results are shown in Table IV.

B. Recognition in noise

In the following the speech recognizers evaluation under noise adversity of low and high degrees is described.

Acquisition of noise: For the environmental conditions *calm outdoor environment* and *busy street*, the noise was recorded with the same microphone used for creating the acoustic corpus. The adjustment of the recording volume was done manually such that it was initially set to zero and continuously increased up to a good modulation of amplitudes between values of 0.5 and -0.5. For every recording, the sound pressure level was measured in dB with a sound level meter. Noise of the high adversity environments *babble* and *track vehicles* was taken from the corpus *Noisex* [14].

Overlaying procedure: Both the speaker-dependent and speaker-independent models were evaluated. For speaker-dependent evaluation in noise, test utterances of speaker RC were used. For speaker-independent evaluation in noise, test utterances of all speakers were used. Furthermore, noise adversity was simulated by artificially superimposing the clear commands from the test corpus with the software tool *FaNT* (Filtering and Noise Adding Tool, see [15]). The operation of FaNT requires SNR values to be specified which represents the intensity with which the noise superimposes the speech signal. The ratio of signal to noise depends on the sound level of speech and on the sound level of the noise. Sound levels of noise were measured in case of recording and are specified by *Noisex* [14] in case of noise corpus usage. Sound levels of speaking styles are taken from Lazarus et al. [16]. They provide average sound levels of different speaking styles, i.e., whispering, speaking softly, and relaxed speaking. Therefore, men produce by whispering at a distance of one meter a sound pressure level of 36 dB. By screaming, up to 96 dB can be achieved in some cases. For a summary of the data collected see Table V. Thus, utterances were superimposed at several SNRs in the range of small SNRs where the noise was barely noticeable up to large SNRs where the speech was hardly intelligible. In particular, superimposition ranged from -5 dB to 50 dB SNRs in 1dB steps. For the various noise scenarios, the test corpus was superimposed several times and new modified testing corpuses were created. The speech recognizer was then scheduled on the created corpora and word recognition rates were logged. This overlaying procedure has been used for noise evaluation of speech recognition in several works, e.g., [17], [18].

Overlaying Results: The sounds of a *calm outdoor environment* were obtained by recording at an average sound pressure of 39 dB. It can be seen that in a quite acoustic environment with a noise level of 40 dB, it is sufficient to speak softly to achieve very good recognition rates of at least 95% (see Figures 4 and 5). The sounds of a *busy street* were obtained by recording in a distance of 5 meters at an average sound pressure of 61 dB. The experiment showed that no good word recognition rates were possible when speaking relaxed. But by increasing the speaking volume good detection rates above 90% were achieved (see Figures 6 and 7). The *babble sounds* came from a large hall in which 100 people spoke to each other producing an average sound level of 88 dB. Hence, by

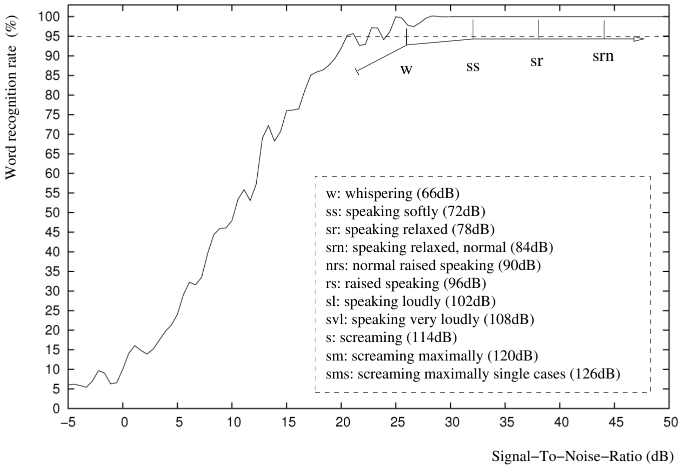

Fig. 4. Speaker-dependent recognition in 40 dB noise of a calm outdoor environment

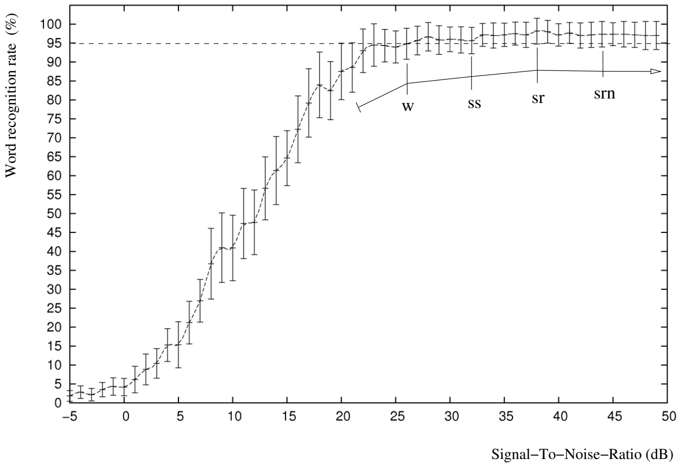

Fig. 5. Speaker-independent recognition in 40 dB noise of a calm outdoor environment

speaking very loud with 108 dB effecting an SNR of 20 dB, it could still be possible to achieve acceptable word recognition rates of around 90% (see Figures 8 and 9). The in-vehicle sounds came from *track vehicle 1* driving at a speed of 30 km/h producing an in-vehicle sound level of 100 dB. Good detection rates were virtually not able to be achieved. With a maximum achievable speaking volume of 120 dB, it would be theoretically possible even to achieve 80% recognition rate (see Figures 10 and 11). The in-vehicle sounds came from *track vehicle 2* driving at a speed of 70 km/h. The sound power level was specified with 114 dB. The results of the experiment may be taken from Figures 12 and 13. For those background noises virtually no satisfactory recognition rates were achieved.

V. Discussion and Conclusions

This section describes finally which conclusions were made and how this work can be used as a basis for further developments.

A. Acoustic modeling and degree of speaker independence

The training of acoustic models in Section III-C proved, that a number of around 20 samples per hidden markov model can be sufficient for normal operation of a HMM based speech recognizer. In the evaluation of speaker independence, it was shown that in a speech recognizer with a small vocabulary and a small number of speakers of around 10, a relatively high degree of speaker independence can be achieved.

B. Noise vulnerability

The evaluation had shown that when using a speech recognizer with vocabulary of solely 30 words in adverse environments of around 60 dB noise can be tackled by speaking with a raised voice in order to achieve a recognition rate of about 95%. In environments with extreme noise conditions from 80 dB up to 150 dB, the speech recognizer can no longer be used satisfactorily due to detection rates of around 80%. Here, a method for compensation of noise should be taken into account in conception of the speech recognizer. It could be summarized that keeping a speech recognizers vocabulary small does not compensate adverse noise of high sound levels above 100 dB.

However, it should be noted that when speaking louder, not only SNR increases but also the vocal tract changes its shape and produces frequencies for which the acoustic models were not trained. The results obtained here are subject to some inaccuracy since the identified speech sound levels were calculated directly at the mouth and thus only represent an estimate. Furthermore, many microphones feature polar patterns so that the noise received on the side of the microphone is attenuated more than those which enter head-on. It can be concluded that slightly higher SNRs and better recognition rates could be achieved. The comparison of the speaker-specific and speaker-independent results suggests that models that were trained by much more data and therefore having a greater generality, do not necessarily offer worse results than models that were only trained by a speaker and are much more specific.

Regarding possible further developments noise sensitivity can be reduced based on several methods. Besides conventional signal filtering methods human strategies for speech understanding in noise can be employed. A recent survey about findings of human strategies for noise compensation can be found in *Loizou* [17].

C. Voice as input mode for navigation tasks

The usage of speech as an input mode for the control of robots must be carefully planned. In this work, speech which represents a verbal mean is used to perform a spatial continuous operation task. The objective called to enable a discrete navigation of the robots on an arbitrary two-dimensional ground. In considering how this task could be completed by means of speech, the continuous task was transformed into a discrete task by instructing the user to specify a target coordinate in a two-dimensional system that the user must consider first. The spatial thinking user has to transform his intention to move first into a verbal command which causes an additional cognitive load and costs time.

Regarding possible further developments, a holistic designed interface could take the requirements of the operation task and the expectations of the operator into account. The development should take place through an iterative design-implementation approach and the human-robot interface in field evaluation should be kept at pace with development. The result should be an effective human-robot interface that allows the user, even under extreme conditions like stress and noise, for a consistent, effective, and fast control of the robot. For control by voice discrete operating activities are suitable. It would be conceivable to raise the navigation commands for navigation to a higher level of abstraction. For example, the user could navigate the robots as follows:

- "Drive back to command center", or
- "Drive to robot group A, drive to robot group B"

Furthermore, semi-autonomous functions of the robot could be controlled. Examples of such instructions are:

- "Follow robot A",
- "Explore area, radius 50 m", or
- "Search for intruders".

The Role of the Newly Introduced Word Types in the Translations of Novels

Maria Csernoch
University of Debrecen,
Egyetem tér 1. Debrecen, H-4029, Hungary
Email: csernoch.maria@inf.unideb.hu

***Abstract*—The project detailed in the article is able to find the vocabulary rich segments of novels in different languages. The method used here takes into account the frequency of the words of the text, and based on this information we are able to create artificial texts with the same parameters. Since the original and the artificial texts share parameters they are comparable and we can find those segments of the original text which are richer in vocabulary then it is expected as compared to a random selection of the words. The advantages of finding these vocabulary rich segments of the text, beyond that they give an insight of the development of the vocabulary of a novel, is that in any translation, adaptation process it is a great advantage being familiar with these sections of the text.**

I. Introduction

THE PRIMARY goal of this project was to find a dynamic first-order statistical model [5] with the help of which we are able to find the vocabulary rich segments of the texts written in natural languages. By vocabulary rich segments we understand those sections of the text where the number of the newly introduced words is higher than it is predicted by the model. These sections of the text make their stand out by being richer in vocabulary than the main body of the text.

After finding such a model, and – based on the model – the text slices corresponding to the vocabulary rich segment of the text the question arose, what could be the reasons for their presence. I found several previously published works which venture to give explanations for this phenomenon but these opinions are subjective, mainly based on the intuitions of the reader. I was interested in finding more objective explanations, which are based on quantitative data, for what makes the author of a text to increase the number of newly introduced words so intensively that the process makes qualitative changes in the text.

Finally, my aim was to explore how the proportion of newly introduced words varies in different adaptations of the same text. The term ‘adaptation’ is used here to include both intralingual and interlingual adaptations, whether involving reduction in text size or not. This means that beyond the theoretical significance that we were able to find a method with the help of which we can separate the vocabulary rich segments from the main body of the text, the practical usage of the method is also remarkable. One of the advantages of this statistical analysis is that it is invariant to the fact that translators are free to use words, expressions, structures, different kind of techniques well known in translation studies. The only expectation here is that in a faithful translation the text segments in the target language should be as rich in vocabulary as they are in the original text. Both translators and critics are offered the location and the intensity of the vocabulary rich segments of a text. On the one hand, prior to the translators’ effective work becoming familiar with the vocabulary rich text segments of the original work might help the translator(s) to pay more attention to these unique slices of text. They are unique in the sense that the author of the original text used richer vocabulary to call the readers’ attention to them. As a result, we would be able to reach a more faithful translation. On the other hand, being familiar with the vocabulary rich text segments of both the original and the translated texts means that a new set of parameters is added to the tools of translation criticism. Here we would be able to provide more objective analysis of the translation(s), we would be able to tell how close a translation is to the original text in vocabulary, or decide which translation is closer to the original text.

II. Methods

A. Newly introduced words (word types and lemmas)

The analyses of texts highly depend on the notion of newly introduced word types. First the definition of newly introduce word types should be given.

Newly introduced word types have meaning in a closed text, at a certain point of that particular text. When the first appearance of the word is detected at a certain point of the text, the word is considered as newly introduced in that text.

Beyond that newly introduced word types are understood within a closed environment, unlike other word concepts newly introduced word type is relative. The title being newly introduced is only temporary, and the word is in the range of this concept until its second appearance in the text. The definition of newly introduced words contain that hapax legomena of the text are those words which never loose this title.

B. Dynamic first-order statistical models

To be able to follow the flow of a text instead of the previously used static models a dynamic model should have been created. The advantage of the dynamic model to the static models is that it gives data not only in general but in

978-83-60810-27-9/09/$25.00 © 2010 IEEE

the comparison to the original text it is able to follow the changes of the text.

The model belongs to the category of first-order statistical models [5] because it takes into consideration only the frequency of word types of the original text. A first-order statistical model can be created with the urn model. The urn model for word frequency distributions compared the use of words to the sampling of marbles, balls from an urn [3]. The essence of urn model is the following. Consider an urn containing marbles of various colors. Each color corresponds with a marble type. A particular color may be extremely rare, or it may be represented by a great many individual marbles, the marble tokens. We randomly draw N marbles from the urn, assuming that the outcome of a given trial is completely independent from the outcome of any other trial [17], [19], [27], [1], [2], [3]. In Baayen's opinion [2], [3]the urn model is responsible for the overestimation bias, which means that using a model, where the polynomial distribution of words are assumed, produces a larger size of vocabulary, specially in the first half of the text than the observed vocabulary.

To decrease the difference between the observed and the predicted vocabulary instead of assuming the polynomial distribution of the words, the hypergeometrical distribution of them should be applied. The difference between the two models seems to be minor, but assuming the hypergeometrical distribution of the words the overestimation is usually not longer than a couple of thousand words at the very beginning of the texts and later on the observed vocabulary fluctuate around the expected vocabulary.

If we assume that the word types of the texts can be modeled by the balls with different colors of an urn, and from each color as many balls are stored as the frequency of the word type than for polynomial distributions the balls are randomly selected from the urn and are returned after taking notes of its color [3], [7], [8]. The selection of balls is continued until we reach the number of tokens of the original text.

With the assumption of the polynomial distribution of the words, however, there is no clear guarantee that when reaching the desired number of tokens the number of different word types of the observed text equals the number of the different word types of the model.

The hypergeometric distribution of the words, on the other hand, can be modeled by an urn where the balls are not returned after inspecting its color. With word types the algorithm is the following. The number and the frequencies of the different word types of the original text are counted and then all the found word types are stored in a one-dimensional array as many times as their frequencies indicate. The size of the array equals the size of the text that is the number of the tokens in it. The random selection of a word type beyond inspecting it means the erasing of it from the array. Using this method the algorithm might slow down towards the end of the process, because as we advance in selecting the words the place of the erased words are reselected more often than at the beginning. To speed up the algorithm after selecting and deleting the word from the array the cell was not left on its original location, rather, the array was compressed by moving the elements forward. In the next step a new word was selected from this, one cell shorter, array. As a result, even to the longest novels I ever met the selection was carried out within two minutes. The great advantage of the hypergeometric urn model to the polynomial urn model that the number and frequency of the word types in the model equals to that of the original text. All this was carried out with DyMoCASAT (Dynamic Model for Computer Aided Analyses of Texts), a program designed for these special analyses).

C. Texts and their different adaptations

In this project primarily English and Hungarian novels were compared to their different adaptations. The selected adaptations were the human foreign language translations to English, French, German, and Hungarian, and the machine translations to English and Hungarian languages. Here the only publicly available English–Hungarian translator program [20] was used to create the translations and then the same method with DyMoCASAT was applied to these texts. Beyond these inter-language adaptations the lemmatized and non-lemmatized versions and finally the condensed versions of the texts were compared.

Beyond the comparison of the original texts to their adaptations different translations to the same language are also compared to each other. This kind of comparison might reveal differences in connection with changes in vocabulary. We would be able to find those sections of the texts where the translation is richer or shallower in vocabulary then the original text or another translation. To find explanation for the presence and hiatus of the vocabulary rich segments of the texts the appearance of hapax legomena was also tested. The method for the distribution of hapax legomena were similar to that of the word types.

At this stage of the project the different adaptations of The Jungle Books (Rudyard Kipling), The Da Vinci Code (Dan Brown), The Adventures of Tom Sawyer (Mark Twain), The Adventures of Robinson Crusoe (Daniel Defoe), Alice’s Adventures in Wonderland, Through the Looking-Glass and What Alice Found There (Lewis Carroll), Sorstalanság (Kertész Imre) are analyzed, along with some novel without their translations. However, I have to note that the selected texts and the advancing on the texts highly depend on the availability of the printed and the digitized form of them. Most of these texts are manually scanned and digitized because their availability differs due to various reasons. To get comparable results and make the texts readable for DyMoCASAT, processable for the lemmatizer programs the texts should be converted into plain text with well defined borders of paragraphs.

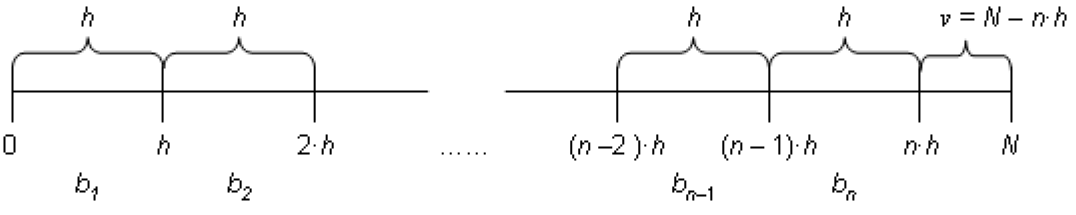

Fig 1. An *N* token-long text is divided into *h*-token-long blocks. The length of the blocks is usually one-hundred tokens. This choice of length is proved to be a good selection because it is longer than the average length of sentences, so syntactic constrains should be taken into account.

III. Results

A. Determining the number of newly introduced word types of a text

To carry out the analysis DyMoCASAT is used [7], [9], [10]. The first step in this process is the analysis of the text. At this stage the number of the tokens (*N*) and then the number of different words (*V*(*N*)) are counted in the text. In the second step the text is divided into intervals of equal length (*h* is the length of an interval, which is usually one-hundred token-long), called blocks.

In each block the different words are identified and the number of their occurrence is counted. The amount of data gained from the text with this method required a time and space consuming data storage. We had to be prepared for further analysis of these data, and had to find a data structure which can be searched with reasonable speed. The solution for this problem is a theoretical three-dimensional matrix. The matrix is theoretical because in practice the data stored in a number of text files. The number of files equals the number of different initial characters found in the text. Each file is identified by these initial characters. This is the first dimension of the matrix. Within each file as many different words are stored as found in the text starting with the same initial character. This is the second dimension of the matrix. Following the paragraph of the word the numbers of occurrence of the word in the blocks are stored. To be able to store numbers greater than ten with only one digits we had to find a numerical system greater than ten. Working with one-hundred token-long blocks even the hexadecimal numerical system seemed small, so we decided on using a system with twenty-seven digits. In this system the numbers are replaced with the letters of the English alphabet and the zero with a character from outside of the alphabet. The last character of the paragraphs indicates the last block where the selected word was found. This is the third dimension of the matrix.

The advantage of storing the occurrence of the words in this theoretical matrix lies again in the numbers. Let us denote the number of different initial characters as k, considering the most frequent initial character as m, and the maximum number of blocks as n. In a real three-dimensional matrix this amount of data requires a k × m × n celled storage place. In practice, however, we might have characters which do not start words, the number of paragraphs in each file differs based on the frequency on the initial character, and finally, the length of the paragraphs also differs based on the last occurrence of the word.

With this method all the information about the appearance of the words is stored, so in case the whole text would be restored within the limit of the length of the blocks.

To each block the number of newly introduced words, the number of hapax legomena, the number of different words can be assigned depending on the goal of the analysis.

Our primary aim was to follow the changes of the newly introduced word types, so the number of these words in each block has to be counted (Fig. 2, upper left panel). In general, the number of newly introduced word types follow a monotonic decay. However, we can find sections where this monotonic decay is reversed and a sudden increase then a sudden drop can be detected in the number of the newly introduced words. We are interested in finding the location of these sections and finding reasons for their presence. By mapping the number of newly introduced words, where the domain of the graph is the blocks of the text and the range is the number of the newly introduced words to each block, the protuberances of the graph suggest the location of these unique sessions of the text. Suggestions however, are closer to subjective judgments than objective facts, so we had to find a more reliable analysis of the graphs than just looking at them. The first step following the mapping of the original data is to rule out the accidental rises of the graph. This can be done by the smoothing of the graph (Fig. 2, middle left panel). As the result of the smoothing only the secondary protuberances of the graph are left, which we are interested in. These secondary protuberances can be grouped into two sets. Those which stand for significant changes create the first group, those which not belong to the second. To be able to distinguish the two sets of the protuberances the following method was invented.

IV. Determining the significant changes in newly introduced words

After collecting the data of the selected text using the same program (DyMoCASAT) first-order statistical models can be built to the text. As it was detailed in Mesthods, the assumption of hypergeometric distribution of word provides more reliable data than the polynomial distribution of them. Based on this assumption DyMoCASAT was extended to be

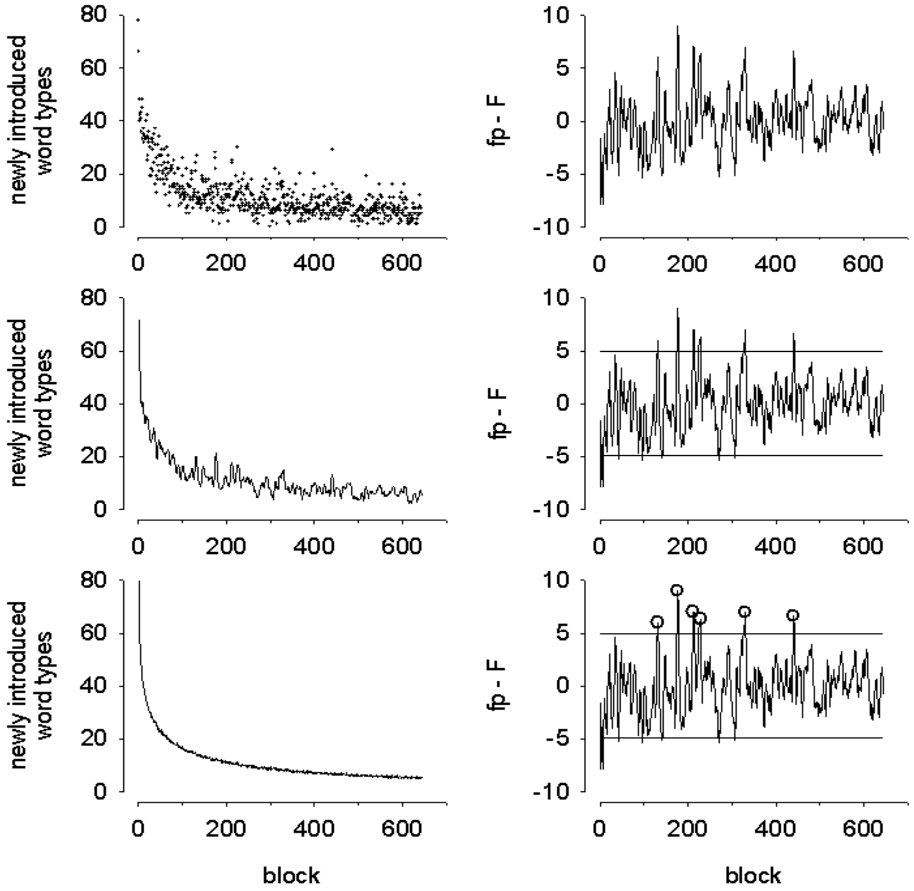

Fig 2. The major steps in the process of analyzing the introduction of word types and lemmas with DyMoCASAT in the condensed English version of The Da Vinci Code. First, the newly introduced words were counted in each block (left, upper), then this function was smoothed (left, middle). In the third step 100 artificial texts were created and the number of newly introduced words was averaged for each corresponding block (left, lower). The difference between the averaged artificial and the smoothed function was calculated (right, upper). The level of significance was determined as M + 2SD (right, middle). Those protuberances were considered significant which exceed the significance level (right, lower).

able to create artificial text. The main characteristic of the artificial text that it carries as many words as the original text with exactly the same frequency. The artificial text is a gibberish, but that is the consequence of the random selection of the words [7]– [9]. To build this model a random selection of words was carried out, the outcome of which was an artificial text.

After creating an artificial text with the same parameters as the original text, the same analysis can be carried out to this text. Using DyMoCASAT, we again are able to create the theoretical three-dimensional matrix, storing all the data considering the appearance of the words. In theory these sets of data are comparable. The random selection, however, by its very nature might cause unpredictable changes in the number of the newly introduced words [27]. To rule this possibility out, a hundred artificial texts were created and averaged ($F(n)$; Fig. 2, left lower graph).

The next step in the process was to determine the differences between the artificial texts and the original ($fp(n)$–$F(n)$; Figure 2 right, upper graph). The mean (M) and the standard deviation (SD) of the differences of $fp(n) - F(n)$ were counted (Fig. 2, right middle graph). The values considered distinguishable are those which exceed the $M + 2SD$ value (Fig. 2, right lower graph). In earlier studies these sudden increases were shown to mark 'longish' inlays in the text and, furthermore, their positions and distribution were found to be unique to the given text [6], [10]).

The result of the analysis is always a graph (Fig. 2, right upper graph – Fig. 2, right lower graph). The flow of this graph is unpredictable, since there is no clear evidence on what it is that makes a writer to increase the number of newly introduced words, and at what point in the story. The corresponding graphs for such pieces of literature always provide protuberances in the graphs.

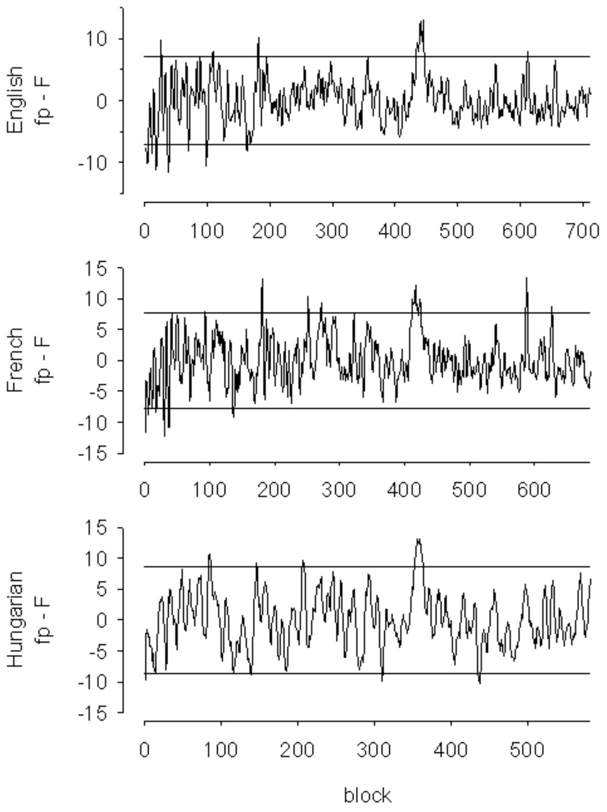

Fig 3. The newly introduced word types of The Adventures of Tom Sawyer and its French and Hungarian translations.

Most of the readers believe that significant changes in the number of newly introduced word types are in close connection with the chapter boundaries. However, in Genette's [16] opinion these vocabulary rich segments of the texts can appear anywhere in the text and carry 'functionally useless' information. This means that if we leave them out the text would still be understandable.

During the proofreading of the texts it was found that these vocabulary rich segments of the text mainly stand for longish descriptions of characters, settings, historical events, and changes in style or language. These vocabulary rich segments of the text are presented on the graph of the newly introduced word types as protuberances. The protuberances have two parameters which are able to describe them. These are the length and the intensity of the protuberances. The length of the protuberances are the number blocks or tokens through which the number of newly introduced word types are over the significance level. The intensity of a protuberance gives the number of newly introduced word types over the significance level. Considering all these we can see that the graph of the newly introduced word types are unique to each text, by them we are able to identify the texts to which they belong. They are like the graphs of sound files. The analyses did not prove that these vocabulary rich segments are expected at the chapter boundaries. They can appear anywhere in the text and the most robust protuberances are proved to be those which are due to changes in style regardless of these boundaries.

In Fig 3 the newly introduced word types of The Adventures of Tom Sawyer are mapped in the original English text, and in the French and Hungarian translations. First the problem of different number of tokens had to be solved ($N_{English} = 711$, $N_{French} = 685$, $N_{Hungarian} = 581$). By the normalization of the domain of the graphs the texts are comparable regardless of their lengths. It is obvious from the graphs that the most robust protuberance is between blocks 434 and 446 in the English text. This protuberance stands for a change in style, the students' writings for their school leaving exam, while the others, smaller both in length and intensively, stand for descriptions. In both translations the change in style is followed remarkably well, while the descriptions are not necessarily. We can find missing protuberances in both languages, and the other way around, protuberances of the translations which were not significant in the original text.

The theory that the protuberances appear at chapter-boundaries was proved wrong by comparing the original texts and their translations where the chapter boundaries of the translated texts are changed as compared to the original text. The vocabulary rich segments of the original and the translated texts stand for the same text segments regardless of the old and new chapter-boundaries.

A. Languages of the texts, word types vs. lemmas

The other question arose in connection with the analysis of the newly introduced word types, and consequently with the vocabulary rich segments of the texts that whether this feature is language independent or not. To test this first DyMoCASAT should be able to read texts of different languages. The primary language of the program is English. However, the program, through its menu, offers the users the opportunity to create their own alphabet, upload this alphabet, and analyze texts in languages different from English. When texts in languages so different in nature are compared the question arose whether the word types are satisfactory enough for such analyses, especially in the agglutinating Hungarian language, due to the fact that affixes attached to the lemmas might increase the number of word types without semantic background. Lemmatization were carried out to English [23], [24] and Hungarian [21], [22] texts. In both languages lemmatizer programs were used to carry out the lemmatization, then the results of the programs were mended to gain comparable data to word types. In this form of the text the lemma and its part of speech tag were concatenated and stored as a single word.

The pattern formed by the newly introduced word types and lemmas show great similarities in both languages [11]. There might be detectable differences between the length and intensity of the vocabulary rich segments. However in general, the vocabulary rich segments of the texts both in the lemmatized and non-lemmatized texts are at the same locations. The only difference found between the English and the Hungarian texts was that at the beginning of the Hungarian non-lemmatized texts the word types might hide significant protuberances by forcing their peaks below the significance level.

B. *Texts and their foreign languages translations*

Analysis of the introduction of new words (either word types or lemmas) in the foreign language translations of a text reveals a novel feature of the translated text. Since texts contain several untranslatable elements, and elements which the translator is not willing to reproduce for various reasons, their replacement with other lexical elements is acceptable [4], [26], [25]. To accept this freedom in the process of translation we can accept the result of the translator program with its serious problems with forming sentences, and finding the suitable words and expressions. From the point of view of translation theory it should be interesting to know how changes in the vocabulary of translations follow the changes of the vocabulary in the original text. With the method described above we can decide whether the translation is as rich in vocabulary as the original text. Our goal is not judging the translation, but checking how faithfully the translation follows the original text in vocabulary. This means that our goal is to highlight those segments of the text which are richer in vocabulary than the main body of the text, and in an already existing translation reveal the shallower and richer text segments.

On the thoroughly analyzed texts (listed in MethodsI) we were able to tell for each translation how faithfully it followed the vocabulary changes of the original texts. On the single texts we were able to find their vocabulary rich segments of them, which might be used for further analyses when their translations are available. However, the found and presented vocabulary rich segments by themselves give useful information for the translators previous to the translation process [12]- [14].

In Fig. 4 the comparison of three different German translations of The Jungle Book to the original text clearly show the differences in the changes of vocabulary. The details of the comparison of these texts reveals the differences of the three translations.

Three different German translations were found for the analysis: Mikush's adaptation from 1951 (from now on Mikush, 1951), and two translations from 1987 from Haef and Harranth (from now on Haefs, 1987, and Harranth, 1987). Among the three texts there is only one which is a full text (Haefs, 1981), unfortunately, the others are cropped to some extent. To be able to make comparison of the three texts they all should have been cropped to the shortest text (Harranth, 1987).

In Fig. 4 the newly introduced word types of the six-story-long English and German translations are mapped. In the order of appearance, the first significant protuberance of the English text stands for the King's Palace in Kaa's Hunting, the second is for the fights of Sea Catch for their territory, the third is the introduction of Rikki-Tikki-Tavi, while the fourth is for the story of Toomai.In Harranth, 1987 all four protuberances are present. However, in this translation new protuberances appeared. One appeared between the original first and second, and stand for the text segment in Tiger-Tiger when Mowgli went to the village. The peak is not too wide, but it is clearly there. The other new protuberance is between the original second and third and represents the search for the Sea Cow in The White Seal. These two new protuberances mean that we were able to find text segments in this newer German translation which are richer in vocabulary than the original English text. Haefs, 1987 has only three significant protuberances: at the description of King's Palace, Rikki-Tikki-Tavi, and Toomai of the Elephants. However, a closer analysis reveals other remarkable similarities. The missing protuberance from The White Seal is clearly there, but its peak is just below the significance level. Interestingly, the second peak of Harranth, 1987 is also detectable in this version.

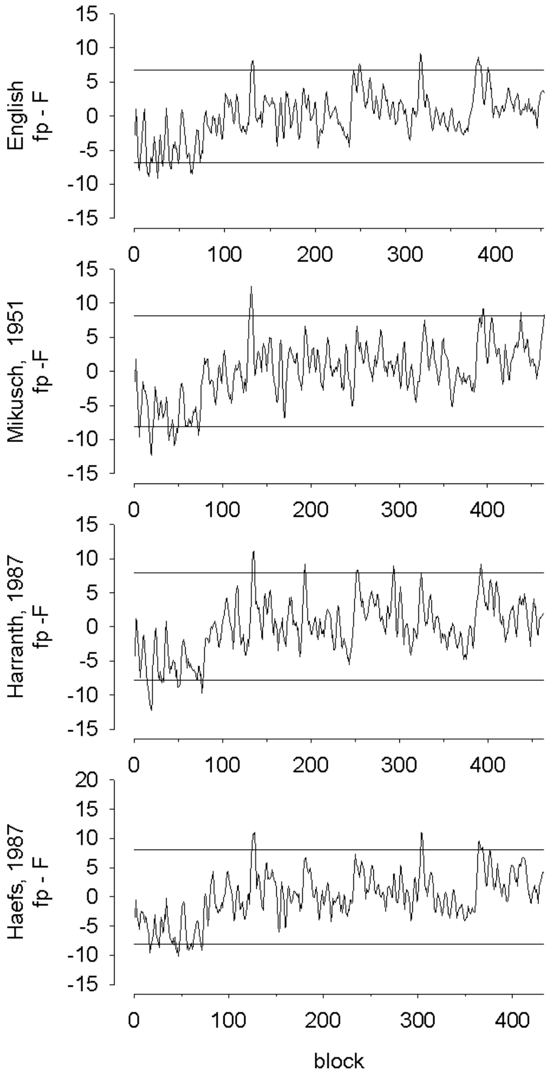

Fig 4 The newly introduced word types of The Jungle Book and its three German translations.

Finally, Mikusch, 1951 seems to be the furthest away in vocabulary from the original English text. While the first peak for the King's Palace is clearly there, the next two, although detectable, did not reach the significance level. Finally, the second of the text matches the fourth of the English text. In addition to these, new peaks appeared, which are unique to this translation: Kala Nag's rush and the song following the story, Shiv and the Grasshopper.

In general, Mikusch, 1951 was found somewhat arbitrary compared to the original English text. The other two translations were able to reproduce the vocabulary rich text segments of the original text much better. Harranth, 1987 goes ever beyond, the translator generated more vocabulary rich text segments than the original text has. Haefs, 1987 seems to be the closest to the original English text.

C. Texts and their different adaptations

Beyond the foreign language translations of novels the analyses of other adaptations of the texts might reveal characteristics which should have be taken care of during the adaptations process. In this project the condensed versions of novels were analyzed and compared to the original texts [12], [13]. Being familiar with the vocabulary rich segments of the texts might help the translators on the decisions which segments of the texts should be left out or shortened. These decisions highly depend on the target group. So being familiar with the advance of the vocabulary of a text might be a great advantage compared to subjective decisions.

On the other hand, the method proved to work on the decision in the direct origin of a second level adaptation of a text. This means that by deciding whether the analysis of the newly introduced word types we were able to show the condensed Hungarian translation of The Da Vinci Code originated from the full-length Hungarian translation or the condensed English adaptation. By the analysis of the advance of the vocabulary we were able to show that the condensed Hungarian text is derived from the condensed English text.

D. The comparison of the results of the analysis with the reviews

For the German translations of The Jungle Book we were able to find previously published reviews [15], [18]. Considering the vocabulary of the novels are these reviews in accordance with the results of our statistical analysis. These reviews state that the Mikush, 1951 translation carries vocabulary which were not meant in the original text [18]. The closest to the original is Haefs, 1987, while Harranth, 1987 gives a good approximation, but a special interpretation of the text resulting in a vocabulary which gives back the original vocabulary rich segments, but beyond that created new segments which are richer in vocabulary than the original text [15].

This example clearly show that being familiar with the position of the vocabulary rich segments of a the texts in advance to the translation process gives the translator information which segments of the texts requires greater attention because it is further away from the random selection of words than the rest of the text. Gives help in creating condensed versions of the text by finding the 'functionally useless' section of the text.

E. Hapax legomena in the texts

It was found that there is a strong correlation between the appearance of the newly introduced word types and the appearance of the hapax legomena, which means in general that if there is rise or a fall in the number of newly introduced word types the same true to the number of hapax legomena. However, rarely there are segments which carry a high number of newly introduced word types and fewer hapax legomena. These words are naturally reused in a later section of the text, and using Genette's expression [16], are less 'useless'. They have function in the text, their specialty is that they were just introduced in that particular block. Those segments which carry both high number of newly introduced word types and hapax legomena are the real 'functionally useless' segments of the text.

V. Summary

The method presented in this article is able to provide those segments of the texts which are richer in vocabulary than the robust part of the text. These segments carry information which is not bound strongly to the flow of the text. They usually give additional information about the settings, the historical background, the characters, or due to severe changes in style. These segments make the novels unique, but if we leave them out the text still would be completely understandable, so they are referred to as 'functionally useless' segments.

To find these vocabulary rich segments of the texts might help us in the analyses of the texts. Beyond that, it was proved that these objective data are able to provide preliminary information for translators by showing the vocabulary rich segments of the texts. Being aware in advance to the translation, or any adaptation of the texts of the position and the intensity of these vocabulary rich segments the translator might pay more attention to them.

***Abstract*—SyMGiza++ — a tool that computes symmetric word alignment models with the capability to take advantage of multi-processor systems — is presented. A series of fairly simple modifications to the original IBM/Giza++ word alignment models allows to update the symmetrized models between each iteration of the original training algorithms. We achieve a relative alignment quality improvement of more than 17% compared to Giza++ and MGiza++ on the standard Canadian Hansards task, while maintaining the speed improvements provided by MGiza++'s capability of parallel computations.**

I. Introduction

WORD alignment is a key component of the training procedure for statistical machine translation systems. The classic tool used for this task is Giza++ [1] which is an implementation of the so-called IBM Models 1-5 [2], the HMM model by [3] and its extension by [1], and Model 6 [1].

All these models are asymmetric, i.e. for a chosen translation direction, they allow for many-to-one alignments, but not for one-to-many alignments. Training two models in opposite directions and symmetrizing the resulting word alignments is commonly employed to improve alignment quality and to allow for more natural alignments. The two alignment models are trained fully independently from each other. Symmetrization is then performed as a post-processing step. Previous work [4], [5] has shown that the introduction of symmetry during training results in better alignment quality than post-training symmetrization.

The approaches from [4], [5] as well as our method still require the computation of two directed models which use common information during the training. Employing a multi-processor system for the parallel computation of theses models is a natural choice. However, Giza++ was designed to be single-process and single-thread. MGiza++ [6] is an extension of Giza++ which allows to start multiple threads on a single computer.

We therefore choose to extend MGiza++ with the capability to symmetrized word alignments models to tackle both problems in one stroke. The resulting tool SyMGiza++ is described in this work. The paper will be organized as follows: Section 2 provides a short overview of Giza++ and MGiza++ and the above mentioned methods of symmetrized alignment model training. In Sec. 3 we give a formal description of our modifications introduced into the classical word alignment models implemented in Giza++ and MGiza++. The evaluation methodology and results are provided in Sec. 4. Finally, conclusions are presented in Sec. 5.

II. Previous Work

A. *Giza++ and MGiza++*

Giza++ implements maximum likelihood estimators for several statistical alignment models, including Model 1 through 5 described by [2], a HMM alignment model by [3] and Model 6 from [1]. The EM [7] algorithm is employed for the estimation of the parameters of the models. During the EM algorithm two steps are applied in each iteration: in the first step, the E-step, the previously computed model or a model with initial values is applied to the data. The expected counts for specific parameters are collected using the probabilities of this model. In the second step, the M-step, these expected counts are taken as fact and used to estimate the probabilities of the next model. A correct implementation of the E-step requires to sum over all possible alignments for one sentence pair. This can be done efficiently for Model 1 and 2, and using the Baum-Welch algorithm also for the HMM alignment model [1].

For Models 3 through 6, a complete enumeration of alignments cannot be accomplished in a reasonable time. This can be approximated by using only a subset of highly scored alignments. In [2] it has been suggested to use only the alignment with the maximum probability, the so-called Viterbi alignment. Another approach resorts to the generation of a set of high probability alignments obtained by making small changes to the Viterbi alignment. [8] proposed to use the neighbour alignments of the Viterbi alignment.

MGiza++ [6] is a multi-threaded word alignment tool that utilizes multiple threads to speed up the time-consuming word alignment process. The implementation of the word alignment models is based on Giza++ and shares large portions of source code with Giza++. The main differences rely on multiple thread management and the synchronization of the counts collecting process. Similarly, our tool in turn incorporates large portions of the MGiza++ source code extending MGiza++'s capabilities of using multiple processors with the ability to compute symmetrized word alignment models in a multiprocessor environment. Since the multiprocessing aspect is mainly

978-83-60810-27-9/09/$25.00 © 2010 IEEE

a feature of the original MGiza++, we will not discuss it in this paper and refer the reader to the original paper on MGiza++ [6].

B. Symmetrized Word Alignment Models

The posteriori symmetrization of word alignments has been introduced by [1]. This method does not compute symmetrized word alignment models during the training procedure, but uses heuristic combination methods after the training. We described it in more detail in Sec. III-E. The best results of [1] for the Hansards task are 9.4% AER (using Model 4 in the last training iterations) and 8.7% AER (using the more sophisticated Model 6).

[4] improve the IBM alignment models, as well as the Hidden-Markov alignment model using a symmetric lexicon model. This symmetrization takes not only the standard translation direction from source to target into account, but also the inverse translation direction from target to source. In addition to the symmetrization, a smoothed lexicon model is used. The performance of the models is evaluated for Canadian Hansards task, where they achieve an improvement of more than 30% relative to unidirectional training with Giza++ (7.5% AER) is achieved.

In [9], the symmetrization is performed after training IBM and HMM alignment models in both directions. Using these models, local costs of aligning a source word and a target word in each sentence pair are estimated and graph algorithms are used to determine the symmetric alignment with minimal total costs. The automatic alignments created in this way are evaluated on the German–English Verbmobil task and the French–English Canadian Hansards task (6.6% AER).

Another unsupervised approach to symmetric word alignment is presented by [5]. Two simple asymmetric models are trained jointly to maximize a combination of data likelihood and agreement between the models. The authors restrict their experiments to IBM Models 1 and 2 and a new jointly trained HMM alignment model. They report an AER of 4.9% — a 29% reduction over symmetrized IBM model 4 predictions — for the Canadian Hansards task.

III. SyMGiza++ — Symmetrized MGiza++

In this section we will describe our modifications to the well known alignment models from [2] and [1].

We do not introduce changes to the main parameter estimation procedure. Instead, we modify the counting phase of each model to adopt information provided by both directed models simultaneously. The parameter combination step is executed in the main thread. In the following subsections, the formal aspects of the parameter combination will be outlined separately for each model. The notation has been adopted from [2] and we refer the reader to this work for details on the original models that will not be repeated in this paper.

A. Model 1

Model 1 is the first of the IBM models described extensively by [2] which have been implemented accurately in Giza++ and MGiza++.

Final alignment

Fig. 1. General training scheme for SyMGiza++

In order to distinguish between the parameters of the two simultaneously computed alignment models we will use α and β as subscripts for the parameters of the first and second model respectively. For our English-French training corpus we compute the following two models:

$$Pr_\alpha(\mathbf{f}|\mathbf{e}) = \frac{\epsilon(m|l)}{(l+1)^m} \sum_{\mathbf{a}} \prod_{j=1}^{m} t_\alpha(f_j|e_{a_j}) \tag{1}$$

$$Pr_\beta(\mathbf{e}|\mathbf{f}) = \frac{\epsilon(l|m)}{(m+1)^l} \sum_{\mathbf{b}} \prod_{i=1}^{l} t_\beta(e_i|f_{b_i}) \tag{2}$$

where l and m are the lengths of the French sentence $\mathbf{f}$ and the English sentence $\mathbf{e}$ respectively, $\mathbf{a}$ and $\mathbf{b}$ are the directed alignments between the sentences and t_α and t_β the directed *translation probabilities* between the French and English words f and e. Due to the simplicity of this model, it is straightforward to introduce our changes in the counting method used during the E-step of the EM-algorithm. The only free parameters of Model 1 are the translation probabilities t_α and t_β which are estimated by:

$$t_\alpha(f|e) = \frac{\sum_{s=1}^{S} c(f|e; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}{\sum_{f'} \sum_{s=1}^{S} c(f'|e; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}, \tag{3}$$

where S is the number of sentences in the parallel training corpus. $c(f|e; \mathbf{f}, \mathbf{e})$ is the expected count of times the words f and e form translations in the given sentences $\mathbf{f}$ and $\mathbf{e}$, in the inverted model $c(e|f; \mathbf{e}, \mathbf{f})$ is used.

In the original model, the expected counts $c(f|e; \mathbf{f}, \mathbf{e})$ are calculated from the t values of the preceding iteration with the help of the following two formulas:

$$c(f|e; \mathbf{f}, \mathbf{e}) = \sum_{\mathbf{a}} Pr_\alpha(\mathbf{a}|\mathbf{f}, \mathbf{e}) \sum_{i,j} \delta(f, f_j)\delta(e, e_i), \tag{4}$$

and

$$Pr_\alpha(\mathbf{a}|\mathbf{f}, \mathbf{e}) = \frac{\prod_{j=1}^{m} t_\alpha(f_j|e_{a_j})}{\sum_{\mathbf{a}} \prod_{j=1}^{m} t_\alpha(f_j|e_{a_j})}, \tag{5}$$

where δ is the Kronecker function[1]. Equations (3) and (4) are common for all models discussed in this section. Our modifications are restricted to (5) which is replaced by

$$\begin{aligned} Pr_\alpha(\mathbf{a}|\mathbf{f}, \mathbf{e}) &= \frac{\prod_{j=1}^{m} \bar{t}(f_j, e_{a_j})}{\sum_{\mathbf{a}} \prod_{j=1}^{m} \bar{t}(f_j, e_{a_j})} \\ &= \frac{\prod_{j=1}^{m} \left(t_\alpha(f_j|e_{a_j}) + t_\beta(e_{a_j}|f_j)\right)}{\sum_{\mathbf{a}} \prod_{j=1}^{m} \left(t_\alpha(f_j|e_{a_j}) + t_\beta(e_{a_j}|f_j)\right)} \end{aligned} \tag{6}$$

Here we see the only difference between the standard Model 1 and our symmetrized version. By taking into account the translation probabilities from the previous iteration of both directed models we inform each model about the estimates of its counterparts. The following intuition applies: a French word is a good translation of an English word, if the English word is a good translation of the French word as well. This cannot be easily captured in the directed models without breaking up its sound probabilistic interpretation, as it happens here. However, since we modify only the way expected counts are obtained, the requirement imposed by [2] that

$$\sum_f t(f|e) = 1$$

still applies. Our modifications do not interfere with the EM procedure. The parameters for the inverted model are obtained analogously.

It should be noted that most of the time — despite the symmetry of the sum $\tilde{t}_\alpha(f|e) + \tilde{t}_\beta(e|f)$ occurring in both counts — $c(f|e; \mathbf{f}, \mathbf{e})$ and $c(e|f; \mathbf{e}, \mathbf{f})$ will have different values for the same words and sentences. This is due to the differences in the alignment direction. Therefore $t_\alpha(f|e) \neq t_\beta(e|f)$ in the general case.

B. Model 2

Although it is common practice to replace Model 2 during the training procedure with the HMM Model described in the next subsection, we need to modify its counting procedure as well. Model 2 is used to score a subset of alignments during the training procedure of the more sophisticated Models 3 and 4 which — in contrast to the lower models — cannot efficiently enumerate all possible alignments.

Model 2 introduces a second type of free parameters: the *alignment probabilities* a. These a parameters capture the probability that given the lengths of both sentences, a French word at position j is aligned with an English word at position a_j. The complete model is given by [2] as:

$$Pr_\alpha(\mathbf{f}|\mathbf{e}) = \epsilon(m|l) \sum_{\mathbf{a}} \prod_{j=1}^{m} \left(t_\alpha(f_j|e_{a_j}) a_\alpha(a_j|j, m, l)\right) \tag{7}$$

The general scheme described in (3) and (4) for the estimation of t values is the same for Model 2 as for Model 1. The alignment probabilities are estimated similarly:

$$a_\alpha(i|j, m, l) = \frac{\sum_{s=1}^{S} c(i|j, m, l; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}{\sum_{i'} \sum_{s=1}^{S} c(i'|j, m, l; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}, \tag{8}$$

$$c(i|j, m, l; \mathbf{f}, \mathbf{e}) = \sum_{\mathbf{a}} Pr_\alpha(\mathbf{a}|\mathbf{f}, \mathbf{e}) \delta(i, a_j). \tag{9}$$

Again, we only modify $Pr(\mathbf{a}|\mathbf{f}, \mathbf{e})$ in (4) and (9) to obtain our symmetrized version of the alignment models:

$$Pr_\alpha(\mathbf{a}|\mathbf{f}, \mathbf{e}) = \frac{\prod_{i=1}^{m} \left(\bar{t}(f_j, e_{a_j}) \bar{a}(a_j, j, m, l)\right)}{\sum_{\mathbf{a}} \prod_{j=1}^{m} \left(\bar{t}(f_j, e_{a_j}) \bar{a}(a_j, j, m, l)\right)} \tag{10}$$

where $\bar{t}(f, e)$ is defined as before for Model 1 and $\bar{a}(i, j, m, l) = a_\alpha(i|j, m, l) + a_\beta(j|i, l, m)$. The effect of information sharing between the two inverted models Pr_α and Pr_β is even increased for Model 2 since translation and alignment probabilities interact during the estimation of both types of parameters for the next iteration.

C. HMM Model

The HMM Alignment Model has been introduced by [3] and is used in the GIZA++ family of alignment tools as a replacement for the less effective Model 2. The HMM alignment model is given by the following formula which at first looks very similar to (7):

$$P_\alpha(\mathbf{f}|\mathbf{e}) = \epsilon(m|l) \sum_{\mathbf{a}} \prod_{j=1}^{m} \left(t_\alpha(f_j|e_{a_j}) a_\alpha(a_j|a_{j-1}, l)\right) \tag{11}$$

The alignment probabilities from Model 2, however, are replaced by a different type of alignment probabilities. Here the probability of alignment a_j for position j has a dependence on the previous alignment a_{j-1} which turns the alignment model into a first order Markov model. The counts for the new a parameter are defined as follows:

$$a_\alpha(i|i', l) = \frac{\sum_{s=1}^{S} c(i|i', l; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}{\sum_{i''} \sum_{s=1}^{S} c(i''|i', l; \mathbf{f}^{(s)}, \mathbf{e}^{(s)})}, \tag{12}$$

[1] $\delta(i, j) = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{otherwise} \end{cases}$.

$$c(i|i',l;\mathbf{f},\mathbf{e}) = \sum_{\mathbf{a}} Pr_\alpha(\mathbf{a}|\mathbf{f},\mathbf{e}) \sum_j \delta(i',a_{j-1})\delta(i,a_j) \quad (13)$$

The definition of the t parameter and corresponding counts remains the same as for Model 1 and 2. Like before we only have to modify the definition of $Pr(\mathbf{a}|\mathbf{f},\mathbf{e})$:

$$Pr_\alpha(\mathbf{a}|\mathbf{f},\mathbf{e}) = \frac{\prod_{j=1}^{m} t_\alpha(f_j|e_{a_j}) a_\alpha(a_j|a_{j-1},l)}{\sum_{\mathbf{a}} \prod_{j=1}^{m} t_\alpha(f_j|e_{a_j}) a_\alpha(a_j|a_{j-1},l)} \quad (14)$$

is replaced by

$$Pr_\alpha(\mathbf{a}|\mathbf{f},\mathbf{e}) = \frac{\prod_{i=1}^{m} \left(\bar{t}(f_j,e_{a_j}) a_\alpha(a_j|a_{j-1},l)\right)}{\sum_{\mathbf{a}} \prod_{j=1}^{m} \left(\bar{t}(f_j,e_{a_j}) a_\alpha(a_j|a_{j-1},l)\right)}. \quad (15)$$

$\bar{t}$ is defined as before for Model 1 and 2.

Here, the alignment probabilities a remain unchanged. For Model 2 we are able to find the symmetrically calculated a parameters just by swapping source and target values. Doing the same for the Markov model would change the interpretation of the alignment probabilities. We would require neighbouring source language words to be aligned only with neighbouring target language words which is to strong an assumption. Nevertheless, their values are still influenced by both models due to the appearance of $\bar{t}$ in the re-estimation.

D. Model 3 and 4

We already mentioned that the parameters specific for Models 3 and 4 are calculated from fractional counts collected over a subset of alignments that have been identified with the help of the Viterbi alignments calculated by Model 2. Therefore it is not necessary to revise the parameter estimation formulas for Model 3 and 4, instead we simply adopt the previous changes made for Model 2. This influences the parameters of Model 3 and 4 indirectly by choosing better informed Viterbi alignments during each iteration.

E. Final Symmetrization

Although the two directed models influence each other between each iteration, the two final alignments produced at the end of the training procedure differ due the restrictions imposed by the models. Alignments are directed and since alignments are functions, there are no one-to-many or many-to-many alignments for the respective directions. There are, however, many-to-one alignments. [1] have proposed a method for the symmetrization of alignment models, which they call *refined symmetrization* and which is reported to have a positive effect on alignment quality.

They first map each directed alignment into a set of alignment points and create a new alignment as the intersection of these two sets. Next, they iteratively add alignment points (i,j) from the union of the two sets to the newly created alignment occurring only in the first alignment or in the second alignment if neither f_j nor e_i has an alignment in the new alignment, or if both of the following conditions hold:

- The alignment (i,j) has a horizontal neighbour$(i-1,j)$, $(i+1,j)$ or a vertical neighbour $(i,j-1)$, $(i,j+1)$ that is already in the new alignment.
- Adding (i,j) to the new alignment does not created alignments with both horizontal and vertical neighbours.

This method is applied as the final step of our computation and will also be applied to the directed alignments created by Giza++ and MGiza++, our baseline systems.

TABLE I
RESULTS FOR THE HLT/NAACL 2003 TEST SET

Alignment Method	Time [m]	Prec [%]	Rec [%]	AER [%]
GIZA++ EN-FR	–	91.19	92.20	8.39
GIZA++ FR-EN	–	91.82	87.96	9.79
GIZA++ REFINED	457	93.24	92.59	7.02
MGIZA++ EN-FR	–	91.19	92.22	8.40
MGIZA++ FR-EN	–	91.84	87.96	9.78
MGIZA++ REFINED	306	93.25	92.60	7.01
SYMGIZA++	332	94.34	94.08	**5.76**

IV. EVALUATION

We compare three systems on the same training and test data: Giza++, MGiza++, and SyMGiza++. For the Giza++ and MGiza++ we run both directed models separately and in parallel and recombine the resulting final alignments with the refined method described in III-E. The tools from the Giza++ family are all run with the following training scheme: $5\times$Model 1, $5\times$HMM Model, $5\times$Model 3 and $5\times$Model 4. All experiments were performed on a test system with 4 CPUs and 8 GB RAM, we plan to increase the number CPUs in the future. Apart from Giza++ all tools make use of all available CPUs, the parallel computation of the alignment model with Giza++ can employ at most two CPUs.

A. Measures and Evaluation Data

The standard metric *Alignment Error Rate* (AER) proposed by [1] is used to evaluate the quality of the introduced input word alignments. AER is calculated as follows:

$$\text{Precision} = \frac{|A \cap P|}{|A|} \qquad \text{Recall} = \frac{|A \cap S|}{|S|}$$
$$\text{AER} = 1 - \frac{|A \cap S| + |A \cap P|}{|A| + |S|} \quad (16)$$

where P is the set of possible alignment points in the reference alignment, S is the set of sure alignments in the reference alignment ($S \subset P$), and A is the evaluated word alignment.

In order to obtain results that can be easily compared with the work summarized in II-B, we evaluated our system on the Canadian Hansards task made available during the HLT-NAACL 2003 workshop on "Building and Using Parallel Texts: Data Driven Machine Translation and Beyond" [10]. The training data comprises 1.1M sentences from the Canadian Hansards proceedings and a separate test set of 447 manually word-aligned sentences provided by [1].

B. Results

Our results — which comprise alignment quality and processing time — are summarized in Tab. I. Processing time is measured from the beginning of processing till the end of the symmetrization process.

It is not surprising that there are no significant differences between Giza++ and MGiza++ when AER is considered. MGiza++, however, is about 33% faster than the two Giza++ processes run in parallel. MGiza++ is also slightly faster than SyMGiza++. This delay of SymGiza++ is caused by the parameter recombination executed between each model iteration and by the idle time if one directed model has to wait for its counterpart. SyMGiza++ achieves the best AER results with a relative improvement of more than 17% compared to Giza++ and MGiza++.

In Sec. II-B we gave the results for a number of other symmetrization approaches. Although we use the same test set our results are not yet fully comparable to the results of other works. We tried but failed to reproduce the results from [5] using the BerkeleyAligner, for which the authors reported an AER of 4.9%. The results reported by [5] for their base line alignments produced with Giza++, on the other hand, are more or less identical to our results. This requires further investigation and we will give a more comprehensive comparison of our results and the results in the literature in an extended paper to come.

V. Conclusions

We have presented SyMGiza++, a tool that computes symmetric word alignment models with the capability to take advantage of multi-processor systems. Our fairly simple modification to the well-known IBM Models implemented in Giza++ and MGiza++ achieves quite impressive improvements for AER on the standard Canadian Hansards task. Our symmetrized models outperform post-training symmetrization methods. On a four processor system, SyMGiza++ is slightly slower than MGiza++, but significantly faster than Giza++ executed in two parallel processes.

***Abstract*—We present a tool that facilitates the efficient extension of morphological lexica. The tool exploits information from a morphological lexicon, a morphological grammar and a text corpus to guide the acquisition process. In particular, it employs statistical models to analyze out-of-vocabulary words and predict lexical information. These models do not require any additional labeled data for training. Furthermore, they are based on generic features that are not specific to any particular language. This paper describes the general design of the tool and evaluates the accuracy of its machine learning components.**

I. Introduction

MANY applications of natural language processing heavily rely on lexical resources. For highly inflected languages, such resources are typically represented as morphological lexica that contain stem entries, inflectional morphemes and derivational morphemes. The formation of words from morphemes is described by a morphological grammar.

In practical applications, lexical resources often need to be extended continually, either to include additional in-domain words or to expand the application to new domains. The manual extension of lexical resources is considered to be expensive. This is particularly true if lexical resources of different languages have to be maintained. In such cases, a trained native speaker may not be readily available.

One way to deal with this problem is to compromise on the quality of the lexicon. For example, out-of-vocabulary words can simply be added as full forms with some minimal specification, e.g. their part-of-speech. Such an approach is problematic for two reasons. First, the underspecification increases the ambiguity in later processing stages such as syntactic analysis or generation. Second, adding full forms is rather inefficient for highly inflected languages, where a single stem can account for many inflected forms and a potentially infinite number of compound words. The latter problem can be partially solved by stripping off the suffix of the out-of-vocabulary word (either manually or by means of heuristics) and allowing the resulting pseudo-stem to undergo arbitrary inflection. This, however, will again increase the ambiguity.

In this paper, we present a tool that facilitates the efficient extension of high-quality morphological lexica, even for a user with minimal knowledge of the underlying linguistic representations and conventions. The tool assists the user in creating the stem entry that is required to correctly analyze a given out-of-vocabulary word. The acquisition process is guided by statistical models whose training requires no additional data apart from a text corpus and some language-specific parameters. The models are based on a set of generic features and thus can be trained for arbitrary languages.

The paper is structured as follows. Section II describes the concepts underlying our tool and illustrates a typical user interaction. Section III is concerned with the statistical models, their training procedures and their accuracy. Related work is reviewed in Section IV and Section V concludes with a final discussion.

II. Tool Design

A. Basic Assumptions

Before describing the actual tool, we want to make certain assumptions explicit. Regarding the linguistic processing, we assume that the morphological grammar is a context-free grammar with atomic-valued attributes attached to the non-terminal symbols. In this setup, a stem entry consists of an orthographic representation of the stem, a preterminal symbol and a value for each attribute. The attributes of the preterminal symbol denote syntactic features (e.g. grammatical gender for German nouns) or inflectional information such as the inflectional class. For example, the stem entry for the German noun *Tür* (*door*) can be defined as follows:

```
NS(sk10,pk4,f) "tür+"
```

The first two attributes denote the inflectional classes for singular and plural inflection, and the third attribute indicates feminine gender. The orthographic representation of the stem is terminated by the morpheme boundary marker +.

Morphological processing may also involve a finite-state transducer (FST). FSTs essentially map the lexical form of a morpheme to one or more surface forms depending on the graphemic context. For example, the surface form of the German verb *handeln* (*to trade*) can be specified as `handel+`. The FST ensures that this lexical form has the surface realization *handl* if followed by an *e* but *handel* anywhere else. Our tool can deal with FSTs by transforming surface forms back to possible lexical forms.

A final assumption is that an out-of-vocabulary word contains exactly one unknown stem. To put it differently, our tool will always look for a single stem that allows to analyze a given out-of-vocabulary word. If the word contains two or more unknown stems, the acquisition will result in a pseudo-stem which is itself a compound.

978-83-60810-27-9/09/$25.00 © 2010 IEEE

B. Acquisition Process

The acquisition process consists of three steps. In the first step, an out-of-vocabulary word is entered and automatically analyzed.

In the second step, the stem's preterminal symbol and lexical form are determined. To this end, the tool shows all possible stem hypotheses that would render the given out-of-vocabulary word analyzable if added to the lexicon. The visualization of the stem hypotheses reflects their relative probabilities, which allows the user to focus on the most likely hypotheses. The user can reduce the candidate set by adding constraints on various levels of linguistic abstraction. The second step is completed by selecting a stem hypothesis.

The morphosyntactic features of the stem entry are determined in the third step. The tool facilitates this task by providing a probability for each potential attribute value. Further, the tool offers different ways for verifying and correcting the predictions.

As soon as the selected feature values are confirmed, a new stem entry is generated and added to a special lexicon. The second and the third step will be illustrated and further detailed in the following sections.

C. Determining the Stem

Figure 1 shows the state of the dialog at the beginning of the second step. Panel 1 visualizes the out-of-vocabulary word under consideration (in the present example the German noun *Dressursport*, engl. *dressage sports*). The possible stem hypotheses are listed beneath this word in the order of their respective probability. The hypothesis on the top, the noun stem with lexical form `dress+`, is the most likely one. In order to help the user in verifying the top-ranked hypothesis, panel 3 lists the five most frequent words that can be analyzed with the respective stem.

In this example, the correct hypothesis (the noun stem `dressur+`) is ranked second. A user which is familiar with the given lexical representation can simply click on the correct stem and thereby proceed to the third step. If the user is less trained or if the correct stem is not among the best few hypotheses, the candidate set can be reduced in three ways.

1) Related words: Panel 5 lists words that can be analyzed with one of the available stem hypotheses *but not* with the top-ranked hypothesis. By clicking on a word, the candidate set is restricted to the stems which would allow to analyze that word. For example, clicking on *dressur* (*dressage*) results in a set of four stem hypotheses, the top-ranked hypothesis being the correct one. The word constraint is added to panel 4 and can be removed with another click. Note that this interaction requires no linguistic knowledge besides some sense of semantic relatedness.

The list of related words is constructed as follows. Starting with the second-ranked hypothesis, each stem hypothesis contributes up to three words that discriminate it from the top-ranked hypothesis. If there are more than three such words, only the three most frequent ones (in terms of corpus occurrences) are considered. Thus, the words at the top of the list correspond to the most probable stem hypotheses.

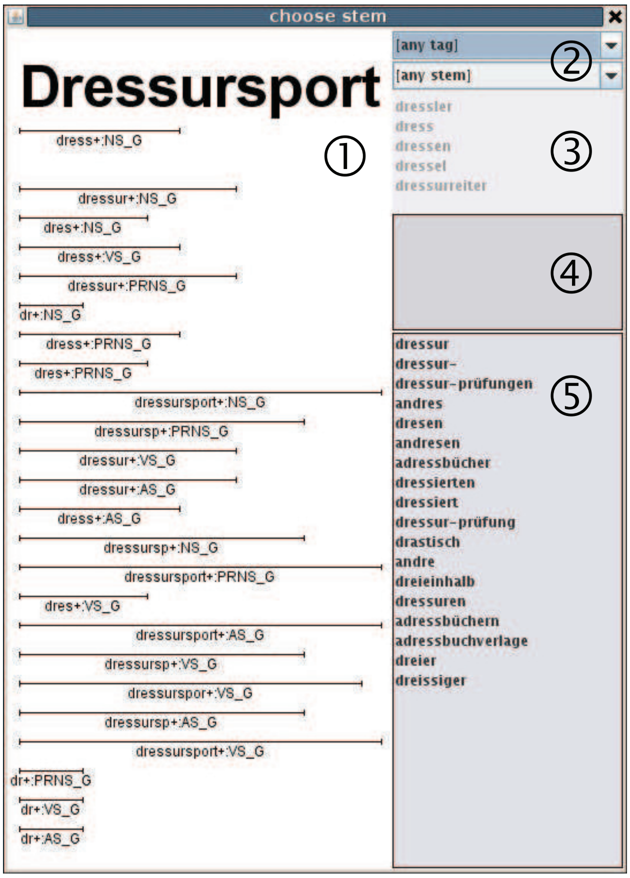

Fig. 1. The dialog for determining the preterminal and the lexical form of the stem. The stem hypotheses shown on the left are ordered by probability, the topmost hypothesis being the most likely one.

2) Stem span: By clicking on a letter of the out-of-vocabulary word in panel 1, the user can specify whether this particular letter should be included in the stem or not. As for the related words, the candidate set is reduced to include only stem hypotheses that fulfill this constraint. For example, clicking on the second letter *'r'* results in a set of 13 candidates. Again, the top-ranked hypothesis happens to be the correct one.

This kind of interaction requires the user to be familiar with the particular notion of a stem that is assumed in the morphological lexicon. This notion may not be intuitive. For example, the lexical stem may differ from the surface stem due to the FST, or parts of the "actual" stem may be represented by special morphemes in order to account for allomorphic variation.

3) Tag and preterminal: A final way of restricting the set of stem hypotheses is to specify the tag or the preterminal symbol in panel 2. The tag is the non-terminal symbol that represents the out-of-vocabulary word on the sentence level. Tags typically correspond to parts-of-speech such as noun, verb or adjective. Even though the tool is able to predict the

Fig. 2. The dialog for determining the morphosyntactic features. The window in front presents corpus examples which indicate that the noun stem *dressur* has feminine gender.

part-of-speech of a word (see Section III-B), this information is currently not used to restrict the candidate sets. The preterminal symbol denotes the category of the stem, e.g. noun stem, verb stem or adjective stem.

D. Determining the Morphosyntactic Features

The dialog for determining the morphosyntactic features is shown in Figure 2. There is a tab for each morphosyntactic feature. A tab displays information for each possible value of its corresponding feature. In particular, it indicates the probability that a certain value is present in the given stem. These probabilities are computed by binary classifiers (one classifier per value) and thus do not sum to 1. The use of binary classifiers is motivated by the fact that values need not be mutually exclusive. For example, the German noun *filter* (engl. *filter*) can have either masculine or neuter gender.

Initially, the most probable value of each tab is checked. If the user agrees with this choice, the tool can directly generate the final stem entry. If not, the selection can be changed by checking or unchecking individual values. The validation and correction of the automatically predicted values is assisted in two ways:

First, the tool can present corpus examples which suggest that a particular value should be chosen. Figure 2 shows 10 corpus examples supporting the hypothesis that *Dressur* is feminine (which it is). The most informative example is shown on the top of the list. In this example, the best indicator for feminine gender seems to be the unambiguously feminine determiner *eine* followed by a word that ends in *-e*. The prototypical female determiner *die* is less discriminative as it can also appear with plural nouns of any gender.

Corpus examples tend to be less useful for verifying inflectional features. For instance, if the best predictor for some inflectional class is the grammatical gender, the tool will present corpus examples which indicate that gender. This information clearly doesn't help the verification. Thus, the tool can visualize the current inflectional paradigm as tables and lists of inflected forms. This layout of this visualization is defined as a grammar and language specific template that has to be created manually. The user can also introduce constraints by restricting the inflected forms for specific syntactic contexts. As a result, the incompatible values will be disabled in the dialog.

III. Machine Learning

The presented tool is based on machine learning components that compute the probability of a stem hypothesis and predict the morphosyntactic features. The underlying models are automatically created from a morphological lexicon, a morphological grammar, a normalized text corpus and some grammar-specific information. In the following, we will first comment on the latter two resources and then describe the main components. Finally, the accuracy of the models will be evaluated.

A. Resources

The most important additional resource is a sufficiently large text corpus. The corpus is assumed to be normalized such that there is exactly one token per line. A token is either a word or an interpunction symbol.

The tool also requires some explicit information about the given language and grammar. First of all, it needs a description of the stem morphemes that are to be acquired. Besides the preterminal symbol, a stem description specifies how each argument has to be handled: an argument can either be determined by the acquisition tool, set to a default value or remain unspecified. Next, the lexical form of a stem has to be described as a regular expression. The lexical form will typically be an arbitrary sequence of characters followed by a morpheme boundary symbol, e.g. `[a-zäöü]+[+]` in the case of our German grammar.

Finally, the explicit information also includes two sets of heuristics that allow for a very crude disambiguation. The first set relates a tag to its preferred heads. For example, German nouns can be derived from noun stems, adjective stems or verb stems, but the preferred head (in case of ambiguity) is the noun stem. The second set excludes certain tags for certain stems. For example, if an overly productive rule allows to create a proper name from each noun, it is hardly possible to train a part-of-speech tagger that can discriminate between these two. Thus, it can be declared that the proper name tag should be excluded if a word can be derived from a noun stem.

B. Part-of-Speech Tagging

Part-of-speech information can be applied on different levels of our approach. We have implemented an HMM part-of-speech tagger similar to the TnT tagger [1]. The tagger is based on a trigram sequence model and exploits suffix statistics for handling unknown words.

The tagger is trained on the text corpus by means of an expectation-maximization algorithm. For each analyzable word, the set of possible tags (i.e. non-terminal symbols) is defined by the grammar and the lexicon. We initially assume that the possible tags are uniformly distributed. The tag distributions of out-of-vocabulary words are estimated from the suffix statistics of the analyzable words. In each training iteration, the forward-backward algorithm is employed to compute the posterior tag probabilities of each word. This information is then used to re-estimate the model parameters. As the forward-backward algorithm is rather slow with logarithmic probabilities, we preferred a scaling approach to avoid underflow [2], [3].

The tagger is used to produce a tagged version of the text corpus. Further, the tag distribution of each word is computed as the average tag distribution for all corpus occurrences.

C. Predicting Stems

Predicting stem entries is considered to be a discriminative reranking task. First, we compute all stem hypotheses that would render the given out-of-vocabulary word analyzable. Next, each stem hypothesis is transformed into a stem entry with unspecified arguments. These additional entries allow to analyze the out-of-vocabulary word w, yielding a set of parse trees $\mathcal{T}(w) = \{t_1, t_2, ..., t_n\}$. A disambiguation model then assigns a conditional probability $P(t|\mathcal{T}(w))$ to each parse tree. The probability of a stem s is defined as

$$\tilde{P}(s|\mathcal{T}(w)) = \max_{t \in \mathcal{T}(w,s)} P(t|\mathcal{T}(w)), \tag{1}$$

where $\mathcal{T}(w,s)$ denotes the set of those parse trees that include the hypothetical stem entry s[1]. The distribution $P(t|\mathcal{T}(w))$ is described by a discriminative log-linear model [6], [7]:

$$P(t|\mathcal{T}(w)) = \frac{\exp(\sum_i \theta_i f_i(t))}{\sum\limits_{t' \in \mathcal{T}(w)} \exp(\sum\limits_i \theta_i f_i(t'))} \tag{3}$$

The real-valued features $f_i(t)$ represent pieces of evidence whose relative importance is expressed by the feature weights θ_i. In the present work, each feature $f_i(t)$ counts how often a certain linguistic event occurs in the parse tree t.

Table I shows the different types of linguistic events that were considered for stem prediction. Actual linguistic events are defined by replacing the arguments X, x, c, M, $i^\star$ or m_i with specific values. The character classes that are used to characterize stem hypotheses are automatically induced from the text corpus with a clustering algorithm [8]. Both 8 and 16 classes are considered in order to capture different levels of abstraction. The stem occurrence information is extracted by analyzing the 500 000 most frequent words in the corpus.

TABLE I
TYPES OF LINGUISTIC EVENTS FOR STEM PREDICTION

stem hypothesis (STH) features
STH has lexical form x
STH covers at most m surface characters ($1 \leq m \leq 10$)
STH contains the lexical character sequence x ($\lvert x\rvert \leq 4$)
STH contains the character class sequence x ($\lvert x\rvert \leq 4$)
STH has lexical prefix x ($\lvert x\rvert \leq 4$)
STH has lexical suffix x ($\lvert x\rvert \leq 4$)
STH has lexical prefix x and preterminal X ($\lvert x\rvert \leq 4$)
STH has lexical suffix x and preterminal X ($\lvert x\rvert \leq 4$)
STH has lexical prefix x and left surface context c ($\lvert x\rvert \leq 4$, $\lvert c\rvert \leq 3$)
STH has lexical suffix x and right surface context c ($\lvert x\rvert \leq 4$, $\lvert c\rvert \leq 3$)
parse tree features
tree contains terminal X
tree contains non-terminal X
tree contains rule X
tree contains lexicon entry X
tree contains morpheme X
tree contains morpheme with lexical form x
tree contains morpheme with surface form x
tree contains morpheme with lexical form x and preterminal X
tree contains morpheme with surface form x and preterminal X
morpheme has lex. prefix x and left surf. context c ($\lvert x\rvert \leq 4$, $\lvert c\rvert \leq 3$)
morpheme has lex. suffix x and right surf. context c ($\lvert x\rvert \leq 4$, $\lvert c\rvert \leq 3$)
capitalization features
word is capitalized and the parse tree's root non-terminal is X
word is not capitalized and the parse tree's root non-terminal is X
stem occurrence features
the corpus contains a word that can be decomposed into the morpheme sequence $m_1, ..., m_M$, where $m_{i^\star}$ is the stem hypothesis. Each morpheme m_i is specified by its preterminal symbol and (optionally) its lexical form.

Estimating the model parameters θ_i requires training examples, each example consisting of a correct parse tree and a set of incorrect parse trees. As the number of parse trees can be huge, a training example is generated by means of random subsampling [9]: we randomly choose one tree that contains the correct stem and 20 trees that contain any other stem. After generating 10 000 training examples for different words w, Charniak and Johnson's MaxEnt reranker [7] is used to compute the model parameters. Note that the potentially very large number of features requires some kind of feature selection. For this purpose, we only consider the first 2000 features that are chosen by a boosting learner [10].

At this point, we still require a list of out-of-vocabulary words for which the correct stem hypothesis is known. As no manually labeled data is available, the lexicon and the text corpus are used to artificially generate such data. This process is described in the following.

An in-vocabulary word w from the text corpus is morphologically analyzed and disambiguated by means of a simple heuristics: a parse tree is preferred if (in decreasing order of importance) its root non-terminal matches the most likely tag of w according to the tagger, if it contains less stems, if it contains more stems that are preferred heads of the root tag (see Section III-A), if it contains longer stems and if it is smaller in terms of tree nodes.

From the resulting unambiguous parse tree, a random stem is selected. This stem will be considered as the correct stem hypothesis. Next, the stem is removed from the lexicon, and

[1] The correct way of computing the stem probability may be considered to be

$$P(s|\mathcal{T}(w)) = \sum_{t \in \mathcal{T}(w,s)} P(t|\mathcal{T}(w)). \tag{2}$$

This probability can be efficiently computed from a packed parse forest representation [4] without explicitly enumerating all parse trees. However, we observed that the prediction of the correct stem hypothesis was significantly less accurate for this approach. In particular, we observed a strong bias towards stems that are more productive in generating parse trees (i.e. verb stems in our German grammar). We believe that this is due to the training procedure, which can be interpreted as maximizing some margin between the correct parse tree and the incorrect ones [5].

TABLE II
FEATURE TYPES FOR PREDICTING MORPHOSYNTACTIC FEATURES

word at position P is x $(-2 \leq P \leq 2)$
word at position P has suffix x $(\|x\| \leq 4,\ -2 \leq P \leq 2)$
stem contains the lexical character sequence x $(\|x\| \leq 4)$
tag at position P is X $(-2 \leq P \leq 2)$

TABLE III
STEM PREDICTION: EVALUATION

approach	*accuracy*
baseline	8%
no stem occurrence features, unconstrained	53%
no stem occurrence features, constrained	57%
stem occurrence features, unconstrained	68%
stem occurrence features, constrained	72%

so are all overlapping stems from alternative parse trees. In general, w will now be out-of-vocabulary, which allows to generate the stem hypotheses. Given the word w, the correct stem hypothesis and the set of incorrect stem hypotheses, a training example for the log-linear model can now be generated.

In order to reduce the mismatch between the training data and the actual out-of-vocabulary words, each (correct) stem occurs about equally often in the training data. This prevents the model from rote learning the properties of a few very frequent stems.

D. Predicting Morphosyntactic Features

Predicting a morphosyntactic feature involves one classifier for each possible value of the given feature. In our German system, for example, there is a classifier which predicts whether a given stem has feminine gender or not.

The decision of the classifier is based on a set of boolean features. Each feature can be thought of as scanning the text corpus and reporting whether the stem under consideration occurs in a specific context. For example, some feature may be true if and only if the corpus contains a word that can be analyzed with the given stem and is preceded by the word *eine*. The basic feature types are shown in Table II. The positions indicated by P are relative to the given stem occurrence, i.e. the word a position -1 immediately precedes the stem occurrence.

The actual classification process is as follows. First, a precomputed index is used to retrieve all corpus words which can be analysed as having the given stem as their rightmost stem. The rightmost stem is typically the head of a compound word. For languages with left-headed compounds (e.g. Vietnamese), the assumed head position can be changed accordingly. Next, a second index provides the positions where those words occur in the corpus. The aggregated value of a boolean feature is computed as the logical disjunction of the feature values for the different corpus occurrences.

The training of the classifiers is straight-forward: training examples can be generated by extracting the feature values for the known stems from the morphological lexicon, which also provide the correct label. As classifiers, we use maximum entropy models [11] with Gaussian priors for regularization [12]. We apply feature selection based on a mutual information criterion: the class label and the value of a particular feature can both be considered as random variables, where the random process consists of randomly choosing a stem occurrence in the corpus. The mutual information of these two random variables provides a measure of the feature's usefulness. For each classifier, we select the 500 features with the highest mutual information.

In addition to the basic features from Table II, we also use so-called joint features. A joint feature is an arbitrary conjunction of (possibly negated) basic features. For example, a joint feature might indicate that the word at position -2 is *die* and the word at position -1 does not end in *-e*. Joint features are created automatically by training an alternating decision tree classifier [13] to predict whether some morphosyntactic feature has a specific value or not. Rather than using information aggregated over the whole corpus, this classifier makes a prediction for a single stem occurrence. Each decision in the alternating decision tree depends on the value of a single basic feature, and a path from the root node to a so-called predictor node corresponds to a joint feature. We used JBoost [14] to create a decision tree from 10 000 labeled stem occurrences. JBoost is run for 100 training iterations which results in 200 joint features.

E. Evaluation

In order to evaluate the accuracy of stem prediction, we randomly chose 1000 out-of-vocabulary words from our German text corpus (220 million tokens of newspaper text). Words with typographic errors, foreign words, dialect words and closed-class words were removed from this set. Also, personal names and geographical names were not considered because they are massively underrepresented in our German lexicon. As it is assumed that compounds do not contain two or more unknown stems, such compounds were excluded as well. Finally, we removed compounds which our German grammar could not account for. For the remaining 530 words, the correct stems were determined manually.

Table III shows the resulting accuracies. The baseline is the expected accuracy when uniformly choosing a random stem hypothesis. The baseline is compared to four variants of our stem prediction algorithm. These variants differ in whether they make use of stem occurrence features (see last item of Table I) and whether tag constraints are applied.

With tag constraints, the best out-of-vocabulary stems are not directly determined according to $\tilde{P}(s|\mathcal{T}(w))$. Rather, the maximization in equation (1) is additionally restricted to parse trees whose root non-terminal matches the most likely tag of w according to the part-of-speech tagger. If the tagger does not make a prediction for w, the algorithm falls back on $\tilde{P}$. Unlike the disambiguation model for stem prediction, the tagger also considers the textual contexts of a word and thus provides additional disambiguating information.

TABLE IV
PREDICTION OF MORPHOSYNTACTIC FEATURES: EVALUATION

gender	*baseline*	*accuracy*
masculine	55%	91%
feminine	62%	96%
neuter	79%	93%
singular declension class	*baseline*	*accuracy*
none	85%	98%
class 1	64%	94%
class 2	73%	89%
class 3	82%	90%
class 4	94%	95%
plural declension class	*baseline*	*accuracy*
none	80%	92%
class 1	94%	98%
class 3	80%	97%
class 4	80%	96%
class 6	91%	98%
class 7	74%	94%

The results show that the presented approach to stem prediction is fairly accurate: the most likely stem hypothesis is correct in almost 3 out of 4 cases. They also suggest that judging stem hypotheses on the basis of corpus occurrence information (rather than just considering the word w in isolation) leads to a much higher accuracy. Using part-of-speech tagging to disambiguate parse trees seems to have a smaller impact. We did not use this information in our tool in order to keep the user interface intuitive.

The prediction of morphosyntactic features was evaluated on about 300 noun stems that were excluded from training. Table IV shows the results for the different values of gender, singular inflection class and plural inflection class. For brevity, the table lists only the values that are observed in at least 5% of the stems. For each value, the baseline accuracy and the classifier accuracy are provided. The baseline accuracy is achieved by assigning each example the majority class. It can be seen that the classifier accuracies are substantially higher than the baseline accuracies. Exceptions are very rare values, for which a negative decision is already very accurate.

IV. RELATED WORK

There are a number of approaches to extracting lexicon entries from text corpora [15], [16], [17], [18]. Here, a lexicon entry consists of a lemma or stem and an inflectional paradigm, though some approaches also consider syntactic features [16], [18]. All approaches explicitly describe word formation, either in the form of a morphological grammar [16] or some representation of inflectional paradigms [15], [17], [18].

The above approaches do not consider existing morphological lexica in the acquistion process. Rather, they employ heuristics which are mainly based on the presence or absence of inflected forms in the corpus. For example, Oliver et al. prefer a hypothetical lexicon entry if it accounts for more inflected forms observed in the corpus [18]. Adolphs additionally considers the coverage of the paradigm, i.e. the fraction of generated inflected forms that actually appear in the corpus [16]. Šnajder et al. compute the corpus frequencies of the generated forms and essentially use the sum of these frequencies as a measure of confidence. Finally, Forsberg relies on handcrafted constraints on the presence and absence of inflected forms [17].

Note that our approach also uses the presence of inflected form as evidence, both for predicting stems and for predicting morphosyntactic features. However, by exploiting the information in an existing morphological lexicon, we are able to compute a dedicated weight for each piece of evidence. Thus, inflected forms which are more reliable indicators have a higher influence on the prediction. The constraints used in Forsberg's approach [17] achieve a similar effect but have to be determined manually. Further, none of the above approaches attempts to analyze compounds: it is assumed that an unknown word is to be decomposed into a single stem and an inflectional ending.

Our approach to predicting morphosyntactic features is mainly related to some work on automatic lexical acquisition for precision grammars. Precision grammars require much richer lexical information than we are aiming at, e.g subcategorization frames. The most closely related work is that of Baldwin [19] and Nicholson et al. [20], who used k-nearest-neighbors classifiers to bootstrap lexical resources by means of corpus data. In contrast to the presented tool, they do not predict the stems of unknown words but assign lexical information to entire word forms. As in our approach, their features are based on word contexts, affixes and character n-grams. The former author additionally considers the output of a chunk parser and a dependency parser. We did not use such tools as they are not available for many languages.

V. DISCUSSION

We have presented a tool for the semi-automatic extension of morphological lexica. The tool facilitates the efficient acquisition of new stem entries from out-of-vocabulary words and ensures a high quality and consistency of the lexical resources.

1) *Efficiency*: Statistical models guide the user in the acquisition process and allow him to focus on the most promising hypotheses. The tool can also be handled by relatively untrained users: it employs concepts that are easily accessible to native speakers and its models capture some of the resource-specific "expert knowledge".
2) *Quality*: The user is offered different ways to verify his decisions, e.g. the predictions and the confidence of the statistical models, evidence from the text corpus and a visualization of the inflectional paradigm.
3) *Consistency*: Sometimes there are different possibilities to specify a stem entry. Sources of uncertainty may be the boundary between stem and affixes or the degree to which stems can include derivational morphemes. The statistical models can capture such tendencies in the original resources and may help to resolve ambiguities accordingly.

For our German resources, we have demonstrated that the machine learning components are able to predict lexical information with a reasonably high accuracy. We argue that the presented algorithms are applicable to a wide range of languages. Apart from German, the tool has already been deployed for Swedish and Finnish[2], the latter being an agglutinative language which is not part of the Indo-European family.

Acknowldegements

We thank SVOX AG for providing us with morphological grammars and lexica for different languages. This work has been supported by the Swiss authorities within the KTI framework (project number 8915.1 PFES-ES).

***Abstract*—Whereas a wide range of methods has been conducted to English multi-word terms (MWTs) extraction, relatively few studied have been applied to Arabic MWTs extraction. In this paper, we present an efficient approach for automatic extraction of Arabic MWTs. The approach relies on two main filtering steps: the linguistic filter, where simple part of speech (POS) tagger is used to extract candidate MWTs matching given syntactic patterns, and the statistical filter, where two statistical methods (log-likelihood ratio and C-value) are used to rank candidate MWTs. Many types of variations (e.g. inflectional variants) are taken into consideration to improve the quality of extracted MWTs. We obtained promising results in both coverage and precision of MWTs extraction in our experiments based on environment domain corpus.**

I. Introduction

AUTOMATIC term recognition (ATR) is still playing an important role in many Natural Language Processing (NLP) applications such as machine translation, book and digital library indexing, hypertext linking, and text categorization. The main objective of ATR is extracting domain specific terms from special language corpora [1].

One of the most important types of ATR is extraction of multi-word terms (MWTs); this comes from the advantages of using MWTs in machine translation, summarization, question answering systems, and many important computational linguistic applications. MWT can be defined simply as a group of words, which are consecutive and constitute a semantic unit [2].

There are three main approaches for extracting MWTs. The first one uses a linguistic filter that depends on syntactic patterns or MWT boundaries detection. The second approach uses a statistical filter to specify the probability of each sequence of words to constitute a MWT. The last one is a hybrid approach of the two previous approaches, this approach extracts candidate MWTs using a linguistic filter, and then it assigns each candidate MWT a score depending on some statistical methods [3].

Most of the statistical methods for MWT extraction concentrate on one of two features: the *unithood* which is "*the degree of strength or stability of syntagmatic combinations or collocation*" [4], and the *termhood* which is "*the degree to which a linguistic unit is related to domain-specific concepts*" [4]. Many methods have been proposed as a *unithood* measure such as mutual information [5], log-likelihood ratio (LLR) [6], and left/right entropy [7], while there is the C-value method [8] as an example of *termhood* measure.

In this paper, we adopt the hybrid approach to extract MWTs from an Arabic corpus. Needless to say that there is a rapid development of computational linguistic applications for Arabic language nowadays, Arabic is the official language of 22 countries, it is spoken by more than 200 million, and it has a very high esteem in the Muslim world [9]. The proposed approach includes two main steps: the linguistic filter and the statistical filter. In the first step, we propose syntactic patterns and use simple part of speech (POS) tagger to extract candidate MWTs. In the second step, two statistical methods are used to rank the candidate MWTs: the LLR method and the C-value method. We consider some related issues like morphological and syntactic ambiguities. For evaluation purpose, we use an environment domain Arabic corpus, the results indicated that our approach is effective, and can be used in many related NLP applications efficiently.

The contribution of our work includes two main points: in the linguistic side, we made an enhancement to the syntactic patterns to be simple and able to exclude a number of wrong candidate MWTs. Moreover, in the statistical side, we take into account both *termhood* and *unithood* measures, since we use a combination between the LLR method and the C-value method in the ranking process.

The paper is structured as follows. Some of the related work is described briefly in section two. In section three we present our proposed approach to extract MWTs. Section four explains how the approach treats the term variations. Section five shows the experiments and the results of applying the extraction approach. The last section contains the conclusion and the future work.

II. Related Work

A lot of work has been done to extract MWT in many languages. This work has been proposed by using linguistic filters, statistical methods, or both as a hybrid approach. However, the majority of the latest MWT extraction systems have adopted the hybrid approach, because it has given better results than using only linguistic filters or statistical methods [10].

978-83-60810-27-9/09/$25.00 © 2010 IEEE

As far as we know, there are a few MWTs extraction systems of Arabic language, one of them is the work which has been presented by Attia, M. A. [11], he has adopted the linguistic approach by doing manual and semi-automatically extraction of Arabic MWTs.

In another work, Boulaknadel, S.; Daille, B.; and Aboutajdine, D. [12] have adopted the hybrid approach to extract Arabic MWTs. The first step of their system is extraction of MWT-like units, which fit the follow syntactic patterns: {noun adjective, noun1 noun2, noun1 preposition noun2} using available part of speech tagger, taken into consideration graphical, inflectional, morphosyntactic, and syntactic variants. The second step is ranking the extract MWT-like units using association measures, these measures are: log-likelihood ratio, FLR, Mutual Information (MI^3), and t-score. The evaluation process includes applying the association measures to an Arabic corpus and calculating the precision of each measure using a collected reference list of Arabic terms [12].

Another system has been proposed by Bounhas, I. and Slimani, Y. [13]; they have proposed a hybrid approach to extract compound nouns. In the linguistic side, they used matcher between POS tagger and morphological analyzer to produce sequences of tokens, each token could be represented by a number of solutions, and then using a syntactic parser to extract candidates of compound nouns. In the statistical side, they applied the LLR method. In the evaluation step, they used almost the same corpus and reference list which have been used in [12]. Their results were promising especially with bigram MWTs [13].

III. Proposed Approach

The proposed MWTs extraction approach has the following features: (i) the system is simple as much as possible to avoid performance and complexity problems, (ii) accurate since there are previous systems [12] and [13] which have got good results, and (iii) able to cover the importance of MWT to increase the possibility for using it in other NLP systems such as summarization and machine translation systems.

The proposed approach for extracting Arabic MWTs is composed of two main steps: (i) the linguistic filter, where we extract candidate MWTs, and extract bigrams from candidate MWTs (ii) the statistical filter, where we rank bigrams by the LLR and C-value scores. In the following subsections, we cover the two steps in more details.

A. Linguistic Filter

There are many types of MWT, such as idioms, phrasal verbs, verbs with particles, compound nouns, and collocations [13]. Our choice was similar to [12] and [13] where we chose to deal with compound nouns, since we agree with the fact that nouns can represent document's subject efficiently [13]. To extract candidate MWTs, we left the syntactic patterns which have been used in many systems like [12], and propose new patterns based on definite and indefinite types of nouns. Table 1 and Figure 1 show our syntactic patterns.

Table 1.
Syntactic patterns of MWT

(1)	definite noun ⇒ one or more definite nouns
(2)	indefinite noun ⇒ one or more indefinite nouns
(3)	indefinite noun ⇒ one or more definite nouns
(4)	(1) or (2) or (3) ⇒ preposition ⇒ (1) or (2) or (3)

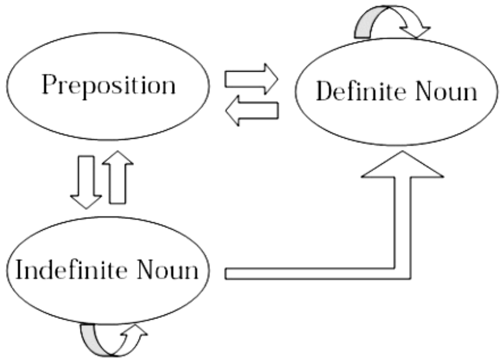

Fig.1: Graphical model of syntactic patterns

These syntactic patterns have some advantages over the patterns used in other extraction systems such as [12]. Firstly, it doesn't require an advanced part of speech tagger. It needs simple one with just three categories (noun, verb, particles). Obviously, this means better performance because most of the POS taggers still have problems in differentiation between nouns and adjectives [11], and less complexity since we don't need many words' classes such as adjectives and adverbs, which advanced POS taggers try to determine. Secondly, these patterns include the entire correct candidate MWTs which might be extracted by patterns in [12], and exclude a collection of wrong candidate MWTs which patterns in [12] may extract. Table 2 shows examples of MWTs extracted from proposed patterns and patterns proposed in [12].

The extraction of candidate MWTs starts with the preprocessing step, which includes four sub steps. The first one is the tokenization, where we separate text into main tokens (words). Words are always separated by white spaces or punctuation marks in Arabic language. The second sub step is the stemming, where the stem of each word is extracted using an available stemmer proposed by khoja, S. [14].

Table 2.
Examples of MWTs Extracted from Proposed Patterns and Patterns Proposed in [12]

Candidate MWT	New patterns	Patterns used in [12]	Is it correct MWT?
التنوع الحيوي biodiversity	yes	yes	yes
تقطير الماء water distillation	yes	yes	yes
تلوث حراري thermal pollution	yes	yes	yes
السماء غائمة the sky is cloudy	no	yes	no

This stemmer specifies the word's stem and type, the types which the stemmer can define are {stemmed word, stop word, strange word}, the stemmer has its own list of stop words which we modify through adding additional stop words. The third sub step is the frequency calculation. In this sub step, we calculate the frequency of each word as well as the frequency of each stem. This sub step is important in dealing with variations. The last sub step is the sentence segmentation. We use simple method for this purpose, where special punctuation marks are used to determine the boundaries of the sentences.

The second step after the preprocessing one is the word's classification (by means of Simple POS tagger). There are three main classes of the word in Arabic: noun, verb, and particle. What we care about in this step is distinguishing the nouns from other classes, since our patterns primarily depend on nouns. Although the available POS taggers can help us very well in this step, we decided to ignore them and adopted the approach which has been proposed by Ahmad T. and Salah A. [15].There are two reasons for that. First, this approach is simple and accurate. Therefore, it is able to keep one of the merits of our syntactic patterns, which is the simplicity. Second, this approach has a morphological analyzer phase. This phase is helpful on dealing with term variations.

The architecture of the adopted approach for words' classification contains three main phases. The first phase is the lexicon analyzer. In this phase a lexicon of stop lists in Arabic language is defined. This lexicon includes prepositions, adverbs, conjunctions, interrogative particles, exceptions, questions and interjections. All the words have to pass this phase, if the word is found in the lexicon, it is considered as tagged to one of the previous closed lists. The next phase is the morphological analyzer. Each word which has not been tagged in the previous phase will immigrate to this phase. In this phase, firstly, the affixes of each word are extracted, the affix is a set of prefixes, suffixes and infixes. After that, these affixes and the relation between them are used in a set of rules to tag the word into its class. It is important to say that this phase is the core of the system, since it distinguishes the major percentage of untagged words into nouns or verbs. The last phase is the syntax analyzer. This phase can help in tagging the words which the previous two phases failed to tag. It is consisting of two rules: sentence context and reverse parsing. The sentence context rule is based on the relation between the untagged words and their adjacent, where Arabic language has some types of relations between adjacent words. These relations can help in tagging the words into its corresponding class. The reverse parsing rule is based on Arabic context-free grammar. There are ten rules, which are used frequently in Arabic language.

The Third step to extract the candidate MWTs is extraction of sequences of nouns, as well as sequences of nouns that connected by a preposition. In this step, we consider each sentence as a separated unit, and using the words' classification approach to extract sequences of nouns. For the sequences of nouns that connected by prepositions, we had two types of prepositions: prepositions which constitute a separated word and prepositions which are stuck with another word. We deal with the two types because our syntactic patterns consider prepositions from the two types. Table 3 shows examples of prepositions' types. Table 4 shows examples of extracted sequences of nouns.

Table 3.
Examples of Prepositions' Types

separated proposition	من	e.g. التخلص من النفايات disposal of wastes
stuck preposition	ب	e.g. الري بالتنقيط drip irrigation

Table 4.
Examples of Extracted Sequences of Nouns

sequence of nouns	e.g. منظمة الأرصاد الجوية العالمية world meteorological organization
sequences of nouns that connected by a preposition	e.g. التحكم عن بعد remote control
	e.g. التعبير بالإشارة the expression by reference

The last step is testing each extracted sequence based on MWTs syntactic patterns, the sequences which fit the patterns will be considered as candidate MWTs. Figure 2 shows the main steps for extraction of candidate MWTs using the linguistic filter.

MWT might be classified based on the number of words. Bigram term is the term of two words. We decide to consider bigrams and discard the other terms which consist of more than two words. Simply, we noted from the terminology databases that the major percentage of compound nouns is bigrams.

In our work, we extract the bigrams from each candidate MWT. We noted that some bigrams are MWT while others are not. However, this is the last step before using the statis-

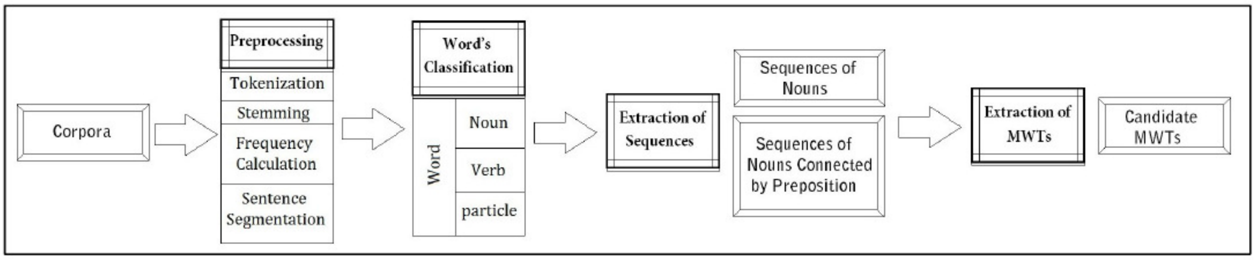

Fig. 2: The main steps for extraction of candidate MWTs using the linguistic filter

tical methods to rank the terms. Table 5 shows an example of bigrams' extraction.

TABLE 5.

	المتحدةلبحوث united for research	NOT MWT
	لبحوث القطب for Antarctic research	NOT MWT
	القطب الجنوبي Antarctic	MWT

B. Statistical Filter

Using statistical methods can help with morphological and syntactic ambiguities and therefore, increasing the quality and the quantity of correct extracted MWTs. In this step, we consider both *termhood* and *unithood* measures to get better results than using only one measure type [16].

To consider the *unithood*, we chose LLR method because it gives good results with Arabic MWTs extraction [12]. For the *termhood* we adopted C-value method because it has a wide acceptance as a valuable method to rank candidate MWTs [16]. LLR method can be used efficiently as significance of association measure between the two words in the bigram [17]. Regarding the C-value method, it requires simple modification to be able to rank the extracted bigrams. We list the entire candidate MWTs and the extracted bigrams as the first step, and then we apply the C-value equation only to the bigrams. Note that we would not be able to calculate the C-value score for the bigrams without some information about the candidate MWTs which contain those bigrams.

Practically, we make a list of bigrams ranked by the LLR. We make another list, which is ranked by the C-value method. Lastly, we combine the two lists to get a new list ofbigrams ranked by the two statistical methods. Figure 3 shows the Log-Likelihood ratio equations, and Figure 4 shows C-value method equation. Figure 5 shows the algorithm of proposed statistical filter.

Contingency table

	$V=v$	$V\neq v$
$U=u$	$O11$	$O12$
$U\neq u$	$O21$	$O22$

U: first word of the bigram. V: second word of bigram
$O11$: #compound nouns with U and V.
$O12$: #compound nouns with U but without V.
$O21$:#compound nouns with V but without U.
$O22$:#compound nouns without V and without U.

$$R1 = O11 + O12 \qquad C1 = O11 + O21$$

$$R2 = O21 + O22 \qquad C2 = O12 + O22$$

$$N = O11 + O12 + O21 + O22 = R1 + R2 = C1 + C2$$

$$LLR = -2\log\left\{\frac{L(O11, C1, r) * L(O12, C2, r)}{L(O11, C1, r1) * L(O12, C2, r2)}\right\}$$

$$L(k,n,r) = r^k \times 1 - r^{n-k}$$

$$r = \frac{R1}{N} \qquad r1 = \frac{O11}{C1} \qquad r2 = \frac{O12}{C2}$$

Fig.3: Log-Likelihood ratio equations

$$C-Value = \begin{cases} \log_2|a|.f(a) & \text{If a is not nested} \\ \log_2|a|(f(a) - \frac{1}{p(Ta)}\sum_{b\in Ta} f(b) & \text{Otherwise} \end{cases}$$

a :	The candidate MWT.
b :	Longer candidate MWTs.
$\|a\|$:	Length of the candidate MWT.
$f(a)$:	Frequency of occurrence of a in the corpus.
Ta :	Set of extracted candidate MWTs that contain a.
$P(Ta)$:	Number of candidate terms in Ta.
$f(b)$:	Frequency of occurrence of longer candidate MWT b in the corpus.

Fig. 5: The statistical filter Algorithm

IV. Term Variations

When we try to extract MWT, term variation is one of the significant factors that should be studied, in other words, it is important to show how the proposed approach deals with different types of variations.

In our proposed approach, we started dealing with the term's variations in the statistical step. As we mentioned before, the input of the statistical step is the extracted bigrams which we try to rank using the statistical methods. Obviously, these methods use the frequency as a primary factor of weighting. What we did here is using the stem's frequency of nouns instead of word's frequency, it's clear that verbs are excluded from the stem's frequency calculating process.

To clarify the point, suppose we have the following bigrams which have graphical and inflectional variants:

(Environmental pollution)

تلوث البيئة	تلوث البيئه	بتلوث البيئة
لتلوث البيئة	تلوث البيئات	التلوث البيئي

The first word in all bigrams has the same stem, and we can say the same about the second word. This means that the statistical methods will consider these bigrams as identical, and it will give them the same score. After completing the list of ranked bigrams, an enhancement process will be available for this list; all the bigrams with graphical and inflectional variants will be removed except the best one, we consider the best choice is the bigram which has the smallest number of common affixes that might be existed in different inflectional forms. Moreover, some prefixes of words in bigrams are removed before choosing the best bigram. The best choice for the previous bigrams is [تلوث البيئة].

Morphosyntactic and syntactic variants are more complex than the previous ones, and need advanced linguistic processing to deal with, our proposed system can deal efficiently only with some types of morphosyntactic variants, as well as syntactic variants from modification type and postposition sub-type. Table 6 shows examples of variants' types that our approach deals with.

Table 6.
Examples of variants that our approach deals with

graphical variants	e.g. تيارات حرارية /تيارات حراريه (thermals)
inflectional variants	e.g. سماد نباتي (vegetable mould) أسمدة نباتية (vegetable moulds)
morphosyntactic variants modification/postposition	e.g. مدى الرؤية (visibility) مدى الرؤية الرأسي(vertical visibility)
syntactic variants	e.g. تلوث إشعاعي/ التلوث بالإشعاع (radioactive pollution)

V. Experiments and Results

A. The corpus

The lake of Arabic specialized domain corpora forced the researcher to build new corpora to evaluate their approaches. In fact, using different corpus from different terminology extraction approaches has a negative impact of the ability to compare between them.

To keep our system comparable (as much as possible) with previous work on Arabic MWTs, we used corpus with some similar properties to that which used in [12] and [13].

The corpus belongs to the environment domain and collected from number of websites. The website[1] which has been used in [12] and [13] is part of the corpus. Table 7 shows some information about the corpus.

TABLE 7.
STATISTICAL INFORMATION OF THE CORPUS

number of words (tokens)	522845
number of stemmed words	495618
number of nouns	281531
number of sequences of nouns	62761
number of candidate MWTs	43018

B. Evaluation and Results

Evaluation of ATR approaches is a complex task, basically, there are no specific standards for evaluate and compare different ATR approaches. However, the most of the approaches have used one of two evaluation methods (and sometimes both): reference list and validation [17].

For the evaluation purpose we decided to evaluate our approach using two methods. In the first one, we used the same way used in [12] and [13]. We consider the MWT is correct, if its translation is included in Eurodicautom[2] (terminological database). Unfortunately, Agrovoc[3] (terminological database includes Arabic terms) is not available currently. The second method is the manual validation of the terms. In fact, we found many correct MWTs which are not included in the used terminology database.

The results of our approach are given in Table 8. Obviously, the results show that using C-value method gives better results than using LLR method, while using the combination between the two methods gives us the best results. For the results of LLR method, we can explain the differences between our results and the results obtained in [12] to the difference of the used corpus.

Indeed, it is important to say that we count the terms with basic singular-plural and definitude variation as correct terms, since most of ATR studies allow for these kinds of variations [4]. Figure 6 shows the results of the proposed approach. Figure 7 shows sample of extracted Arabic MWTs ranked by the combination between C-value and LLR methods.

VI. CONCLUSION

In this paper, we have presented a hybrid approach to extract Arabic MWTs. We have concentrated on compound nouns as an important type of MWT, and chose to extract bigram terms, which constitute a high percentage of compound nouns. Extraction of MWT required substantial software development effort. The proposed approach started with the linguistic filter step, this step contains: preprocessing, word's classification, extraction of nouns' sequences, as well as nouns' sequences that connected by prepositions, testing each extracted sequence based on MWTs syntactic patterns, and finally, extraction of bigrams from candidate MWTs.

The next step is the statistical filter. This step includes rank the bigrams based on LLR and C-value methods, and this step follows by dealing with different types of term vari-

Fig.7: Sample of extracted Arabic MWTs ranked by the combination between C-value and LLR methods

ation. The results show that our approach of using a combination between LLR and C-value methods in the ranking process gave better results than using only one of them. In general, we obtained promising results in both coverage and precision of MWT extraction in our experiments based on environment domain corpus.

In the future, we will work to enhance the linguistic filter to be able to extract more complex types of MWTs, use more combinations of statistical methods to rank the candidate MWTs, and extend our method to deal with n-grams MWTs.

“Beautiful picture of an ugly place”. Exploring photo collections using opinion and sentiment analysis of user comments

Slava Kisilevich*, Christian Rohrdantz†, Daniel Keim‡
Department of Computer and Information Science
University of Konstanz, Germany
{slaks*,rohrdantz†, keim‡}@dbvis.inf.uni-konstanz.de

***Abstract*—User generated content in the form of customer reviews, feedbacks and comments plays an important role in all types of Internet services and activities like news, shopping, forums and blogs. Therefore, the analysis of user opinions is potentially beneficial for the understanding of user attitudes or the improvement of various Internet services. In this paper, we propose a practical unsupervised approach to improve user experience when exploring photo collections by using opinions and sentiments expressed in user comments on the uploaded photos. While most existing techniques concentrate on binary (negative or positive) opinion orientation, we use a real-valued scale for modeling opinion and sentiment strengths. We extract two types of sentiments: opinions that relate to the photo quality and general sentiments targeted towards objects depicted on the photo. Our approach combines linguistic features for part of speech tagging, traditional statistical methods for modeling word importance in the photo comment corpora (in a real-valued scale), and a predefined sentiment lexicon for detecting negative and positive opinion orientation. In addition, a semi-automatic photo feature detection method is applied and a set of syntactic patterns is introduced to resolve opinion references. We implemented a prototype system that incorporates the proposed approach and evaluates it on several regions in the World using real data extracted from Flickr.**

I. Introduction

With the fast development of user-centered Internet technologies, we witness a rapid growth of Web resources, which not only allow users to consume textual information, but also to generate their own. This leads to dramatic improvements of products and services. For example, nowadays it is difficult to imagine that we would book a hotel room without checking the hotels overall ranking or without reading comments previously written by other users. We are also less inclined to buy a product without reading comments or ratings about its quality. In fact, written opinions have become essential components in decision-making processes. Furthermore, opinionated texts are now common in almost all parts of our life. They are essential parts of blogs, news, financial market reports, product reviews, etc. However, textual information generated on the Web almost grow at an uncontrollable pace, and manual skimming through user opinions has become a time consuming process.

There has been extensive research within the past ten years on automatic opinion and sentiment analysis. Different algorithms and approaches have been proposed for the analysis of customer feedback data from web surveys [1], movie reviews [2], [3], [4], news articles [5], product reviews [6], [7], financial blogs and news [8], [9], stock message boards [10], opinions in the domain of fast food restaurants [11], and blogs [12].

A typical task in opinion mining is to determine whether a document (review, comment) is bearing a positive or negative connotation [13], [2], [6], [3], [10], [11], [14]. If either connotation is present, the task can be formulated as a classification problem with two class labels (positive and negative) [15]. Three different kinds of approaches have been used: Unsupervised [2], semi-supervised [14] and supervised [1], [3], [12], [10], [16], [9] ones. Supervised machine learning approaches perform good if sufficient labeled training data exist (for example, in the movie reviews domain users assign ranks to movies along with their opinionated text). However, in domains where labels are not easy to acquire or where opinion orientation is measured on a real-valued scale [17], unsupervised approaches are more favorable.

In this paper, we consider the problem of opinion and sentiment analysis of users' comments written for photos, uploaded to photo sharing web sites. Photo sharing web sites, in general, allow users to maintain their own albums of photos. Users can view photos of other members and write comments for a particular photo. In this paper we work with photo comments from Flickr[1].

Before proceeding further with the analysis, we need to understand what are the similarities and what are the differences between the domain of user photo comments and other domains. Having manually examined hundreds of user comments, we found some similarity to blogs [12], where opinions are stated in the beginning of the paragraph. Similar to blogs, the same user can write several comments about the same photo, but usually the first comment contains the opinions and sentiments, while subsequent comments mostly include neutral information like responses to comments of others or the photo owner. The following example shows two comments from the same user. In the first comment there is an expression of sentiment like “Powerful place and story”, while the second comment was made after the owner of the photo wrote his response.

[1] http://www.flickr.com/

978-83-60810-27-9/09/$25.00 © 2010 IEEE

(1) *this is great. I visited Dachau, but don't remember this part. but I hear they have added some things in the last 5 years. Powerful place and story, thanks for sharing*

(2) *I was there about 8 years ago and I don t recall this hall way. Was this one of the houses, or near the main complex where the museum and films were?*

As already mentioned, the owner of the photo can also participate in the discussion about his own photo. In this case, his opinions can introduce a certain bias, which suggests that comments of the photo owner should be excluded from the analysis. The following is a short example of two comments written by the owner of the photo to people as a response to their comments.

(1) *thanks for the comments. i also found the colors both beautiful and chilling...a very creepy place for sure*

(2) *Thanks! I was fortunate to actually capture the impression it made on me standing there in person*

Detailed inspection of user comments revealed that comments are noisy, relatively short, and with only few negations. They may be written in any languages, contain arbitrary syntactic structures and typos. Moreover, they may contain a mixture of opinions on the quality of the photo (usually positive) "Great shot", "Nice picture" and sentiments or moods expressed towards objects depicted on the photo ("Sad place"). As mentioned above, a widely used approach is to classify documents using a binary classification. This approach seems inappropriate in our case for two reasons: (1) Photo comments have two subjects of opinions (opinions on the photo and sentiment towards objects). Consequently, we will loose valuable information if the overall score will be a mixture of two opinion scores. (2) Since most of the opinions are positive, we will end up with most of the photo comments classified as positive. In order to draw a clear analysis, we propose two improvements over existing approaches. We extract two types of opinions: (1) opinions that relate to the photo quality, and (2) general sentiments targeted towards objects depicted on the photo. Supervised machine learning approaches are not feasible in our case since it is very hard to find agreements between human annotators on a real-valued scale, e.g. the difference in opinion strength between "Great shot" and "Amazing photo" cannot be clearly defined. For that reason, we propose an unsupervised approach for opinion scoring using concepts of word importance based on statistical properties derived from the field of information retrieval [18]. Further observations revealed that opinionated pieces of text are mostly accompanied by adjectives, which is in accordance with past findings [19], [20]. Based on these facts, we generated our own lexicon of adjectives extracted from the corpora of user comments, and analyzed its usage with respect to photo quality opinions and general sentiments, as well as their usage by commenters. We found that in the majority of cases adjectives are used directly with the subject of the opinion ("Great shot") and that the most frequently used adjectives are the same, even if different regions of the world are considered with photos of different topicality. The latter suggested that a finite lexicon of adjectives can be used for opinion analysis of photo comments in many regions around the world. In addition, we also discovered an interesting property of the frequency of adjectives, which is perfectly described by Zipf's law [21]. Our approach is based on a sentence-level opinion analysis, which makes it scalable in dynamic environments like photo comments, where a comment can be added at any time by any of the members.

We developed a desktop Google Earth-based system [22] that combines map navigation and photo exploration using *opinion* and *sentiment* scores as well as a number of derived textual features. The system is capable of showing the photos filtered by one of the features, locating them on the map or seeing them sorted sequentially in an additional window. We believe that our approach can be a very useful extension of photo sharing web sites that will enrich and improve the currently available service capabilities.

The main contributions of the paper can be summarized as follows:

- Our model is based on the corpora extracted from users' photo comments.
- We construct and work with a finite lexicon of opinion words in contrast to the majority of approaches in which seed lists are used to infer scores of unknown opinion words.
- We develop a model that consists of two types of scores: *opinion* regarding the photo and *sentiment* towards the subject of the photo. For this purpose, we suggest a semi-automatic extraction of photo features and a set of syntactic opinion reference patterns.
- We model the orientation strength based on word distributions without using any external dictionaries, while the semantic orientation (positive or negative) of a word is determined by the predefined lexicon of positive and negative opinion-bearing words.
- We provide a continuous scale for opinion and sentiment orientation.
- Our approach allows dynamic updates of scores when new comments are added to the system, which makes the whole method readily applicable in real-world tasks.
- We demonstrate our approach using a Google Earth-based framework.

II. Related Work

Existing approaches in the context of opinion analysis can be broadly divided into several categories. We will review the following categories as they are closely related to our work *opinion classification and orientation*, *lexicon generation* and *feature-based opinion analysis*. A more detailed overview can be found in [15].

A. Opinion classification and orientation

An unsupervised approach for review classification was applied in [2] using pointwise mutual information (PMI) between a phrase containing an adjective or adverb, and the positive word "excellent" and negative word "poor". The PMI probabilities were calculated based on the number of pages, retrieved by the AltaVista search engine, that contain one of the phrases or two phrases together. The review was classified as positive or negative using the average opinion orientation of all phrases.

[23] proposed a similarity measures of adjectives for semantic orientation using the WordNet [24] synonymy relation. The idea is to count the geodesic distance (similarity relation) of an arbitrary word to a word *good* and *bad* and to determine its orientation based on its similarity relation to one of these words.

A Naive Bayes Classifier was used in [3] for classifying movie reviews, while [10] use Naive Bayes as one of five classifiers with majority voting. A Support Vector Machine (SVM) classifier was used by [1] for classifying customer feedback data. [9] applied SVM on financial blogs.

[17] proposed a real-valued scale opinion orientation based on a classification of adverbs (doubt, strong and week intensifiers, negation and minimizers), different verb categories (positive, negative, conjecture and declarative verbs) and complex relationships of adverbs, adjectives and verbs in the text.

B. Lexicon generation

[13] proposed an approach for the identification of semantic orientations of words using a seed list of positive and negative orientations and the conjunctions (and, or, but) between adjectives with known orientation. [5] used a seed lexicon containing eight positive and eight negative words from the news domain to classify a news article as positive or negative. A vector of words from an article was constructed and similarity between it and the vector of negative and positive seed words was measured using cosine measure. A novel approach was proposed in [7] to construct a domain sentiment lexicon using a seed list of sentiment words and relations of these words to specific topics (in the product domain). The key observation is that sentiment words are directly associated with product features. This observation was used to identify new sentiment words using features and new features using new sentiment words. [12] used a Wikipedia dictionary to determine the polarity of adjectives. [25] generated a dictionary called SentiWordNet using WordNet with three sentiment scores (positive, negative and objective) for each WordNet synset.

C. Feature-based opinion analysis

In addition to the approaches that try to detect the sentiment of sentences or even documents as a whole, the task of feature-based analysis is to investigate to which feature (e.g. entity, topic, attribute) a sentiment or opinions refers. This is also very important in our case since we want to separate opinions that refer to photo features from other opinions. Having identified a set of features and a set of opinion words with respective orientation values (+1/-1) in a sentence, the task is to assign the opinion words to features. Different approaches have been suggested in the past. Some of them use distance-based heuristics ([26], [27]). The closer an opinion word is to a feature word, the higher is its influence on the feature. Other approaches exploit advanced natural language processing methods, like dependency parsers, to resolve linguistic references from opinion words to features.

[28] extract pairs (opinion word, feature) based on 10 extraction rules that work on dependency relations involving subjects, predicates and objects gathered from the Minipar dependency parser[2]. [29] use lexico-syntactic patterns in a bootstrapping approach for subjectivity classification. They define a set of 13 syntactic templates (e.g. subject passive-verb) and concrete example patterns for such templates (e.g. subject was satisfied). However, the purpose is only to resolve relations between opinion holders and verbs for subjectivity classification.

III. Photo Comment Corpus

In this section we outline the photo comment collection, the creation of the corpus and the preprocessing techniques.

A. Data Collection

We collected photo comments from Flickr, the largest web community for photo and web sharing, using its publicly available API[3]. Since the API does not allow downloading metadata for a particular region in the World, the downloading was performed as follows: An initial user id was used to download his photo metadata (owner id, photo id, photo url, date a photo was taken, geotagged information, comments). Then, we downloaded all the users' contacts. To speed up the process of retrieving heterogeneous users, we retrieved all groups to which the individual user belongs, and using group information, we were able to retrieve all the people who belong to these groups. Beginning in June, 2009 (as part of another project) we collected metadata for about 90 million geotagged photos from about 7.6 million users by the end of April, 2010.

B. Development of Corpora

1) Region selection: Five regions (Dachau, Auschwitz, Wisla, Krakow and Warsaw) were defined for analysis. The rationale behind selecting these regions is that we want:

- To find differences in comment types between regions
- To find differences in the usage of parts of speech (adjectives and nouns)
- To build a model that better reflects different kinds of comments

We assumed that Dachau and Auschwitz concentration camps should contain special kinds of comments (negative emotions) that would differ from comments in general touristic places. Wisla, we assumed, is a neutral region visited rarely by tourists while Krakow and Warsaw were selected as large Polish cities that include many touristic attractions.

Table I summarizes the statistics related to the selected regions.

[2] http://webdocs.cs.ualberta.ca/~lindek/minipar.htm

[3] http://flickrnet.codeplex.com/

TABLE I
STATISTICAL INFORMATION RELATED TO FIVE REGIONS SELECTED FOR ANALYSIS

Region	Area	# commented photos	# owners	# commenters
Krakow	$120km^2$	8127	1257	23045
Warsaw	$60km^2$	8690	1140	22695
Wisla	$43km^2$	117	39	603
Auschwitz	$12km^2$	505	138	1687
Dachau	$14km^2$	329	121	1062

2) Preprocessing: For every region, we selected photos that contain at least one comment. Photos that do not contain comments were removed from further analyses.

Photo comments are very noisy and unstructured. They may contain HTML tags which should be filtered from the original text. In addition, they may contain different irrelevant sections that have to be removed such as URL links or invitations to join a group. Below are two examples of comments (punctuation is preserved) that require the removal of URL links and invitations to join groups

(1) *Greetings!Using the "blog this" function above your picture, we have linked your picture to our WordPress blog <a href=http://osiddhartha.wordpress.com>SIDDHARTHA</a>*

(2) *Hi, I m a member of a group called <a href=groups/fiveflickrfavs>Five Flickr Favs</a>, and we'd love to have your photo added to the group*

Photo comments can be written in different languages or may contain mixtures of several languages. In order to analyze parts of speech usage, we had to apply a POS-tagger. Since there is no universal POS-tagger that can work on any language and we don't know exactly what languages are used in comments, we decided to remove all comments that are not written in English. For this, we used the TextCat language guesser[4]. The following languages were identified while scanning all the comments: *Polish, English, Swedish, Slovenian, Slovakian, Danish, Italian, Dutch, Spanish, French, German, Finnish, Albanian, Hungarian, Norwegian, Unknown.*

After removing all non-English comments, we were left with 4214 commented photos in Krakow, 4098 commented photos in Warsaw, 56 commented photos in Wisla, 311 commented photos in Auschwitz and 179 commented photos in Dachau.

In the next step, we applied the Stanford POS Tagger[5] on the English comments.

IV. METHOD

A. Definitions

Different terminology definitions are provided in the sentiment and opinion analysis literature. The terminology used in this paper mostly sticks to the definitions given in [15], but makes a clear distinction between opinions and sentiments. The important terms and their definition for this paper:

- **Photo Feature:** Nouns that describe the photo features - attributes, components or characteristics of the photo, e.g. "shot", "photo", "color", "composition", "light". Photo features in our case are usually directly related to the quality of the photo. It is common to distinguish between explicit and implicit features, i.e. features that are mentioned in a sentence and features that are not explicitly mentioned but implicitly referenced.
- **Orientation:** The semantic orientation of a word or a comment as a binary categorical variable with the parameter values "negative" and "positive" (the third possibility "neutral" is omitted in our scenario).
- **Orientation Strength:** The numerical strength of the orientation value ranging from 0 to ∞ in absolute numbers, whereas negative orientations are indicated by the algebraic sign "-".
- **Photo Opinion (PO):** Negative or positive user statements, that clearly refer to photo features of a certain photo, are summarized as the respective photo opinion. They express the users' opinions on the technical and artistic photo quality. For simplicity, we will only speak of opinions when we refer to photo opinions.
- **General Sentiment (GS):** Negatively or positively connoted user statements that cannot be attributed to a photo feature. As implied by the denomination, the general sentiment shall capture orientation statements that have a broader nature than opinions, i.e. sentiments and emotions that are evoked by the photo content. For simplicity, we will only speak of sentiments when we refer to general sentiments.
- **Ambiguity:** Not all users have concordant opinions or sentiments when commenting on a photo. However, at the end one single PO and GS value is computed for each photo that does not account for potential disagreements among users. Accordingly, for both PO and GS ambiguity values are provided that indicate perfect agreement (0.0) or complete disagreement (1.0) among users, as well as arbitrary real values in between.

B. Corpus-based lexicon generation

Opinion mining is heavily dependent on an opinion lexicon. The two common approaches for lexicon generation are dictionary-based and corpus-based ones. The former is based on bootstrapping a seed of opinion words from dictionaries like WordNet, SentiWordNet or Wikipedia, the latter is based on the corpus and, thus, inherently domain dependent.

We applied a corpus-based lexicon generation due to several reasons:

- We want to generate a new lexicon in the domain of photo comments since currently, at least to our knowledge, no such lexicon is publicly available
- Dictionaries like SentiWordNet may supply only a binary opinion orientation, while our task is to model opinion orientations on a real-value scale
- We want to investigate statistical properties of words used for commenting

[4] http://odur.let.rug.nl/~vannoord/TextCat/

[5] http://nlp.stanford.edu/software/tagger.shtml

It was shown in past research that there is a strong correlation between the presence of adjectives and opinions [19], [20]. Indeed, a careful analysis of photo comments showed that people often use short sentences like “Great photo”, “Nice picture”, “Sad place” to express their opinions or sentiments. The analysis also showed that the number of positive adjectives used in photo comments is higher than for negative ones and, overall, the number of positive comments is much higher than the number of negative comments. Any lexicon of positive and negative words will show that the words “great” and “nice” are positive. However, it is difficult to estimate which of these two words is “more positive than the other” using lexical features alone. For that reason, we decided to apply a measure, which is similar to the TF-IDF (Term Frequency-Inverse Document Frequency) measure used in information retrieval and text mining [18]. The idea is that standard opinion or sentiment words that are used frequently by majority of people receive lower scores than words that are used infrequently. In order to acquire word distributions, we extracted adjectives and nouns from the corpus, counted their occurrences in the five selected regions separately, and sorted them according to their occurrence from the highest to the lowest. Nouns were extracted in order to learn what words are commonly used as photo features. We used Yago-Naga stemmer[6] to convert all nouns into a singular form.

In order to minimize the bias of some active commenters, we counted word occurrence only once for each person. The reason why we selected five separate regions is that word occurrences may differ due to different topicalities. Moreover, the number of commented photos is different from region to region and the word distribution would inevitably be biased towards words used in regions with a lot of comments. Table II summarizes frequencies of adjectives in five areas.

An inspection of the results shows the following interesting patterns: The words *great, nice* and *beautiful* are the most frequent and equally ranked adjectives in all five regions, 33% of the adjectives are found within the 20 most frequent adjectives in every region, 58% of the adjectives are found in at least one region and 42% of frequent adjectives are found only in one region. This suggests that people use many common opinion words even if the context of photos is very different (Dachau concentration camp and Nature).

Another interesting finding is that the distribution of adjectives in all five regions can be described by Zipf’s law, which stays that if f is the frequency of a word in the corpus and r is the rank, then

$$f = \frac{k}{r} \qquad (1)$$

where k is a constant for the corpus. When we take the logarithm of both sides, we obtain a linear function with the slope of -1. The slope coefficients we obtained for Krakow is -1.138, Warsaw: -1.136 , Auschwitz: -0.988 and Dachau: -0.95 (Wisla was excluded because it does not have enough words for a reliable slope estimation). Apart the statistical properties of the word distribution, Zipf’s law can be also explained in terms of “least effort” principle: [30] *the tension between the goal of the speaker to minimize production efforts by using only few words very frequently and the goal of the listener to minimize perceptual confusion by having a large vocabulary of distinct words.*

TABLE II
20 MOST FREQUENT ADJECTIVES AND THEIR FREQUENCY IN FIVE SELECTED AREAS. WORDS THAT ARE COMMONLY USED IN FIVE REGIONS ARE COLORED IN YELLOW, IN FOUR REGIONS - GRAY, IN THREE - PINK, IN TWO - GREEN, IN ONE - WHITE

Krakow	Warsaw	Wisla	Auschwitz	Dachau
great,1469	great,1403	great,26	great,129	great,65
nice,864	nice,856	nice,14	nice,61	nice,29
beautiful,829	beautiful,756	beautiful,13	beautiful,57	beautiful,29
good,311	good,306	lovely,8	good,42	fantastic,17
wonderful,271	wonderful,257	awesome,7	powerful,31	powerful,14
lovely,238	amazing,215	amazing,6	amazing,30	excellent,14
amazing,202	cool,191	cute,6	impressive,27	awesome,11
interesting,200	lovely,184	good,5	sad,24	amazing,11
cool,196	fantastic,181	such,3	wonderful,24	sad,10
fantastic,168	excellent,174	excellent,3	excellent,22	impressive,10
excellent,153	interesting,173	wonderful,3	fantastic,18	very,8
awesome,137	awesome,166	right,2	awesome,17	interesting,8
very,129	very,133	pretty,2	interesting,16	such,7
perfect,116	perfect,104	cool,2	very,15	wonderful,7
gorgeous,74	gorgeous,79	new,2	strong,13	dark,7
such,71	cute,78	very,2	many,12	lovely,6
cute,68	little,61	fantastic,2	same,11	cool,6
much,62	such,55	terrific,1	white,11	scary,6
little,58	stunning,47	fierce,1	such,11	dramatic,6
black,55	impressive,45	perfect,1	cool,11	good,6

C. The Adjective Weighting Model

Having defined statistical and linguistic interpretations of the distributions of adjectives in the photo comments corpus, we are now ready to propose an adjective weighting model for opinion orientation.

We define the word opinion orientation w_{oo} using the principles of word relevance as defined in the TF-IDF measure and word distribution properties of Zipf’s law as follows:

$$w_{oo} = orientation(w) * log(\frac{f_{w,r=1}}{f_w} + 1) \qquad (2)$$

where $orientation(w)$ is a function which assigns 1 if the word w is positive and -1 if it is negative, $f_{w,r=1}$ is the frequency of the word having the rank 1 (Equation 1) and f_w is the frequency of the word w in the whole corpus.

The difference between TF-IDF and our approach is that the importance of the word in TF-IDF is measured for every word independently, while opinion orientation score is calculated relative to the most frequent word in the corpus. Thus, if the most frequent word is “great” with frequency of 1469 (see Table II) and the word ranked second is “nice” with the frequency of 864, “great” will get a score of 0.30 (log (1469/1469 + 1)), while the score of “nice” will be 0.43 (log

(1469/864) + 1). One is added to *log* to avoid zero score of the most frequent word.

We should note, that the word frequency in the Equation 2 is absolute and can be applied to five regions separately. In order to make a global model that takes into account different word distributions, we need to find the relative order of all words from five regions. We proceeded it as follows:

- We calculated a ratio $\frac{f_{w,r=1}}{f_w}$ for every word
- An average of ratios for every word was calculated taking these ratios for the same word $w_{i,n}$ from every region n
- If the word $w_{i,n}$ was not found among the lexicon of the region n, its ratio was assumed to have the ratio of the last word in the lexicon of the region n

After building a weighted ratio for every word, we applied Equation 2 to obtain the global adjective weighting model.

D. Automatic Opinion and Sentiment Analysis

The automatic opinion and sentiment analysis consists of several interdependent steps as outlined in Figure 1. The analysis relies on both resources derived from the photo comment corpus itself and external resources. The details are provided in the following subsections.

1) The Photo Features: In order to determine which opinions relate to the photo, first a list of photo features had to be compiled. For this purpose a term extraction method was created that exploits certain characteristics of photo features: (1) such features usually correspond to nouns, (2) such features should not depend significantly on the photo location, and (3) such features should be frequent in photo comments. Consequently, (1) all nouns where extracted, that (2) appeared in photo comments of at least 4 out of 5 locations, and finally (3) the 100 most frequent among these terms were extracted as candidate photo features. The list was then manually revised and finally, 60 out of these nouns where considered in the analysis as photo features. The top 10 frequent nouns present in at least 4 locations were, in decreasing frequency order, “shot”, “photo”, “color”, “composition”, “light”, “picture”, “capture”, “love”, “image”, “work”. Here, “love” is one example that was manually deleted. In this case we could observe that high frequency of the noun “love” was due to a repeated error of the part-of-speech tagger, when occurrences of the verb “love” in very short sentences (e.g. “Love it!”) were misclassified as nouns.

Implicit features: If sentences were shorter than 6 words and did not contain a noun, it was assumed that comments implicitly meant the photo (e.g. “I love it.”, “Well done.”, “Very nice.”).

2) The Word Orientation List: As already mentioned, a manually enhanced version of the widely used Internet General Inquierer lexicon [31] was applied. It was used to determine the orientation of the word and incorporate it into Equation 2, i.e. +1 for positive, -1 for negative and 0 for neutral words (not contained in the orientation list). Before, words were reduced to their base form with Kuhlen’s algorithm [32], in order to increase the number of matches.

All words not contained by the adjective weighting model of Section IV-C, because they either did not appear in the photo comments or belong to a different part-of-speech category, were allocated the weight 1.

3) Syntactic Opinion Reference Patterns: In order to detect references of opinion words to photo features, a set of syntactic opinion reference patterns was defined, based on linear word order part-of-speech sequences[7]. A very simple example is the pattern “JJ NN” which stands for an adjective (JJ) directly followed by a noun (NN). In this case we can be sure, that the adjective refers to the noun. Hence, if the noun is a photo feature then the adjective and its orientation can be assigned to this feature. While in theory recursive patterns of arbitrary length (e.g. JJ* NN) are possible in natural language, in practice such patterns do not appear to a noteworthy extent. We could observe that the limited pattern set we defined, covers the vast majority of cases. The whole pattern set is provided in Figure 2. One main advantage is that the patterns encode the available linguistic knowledge about opinion references without requiring the time-consuming parsing of a full syntax structure tree or a typed dependencies graph. Our syntactic reference patterns cover most of the cases that other approaches detect with dependency parses. This is due to the fact that in English adjectives are usually very close to the nouns they refer to. Only very exceptional and infrequent cases like relational phrases ”‘the photo, that shows a tree, is really nice”’ cannot be resolved by our means. In case of verbs, our approach is not able to distinguish explicitly whether the feature is the subject or the object of the verb. In our tests, however, we could observe that this is not a problem. Verbs that express opinions (”‘to hate/to like”’) cannot have a photo feature as subject and in cases in which they are objects, they are covered by our analysis patterns. In addition, our method is less error-prone than dependency parsing, especially when applied to less formalized and clean writing, as in user-generated content.

[7] The used part-of-speech tags follow the Penn Treebank Tag-set definition: http://www.comp.leeds.ac.uk/ccalas/tagsets/upenn.html

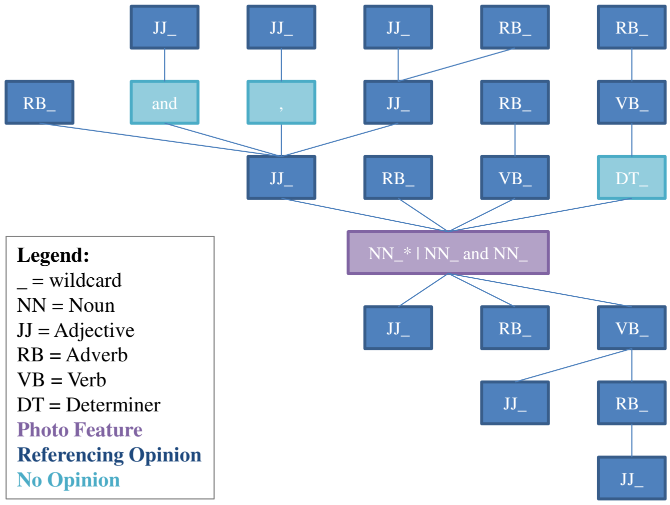

Fig. 2. Syntactic Opinion Reference Patterns. Word order patterns go from top (before photo features) to bottom (after photo features), the level indicates the exact position.

4) Identification and Separation of Photo Opinions and General Sentiments: One crucial point of the automatic text analysis is the detection and separation of (1) opinions about the photo quality (PO) and (2) general sentiments expressed about the photo content (GS).

The first part (1) is based on the extraction of photo features and the mapping of opinion statements to photo features. The described set of syntactic opinion reference patterns was applied for this mapping. For each photo feature in a sentence, all words were extracted that describe the feature according to one of the syntactic opinion reference patterns. The orientation scores of these words were then summed up to yield a photo opinion value. In this process, a simple heuristic is used to invert the orientation of negated words.

Accordingly, step (2) is based on all sentiment expressions that could not be attributed to photo features during step (1). This means that all words not referring to photo features were considered and their orientation scores summed up to yield a general sentiment value.

It should be noted that general sentiments only in very rare cases are falsely classified as photo opinions, whereas the contrary could be observed more frequently, due to different reasons (missing photo feature, implicitness).

Additionally, in both steps the ambiguity of comments is analyzed. This implies investigating whether different users express different opinions or sentiments on the same photo. The output of steps (1) and (2) are an opinion and sentiment value for each user comment. The ambiguity is then calculated separately for the opinions about a photo and the sentiments about a photo. Equation 3 shows how the opinion ambiguity value is calculated for a photo, based on the number of user comments with positive opinions ($\#pos$) and the number of user comments with negative opinions ($\#neg$). For the sentiments this works analogously.

$$amb = \begin{cases} 0 & \textit{if } (\#pos = 0) \vee (\#neg = 0), \\ \frac{Min(\#pos,\#neg)}{Max(\#pos,\#neg)} & \textit{else.} \end{cases} \qquad (3)$$

E. Statistical Proof of Concept

Because of the lack of an appropriate Gold Standard it is not easy to evaluate the sentiment and opinion analysis. Instead, we try to gain evidence for the suitability by performing statistical analysis. Table III shows mean and standard deviation values of opinions and sentiments for the different regions. As expected, the relative difference of mean photo opinion values between different locations is much smaller then that of mean general sentiments. This is in accord with our expectations, because the general sentiment is much more dependent on the location than the photo quality. There is a certain correlation between photo quality and general sentiments, which could be due to the fact that both cannot be separated unambiguously in all cases. However, the two concentration camp memorials Ausschwitz and Dachau, as expected, have very low general sentiment values and the two popular tourist places Warsaw and Krakow are allocated much higher values (even the same mean). Wisla, which we anticipated to be a rather neutral place, lies between the extrema with its general sentiment values. All in all, the statistics indicate that a reasonable separation of opinions and sentiments could be achieved.

Location	Op. Mean	Op. Stdv.	Sent. Mean	Sent. Stdv
Auschwitz	0.827	1.847	0.318	1.202
Dachau	0.776	2.16	0.268	1.026
Krakow	1.003	2.068	0.736	1.544
Warsaw	0.976	2.618	0.736	2.483
Wisla	0.945	1.209	0.516	1.314

TABLE III
AVERAGE AND STANDARD DEVIATION OF OPINION AND SENTIMENT SCORES

V. APPLICATION

In this section we demonstrate the desktop application that combines Google Earth[8], the custom engine built on top of Google Earth [22], and the navigation and filtering toolbox that implements the method for opinion and sentiment analysis of photo comments.

A. Usage Scenario

Our goal is to enrich the user experience by improving photo navigation in a selected region and adding more options for exploring the area. Google Earth has become a favorite platform among Internet users for map navigation and exploration. Google Earth contains different layers that include points of interest, photos, etc. At any time the user can navigate to a specific region in the World and explore the points of interest or photos that were taken there by tourists.

[8] http://earth.google.com/

The difficulty is that photos are displayed in Google Earth as small rectangular thumbnails. The actual image is displayed only when the user clicks on the thumbnail. To gain an actual view of the place, the user has to click on the thumbnails many (several) times and search through different photos. Similarly to Google Earth, the Flickr web site allows the navigation to a particular place using the provided search field. The web page will display large image thumbnails in a sequential order with an overall statistic of how many images were found. For example, for May 25, 2010, Flickr reports $256,827$ results when Warsaw is used as a keyword. Flickr allows sorting the results using three options *Relevant, Recent* and *Interesting*. In addition, Flickr allows locating photos on the map using its WorldMap[9] by providing the location and optionally the category (architecture, urban, forest). By issuing a search for Warsaw, Flickr found $73,174$ geotagged photos, displayed as image thumbnails on a horizontal strip and sortable according to two parameters: *Interesting* and *Recent*. The *relevant* option allows searching for images that contain the search keyword in their titles, while the *interesting* option is based on the non-disclosed algorithm that takes into account such features like *number of views, comments, etc*.

In our application, we implement two main features that are the core of the algorithmic part of the paper, namely *opinion* and *sentiment*, three derived features, namely *number of sentences in comments, opinion and sentiment ambiguities* and *the number of positive and negative opinion words in comments*. Additionally, we included an additional feature, which is part of the downloaded metadata *the number of times the photo was viewed*. The application has two main views and will be described in the following subsections.

B. Photo sorting

The control panel displayed in Figure 3(a) allows the user to receive information about the boundaries of the selected region (label 1). When the user changes the boundaries by manipulating the Google Earth map, the application connects to the server and updates statistical information related to the photos (label 2). In particular, the following statistics are sent by the server: total photos in the region, minimum and maximum opinion and sentiment scores, minimum and maximum number of sentences in comments, positive and negative opinion words and opinion ambiguity, minimum and maximum number of viewed photos.

The central part of the control panel contains a number of filtering options (label 3): filtering by *opinion*, *sentiment*, *sentences*, *ambiguity*, *number of positive and negative words*, etc. In addition, two *quantity filters* (label 4) allow limiting the number of displayed photos on the map view and in the control panel.

When one of the filtering options is invoked, the request is sent via REST protocol to the server along with all relevant information. The server generates two types of responses that are sent as one string to the client. The first response is formatted as Keyhole Markup Language (KML), an XML-based language for the visualization of geographic entities and the one which is used by Google Earth. In our case it contains a photo URL and all the relevant information about the photos (opinion and sentiment scores as well as comments). The KML file is extracted from the response and delegated to the underlying Google Earth engine for visualization. The second response is used by the control panel to show N-top photos (label 5) filtered by one of the provided options.

If the user clicks on one of the photos, the information about the selected photo is displayed on the left side including the coordinate of the photo, comments and scores (label 6). A double-click on the photo positions the map around that photo on the map view.

C. Map navigation

Map navigation (Figure 3(b), label 1) allows exploring the photos using the map view after they were filtered by one of the available scores. The exploration is similar to the functionality provided in the stand-alone Google Earth version or Flickr MapView. However, the difference is that the thumbnail of the image is directly visible on the map. This can save time as it does not require clicking on every thumbnail to see the underlying images. When the image thumbnail is clicked, the large image is displayed along with its comments and scores (see Figure 3(b), label 2). Since the data interchange format is XML-based, information about the whole set of filtered photos or an individual photo can be saved into the file and later visualized in any application that supports KML (label 3).

VI. Conclusions

This paper introduces a practical unsupervised approach for improving the user experience during the exploration of (geotagged) photos on photo sharing web sites by filtering and sorting photos using opinions and sentiments expressed in user comments written for uploaded photos.

Our approach is able to identify two types of opinions from the comments: opinions that are related to the photo quality and general sentiments or moods expressed towards the objects shown on the photo. Unlike most of the existing approaches in which binary (negative or positive) opinion orientation is used, we model opinion orientation using a real-valued scale. Using linguistic features, we build a finite lexicon of adjectives and calculate their opinion strength using a word importance paradigm borrowed from the information retrieval field. The opinion orientation (negative or positive sign) is calculated using a predefined lexicon of positive and negative opinion-bearing words. The identification and separation of photo opinions is based on a semi-automatic method for photo feature extraction and a set of predefined syntactic opinion reference patterns. The overall opinion and sentiment scores for a photo is the cumulative sum of all scores in the comments. This allows a dynamic update of scores if new comments are written for the photo.

Comments
This is a very impressive image, indeed.
I just hope people like the Iranian president watch these photos (and other photos available to whom might care). It s incredible how some people still say this never happened!
very nice!
This is a very powerful set of shots Jez.
Very impressive series, Jez. Images from this place always do it to me...-H
WOW! You went there, Jez? What did it feel like? Crumbs what a place to visit!
So strange! I was finding this shot beautiful and sad, but suddenly I thought: this seems Auschwitz. Then I read it. So strange that

(a) Control view. Filtering according to opinions, sentiments and other derived textual features. N-top ranked photos according to the filtering parameter selected are displayed with the relevant information

This is too good!!! As a Polishman, I say - send it to any photo competition concerning Warsaw and you win ;) Realy like your face expression=) Thats awesome! Hahaaaaaaa I love it ;) love the action, the colors... That s a cool, a really cool photo!! The shot is perfect! I am really curious about camera settings! (?) But the biulding...well I think is ugly as sin. In the whole Warsaw!!! very nice !!! great idea! Great shot, great work! really funny shot ... So cool, like it a lot, guys :) Nice project!! cool seen in Explore hehehe Polskaaa:D My dear country, nice shots, love! Brilliant my friend! Congrats for this nice shot found on Explore, no. 189!! wonderful!! check out www.actionshotrevolution.blogspot.com I d love to feature this shot on the daily blog :) fuck it, thats amazing! really nice work here dude :) great shot !! Nicely done. I like how you used a different light to illuminate Éole and Jérém. Your timing was great. I love it! I WIsh I was there with you!!! hahahaahah ! great ^^ yeah thats a nice picture!!!! please add me as a friend!! woooonderful jump my friend! wow you are really traveling around! cool capture, perfecet lighting, wonderful night shot :-) That is terrific! www.jumpbecause.com Very funny photo. Looks like you had a wonderful time. this is cute and cool ! Nice project and great picture ! great light !!! This photo is really fantastic :) Cool!!! I was right there last weekend! :)

Fig. 3. Google Earth-based application for photo search using opinion and sentiments scores

We implemented a prototype desktop Google Earth-based system that implements the method described in the paper. It allows the exploration of geotagged photos using opinion and sentiment scores combined with the visualization of photos on the map.

In our future work, we shall concentrate on the improvement of the score assignment algorithm and work on multi-lingual solutions.

ACKNOWLEDGEMENTS

Abstract—**Pronunciation dictionary is a crucial part for both Text-To-Speech and Automatic Speech Recognition systems. In this paper, we propose a tool to easily create and edit Thai pronunciation dictionary, called LEXiTRON-Pro Editor. This tool integrates Thai word segmentation, Thai Grapheme-to-Phoneme (G2P) conversion, and database system with statistics. It automatically proposes a word's pronunciation to users by 1 of the 3 options in the successive order: the pronunciation from LEXiTRON-Pro database, the pronunciation combined from syllables with highest probability, and the pronunciation from Thai G2P. However, users can switch to another option or even directly input their own pronunciation with an easy interface editor. Our LEXiTRON-Pro database contains initially 105,129 unique words and 24,736 unique syllables with pronunciations. Compared to the previous version, our new program can reduce the process of dictionary development from 5 to only 1 step and the number of tools used by linguists from 3 to only 1. Moreover, our experiment shows that the time consumption and the number of ungenerable words are significantly reduced while the pronunciation accuracy is considerably improved.**

I. Introduction

PRONUNCIATION dictionary is an essential component for both Thai Text-To-Speech (TTS) and Automatic Speech Recognition (ASR) systems. However, the procedure of developing a pronunciation dictionary is quite complicated and requires a lot of man-hours from linguists. To help them, many recent studies have focused on the Grapheme-to-Phoneme (G2P) conversion system to automatically generate phonemes of words and create easier the pronunciation dictionary. Several approaches have been proposed in the development of G2P to improve the phonetic transcriptions, such as Decision Tree, Statistical method, Pronunciation-by-analogy, and Rule-based approach. Some systems even combine various approaches together to increase efficiency. For example, Tarsaku *et al.* [1] had developed Probabilistic Generalized LR (PGLR) by combining Ruled-based and Decision Tree approaches which can achieve 72.87% of transcription accuracy. The Example-based Grapheme-to-Phoneme (EBG2P) conversion approach, developed by Paisarn Charoenpornsawat and Tanja Schultz [2], which generates pronunciations from syllables found in the training corpus, can reach 80.99% of transcription accuracy.

However, it is found that using only G2P to create the pronunciation dictionary has caused several problems. Firstly, Thai G2P cannot correctly deal with ambiguous strings that contain more than one possible segmentation. For example, "ตากลม" has two patterns of segmentation and accordingly two pronunciations, i.e. "ตาก|ลม|" (t-aa-k^-1| l-o-m^-0| : to be exposed to the wind) and "ตา|กลม|" (t-aa-z^-0|kl-o-m^-0| : round eyes). Unfortunately, Thai G2P always gives only one answer which is not always the right one. Secondly, words having more than one possible pronunciation could not be handled correctly. For example, "ประวัติศาสตร์" (history) can be pronounced "pr-a-z^-1| w-a-t^-1 t-i-z^-1|s-aa-t^-1|" or "pr-a-z^-1|w-a-t^-1|s-aa-t^-1|" but Thai G2P shows only one pronunciation. Lastly, Thai G2P could not correctly transcribe Thai Named Entities that are not typically found in the database, such as person names, acronyms, road names, points of interest, etc.

Given the above difficulties of Thai G2P, linguists or phoneticians are still indispensable in the development of the pronunciation dictionary. However, the previous version of Thai Pronunciation Dictionary, called LEXiTRON-Pro Version 1.0, required too many man-hours of linguists because there were several steps of manual tasks. Therefore, it is quite difficult and inconvenient to improve our LEXiTRON-Pro dictionary or create another one.

In this paper, we propose LEXiTRON-Pro Editor. It is an integrated tool to create a pronunciation dictionary more easily. This tool combines together Thai word segmentation, Thai G2P and Database with statistics, to enhance the accuracy of the phonetic transcription.

This paper is organized as follows. In the next section, we review basic concepts of the Thai language, the pronunciation dictionary and Thai word segmentation. In Section III, we summarize the previous version of LEXiTRON-Pro dictionary. Section IV explains how we reuse the old data. We propose our new application and explain the program interface in Sections V and VI. An experimental evaluation to compare our new program with the pre-

This work was supported by BEST Project under KET Platform of NECTEC.

vious system is done in Section VII and we conclude our paper in the last section.

II. Basic Concepts

A. Thai Language

The Thai language has 44 consonants and 24 vowels including 9 short vowels, 9 long vowels, and 6 diphthongs. Thai sound system can be derived in the format of /Ci-V-(Cf)-T/, where Ci denotes an initial consonant, V a vowel, Cf a final consonant which is optional, and T a tone [3].

Table I.
Thai consonant mapping to phonetic symbol

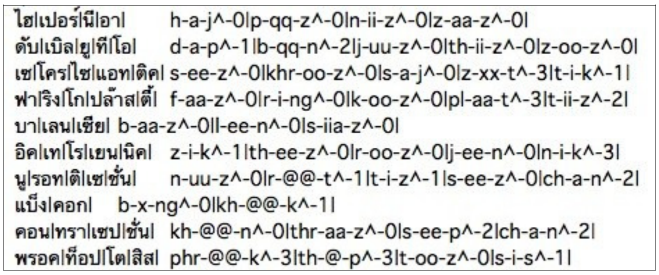
Consonant	Phoneme		Consonant	Phoneme	
	Initial (Ci)	Final (Cf)		Initial (Ci)	Final (Cf)
ก	k	k^	บ	b	p^
ข,ค,ฆ	kh	k^	ป	p	p^
ง	ng	ng^	ผ,พ,ภ	ph	p^
จ	c	t^	ร	r	n^
ฉ,ฌ,ช	ch	t^	ล,ฬ	l	n^
ซ,ศ,ษ,ส	s	t^	ว	w	w^
ญ,ย	j	j^	ห,ฮ	h	-
ฎ,ด	d	t^	ฝ,ฟ	f	p^
ฏ,ต	t	t^	ม	m	m^
ฐ,ฑ,ฒ,ถ,ท,ธ	th	t^	อ	z	-
ณ,น	n	n^			

Table II.
Thai vowel and mapped phoneme

Tongue Height	Tongue Advancement		
	Front (short, long)	Central (short, long)	Back (short, long)
Close	i, ii (อิ, อี)	v, vv (อึ, อือ)	u, uu (อุ, อู)
Mid	e, ee (เอะ, เอ)	q, qq (เออะ, เออ)	o, oo (โอะ, โอ)
Open	x, xx (แอะ, แอ)	a, aa (อะ, อา)	@, @@ (เอาะ, ออ)
Diphthongs	ia, iia (เอียะ, เอีย)	va, vva (เอือะ, เอือ)	ua, uua (อัวะ, อัว)

B. Pronunciation Dictionary

The pronunciation dictionary is a collection of words associated with their pronunciations in the form of phoneme sequences. Phonemes could be derived from standard sound representatives such as International Phonetic Alphabets (IPA) or Speech Assessment Methods Phonetic Alphabets (SAMPA). A letter-to-sound conversion (LTS) module takes the pronunciation dictionary as a primary source of knowledge to convert any textual word to its corresponding phoneme sequence. The LTS module plays an important role in building the phonetic transcription of speech corpus given speech orthographies. The output from the LTS tool is shown in Fig. 1. The first column is word list with syllable segmentation by "|" symbol and the second column is word's pronunciation. The pronunciation represents the word in the form of phoneme sequence with syllable segmentation and syllabic tone marked.



```

Fig 1. LTS output in LEXiTRON-Pro format

C. Thai Word Segmentation

Since Thai has no word boundary, word segmentation is the first thing to do. At present, there are two main approaches on Thai word segmentation. The first approach is machine learning based (MLB) approach which is a technique that learns from a tagged corpus in which word boundaries are explicitly marked with special annotations. This algorithm creates statistical models based on the features of characters surrounding the boundaries (e.g., n-gram of a candidate word boundary). The other approach is dictionary-based (DCB) approach which is based on string parsing technique – i.e., input characters are scanned and matched with word set from dictionary [4].

LongLEXTO, the Thai word segmentation tool used in our application, was developed by Human Language Technology Laboratory (HLT). This tool is dictionary-based approach using the longest matching (LM) technique. The longest matching is a selection algorithm for solving the ambiguity problem by scanning the input text from left to right and then selecting the longest match with a word in dictionary [5]. The main dictionary is extracted from LEXiTRON, English-Thai online dictionary, containing 35,936 words.

III. Previous Version of LEXiTRON-Pro dictionary

In the previous version, most work was done by hand, which can be summarized as follows:

- Extract a word list from variety of text articles
- Compare the word list with the original pronunciation dictionary (if exist) and extract only new words
- Generate pronunciations of new words with letter-to-sound conversion (LTS)
- Manually check and correct the results of LTS
- Add new word entries to the pronunciation dictionary

105,129 words were extracted by linguists. There were quite a variety of sources ranging from general words, road names, person names, and abbreviations. All words were then converted to phoneme sequences using LTS conversion. All entries were verified by hand before importing to the LEXiTRON-Pro dictionary. This dictionary will be used as a primary resource in our LEXiTRON-Pro Editor.

IV. Data Preparation

Before using the new program, we had to prepare some more data. We analyzed all syllables with consistent pronunciation in LEXiTRON-Pro dictionary and found 364,707 syllable entries. After that, we counted the frequency of the same syllables and found 24,736 unique entries. Then, all unique entries were imported to the LEXiTRON-Pro database.

The probability of each syllable's pronunciation is calculated by the frequency of each syllable's pronunciation compared with the total frequency of all possible pronunciations for that syllable. We use the following equation:

$$(\%) = \frac{f}{\sum_{i=1}^{n} (fi)} \times 100$$

When % is the probability of syllable's pronunciation
f is the frequency of syllable's pronunciation
n is the number of possible pronunciations for the same syllable

For example, the term “เศรษฐกิจ” (/set-tha-kit/: economy) contains syllables “เศรษฐ” and “กิจ”. The syllable “เศรษฐ” has 4 possible pronunciations: “s-ee-t^-1|”, “s-ee-t^-1 th-a-z^-0|”, “s-ee-t^-1 th-a-z^-1|”, and “s-ee-t^-1 th-a-z^-3|” with the frequencies of 16, 4, 54, and 2, respectively. Their calculated probabilities are then 21.05%, 5.26%, 71.05%, and 2.63%, respectively. All values are recorded in LEXiTRON-Pro database to help users to decide which pronunciation they want to use.

V. LEXiTRON-Pro Editor

A. Input Format

LEXiTRON-Pro Editor accepts the input file in plain text with TIS-620 or UTF-8 encoding. This file can contain word lists or paragraphs and may contain foreign words, punctuations, or numbers, all of which will be ignored.

B. Pronunciation Generation

Normally, the pronunciation dictionary is manually created, checked, and rechecked by phoneticians or skilled linguists. However, this method is inconvenient and time-consuming [6], [7]. Therefore, we have developed LEXiTRON-Pro Editor that generate pronunciation automatically, based on database system with statistics, incorporated with Thai word segmentation tool and Thai G2P. The procedure to generate pronunciation of LEXiTRON-Pro Editor is shown in Fig. 2.

In the first step, the input file, which may contain multiple paragraphs, is read by LEXiTRON-Pro Editor and then segmented into words using LongLEXTO. After that, these words will be further segmented into syllables by Thai G2P. The results from G2P algorithm are syllable-segmented words with symbol “|” and their pronunciations that will be used in the modification process. Next, each word from the previous process will be compared to LEXiTRON-Pro database. There are, at this step, three possible scenarios:

- If that word matches a word in the database, then retrieve its pronunciation from the database and display the result.
- If not, then use its syllables from Thai G2P instead to compare again to LEXiTRON-Pro database, syllable by syllable. if all the syllables are found in the database but there may be more than one possible pronunciation, our system will choose the most probable one and then combine all syllables' pronunciations together before displaying the result which is supposed to be the pronunciation of that word.
- If not all of the syllables are found, then display the word's pronunciation from Thai G2P instead.

For the first case, the results will not be checked again because they come from the validated database. For the second and third cases, the results must be checked and corrected by linguists.

C. *Pronunciation Verification*

Although the automatic generation of pronunciation is more convenient and can help linguists to reduce time, the results may contain some errors. Therefore, it is necessary to modify some results. We propose an easy interface to modify the pronunciation which will be explained in the section VI.B.

After verification, all data will be sent back to update the LEXiTRON-Pro database.

D. *Output Format*

The output file from LEXiTRON-Pro Editor has two options: word list format or paragraph format. The first format contains alphabetically ordered word list, divided into three columns: original words, words' syllables, and words' pronunciations. The other format contains alternate lines between word segmented text and words' pronunciation. The order of words' appearance is the same as the input file.

VI. Program Interface

LEXiTRON-Pro Editor has two major user-interfaces:

A. *Main Interface*

LEXiTRON-Pro Editor automatically generates pronunciations from files and displays results in three columns as shown in Fig. 3. Words in the left table are sorted according to the order of appearance in the input file. Each line contains ordinal number, original word, word's syllables, and word's pronunciation. When a line is selected, every syllable and pronunciation of that word will be displayed in the right table, one syllable per line. It is possible to edit each pronunciation by double-clicking on it to open another window, which will be explained in the next subsection.

The main interface includes two other useful features:

- Word Combination: since LongLEXTO may commit some errors by segmenting one word into two or more, it is necessary to combine them to make a single word by selecting them and clicking on this button.
- LongLEXTO's dictionary update: after combining words in the previous step, we can update the LongLEXTO's dictionary with this button. In addition, we can add a new word by ourselves to the LongLEXTO dictionary. The modification will take effect immediately.

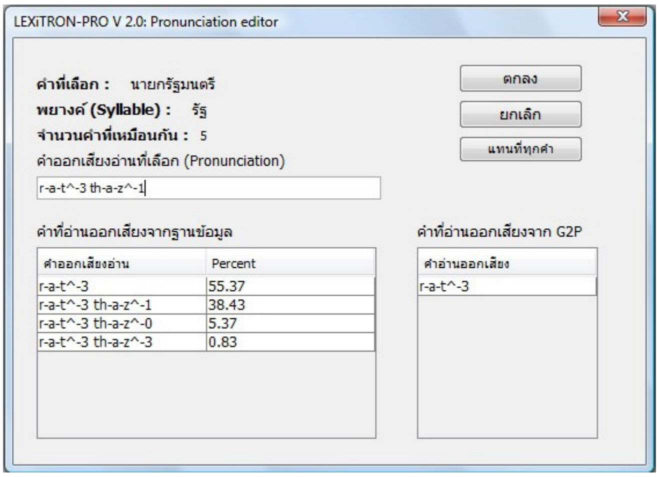
Fig 3. Main Interface

B. Pronunciation Editor

Since the automatic generation of pronunciation may be erroneous, especially when dealing with compound words, homographs, allophones and foreign words transliterated into Thai, we developed Pronunciation Editor for users to modify the syllable's pronunciation of the words with ease.

As shown in Fig. 4, users can edit any pronunciation by three methods:

- First, users can enter a new pronunciation by themselves in the top-left box.
- Second, users can choose the pronunciation proposed by Thai G2P in the bottom-right box.
- Last, users can choose one of the pronunciations from LEXiTRON-Pro database, as seen in the bottom-left box. If there are many possible pronunciations, they will be sorted by their calculated probability, as described in the section IV.



LEXiTRON-PRO V 2.0: Pronunciation editor

VII. Experimental evaluation

To evaluate the performance of LEXiTRON-Pro Editor compared with the previous system, we performed an experiment on both systems to generate a pronunciation dictionary with a test set of 1,072 Thai named entities, including names of universities/colleges, mosques, temples, hospitals, police stations, train stations, government offices, monuments, etc. The performance was evaluated in three aspects: generation time, pronunciation accuracy, and number of ungenerable words. The results are presented in the Table III.

Table III.
Systems' evaluation

Aspect	Previous system	LEXiTRON-Pro Editor
Generation time	5 min.	45 sec.
Pronunciation accuracy	18.1%	73.6%
Ungenerable word	60 words	0 word

The results show that LEXiTRON-Pro Editor can reduce time consumption from 5 minutes to approximately 45 seconds in pronunciation generating process, while the accuracy is largely improved from 18.1% to 73.6%. Lastly, the number of ungenerable words, found 60 words in the previous system, becomes zero.

VIII. Conclusion

The goal of this application is to assist linguists to reduce time and errors from manual work by simplifying several steps of development process, changing some tasks to automatic methods and proposing an easy interface to users.

Compared to the previous version, our new program can reduce the process of dictionary development from 5 to only 1 step and can reduce the number of tools used by linguists from 3 to only 1 program. In addition, LEXiTRON-Pro Editor can automatically propose a word's pronunciation to users by 1 of the 3 options in the successive order: pronunciation from LEXiTRON-Pro database, pronunciation combined from syllables with highest probability, and pronunciation from Thai G2P. However, users can switch to another option or even input directly the pronunciation they want by themselves with our easy interface editor.

Our experiment shows that, with LEXiTRON-Pro Editor, the time consumption and the number of ungenerable word are significantly reduced while the pronunciation accuracy is considerably improved as well.

We plan to use this program to develop LEXiTRON-Pro Dictionary Version 2.0 by increasing its size to more than 130,000 words in the near future.

Since Thai pronunciation dictionary is a crucial component in other speech processing applications such as Thai TTS and ASR, the more completed dictionary means an opportunity to the more successful speech applications too.

Automatic Detection of Prominent Words in Russian Speech

Daniil Kocharov
Saint-Petersburg State University
Universitetskaya emb., 11, 199034,
Saint-Petersburg, Russia
Email: kocharov@phonetics.pu.ru

***Abstract*—An experimental research with a goal to automatically detect prominent words in Russian speech is presented in this paper. The proposed automatic prominent word detection system could be further used as a module of an automatic speech recognition system or as a tool to highlight prominent words within a speech corpus for unit selection text-to-speech synthesis. The detection procedure is based on the use of prosodic features such as speech signal intensity, fundamental frequency and speech segment duration. A large corpus of Russian speech of over 200 000 running words was used to evaluate the proposed prosodic features and statistical method of speech data processing. The proposed system is speaker-independent and achieves an efficiency of 84.2 %.**

I. Introduction

THE SOLUTION of the prominent word detection task is to be used within the field of speech technologies while developing automatic speech recognition, unit-selection text-to-speech synthesis, spoken term detection, video and audio data indexing. For example, natural speech understanding systems need to know not only "what" has been said, but also "how" it has been pronounced. Intonation prominence is very important linguistic information for speech understanding, i.e. [1] showed that the use of word prominence degree helped to disambiguate the meaning of utterances.

The procedures of speech signal processing, prosodic features extraction and statistical speech data processing were developed during a series of investigations. The experiments used the data of CORPRES speech corpus created at the Department of Phonetics of Saint Petersburg State University [6]. The paper contains the experimental results and efficiency evaluation of the developed automatic prominent word detection system.

II. Prosodic Features of Word Prominence

A speaker prosodically emphasizes a word in an utterance to make it stand out of the surrounding words. The most common cure for doing that is a pitch accent that is acoustically expressed by the increase of local pitch maxima and minima. Intonational prominence reflects different aspects of pragmatics. It can express attitudes such as doubt, uncertainty and surprise, demonstrate anaphora references, the location of rheme and theme in the utterance, as well as show whether the utterance is a question or statement. Recently many research efforts have been dedicated to prominence detection due to its importance in such fields as natural speech understanding and emotion recognition in spontaneous speech. Almost all researchers assume that relative syllable and sound length, melody and loudness are highly connected with prominence [2]. The first research goal was to find the most efficient acoustic features for automatic prominent word detection.

A. Relative syllables and sounds length

The relative length of syllables and sounds is an obvious prominence feature. The speaker usually stretches a word if s/he wants to emphasize it. As there is no reliable algorithm of syllable detection for Russian and there is no syllable transcription in CORPRES, the speech corpus of Russian speech used in the present experiment, relative syllable length was not used. Two temporal features were used. The first feature is total word length in milliseconds. The second one is relative sound length within a current word that is expressed by the ratio of sound length within a current word and the length mean for the sound. The means were calculated for sound samples within the speech corpus. These features are possible to calculate as there is phonetic transcription with precise speech sound boundaries and orthographic transcription with precise word boundaries in CORPRES. Thus, there is no need to detect speech segment boundaries automatically, but it should be done by means of the automatic speech recognition in real-life applications.

B. Melodic features

The majority of researchers support the idea that melodic features are the most crucial for speech prominence, i.e. see [8]. In present research, the melodic contour of every word was examined separately. An original recently developed method of melody processing [6] was used. This method showed its efficiency in the system of automatic interpretation of tone unit prosody.

The melodic features were extracted from a preprocessed and smoothed melodic contour. The melodic contour is achieved as a result of automatic pitch detection system that has been developed earlier at the Department of Phonetics of Saint-Petersburg State University. The goal of preprocessing

This work was supported in part by the "Research Potential Development of Higher Education Institutions" Federal Program ("Automatic Interpretation of Prosody" Project)

is to eliminate microprosodic events and to get a smoothed melodic contour. This allows to get rid of calculation errors occurring within microprosodic events. Automatic melody preprocessing consists of the following four steps:

1) detection of voiced parts of the speech signal;
2) pitch detection within voiced parts;
3) microprosody and laryngalization rule-based processing;
4) melodic contour smoothing based on the algorithm of moving average.

The following melodic features were selected for prominence detection based on the analysis of other research and solutions as well as a series of experiments: maximum, minimum, mean and standard deviation of the fundamental frequency within a word. The rate of fundamental frequency change is also taken into account to model not only the fundamental frequency itself but the extent of its change as well. Thus, maximum, minimum, mean and standard deviation of the fundamental frequency change within a word were applied for this purpose. These features are applied based on the idea that the change of fundamental frequency is higher within a prominent word.

C. Intensity of speech signal and its spectrum

Speech loudness also correlates with prominence. Speech loudness corresponds with speech signal intensity or, more precisely, with its spectrum intensity. Meanwhile there are two main ways of modeling speech loudness. The first one is a calculation of spectrum intensity within certain, most significant frequency bands. The second is a calculation of speech signal intensity. The latter does not require FFT calculation that leads to much faster feature extraction. It is worth saying that the efficiency of signal based features is equal to the efficiency of spectrum based ones. The following features were used to express word loudness: maximum, minimum, mean and standard deviation of speech signal intensity within a current word.

The discrete extraction of signal intensity features is used. The speech signal within a word is divided into processing windows. Window length is 10 ms and window step is also 10 ms, that is windows do not overlap. The signal intensity within a processing window is a mean of signal amplitude values within the window. Thus, we calculate a single signal intensity value every 10 ms. This value array is used to obtain the features listed above.

D. D. General overview of proposed acoustic features

The acoustic features described above express three different aspects of speech prosody: melodic, dynamic and temporal description of prosody. They are independent at the first glance, that is changing one of them does not influence the others. But that is not really true. Changing one of them will influence the perception of the others. The perceptual characteristics of speech are more important than its real acoustic characteristics when one considers speech prominence. That is why all the features should be taken into account. For example, an increase in signal intensity leads to an increase in perceived pitch and an increase in fundamental frequency leads to an increase in perceived loudness [3]. It is quite obvious how to extract temporal and dynamic information. The task of key melodic feature extraction still requires a solution because it is not obvious what melodic features are the most important for automatic prosody interpretation. However, to make the feature extraction process consistent, it was decided to use the following list of features to model word prominence:

1) total word length, relative sounds length;
2) maximum, minimum, mean and standard deviation of the fundamental frequency within a word;
3) maximum, minimum, mean and standard deviation of the fundamental frequency change within a word;
4) maximum, minimum, mean and standard deviation of the speech signal intensity within a word.

The use of these acoustic features is based on the following reasons. First of all, it is well known that short words are rarely prominent, but the melodic contour within them usually changes greatly and rate of F0 change is a correlate of prominence. Thus, the use of word length as an acoustic feature helps to detect such words as non-prominent. The melodic and dynamic features are designed following the same principles: maximum, minimum, mean and standard deviation are calculated. This allows to estimate the range and variance of prosodic features. On the other hand, it allows to examine how words differ from each other, especially by statistical measures such as mean and standard deviation. These prosodic features are essential and almost all other features are based on them.

III. Statistical Processing of Prosodic Data

The choice of statistical data processing and acoustic modeling method that allows to achieve the best efficiency of automatic prominent word detection is no less crucial than the choice of acoustic features. The main statistical framework applied in speech technology at the moment is hidden Markov models (HMM) that would be perfect for the solution of this task within an automatic speech recognition system. HMM is the best choice when one needs to reveal a context dependency of objects or a dependency of certain objects appearing next to preceding objects. The solution of current task does not require this; it is possible to make an assumption about context independence of word prominence from the prominence of preceding words. Thus it was decided to use another method. It seems reasonable to use classification and regression trees (CART) to detect prominent words as it was done in [5]. CART is an effective classification method when classified objects are independent from each other. Besides that, CART allows to define a relative significance of features for a classification task. It is especially valuable from scientific point of view and allows us to develop, test and apply acoustic features that are more and more effective and reliable for a task of modeling and detecting prominent words. Usually the entropy is used as a splitting criterion in a CART framework. However, it has been decided to use probability of prominent words as a splitting criterion in the current system. There are two

TABLE I
THE EVALUTION RESULTS WITH DIFFERENT SETUPS

Experiment	Efficiency	Precision	Recall
SpInd	84,2	83.3	79.1
SpDep	77.1	81.2	73.4
Male Voices	89.7	90.4	80.1
Female Voices	87.3	88.2	78.8

reasons for that. The first one is the fact that when entropy is calculated all classes are supposed to be equally probable, but the number of prominent words is 4 times smaller than the number of non-prominent words. In case of using entropy this could lead to the situation when there are objects of different classes in all CART leafs: many non-prominent words and several prominent words. The other reason is that there are just two classes in this case: prominent and non-prominent words. Thus, uncertainty degree is unambiguously defined by a probability of one class. The experimental results showed that the probability of prominent words is a much more efficient splitting criterion than entropy.

IV. Experiments

A. Experimental Data Description

All the experiments were carried out with the CORPRES (Corpus of Russian Professionally Read Speech) corpus. It consists of recordings from 8 speakers, four men and four women. It contains 25 hours of fully annotated speech [7], three hours per each speaker. The corpus contains the following annotation levels:

1) pitch marks – boundaries of fundamental frequency periods;
2) phonetic events labeling – boundaries and labels of phonetic events;
3) phonetic transcription – boundaries and labels of speech sounds;
4) orthographic transcription – boundaries and labels of words;
5) prosodic transcription – boundaries and labels of tone units and pauses.

There are 211 383 running words in the fully annotated part of the speech corpus and 40 547 of them were labeled by experts as prominent.

B. Experimental Results

Cross-validation has been applied for efficiency measurement during experiments. This method is widely used in cases of lack of data and non-uniform data. Prominent words are non-uniformly distributed over the speech corpus and non-prominent words would be considered as a more probable class. The cross-validation allows to avoid that. It has been decided to use the same efficiency metrics as the ones used in search tasks for the task of prominent word detection can be considered a search task. These are error-rate, precision and recall. A series of experiments was held to estimate the efficiency of automatic detection of prominent words using the above mentioned prosodic features and statistical classifier.

A series of experiments was held:

1. Speaker Independent (SpInd): All data were uniformly devided into 10 parts, i.e. the recordings of every speaker were divided into 10 parts. Nine parts were used as training data and one part was used as test data, thus there were about 22.5 hours of training data and 2.5 hours of test data.

2. Speaker Dependent (SpDep): The purpose of the experiment was to evaluate the efficiency of the system when the recordings of one speaker are used as training data and the recordings of other speakers are used as test data. The data were divided in the following way: the data from 7 speakers (about 22 hours) were used for training and the data from 1 speaker (about 3 hours) were used for evaluation.
