Some previous solutions have been accomplished for helping blinds to recognize the surroundings and figure out the objects they interact with such as the VizWiz [6] and VizWiz Social systems [7]. The VizWiz backbone is mainly based on two important concepts: crowdsourcing [8] and Mobile-Q&A [9] [10]. In the VizWiz system, the blind recruit a number of employees (i.e. crowdsourcing) to answer the audio questions related to a photo taken by their mobiles (i.e. Mobile Q&A). The suggested VizWiz system gives them the full confidence that they are basically depending on their selves rather than asking for help from friends or family members through the traditional social networks (i.e. friendsourcing) [8]. However, it is not a free service and does not support any automated process for recognizing the captured photos that clarity degree basically depends on the mobile model that the blind regularly use. At the same time, it is difficult for blinds to correctly target their mobiles' camera in order to capture clear and easily recognizable pictures.

The VizWiz Social is a free application installed on iPhone and has three separated distinguished features: (1) accessing the original VizWiz with no cost, (2) automated object or photo recognition, and (3) social-based application. The study run over this application in [7] demonstrated that most of the involved blinds, who have involved in a survey sample, preferred to access the original paid VizWiz instead of the new two features added to VizWiz social. This is due to the some technical challenges in the automated object recognition such as the picture obscurity and the inaccurate results received. Regarding the social-based feature, there is a delay (approaches to an average of a full day) in the answers the blind users obtain due to the unavailability of the trusted friends or family members. Additionally, the blinds have anxious feeling about their privacy and independence when sharing their data and photos online.

The work in [11] [12] presented a hybrid system of special camera glasses connected to a mobile device through Bluetooth technology in order to transfer the captured images to a Cloud platform to speed up the matching and recognition processing time and obtaining accurate results in which the blind society can depend. Also, the work in [13] introduced the possibility of combining social networks with Cloud environment through analyzing the taken photos from blinds phones by either Clouds, or friends subscribed in social networks who are sharing the same geographical locations in order to obtain quick and accurate answers.

Neither of the previous work is considered as a complete solution for the blind community. VizWiz [6] [7] does not support full automated answers and imposes a charge of the Q&A service. The VizWiz Social [7] [14] fails to address the accuracy and the users' privacy while the remaining stated work [11] [12] [13] are only focused on the navigation problem. Moreover, neither of the described work discusses how the taken photos and sent data are proceed and stored. Furthermore, none of the explained work in this section is suitable for the Arabian region as English is the main language within all those applications/solutions. Additionally, the blinds are the main focus of the study of the listed work and nothing is there about deaf people and their own needs and language. Last but not the least, the interactions emotions and feelings of both the blinds and their peers (e.g. friends) have been neglected and should be studied properly due its gorgeous impact in improving the interconnectivity among them. By including these two features, the blinds would be able to feel like normal ones.

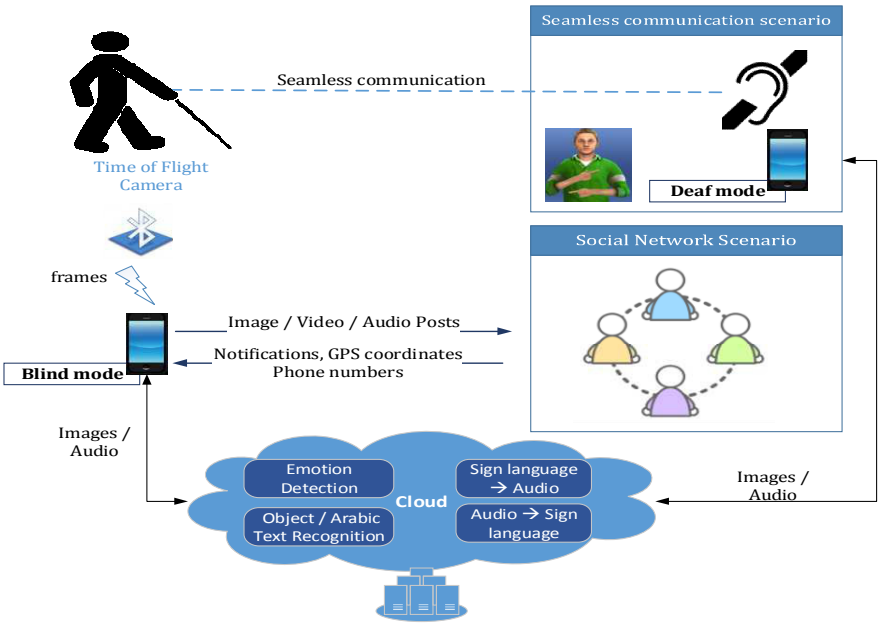

Figure 1. SoNetDBlue General Framework

III. THE PROPOSED FRAMEWORKE

The blind and visually impaired people, especially in Arabic countries, have limited opportunities for social interaction compared to those without visual impairments. At the same time, there is no much attention by assistive technology researchers for this topic. In this paper, we present SoNetDBlue (**So**cial **Net**work for **D**eaf and **Bl**ind **us**ers) framework that tries to help those people to improve their social life.

SoNetDBlue proposes a mobile-Cloud framework shown in Figure 1. In which a speech interface on the mobile is used to take commands in Arabic language from the user while visual data is captured by camera modules integrated into sunglasses and fed to the mobile device through the Bluetooth technology. Bluetooth has been chosen here due to its proven effectiveness and popularity. Machine instances in the Cloud are utilized for running complex and time-consuming tasks that cannot be achieved on the mobile device with its limited CPU power and memory capacity.

The proposed framework is based on a collaboration model between everyday mobile devices, and the computational power provided by the Cloud infrastructure. All required complex algorithms will run in the Cloud while the thin client on the mobile device is used to capture images or audio signals and send them to the Cloud for further processing. The proposed framework is based on three major subsystems:

- ***Integrated Camera***: We consider here the time-of-flight camera, a new technology used in real-time three-dimensional imaging. This technology has produced promising results in many fields including face recognition [15], gesture recognition [16], and real time motion capture [17]. These cameras provide real-time depth information about pixels of a captured image and the camera modules are made available by manufacturers at decreasing prices with the advances in the underlying technology. Currently available time-of-flight cameras provide ranges of about 10 meters and high frame rates of about 100 frames/second making them even more attractive for dealing with dynamic environments with fast moving objects.

  As opposed to using the camera of the mobile device, the time-of-flight camera module will be integrated into glasses to be worn by blind users (an eye-level placement) that will help them to easily capture context-relevant pictures

- ***Mobile Application***: We are planning to support iOS and Android mobile platforms due to their great popularity, support for multi-tasking and accessibility features. Android and iOS based devices come with integrated speech recognition and text-to-speech engines that will facilitate the design of an easy-to-use interface for disabled people. The application supports two basic functionality modes: blind and deaf. More details about these modes will be provided in the following sections.

- ***Cloud Infrastructure***: The suggested framework is built upon the computational power of Cloud to overcome the shortage of available resources on mobile devices. The Cloud is settled to accomplish computationally-intensive algorithms including emotion detection, object and Arabic text recognition, and the conversion from Arabic language to sign language and vice versa.

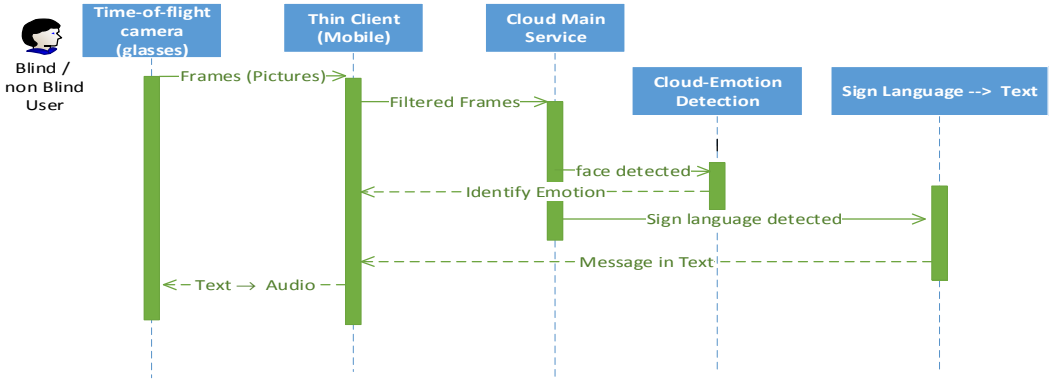

Figure 2. Sequence Diagram of Blind Mode – Seamless Communication Scenario

Our initial prototype is deployed on a private Cloud built using the OpenStack [1] Cloud operating system upon the infrastructure of the Suez Canal University, Egypt. OpenStack is open source software designed to provision and manage large networks of virtual machines, creating a redundant and scalable Cloud computing platform. It gives you the software, control panels, and APIs required orchestrating a Cloud, including running instances, managing networks, and controlling access through users and projects. OpenStack APIs are compatible with Amazon EC2 and Amazon S3 [2] and thus client applications written for OpenStack can be used with Amazon Web Services with minimal porting effort. [12]

This degree of compatibility will help us to port our final work to a commercial Cloud (e.g. Amazon EC2) to determine the overall cost expected by our system and to compare the system efficiency and reliability over different Cloud platforms.

SoNetDBlue focuses mainly on two basic scenarios: seamless communication with deaf people and social network for blind users. In the following sections, we are going to deliberate the two scenarios in detail and discuss the major challenges expected during the implementation of the system.

IV. SEAMLESS COMMUNICATION

In this section, we will concentrate on the first objective of the SoNetDBlue framework that is to provide an independent communication between blind and deaf people as depicted in the top portion of Figure 1. To achieve this objective, the thin client on the mobile phone should be configured to one of two available modes: blind and deaf modes. The thin client behavior is automatically adapted according to the selected mode. In the rest of this section, the functionalities of each mode are explained in more details.

The sequence diagram shown in Figure 2 concludes the flow of actions in case of the blind mode:

1) The time-of-flight camera integrated in the sunglass records a video for the conversation's partner (deaf user) and sends it to the thin client resident on the mobile device through a Bluetooth connection.
2) Depending on the CPU power of the mobile device, the thin client may decide to apply a preprocessing stage to filter the captured frames and to extract the key ones while the other frames will be regenerated on the Cloud. This step will reduce the amount of data transferred on the network and thus reduce the overall cost of the service.
3) The thin client submits the filtered frames to a machine instance on the Cloud responsible for running, controlling and synchronizing the required processing.
4) On the Cloud, a scientific workflow management system (e.g. SWIMS [18]) is used to process received frames in parallel over available computational nodes. Various algorithms, explained below, are applied to notify the blind user about the current feelings of the conversation's partner and a translation of his sign language into Arabic text that is sent back to the thin client.
5) The received text is converted into speech using the text-to-speech engine assimilated in the mobile device.

In our work, we focus on facial expression recognition as a key index of human emotion based on the six basic emotion-specified facial expression (i.e. happiness, sadness, fear, disgust, surprise and anger) defined by Ekman [19]. Based on our architecture requirements (i.e. accuracy and response time), we will consider and evaluate the work by Mase and Pentland on advanced face detection and recognition using relatively low computational power [20] and the algorithm that classifies face emotions through eye and lip features using particle swarm optimization [21].

[1] http://www.openstack.org/
[2] http://aws.amazon.com/ec2

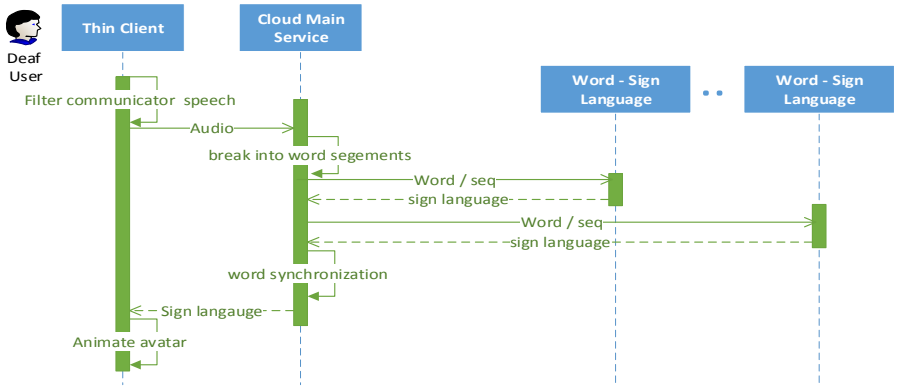

Figure 3. Sequence Diagram of Deaf Mode – Seamless Communication Scenario.

For the Arabic Sign Language (ArSL) recognition, we concentrate on testing two algorithms that achieve real time translation of dynamic gestures. The first algorithm involves two stages for automatic translation of dynamic gestures into the ArSL; in the first stage, it recognizes the group of the gesturer and the second stage interprets the gestures within the groups based on spatial domain analysis and hidden markov model [22]. The second interesting algorithm is a vision-based automatic sign language recognition system for Arabic letters with no need for any additional hardware such as gloves or sensors. The algorithm uses predefined Haar classifiers to track and detect the hand's position, then it detects the skin color, transforms the images into frequency domain, and finally uses a simple classification technique (K nearest neighbor); this algorithm achieved up to 90.55 % recognition accuracy at real time [23].

The deaf users should configure their mobile devices to the deaf mode in which the thin client records the Arabic speech and filters it to extract the signal of the conversation's partner (blind), and submits it to the Cloud for processing as illustrated in Figure 3:

1) The speech is translated into Arabic text and segmented into separated words.
2) Each word is translated into its equivalent sign language in parallel on different available computational nodes to speed up the total response time. The outcome of this step is an animation sequence that represents the sign language of the word under processing.
3) Accumulated results of step 2 are synchronized and sent back to be displayed on the thin client through a digital avatar as shown in Figure 1.

Several research projects have made efforts in translating English text into sign language [24]. However, research work focusing on Arabic language is quite limited. An early work in the field of ArSL translation shows a poor consideration of the deaf community in the Arabic world, for example, the system build by Mohandes wrongly assumes that ArSL depends on the Arabic language and shares the same structure and grammar [25]. A more powerful work has been presented in [26]; in this work the authors considered the ArSL's unique linguistic characteristics (e.g. its own grammar, structure, and idioms) and provided a full working prototype, ArSL translation system, for helping Arabic deaf community to access published Arabic text. Another interesting work that we have to consider is the translation tool introduced in [27] as a part of a full chat system for deaf people; it provides two different modes for translating from ArSL to Arabic language and vice versa; it is based on a word to word translation, and if a word does not exist in the system's database, a letter by letter translation is encountered.

An important question that may jump to the mind is how can blind and deaf people initiate communication while the blind cannot see the deaf and the latter cannot hear the blind one? For sure the one with vision capability (the deaf) should start his program that broadcasts an audio message. This message will notify the blind to initialize his application and to target his eyes to the deaf person to be able to capture his signs.

V. SOCIAL NETWORK

The second major objective of the SoNetDBlue architecture is to connect deaf and blind people with their cycle of friends (with or without disabilities) anywhere and at any time. This will help them to integrate in the community and to gain better social skills for a more successful life. To hit this goal, SoNetDBlue framework embraces a social site connecting blind and deaf users with their cycle of friends including people with or without disabilities. Figure 4 presents a use case to show the various activities that can be accomplished in this scenario:

- **Post text / audio messages:** users can post messages either in text or audio. Text messages can be entered in ArSL using a special keyboard as the one designed for the chat system presented in [27]. The received message can be also translated into one of the available format (i.e. audio, text or sign language). The camera module integrated in the blind users' sun glasses or the mobile's camera can be exploited to capture an image or a video to be attached with the posted message.

- **Find/call nearest friends:** SoNetDBlue users can utilize the thin client installed on their mobile devices to locate their nearest friends, using the GPS module installed on the mobile device, and to contact them either through calls or SMS messages. This can be very helpful for disabled people, especially in case of emergency situations.
- **Identify objects / Arabic text:** The goal here is to help blind users to identify the class of objects (e.g. car, building) in front of them. In addition, the algorithm should search for a textual note in the image to give a more descriptive explanation about the detected object (e.g. a building of Suez Canal University). According to the evaluation in [28], the Lehigh Omnidirectional Tracking System [29] is one of the best algorithms for object detection in video streams. For detecting textual notes, we have to evaluate existing Arabic optical character recognition and natural language processing algorithms to select the best of them while considering that the textual notes may contain bilingual sentences (e.g. Arabic / English) and different number system (i.e. Arabic and Indian numbers).

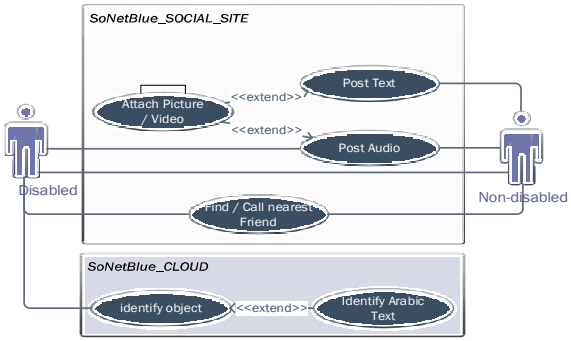

Figure 4. Use Case of the Social Network Scenario

VI. ARCHITECTURE CHALLENGES

The major challenges of the SoNetDBlue framework are fourfold: data stored on the Cloud, user's security (privacy and authentication) , Arabic language recognition, and evaluation of the proposed solution. Data stored on SoNetDBlue Cloud infrastructure is enriched with semantic annotations to determine (a) the owner of the data (user) and (b) the context in which the data has been collected [30]. This may lead to data duplications to some extent, but it will have a great impact on the response time of available Cloud services as the search scope will be limited to a certain user at a certain context. At the same time, the Cloud infrastructure will utilize advanced frameworks to manage the replication of its services [31] and expected privacy issues [32]. SoNetDBlue could be used to help a blind user to get a specific location using Global Positioning System. However, this could put the user in risk while submitting his location information to the Cloud. This information could be used by a malicious party to locate the blind user and then exploit this user for his/her own benefit. Thus, unlink-ability techniques of the user identity should be used to overcome this problem. Another aspect of privacy concern is as follows. SoNetDBlue, using Time-of-Flight camera in the blind mode, requires continuous capturing of the surroundings around the user to be sent to a dedicated website. It is crucial that the user anonymity is preserved, i.e. providing unlink-ability to the recordings. This is because these videos would disclose lots of information about the places visited by the blind user.

Another security issue is the mobile authentication. A survey in [33] reported that7jhli 40% of mobile users used to enter a password on a daily basis. In addition, 56% of these users mistype a password at least once out of ten. Users find that entering password on Mobile Internet Devices (MIDs) is more frustrating than lack of coverage, small screen size, or poor voice quality. Surely, for blind users, these limitations of using traditional password as authentication method are more frustrating. Therefore, especially for blind users, MIDs require another way for authentication such that the users' involvements are very limited or without any involvement. Furthermore, as reported in [34] after interviewing 13 blind users of smartphones, it has found that most them were not familiar with potential security threats of not using authentication methods such as a password-protected screen lock. Implicit authentication [33] [35] could be used to address these limitations. It could be used as a secondary factor for authentication to augment passwords, thus achieving a higher-assurance authentication. For blind users, this implicit authentication is very promising as they are not required to memorize how to enter a password.

The challenging bit of the ArSL is mainly concerning the accuracy of the obtained results. Comparing to the American Sign Language, the ArSL still requires more work to reach the same level of accuracy. As reported in [36], American Sign Language has achieved a word accuracy of 99.2% (users have to wear a special glove) whereas in [37] American Sign Language has accomplished an accuracy of 98%. On the other hand, the best result of the ArSL is 90.55 %, as reported in [9]. The reasons of this problem are summarized as follows [12]. ArSL, like other natural language, is an independent language which has its own structure, grammar, and idioms. In addition, it is not hand/finger spelling of the Arabic alphabet. The finger spelling is only used for places or names which that do not exist in ArSL. Furthermore, ArSL does not have a documentation system which could be utilized while building a translation corpus. Therefore, deep research should be done to address this difficulties and to fill the gap of the accuracy between the ArSL and American Sign Language. It is believed that the high accuracy of ArSL, the high adoption of the proposed SoNetDBlue solution.

VII. CONCLUSION AND FUTURE WORK

In this work, a Mobile-Cloud framework is presented to help blind and people with visual impairments to gain better social skills that are important for healthy and successful life. Moreover, the introduced framework is structured to bridge the communication gap between the blind and deaf persons, particularly in the Arabic section. Finally, we showed how several technologies and methodologies including social networks can be integrated to recognize all possible obstacles and persons to assist the blind people to feeling and visualizing the surroundings.

Our future work involves two main steps: the first one, as mentioned above, we have started to implement the suggested architecture in an OpenStack Cloud environment, we aim to complete the entire architecture implementation and its interrelated components and testing its behavior in order to meet the analyzed requirements and estimated objectives. The second step includes moving the implemented system to a commercial Cloud and practicing the expected behavior with real pupils. Also, this stage will be concluded by a real-time survey to measure the blind/deaf people satisfaction about the produced system including the performance and accuracy.

***Abstract*—This article provides an insight into the topic of ad-hoc protocols used for routing, namely proactive and reactive protocols. It depicts the general concept how these protocols can find a path in a network between two nodes and it also presents the evaluation of the methods of tracking the node path in a wireless ad-hoc network through investigating the available mobile routing protocols.**

The main focus is on the throughput and the average end-to-end delay in a network, using for the simulation OMNeT++ environment. Three protocols were chosen for the final testing: Ad-hoc On-demand Distance Vector (AODV), Optimized Link State Routing (OLSR), and Dynamic Source Routing (DSR).

I. Introduction

AD-HOC networks originated in 1960s when the ALOHA project was emerging from the shadows. Even though the dynamically established network was not the first outcome of this project (it was based on fixed nodes with the single-hop option only), the idea of a shared medium for client transmissions remained. The earliest wireless ad-hoc networks were the "packet radio" networks (PRNETs) already proposed in 1970. Since then, project and ad-hoc networks have been developed continously.

In general, an ad-hoc network is a collection of wireless mobile nodes (e.g. smart phones, laptops, cameras etc.) that is formed only for a short period of time when wireless devices come within each other's communication ranges. Nodes are the users or devices forming the network [1]. This set-up is created dynamically without using a preconfigured network infrastructure (a simple example of an ad-hoc network is shown in Fig. 1). If a network is set up for a longer period of time, it is just a plain old local area network (LAN). Finally, it is said that an ad-hoc network does not have any centralized architecture, what means that any node is a peer. In a peer network, each node is a client, a receiver (server), or a mediator of a packet that routes packets to other nodes that are out of range of the sender [2]. Moreover, an ad-hoc network can operate as a stand-alone, closed group as well as a network with a connection to the Internet.

This definition indicates that the mobility of the nodes leads to fast and sometimes enormous changes in the wireless network topology. In addition, other obvious attributes such as a large size of the network, bandwidth, large diversity of available devices, and their power consumption may cause large problems for today's routing protocols. They may all be a huge challenge if ad-hoc network users want to receive a reliable and high quality service, not to mention other problems that can be enumerated: physical obstacles, indirect communication between two nodes, imperfections of network elements causing delays, battery constraints etc.

The first idea is based on fast routing protocols. User mobility influences the changing topology of an ad-hoc network, so it is possible that some old nodes are no longer available but new have just appeared. In theory, a routing protocol could still handle this change somehow in order to connect the required nodes, but there are some protocols that cannot do that. Therefore, it is necessary to use the protocols that are dedicated for ad-hoc networks and, providing they are fast enough, they can solve the mobility problem. Routing in ad-hoc networks is a combination of dealing with topology adjustments and minimizing the routing overhead. There are proactive and reactive protocols as well as the hybrid of those two solutions which tries to combine the best features of each protocol [1].

In networking, a hop represents one fragment of a path between the source and the destination. It is a well-known phenomenon that data passes through an unknown number of intermediate gateways until it reaches its destination. For example, on the Internet packages are routed between various sub-networks. Moreover, the definition of a hop distance should be useful. It is a unit of measurement used to express the number or routers that a packet must pass through on its way to its destination.

Therefore, in a wireless network, single-hop means that there is only one hop between the source station and the destined host. At the same time, multi-hop refers to a situation when the packet of data must travel through more than one hops. The hop count is important for the basic network operating principles. Fig. 1 clearly presents both expressions.

The perfect routing protocol has to combine the goal of dynamic adjustment to changing conditions in an ad-hoc network and of low overhead. Due to this combination, several different approaches were introduced in the field of routing protocols. Some of them will be presented and discussed in the following sections. Figure 2 shows a possible classification of routing protocols that is taken from Latiff et al. [3].

978-83-60810-53-8/$25.00

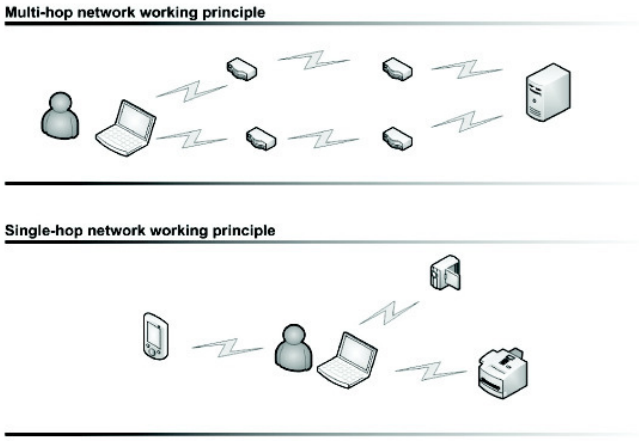

Fig. 1 Examples of single-hop and multi-hop ad-hoc networks.

II. Flooding

According to Mohapatra and Krishnamurthy [4], flooding (network-wide broadcasting or pure flooding) is a way to deliver data from the source node to the destination node through every outgoing link. It means that every attached node will receive source data packets via a MAC layer broadcast mechanism and, finally, every node in the connected component of the network will deliver the data.

There is the basic rule that is followed in order to avoid looping in the network: "every node transmits only once". If a node collects data for the first time, it re-broadcasts it. This algorithm guarantees the end of the procedure eventually and is easy to implement. Additionally, no prior knowledge about the network topology is required and, in some cases, when mobility of the nodes in the network is so high that even unicast protocols cannot handle it, the flooding may become the only reasonable alternative for routing data rationally [4].

This protocol technique can have a big contribution to an overall throughput in the network – the higher number of packets in a network means that there is a higher chance for a collision, what influences the success rate of the packet delivery directly.

III. Proactive Protocols

The main operating principle of proactive routing protocols is that they maintain unicast paths between all pairs of nodes, even when routes are currently idle. They are also called "table-driven" routing protocols. A node can decide to update its routing table after either receiving an update message from a neighbor or detecting a change in the status of a link to a neighbor. Hence, when the source wants to start a connection with a remote destination node, the process can immediately begin because the path is ready and available at any time. No other request or path discovery is required and, therefore, the delay of such nature can be eliminated. It is assumed that the protocols are capable of finding the shortest and the most optimal route for a given model of link costs.

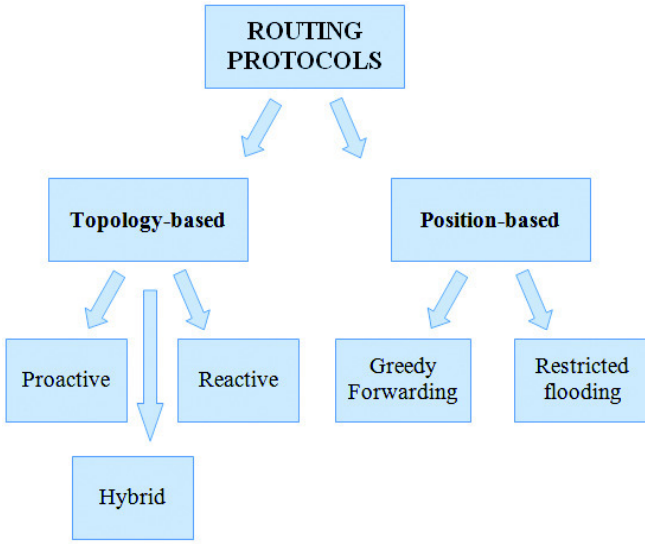

Fig. 2 Categorization of MANET routing protocols.

Optimized Link State Routing (OLSR) is a member of the proactive protocols group and, as such, it is also a table-driven protocol, which assumes that nodes in an ad-hoc network will update each other regularly and will cooperate in order to send data from the source to the destination using the most optimal path. This protocol uses the Mohapatra and Krishnamurthy [4] concept of Multipoint Relays (MPRs), mentioned in this paper before.

In a general operating mechanism, only the nodes that were selected as responsible for their area are allowed to generate link state updates. Additionally, these updates must include information on the links between MPR nodes only [2]. No other node has been granted the privilege to do so in order to keep the update size as small as possible. This way, even though there may be other routes available, only a part of the network topology is revealed to other nodes. This may seem dangerous for network routing; however, this partial information is fully sufficient in order to locally calculate the hop count to every node because it is certain that a path that consists only of MPRs exists.

One of basic principles of OLSR is that it uses only periodic updates in order to keep all nodes up-to-date with the link state. Whenever traffic in a network is dense, the protocol reduces the overhead as compared to the time when traffic is lower or the network is sparse. Additionally, the interval between subsequent updates is critical for reacting to topology changes and should be accurately considered.

What is really distinguished for OLSR is that it can minimize the overhead from flooding of control traffic effectively only by using carefully selected MPRs to retransmit control messages. This way, not all nodes have to be occupied with retransmission but messages still reach all nodes in an ad-hoc network [4]. Moreover, in order to find the most optimal route, the OLSR protocol needs only a partial link state to be sent through the whole network. This minimal information about link states includes the links to all nodes in the region under MPR responsibility (however, the redundancy is also possible).

The performance of the OLSR protocol was also tested in comparison to other various types of protocols. It was discovered that OLSR shows a good resilience to a suboptimal link state situation in a network where the routes are constantly changing (as nodes move in counter-rotating circles) and the network picture never converges permanently [5].

IV. Reactive Protocols

Reactive routing protocols, also called "on-demand" protocols, are quite different from the traditional proactive manner. The main difference lies in a route preservation mechanism – while proactive protocols keep all routes available for use at any time, reactive protocols maintain only the paths that are currently needed. The advantage of this technique is that a huge amount of routing data does not have to be stored and updated all the time. However, good algorithms are needed for instant path discovery that would not create too big delays and queues. Still, this kind of protocols should be perfect for networks where the traffic is small and sporadic.

Ad-hoc On-demand Distance Vector [6] belongs to the reactive protocols family and discovers a route from the source to the destination when it is needed. All possible routes are not maintained the whole time. Basically, AODV relies on the distance vector technique. This term refers to the method which uses the arrays of distances to other nodes in a network. Instead of saving knowledge about all routes in a network, it is enough to know the direction of forwarding the message (or the interface that should be used) or the distance from its destination (in reasonable units).

So, keeping those two basic rules in mind, AODV depends on dynamically established route table entries at nodes between the source and the destination. This means that AODV protocol requires a much larger overhead in order to piggyback source routes in each packet, what is unthinkable for proactive protocols. Each entry consists of the destination address, the next hop address, the destination sequence number, and the hop count.

Another characteristic of AODV protocol is the sequence number, which is incremented monotonically at each node of the network separately. The combination of above features results in an algorithm that can use an available bandwidth efficiently and can adapt to changes spotted in an ad-hoc network.

Each router based on the AODV protocol is more or less a state machine that works using a simple algorithm. If a route exists, then the message is forwarded. Otherwise, the message enters a queue and the router sends a route request in order to search for a possible path. According to received information, the router can update the table and even transmit the message if the path to the destination has built up.

The AODV protocol uses four types of messages that the nodes can distinguish [4]. The route discovery is handled by Route Request (RREQ) and Route Reply (RREP). The needed paths are maintained by Route Error (RERR) and HELLO messages.

Dynamic Source Routing is the reactive protocol that uses a source routing mechanism. The sender of the packet generates a header that can contain all addresses of the nodes in a network which a packet must be forwarded through in order to reach the destination node [7]. It means that the source needs to know the whole hop-by-hop path that can be stored in a route cache. This memory should be maintained by each node of an ad-hoc network which wants to participate in the traffic share. If this cache does not enclose the required path, the node simply needs to use the standard discovery process for the wanted route in order to dynamically determine the path to the destination node. It is accomplished by flooding the network with RREQ messages, also called queries [4].

The route discovery technique is based on route requests which are re-broadcasted by each intermediate node if it is not a destination node or if it does not know the path to the destination based on a route cache. Otherwise, the node answers with the PREP message and the packet with the entire route is sent back to the origination node. And finally, this path is, of course, saved for later in a route cache by each node which does not know it [4]. Like in the case of the AODV protocol, the RERR packet is generated if any node detects a broken link that cannot be longer used for the traffic. This kind of message triggers the removal of the given route from the route cache as well as all entries that are affected [4].

V. Running Simulations

We have decided to use OMNeT++ [8] for the simulations library, which is rather a good provider of infrastructure and tools than a simple simulator of a network. The main advantages of this tool are as follows: free for academic use, the engine runs event-driven simulations of communicating nodes on a wide variety of platforms, support of graphical network creation, the framework is fully extensible and modular (based on C++ language), the documentation and the tutorials are properly maintained and developed by an increasing number of new users, and there exists a great diversity of available libraries and featured projects compatible with the OMNeT++ platform.

We performed the tests only in a random grid, but we were aware of the disadvantages of the linear or grid topology that may cause problems in ad-hoc network routing. Nevertheless, we wanted to have a more realistic topology, so the random one was the most reasonable (Fig. 3). All the nodes in our simulations were moving all the time with variable speed and direction of movement without a pre-determined path.

All tests had the common goal of adjusting the final simulation parameters because the default ones are not always the most suitable for the wanted results. Table (Table I) presents the output of all testing and verification processes.

The preparation for simulation was not only focused on investigating the best parameter set but also on adjusting the behavior of a singular node. The inner construction of the mobile device was based on the TCP/IP model. It was decided that it would employ 802.11g technology for MAC layer, UDP was used in transport layer, and UDP APP for application layer.

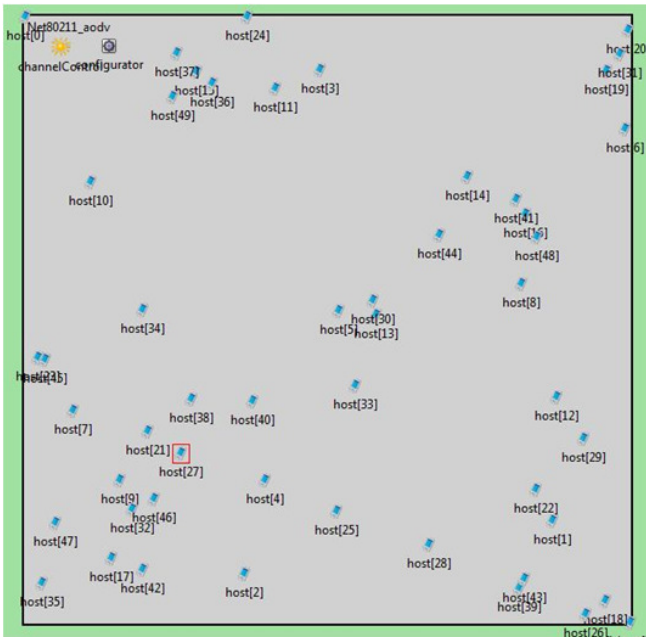

Fig. 3 Snapshot of the random topology.

VI. RESULTS

With all predefined parameters of the simulations, we were able to obtain the relevant output – the average end-to-end delay and the average throughput of the network. The average delay time involves all possible reasons, such as queuing time, packet transmission, and propagation time or retransmission time.

We think that the delay is important for a dynamic ad-hoc network and should be as small as possible but, at the same time, the successful rate must be tolerable. Please have a look at the results that we got separately for the AODV, OLSR and DSR protocols (the plots are presented in Fig. 4, 5 and 6, respectively).

With the increased number of nodes in a network, packet collisions may occur more often and this will lead to a higher number of retransmissions. This kind of situation would definitely influence the overall delay and it can be observed in all of these plots.

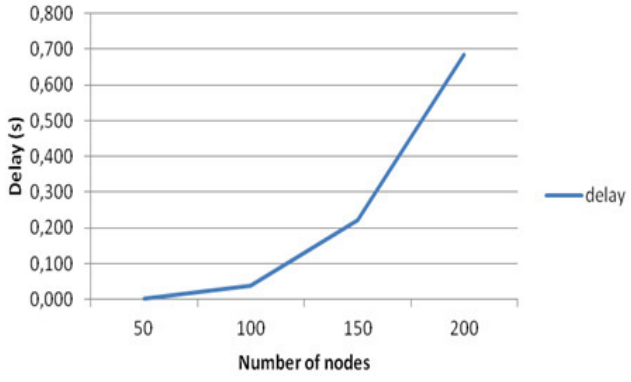

Fig. 4 Average end-to-end delay for the OLSR protocol.

TABLE I.
SIMULATION PARAMETERS CHOSEN FOR THE FINAL TESTS.

Parameter	Value
Simulation time	600 s
Topology	Random location of nodes (network of mobile devices)
Number of nodes	50, 100, 150, 200
Ad-hoc protocols	OLSR, AODV, DSR
Transmission range	100 m
Mobility model	Random way-point

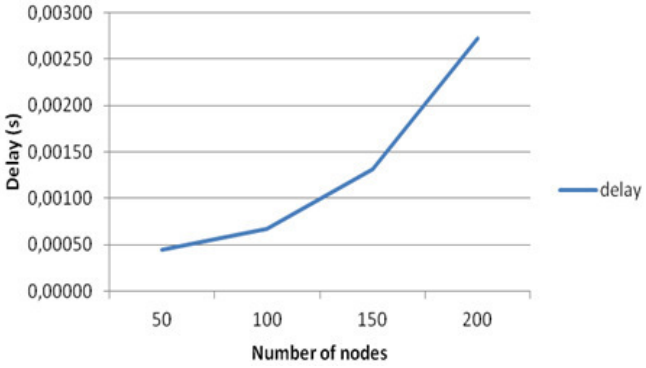

Fig. 5 Average end-to-end delay for the AODV protocol.

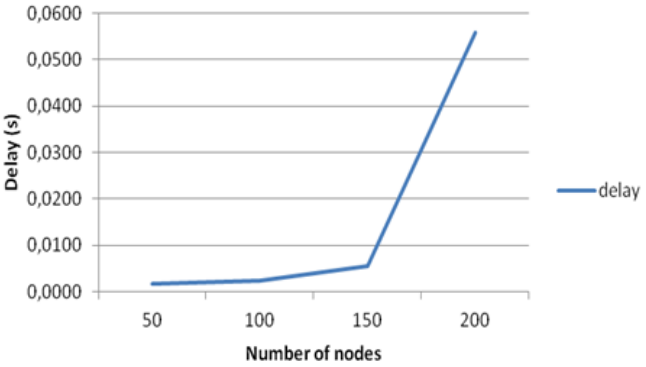

Fig. 6 Average end-to-end delay for the DSR protocol.

However, the smallest delay can be noticed in case of the AODV protocol application.

The average throughput of all three protocols is compared by measuring the average rate of successful message delivery over a communication channel. This is calculated in bits per second, what emphasises the vitality for ad-hoc network operation. The higher this number is, the higher the throughput is.

When the number of nodes increases, more packets of data come to the network; it can be observed that the highest throughput of all three investigated protocols was reported in the AODV protocol (please compare the plots presented in Fig. 7, 8 and 9).

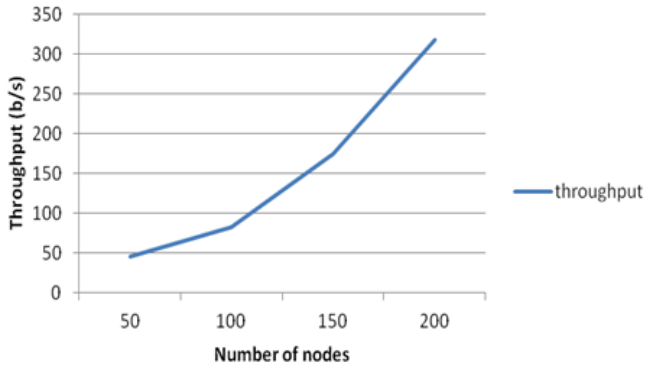

Fig. 7 Average throughput for the OLSR protocol.

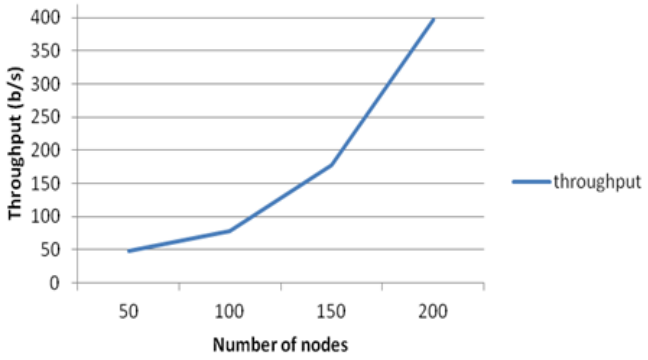

Fig. 8 Average throughput for the AODV protocol.

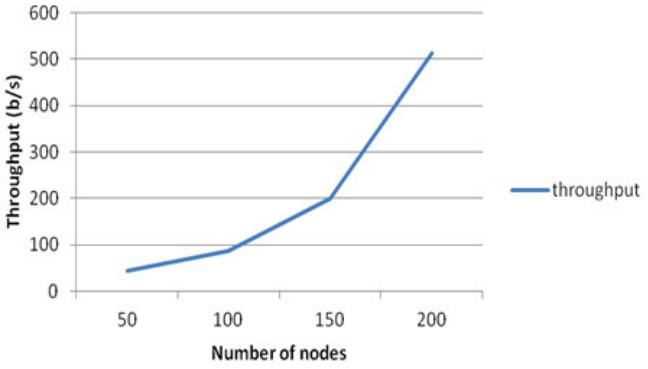

Fig. 9 Average throughput for DSR protocol.

VII. Discussion

We have examined and analyzed three routing protocols from both proactive and reactive groups, namely Ad-hoc On-demand Distance Vector (AODV), Optimized Link State Routing (OLSR), and Dynamic Source Routing (DSR). The simulation tests involved measuring metrics such as throughput and end-to-end delay.

The presented results indicate that the performance of the AODV protocol is superior as compared to the two other protocols that have been taken into account. It can be easily noticed that the AODV protocol handles the network traffic better when more and more nodes are added to an ad-hoc network. Still, according to the theoretical background, smaller networks (up to 10 nodes) might have been handled better by the DSR protocol.

Nevertheless, the DSR protocol was inferior in both end-to-end delay and throughput, even when there were only 50 nodes in the network. The poor performance of DSR with respect to time for packet delivery is mainly due to caching the routes and the lack of mechanism for deleting the stale paths. We think that it is the reason why DSR did not perform so well, even though it belongs to the same group of reactive protocols as the AODV protocol.

It was also observed that, for a relatively small number of nodes, all routing protocols are similar when throughput was under test. However, the average end-to-end delay could be easily compared for even the smallest number of nodes and the AODV protocol was incredibly fast in delivering packets. This is why we assume that the AODV protocol would be preferred for real time traffic over DSR or OLSR.

Whenever throughput is considered, results show that DSR does not handle it well because it consumes a considerable amount of power. If it was a real environment involving mobile devices, the batteries would run out of power pretty quickly.

During the testing process, some problems occurred and those influenced directly the developing and testing time. The parameters were difficult to adjust because the default ones did not give the wanted results and looking for better values consumed a lot of time. Additionally, testing the performance of the DSR protocol was difficult in terms of the processing power of computer (this protocol uses the caching routes technique, so the bigger the number of nodes was, the more resources it was consuming for the test). Finally, the OMNeT++ testing environment gives different debugging messages in each operating system, so we had difficulties solving, for example, Cygwin problems during the testing process.

Abstract. **In the recent years, the Global Positioning System (GPS) has become a standard for the location and navigation for a huge number of people all over the world. This system is unquestionably one of the most significant developments of the twentieth century. GPS employs a great variety of applications from car navigation and cellular phone emergency positioning even to aeronautic positioning. Despite the fact that it plays an essential role in today's world, GPS has some limitations. The main disadvantage is the inability to operate inside the buildings because of the loss of signal from the satellites. During the last decade, the interest in location based services has significantly increased. It is related to the existence of ubiquitous computers and context awareness of mobile devices. Information about the position plays the great role in the field of security, logistics and convenience nowadays. Thus, it is necessary to fill the gap at the point where Global Positioning System does not perform satisfactorily.**

I. Introduction

THE idea is to design the system complementary to GPS which would be able to determine the location in the places where GPS is not. It is possible to use a wireless LAN system and its existing infrastructure to find the users location indoors. The wireless communication system was designed to provide users with a possibility to move around and still be connected to the local network or be able to use Internet access without cables. Nevertheless, it is possible to use some of the properties of wireless communication to determine the location. Analyzing the transmitted signal, a mobile device can estimate the distance between the access point and the terminal itself. Then, by combining the measurements from more than one access points, the mobile device can determine the exact location of the terminal.

II. WLAN Positioning Principle

In recent years, the WLAN IEEE 802.11g standard has gained high popularity; the number of devices using wireless networks is still constantly increasing. Nowadays, WLAN infrastructure is maintained nearly everywhere where people appear frequently. This enables customers to connect to the Internet in public places such as airports, hospitals, universities, or shopping malls. The majority of modern mobile devices is equipped with a WLAN interface and that enables them to connect to wireless access points. In recent years, the position information as well as the WLAN standard IEEE 802.11g have become very common. This motivates developers to produce systems based on WLAN networks which are able to determine a user's location.

To estimate the real-time location of a user, location systems have to perform a number of steps and various calculations [1],[3]. The estimation of the distance from the access point is the first phase needed to determine the exact location. It is the method of calculating the radius of a circle in two dimensional spaces or a sphere in three dimensional systems. The calculation of more than one distance from several Access Points (APs) could be used to estimate the exact location [2]. A location could be described as a set of coordinates pointing at a particular position in a space or on a map. The majority of the positioning applications require that the position of the user's device be estimated with a good accuracy, but sometimes another criterion, such as no complexity or low costs, is more important. Positioning systems based on wireless networks use the properties of the access to a medium. They use various physical attributes to measure the distance between two terminals [4-5].

The main principle states that signal strength at the receiver is inversely proportional to the square of the distance that the signal travels. Based on that rule and the characteristics of a wireless signal in a researched environment, the distance between two terminals can be determined. In comparison to methods that are based on the time of flight technique, the Received Signal Strength (RSS) approach has a number of advantages. To apply the RSS method, no hardware changes are usually required. This method can be implemented in a customary wireless communication system such as the IEEE 802.11g standard with the facility to read a received signal strength indicator. The special synchronization and timing techniques are not relevant. Owing to the low costs of implementation and the simplicity, the RSS approach has a great chance to become the most popular technique used for indoor positioning systems. Nevertheless, there are some restrictions of the RSS location technique. The electromagnetic signal is very prone to interferences and the effect of multipath propagation. A position awareness system based on RSS method must use a specific database or increase a number of static base stations to achieve higher accuracy [6][8].

978-83-60810-53-8/$25.00

The RSS fingerprinting approach is based on sampling and recording of characteristic patterns of a radio signal in a specific environment and is called pattern recognition or fingerprinting. The location patterning technique is implemented in the software entirely. This reduces the complexity as well as the cost of performance and, at the same time, guarantees high positioning precision. However, a special database must be created for every single area and every change which effects radio propagation requires the re-creation of the whole database[7],[9].

The deployment of a location system based on the position patterning has two measurement phases. The first one, which is called the offline or the calibration phase, results in the creation of the database. The second phase, called the online or operational phase, takes place when the real time signal strength values are matched with the previously constructed database components associated with the reference points.

III. Project Implementation

The created WLAN Positioning applies the position determining approach based on the received signal strength and access point information from the 802.11g wireless network. Tests were conducted in a three-storey building with the overall surface area of about 250 square meters using three access points which were distributed all over the building, each on a different floor.

The client-based approach is applied in the system that includes the offline phase as well as the online phase. The developed application could operate in both modes. The first one is a calibration mode and includes the construction of a radio map of an indoor area containing measurements of the received signal strength from access points in each reference point.

The localization system uses three access points that provide overlapping coverage area, with the strongest signal power in the calibrated arena. Another wireless networks detected by the system are not used by the application because they do not guarantee the sufficient coverage and the high enough signal strength value. The second mode of application is the operational mode and this mode includes the determination of position in real time. In this phase, the application receives a signal from fixed access points and performs the calculations on signal strength to obtain the current position of the device. The approach used to determine the device position is the nearest neighbor method based on the Euclidean distance.

The designed positioning system operates on mobile devices in conjunction with the 802.11g standard wireless access points. The calibration and the operational phase were conducted using already installed access points in the three storey building. The coverage region includes three floors with the surface area of about 250m2. This place consists of 15 different locations where 55 reference points were defined. The plan of each floor with the position of the reference points is presented in Fig 1.

The User Positioning System is a software-based project developed to work on the Sony Ericsson Xperia mobile device. The mobile phone operates using Android 2.1 and is equipped with WLAN card working with 802.11g technology.

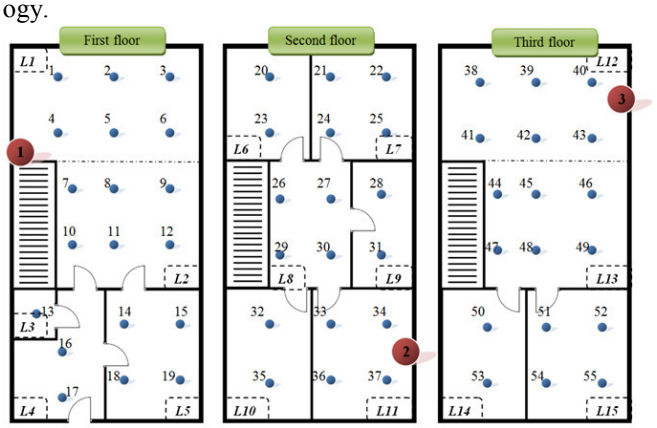

Fig. 1 Plan of the building with tagged reference points.

Due to the fact that the project was designed to work on the mobile phone Sony Xperia, there were some specific hardware restrictions. The system uses the embedded wireless network card and its ability to deliver the received signal strength values. The positioning approach could be chosen from the set of methods that use the RSS approach to determine the location. The approach based on the angle or time of arrival may not operate on available mobile device. (In order to measure the angle, it is necessary to use a directional antenna or an antenna array, where each antenna is tuned to a different optimum frequency. Unfortunately, it is not possible to use this method on a mobile phone, which uses an antenna with properties similar to these of omnidirectional antennas. No possibility of tuning the frequency of the antenna makes it also impossible to construct a suitable antenna array).

Due to the fact that the system was created to operate in a very complex environment where the propagated signal was prone to various distortions caused by multipath phenomena, the propagation model method could not be applied in the described system. The approach which could give the satisfactory results in that complex environment and which was applied in the project was the received signal strength fingerprinting approach that is based on the nearest neighbor algorithm.

The User Positioning System could operate in two modes. The first mode uses the offline phase which contains a collection of reference points, what results in the creation of the database. This phase is performed before the real-time operational phase and provides references for the localization algorithms used in the actual position localization. The constructed database consists of reference points at a specific location and three median values of RSS that correspond to the fixed access points. The main database is associated with the described environment – the three-storey building. This database is used in the real-time operational mode as a reference databank for the application to find the most accurate position of the device.

The second mode of the program is called the positioning phase. In that mode the application matches real time measurements with the database that was already created in the

previous phase. The mobile application in the positioning mode measures the real time RSS values from three access points. Due to hardware limitations, the program could obtain only one sample per two seconds. During this phase, the analysis including a number of sample values resulting from the calibration process was compared with the systems accuracy. The application depending on user preferences could operate in three different modes that vary in the number of samples. The first one uses instantaneous measurements of the RSS value to determine the best reference point, while the other two use three and nine samples to localize the device. The corresponding time of the calibration is two, six, and eighteen seconds. The received RSS values from more than one sample are translated into their analogue median values in order to create a single vector of signal strength values.

The constructed real time vector of measurements is compared with the already created database, using the nearest neighbor algorithm which was already described in detail in the previous section. Each value of received signal strength in the vector is compared with the corresponding values with each reference point from the database, using Euclidean distance. The reference point with the smallest distance is considered the best position by the program. The application displays the determined position at the screen.

IV. Test Measurements

The tests of the project were carried out with various parameters. The actual accuracy of the system varies in the number of samples obtained in real time measurements. The results presented below are divided into three parts as three different approaches have been considered.

The first part includes only real time RSS values from all access points. This leads to a very quick determination of the position; however, this approach cannot provide the efficient accuracy. The next approach compromises on the time of calculations and the accuracy and uses the measurements of three samples which require six seconds for locating the position. The last approach uses measurements of nine samples which give the best accuracy; however, this method takes eighteen seconds to determine the current position.

The first approach, which measures one instantaneous RSS value, does not provide the satisfactory accuracy (Fig 3.). The analyses have shown that only in 17% of the tested positions the location was determined correctly. Only in 36% of the cases, the position was estimated correctly as being located within a room.

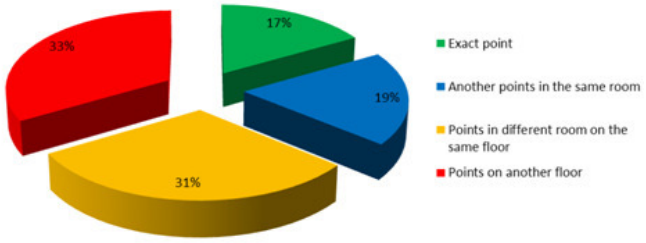

Fig. 3 Accuracy for the single sample approach.

The second approach, which measures three instantaneous RSS values, provides better accuracy (Fig 4). The analyses have shown that in 32% of the tested positions the location was determined correctly and in 53% of cases the position was estimated correctly as being located within a room.

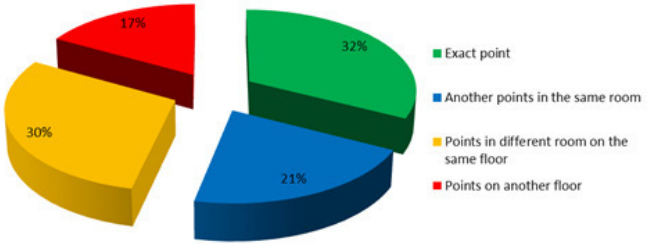

Fig. 4 Accuracy for the 3 samples approach.

The last approach, which measures nine instantaneous RSS values, provides the best accuracy. The analyses have shown that in 48% of the tested positions the location was determined correctly and in 81% of cases the position was estimated correctly as being located within a room.

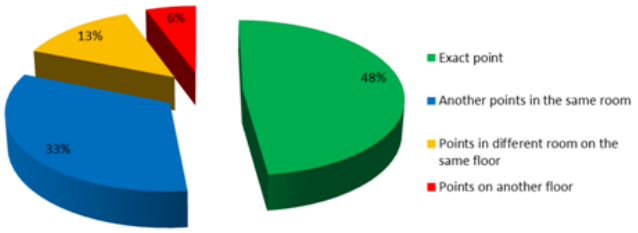

Fig. 5 Accuracy for the 9 samples approach.

V. Conclusions and Future Work

The system tests were performed with three different approaches. They vary in the amount of samples in real time measurements, what results in the difference of position estimation time as well.

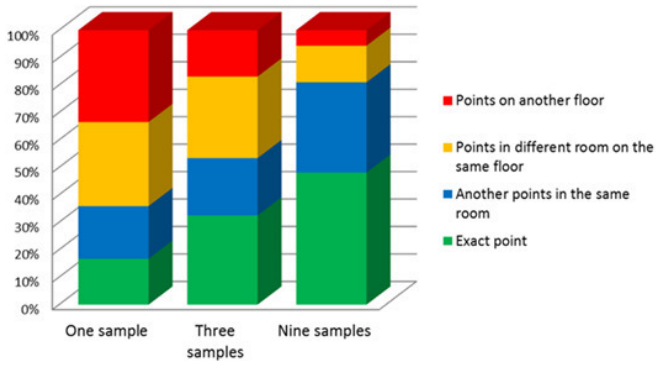

Fig. 4 The comparison of the system performance for the three approaches.

Undoubtedly, the approach that measures 9 samples provides the best accuracy. However, 18 seconds to obtain the position is too long (during this time the real positioning can change). The compromise might be the three samples approach that has the satisfactory accuracy and does not take too long to calculate the location.

The goal of the project was to design the positioning system for mobile devices that would perform satisfactorily in an environment where the Global Positioning System could not operate effectively. The project was successfully implemented using the already existing infrastructure of WLAN networks in a three-storey building. The most suitable approach for WLAN positioning was chosen after a careful literature review. The method implemented in the localization system is the RSS fingerprinting technique based on the nearest neighbor algorithm.

The User Positioning System for Mobile Devices that works on mobile phones with the Android operating system has been successfully implemented. The designed application could work in two modes. The program working in the first mode constructs the database with access points and RSS values corresponding to them. The result of the calibration mode is the database that is a reference map for the operational mode. The second mode operates in the localization mode and compares real time measurements with the database in order to point the current position. The system has been tested in a three-storey building and has achieved the accuracy of about 80% for the localization within 20 seconds with the accuracy to one area of one room (about 15 square meters). The User Positioning System belongs to a minor group of applications which were developed to operate on mobile devices. The implemented system is not expensive and it can become very popular for handheld indoor positioning because nowadays a lot of people have Android mobile phones and the wireless local area networks are becoming more and more common.

Nevertheless, the system implementation could be improved in some steps in order to increase accuracy and effectiveness. Firstly, the accuracy could be improved by implementing more access points in the building. The number of access points will not prolong the time of calibration dramatically but the higher number of access points is, the better quality of signal strength is and, as a result, the better accuracy of the system is. Moreover, the implemented system is not resistant to environmental changes. Each little change in an environment such people moving, doors closing or opening or even furniture moving could dramatically increase the position inaccuracy. The solution could be the creation of a flexible database that would be able to adapt to environmental changes.

Development of a Mobile Application for People with Panic Disorder as augmentation for an Internet-based Intervention

Stefan Kleine Stegemann*, Lara Ebenfeld*, Dirk Lehr*, Matthias Berking†, Burkhardt Funk*
*Leuphana University Lueneburg, Germany
†Philipps University of Marburg, Germany

***Abstract*—Smartphone technology has recently gained attention in the field of E-Mental Health research and mobile applications for measuring health-related aspects as well as mobile mental health interventions have emerged. However, little work has been done on leveraging mobile technology in combination with internet-based interventions. We argue, that mobile applications can not only enrich mental health treatments but also foster the commercial success of E-Mental Health applications. To this end, we have developed GET.ON PAPP, a mobile application for panic disorder that integrates an internet-based treatment into daily life. In this work, we present the development and structure of GET.ON PAPP and a perspective for its evaluation.**

I. Introduction

E-MENTAL Health, the use of information and communication technology to "support and improve mental health conditions and mental health care" [1], has been and still is a growing field in research and practice [2]. One of the most prominent forms of an E-Mental Health application is the internet-based intervention (IBI), the use of web-sites to deliver self- or low-guided psychological treatments over the internet. With the advent of smartphones in the past years, however, researchers recently started to explore the potential of this technology for E-Mental Health [3, 4].

The ubiquitous nature of smartphones makes them ideal for measuring data on health conditions in daily life. To this end, a number of applications have been developed and evaluated. Examples are the MONARCA self-assessment system [5, 6] and the work of Morris et al. on emotional self-awareness [7]. Furthermore, smartphone sensors have been used in order to amend or replace self-reported data with more objective measures [8, 9].

Self-contained interventions are another area where mobile technology is used in E-Mental Health [3]. Examples include mobile interventions for bipolar disorder, schizophrenia and depression [10, 8]. However, to our knowledge, little work has been done on using smartphones in combination with IBIs.

We argue that by combining mobile applications with IBIs, smartphones can be leveraged to overcome limitations of the internet-only approach, thereby integrating the treatment more closely into daily life. This is important not only from a psychological point of view but also from a commercial perspective. In Europe and in particular, in the Netherlands, UK and scandinavian countries, IBIs are currently being integrated into the routine healthcare system. In recent years, vendors have emerged that specialize in development and distribution of E-Mental Health systems. The use of new technologies together with established approaches can make systems more attractive for both, customers who offer mental health services and end-users.

To explore the potential of a mobile application in combination with an IBI, we developed the GET.ON Panik program, a treatment for people with panic disorder with and without agoraphobia. The treatment consists of two parts, an online training that is delivered via the internet-browser and the mobile application GET.ON PAPP that amends the training. In this paper, we present GET.ON PAPP and discuss its foundation, structure, development process and perspective.

The GET.ON[1] project is an international and interdisciplinary cooperation of researchers and practitioners from the Leuphana University Lueneburg, Phillips University of Marburg, VU University Amsterdam and Minddistrict, a Dutch company specialized in the development and distribution of IBIs. The goal of the EU-founded project is to develop, evaluate and disseminate interventions for common mental disorders, including depression, insomnia and panic disorder.

This paper is structured as follows. First, a brief introduction is given into the background of panic disorder and its treatment as well as IBIs and their limitations. After that, the development process and structure of GET.ON PAPP are presented. Following this, we discuss the evaluation perspective of the mobile application and finally, a conclusion is drawn.

II. Background

Panic disorder (PD) is a common and severe mental disorder that belongs to the category of anxiety disorders. People suffering from PD experience recurrent panic attacks, which happen in an unpredictable manner. A panic attack involves heavy body-symptoms such as palpitations, breathing difficulties and dizziness[2]. Because of this, people often fear that they will die which further exacerbates the symptoms. Panic disorder often occurs in combination with agoraphobia, the anxiety about being in places or situations in which help might not be available or from which escape might be difficult. Examples include driving a car, shopping in a supermarket and going

[2]cp. Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) for diagnose criteria

978-83-60810-53-8/$25.00

to the cinema or theater. As a consequence, people tend to avoid such situations and over time, the fear of panic attacks often becomes a central problem because it severely limits their lives. This leads to a high level of distress as well as social and job-related disabilities [11].

Panic disorders are one of the most prevalent anxiety disorders. Goodwin et al. reported (12-month) prevalences between 0.3% and 3.1% for PD with and without agoraphobia in Europe [12]. For 2010, the total economic cost for Europe was estimated to 11,894 million EUR PPP[3] for PD and to 9,634 million EUR PPP for agoraphobia [13].

A. Treatment of panic disorder

Cognitive behavior therapy (CBT) is a commonly used and effective method for treatment of panic disorder [14] that is adapted by the majority of contemporary computer-based treatment programs, not only for PD but also for other mental disorders [15]. In CBT, "patients are trained to collect information in a systematic fashion to offset the influence of maladaptive information-processing strategies and to conduct behavioral experiments to test the accuracy of their negative beliefs" [16].

CBT for panic disorder typically incorporates two central components: cognitive restructuring and exposure exercises. Cognitive restructuring teaches strategies on how to identify and change negative thoughts. Exposure is a technique where people with PD and agoraphobia expose themselves to situations where they fear to have a panic attack. For people with PD without agoraphobia, a method is used where specific exercises such as hyperventilation are carried out in order to trigger body symptoms similar to those that occur during a panic attack. In both cases, it is vital to the success of the treatment that exposures are done frequently and properly.

In addition to these core components, clients[4] are usually encouraged to keep a self-monitoring diary. This not only helps the therapist to give feedback but also increases the client's awareness for panic symptoms and disorder patterns. Furthermore, self-monitoring accounts for the natural human drive for self-understanding [17] and can thereby reinforce a client's involvement with the treatment.

B. Internet-based interventions

An internet-based intervention for a mental disorder is a variant of computer-based psychotherapy [15] that is provided over the internet. In a nutshell, an IBI is similar to a self-help textbook with the content being delivered over the web-browser, usually in an interactive form and enriched with multimedia elements. Participants work through the intervention either completely independent or guided by a coach who gives feedback and motivation [18].

Compared to traditional face-to-face therapy, IBIs are a low-threshold form of intervention that offer high availability at any time as well as anonymity and thus less stigmata. Protection of privacy is another commonly noted strength of IBIs [2, 15].

Psychological research has shown effectiveness of IBIs for several mental disorders, including PD with and without agoraphobia [18, 19]. A couple of online-programs for PD were developed and evaluated in the past years, such as, for example FearFighter[5] in the UK and Panikprojektet[6] in Sweden. Furthermore, IBIs are now gradually implemented in practice as part of the routine healthcare system in Europe. The leading countries in this development are the Netherlands and Sweden but others start to catch up.

C. Limitations of IBIs

IBIs commonly make use of an internet-browser that is running on a stationary computer or laptop to deliver the treatment. This approach is advantageous to serve larger blocks of information as well as for exercises or quizzes where users fill in (textual) answers. The timeframe of a single interaction between an user and an IBI is typically rather long, ranging up to several hours.

While mobile devices can be used to access an IBI on the go, screen size and unstable internet-connections often impose problems. In addition, entering text on a mobile device can be cumbersome as most of them do not have a dedicated keyboard [20]. As a result, IBIs are limited when it comes to supporting clients in their daily life.

While the above can be said for IBIs in general, we identified the following two key problems with respect to panic disorder.

1) In-situ support: Exposure is a notoriously difficult task to perform. Clients not only need to overcome their inner resistance but also carry out the exercises in a specific and prescribed way while at the same time experiencing high levels of anxiety. Although principles and procedures can be described in an IBI, exposure usually happens far away from the computer. As a consequence clients need to memorize and recall what they have to do. In addition, they can not easily verify that the exposure was performed correctly.

2) Self-monitoring: Diaries are already an inherent part of many contemporary IBIs. However, the limited accessibility of these programs requires clients to recall and sum up their panic attacks and anxiety feelings, typically on a day-to-day basis. As a result, a retrospective bias is introduced, which reduces the ecological validity of the diary data [3]. This is not only unfavorable for clients and therapists but also for the researcher who wants to analyze the data.

III. A MOBILE APPLICATION FOR PANIC DISORDER

Smartphones have become increasingly powerful and almost ubiquitously available in the past years. Consequently, they "play a vital role in the practice of medicine today" [21]. In a review on mobile technology in psychological treatments, Heron and Smyth argued that mobile technology is in particular suitable to bring interventions closer to people's daily

[3]Purchasing power parity

[4]In a psychotherapeutic context, people who seek the help of a psychotherapist are commonly referred to as "clients".

[5]http://www.fearfighter.com/

[6]http://www.kbt.info/behandling/

life [3]. To this end, we have build the mobile application "GET.ON PAPP"[7] for people with PD (with and without agoraphobia) to overcome the limitations we identified above by providing a tool that integrates the treatment in their daily life, where panic actually happens. GET.ON PAPP is not designed to be used stand-alone but as an extension to an IBI that structures the treatment and offers information as well as instructions. In doing so, we strive to use both technologies to their potential. For the remainder of this paper, however, we will concentrate on the mobile part only.

GET.ON PAPP is structured into a diary that covers the self-monitoring aspect and an exposure-guide that supports people in performing exposure-exercises. In the following, we describe and discuss the development process, the different parts of the application and the technologies we used for its implementation.

A. Development

GET.ON PAPP was developed in an iterative process, incorporating experts from various disciplines. Each iteration started by creating a paper mockup for a specific function together with psychologists. The mockup was then refined until it represented the functionality to our satisfaction. In the next step, we created a functional prototype that could be executed on a smartphone. After that, the prototype was tested and gradually improved.

Researchers have mentioned the importance of credibility for the adoption of IBIs [22, 23]. While it is unclear if these findings can be generalized to mobile interventions, Fogg argued that credibility is crucial to facilitate behavioral change in general [24]. He defines credibility has the combination of perceived trustworthiness and perceived expertise and highlights the importance of a product's visual appearance for the perceived first-hand and long-term experience [25, 24]. For that reason, we included visual and interaction designers in the team from the early project stages on.

While it was originally planned to also incorporate potential end-users early in the process, it turned out to be difficult to find people who were willing to talk about their experiences with the disorder. Instead, we decided to employ psychotherapists and researchers with experience in the treatment of PD. Furthermore, we conducted regular but informal tests with team members who were not directly involved with the development.

B. Documentation of panic-related events

As mentioned before, self-monitoring is an important aspect in CBT based treatment of PD. To this end, a diary has been created that enables clients to document and view their panic events. This is not only helpful to increase awareness for how, when and where panic attacks develop but also as an introduction to the treatment that encourages people to reflect on their disorder.

The frequency of panic attacks varies greatly between individuals, ranging from few attacks a week to several attacks a day. Some clients do not even have panic attacks but live in a more or less constant fear of an attack. Therefore, we opted for an event-based design for the documentation of panic-related events [26].

We define a panic-related event as either a full-blown panic attack or the feeling of fear that a panic attack may happen in an ongoing situation. To reduce the retrospective bias, clients are encouraged to document these events immediately after their occurrence. Smartphones are ideal for this task because they are accessible most of the time.

Because panic-related events are documented "on the go", an efficient and unobtrusive user interface is required. For this reason, we tried to reduce the information that a user has to enter to a minimum. We discussed the attributes that are required to accurately describe a panic-event with scientists from the field and psychotherapists. As a result, a set of four mandatory items has been developed, which are answered on a Likert-like scale from 1 to 10.

A goal was to make the rather boring task of entering a number more interesting and engaging yet efficient. Based on the single-dimension mood-scale presented by Morris et al. [7], we created a novel input component for entering data on a numeric scale (fig. 1). Users select a value by moving a finger up and down on the display. The number moves with the finger and the intensity of the background color changes in order to provide an additional visual feedback (high values have a high intensity and vice-versa).

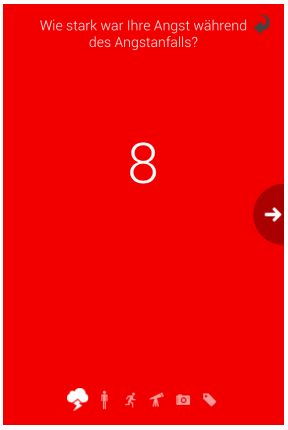

Fig. 1. Entering data on a scale from 1 to 10

To facilitate learning and recognition throughout the interface, we assigned a dedicated color to each question, or more precisely to the concept that underlies a question. For example, the question "How strong was your anxiety during the panic attack?" relates to the concept of anxiety, which is represented in red color. Moreover, the use of colors is not restricted to the diary. Wherever a particular concept appears in the application, the same color is used for it's representation.

We did not do any formal usability testing of the input component so far. However, we conducted a couple of informal tests with PhD-students, asking them to document a panic-event. There was no further information provided on how to

[7]A supercool acronym for GET.ON Panik App

use the component. We observed that when the interface was first presented to the students, it was not immediately clear how to operate it. However, most of them immediately realized the principle when touching the screen and reported that they liked the use of colors. To overcome the initial barrier, we added instructions to the screen which disappear when the user moves the finger. That said, formal usability testing is needed to validate if the design actually works as intended and how it compares to alternative approaches.

Finally, we wanted users to be able to give individual meaning to a panic-related event in a non-prescribed way. We anticipated that some users are more visually oriented while others tend to prefer text. Therefore, we included two additional options in the documentation of events. First, we encourage users to take a photo of either the situation where the event occurred or something that is related to the situation. Second, they may enter textual notes in order to remember feelings or specific aspects of the situation.

C. Visualization of events

To make sense of the past, the diary allows users to browse through panic-related events. For the visualization, we developed a non-technical but more casual approach that is shown in figure 2. Pousman, Stasko and Mateas have discussed the need of casual information visualization for non-work related tasks and populations that are not experts in a domain [27]. To this end, we build on the work of Ljungblad, Skog and Holmquist on ambient information displays [28, 29] and developed a Mondrian-style approach to visualize the four questions that are used to document a panic-related event.

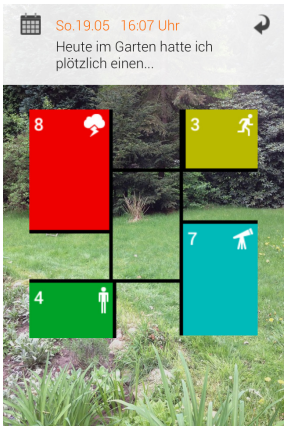

Fig. 2. Mondrian-style visualization of a panic-related event

Four colored rectangles are used to display the information. Each rectangle corresponds to a specific question which is represented by the color and an additional icon. The size of the square as well as the intensity of the color is used to visualize the value between 1 and 10. Apart from aesthetic aspects, this type of display has the additional advantage that users can see the values in relation to each other and thereby identify patterns such as the relationship between anxiety and avoidance. Furthermore, if a photo has been taken, it is displayed as background image to facility fast recognition of the documented event.

In their work on informative art, Ljungblad, Skog and Holmquist reported that their Mondrian-style display created an aesthetic experience for viewers [28]. However, they also noted that, without further information, no one was able to understand how the display actually worked. Some did not even recognize the artifact as an information display at all. That said, with a brief introduction, most people quickly grasped the underlying concepts. We got similar results when presenting our display to students, although at least some candidates interpreted it correctly without any help. This might be tributed to the fact that the context of the display was clear and that the amount of visualized information is rather small in comparison to the work of Ljungblad, Skog and Holmquist. However, in order to ensure that people understand the display properly, we give them a brief introduction.

D. Daily summaries

Fogg notes that giving users ongoing information about their state and progress on a task can help to stimulate their intrinsic motivation [24]. Therefore, we wanted to give clients the ability to document their progress and to be able to track their personal development over the course of the treatment. Furthermore, the development of a client is important not only from a client's perspective but also from a researcher's as well as from a therapist's point of view.

Panic-related events are not suitable to document progress because frequency as well as severity of attacks varies over time, even for a single person. Apart from this, it may be the case that a client has more frequent and more heavy panic attacks at the beginning of the treatment. From a therapeutic point of view, however, it is important how much the PD limits a client's life. To this end, the general level of anxiety as well as the degree of avoidance [8] are relevant variables. Building on this idea, daily summaries have been added to GET.ON PAPP in order to measure these variables not at the event but at a daily level.

A fixed-schedule diary was used to implement daily summaries [26]. Clients are asked to choose a fixed time each day, preferably in the evening, where they reflect on the past day and fill in a daily summary. In order to visualize a client's development and progress, the application can plot the daily summaries over time. Furthermore, the plot illustrates how exercising can reduce panic symptoms by depicting for each day how many exposure exercises have been performed.

E. Guiding exposures

When technology is used as a tool that leads people through a process which would otherwise be difficult or impossible to perform, it can support the change or adoption of a desired behavior [24]. As mentioned above, exposure exercises are the most difficult part of a treatment. Motivating people to confront themselves with a threatening situation or body

[8]Avoidance refers to the fact that people with PD and agoraphobia often avoid situations in which they fear to have a panic attack.

symptoms is difficult. We argue that by creating a tool that guides users and offers feedback, we can lower the barrier, thereby making it easier to persuade people to actually face exposure tasks. Therefore, we integrated an exposure guide into GET.ON PAPP.

The exposure guide supports a) in-vivo exposures, where people approach a situation in which they fear to have a panic attack and b) interoceptive exposures, where body symptoms are triggered by carrying out body-exercises. The guide is constructed as a wizard which leads the user through a sequence of steps while at the same time offering instructions and orientation. In addition, at certain points, the user is asked to answer questions in order to measure if the exposure has been performed correctly (for example the level of anxiety, the degree of avoidance and the severity of body-symptoms). For the sake of consistency, the same input component as in the diary is used to answer those questions.

Therapists noted that when they perform exposures together with clients in a face-to-face setting, people are sometimes so proud of what they achieved that they ask for a photo of the situation. Consequently, we added the ability to take a photo with the smartphone after an in-vivo exposure is completed. Users can view these photos in a gallery together with the feedback and a description of the situation. We hypothesize that taking photos and looking at them retrospectively can act as a self-rewarding mechanism and hence increase motivation for the treatment.

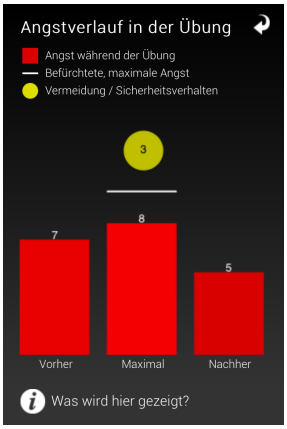

Fig. 3. Feedback for an in-vivo exposure

The feedback after an (in-vivo) exposure allows people to see if the exposure worked and to reflect on the situation (fig. 3). For example, it is important to stay in the situation until anxiety begins to drop without using any avoidance strategies. Furthermore, users can validate if their belief about how much anxiety they will feel was correct.

F. Cross platform development

A common setting for the evaluation of mobile applications in the field of e(Mental)Health is to conduct a study and hand out mobile devices with the pre-installed application to the participants. Examples for this approach are the work of Morris et al. [7] and Cafazzo et al. [30]. On the contrary, we want to reach people who are experienced with smartphones and thus most likely already own such a device. We argue that giving them a second phone is likely to harm the adoption of GET.ON PAPP because carrying around a second smartphone for a sole application is not very convenient. As a result, the ecological validity of the evaluation could be reduced. Consequently, we decided that people will use their own smartphones to execute GET.ON PAPP. To reach a larger population, the application has been developed for the two currently most widespread mobile operating systems, Google Android and Apple iOS.

Developing a mobile application for multiple platforms is challenging because each vendor has its own, very specific, development kit and environment [31]. As a consequence, development expertise for each platform is needed and implementation time is effectively doubled. Recently, practitioners as well as researchers have advocated the use of web technology as an alternative for the development of cross-platform mobile applications [31, 32]. Frameworks such as PhoneGap[9] carry this method even further by providing a runtime environment in which a web application is hosted inside a native app and thus pave the way for an almost native user experience.

Despite known performance issues [33], we employed the PhoneGap framework for the development of GET.ON PAPP. The use of web technologies not only enabled almost trouble free deployment on both platforms but also supported the rapid prototyping approach we used for development. That said, we experienced indeed a number of performance-related problems, for example when displaying photos that have been taken with the smartphone camera or transferring data to the server. However, we were able to solve these problems by implementing native plugins for each platform. The PhoneGap framework offers a dedicated API for this purpose and we consider the combination of a shared, web technology-based codebase with a few, specialized native plugins as ideal.

A major problem was, however, not related to performance but to the user experience. Creating a true mobile feeling with web technologies can be cumbersome, especially when it comes to gesture detection. For example, the swipe detection mechanism implemented in frameworks such as jQuery Mobile [10] turned out not be very robust. As a result, swipes where not properly detected on some devices or versions of the operating system. Another example is a delay between the user tapping on the screen and the "click"-event being fired, which resulted in a rather sluggish interface feeling. To work around these problems, we had to implement our own event handling system. Nevertheless, we would still recommend the web-based approach if the performance issues reported by Corall, Sillitti and Succi [33] are taken into account.

[9]http://phonegap.com
[10]http://jquerymobile.com

G. System structure

Figure 4 gives an informal overview over the system structure of the GET.ON Panik program. As mentioned above, the program is structured into an IBI and GET.ON PAPP, the mobile application which is presented in this paper. During the treatment, a client is guided by a coach who gives feedback and offers help with problems. For the feedback, the coach uses data from both, the IBI and the mobile application.

The IBI is developed and hosted inside a commercial content-management system that is provided by Minddistrict. Apart from serving the intervention content, it also offers facilities for secure conversations between coach and client.

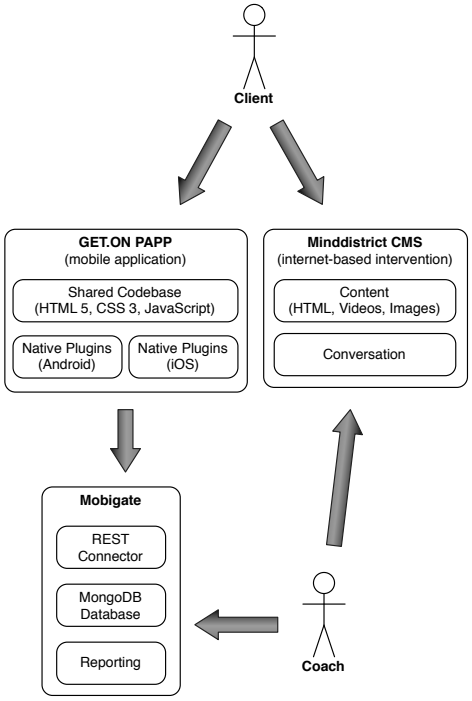

Fig. 4. Structure of the GET.ON Panik program

The mobile application periodically uploads the data entered by clients to the Mobigate backend through a REST interface which is implemented in Python using the flask micro framework[11]. The Data is stored using MongoDB, a document-oriented database from which it is accessed by a component that generates reports for the coach.

We intentionally kept the system structure simple, especially with respect to the integration of the mobile system with the CMS. In the context of this project, it was not feasible to implement an interface between the two systems for both, organizational and security reasons. However, for the system to be used in practice, closer integration would be necessary.

IV. Perspective evaluation

We currently undertake a feasibility and acceptance study (n=10) of the GET.ON Panik program that covers the IBI as well as GET.ON PAPP. Apart from getting first insights into the clinical effectiveness, at the end of the study, we will carry out a semi-structured interview with participants about their usage of GET.ON PAPP. Our goal is to investigate how the mobile application is accepted as well as potential technical problems and opportunities for improving the application. While the study did start only recently, first comments from participants on GET.ON PAPP have been positive. However, at the time of this writing, we cannot make any substantial statement about how the application is received.

After incorporating feedback from the feasibility study, a randomized controlled trial (RCT) will be conducted (n=90). The primary outcome of this RCT is the clinical effectiveness of the GET.ON Panik program. However, in the course of the trial, we plan to perform an in-depth evaluation of the usability of GET.ON PAPP. To this end, the System Usability Scale [34] will be used as well as usability data collected from the mobile application [35]. In addition, we strive to carry out a systematic investigation of the acceptance of GET.ON PAPP using the Technology Acceptance Model in a longitudinal study [36].

Finally, we plan to conduct a formal usability test for the Likert-like scale input component, in particular, to evaluate its efficiency and engagement potential. Therefore, we will carry out an experiment to compare our input component with more traditional approaches. In addition, we want to know if and how the use of colors influences a user's input.

V. Conclusion

The ubiquitous nature and extended capabilities of contemporary smartphones have made them attractive for researches from the field of E-Mental Health, not only to measure health behavior but also to integrate interventions into the daily life. Furthermore, the use of mobile technology can make E-Mental Health more attractive for end-users, thereby fostering its dissemination and implementation in practice.

To combine the potential of mobile applications with the advantages of traditional internet-based interventions, we developed the GET.ON Panik program which integrates an IBI with a mobile application. The program can be used by people with panic disorder with and without agoraphobia.

In this paper, we presented the mobile application of the GET.ON Panik program, GET.ON PAPP. The application was developed in an iterative process, incorporating experts from psychology, computer scientists and visual designers. In order to target Android and iOS systems, a cross-platform approach based on web-technology was used. We outlined how the application was designed to integrate the treatment into daily life while at the same time striving to engage and motivate users.

Future research will show if GET.ON PAPP is accepted by its users and if the approach is as beneficial for the treatment as we believe. To this end, a feasibility study has been started and a randomized controlled trial will follow. We hope that systematic studies on usability and technology acceptance will contribute to our understanding on the potential of mobile technology in E-Mental Health.

***Abstract*—This paper presents the design, implementation and user study of *Vertoid* — a mobile system for providing context-aware cues that help users limit domestic greenhouse-gas emissions. We have designed an Android-based mobile application that provides user with tips on simple eco-friendly actions in relevant locations. We then conducted a medium-term field study to evaluate the system. Our study shows that while context-aware cues have the potential to be a useful way to deliver customised content, they may as well provide unnecessary distractions. Based on the results of our study, we discuss how location awareness can be used to support persuasive systems and outline several design considerations for providing context-aware cues.**

I. Introduction

MANY researchers share the belief that technology can be effectively used as means to persuade users to change their habits and alter current behaviours [1]. Emerging technologies will try to persuade us to enjoy a healthier lifestyle and buy products from preferred suppliers. In our work, we aimed to investigate if this kind of potential can be used to support a more social cause where direct impact is harder to observe. Inspired by many social campaigns by those battling for reducing greenhouse gas emissions, we investigated that problem in detail. A unique feature of this particular case is the fact that only a large collective of users over a long period of time may make an impact. We have decided to explore possible answers to that challenge by designing a mobile system that provides information on how to limit greenhouse gas emissions only in locations where users can affect the emission levels.

In the remainder of this paper, we discuss related research and describe *Vertoid*'s design process. We then provide details on how the system was implemented and evaluated in a user study. The main contributions of our work include: the design and implementation of a persuasive mobile application for limiting greenhouse gas emissions, an exploratory user study of the application and a set of design notes that can be used with future systems.

II. Related work

Several past projects have explored the use of mobile devices in persuasive systems. Consolvo *et al.* [2] pointed to the unexplored potential of mobile phone displays for persuasive use. They investigated a system called *UbiFit* that facilitated physical activity self-monitoring. Their results show that a personal mobile display can increase awareness and support positive lifestyle changes. Contrary to *UbiFit*, in *Vertoid* we aim to avoid introducing additional devices to be carried, but try to cater to users already carrying a smart phone on a daily basis. In a similar vein, Gasser *et al.* [3] compared mobile and web-based activity and nutrition monitoring systems. While the study found no significant differences in the effectiveness of the systems, a significant advantage of an enhanced user experience was observed in favour of the mobile application. We aim to build on that potential and explore the mobile setting as a change enabler.

A critical design perspective on designing for self-reflection on the go was presented in *Fit4Life* by Purpura *et al.* [4]. Similarly to *Vertoid*, this project aims at promoting social change through small, individual steps. *Fit4Life* aims at supporting individual healthy behaviours to stop the spreading of obesity in the population. Similarly, *Vertoid* employs a system of persuasive messages to stimulate the user and provide guidelines on proper behaviours. As *Fit4Life* is mostly a conceptual prototype it uses a wide range of sensing technologies to provide context-aware cues. As *Vertoid* uses everyday smart phones, its sensing capabilities are limited, but it follows a similar design pattern. However, it is significantly different from *Fit4Life* as it addresses a problem where positive actions are harder to observe. An analysis of the literature available shows that most persuasive mobile applications have focused on improving health and fitness. Several other examples worth noting include: Exergaming [5] where a mobile app encouraged youngsters to exercise; MONARCA [6] which was used for helping patients with bipolar disorder; and CAMMInA [7] which promoted physcial activity among elders.

Gabrielli *et al.* [8] conducted design studies for a mobile application aimed at supporting sustainable transportation solutions. Their investigation included users that are not motivated by environmantal factors. *Vertoid* is aimed at users that are aware of the global warming problem and attempts to improve overall attitudes and promote principles rather than focusing on specific point-to-point transport tasks.

Creating user engagement is also an emerging theme in recent research. As Rogers [9] suggests, sometimes designers should sacrifice seamless usage to create excitement and cause

978-83-60810-53-8/$25.00

change. in *Vertoid*, we try to build on that notion and determine if messages provided in between everyday actions can be an effective persuading factor and, potentially, produce a long-term effect. This is also in line with an emerging trend for promoting engagement through mass-scale easy prototyping with high participation of the user base [10].

III. Design

We have endeavoured to design a system that would help the users make environmentally-conscious decisions when performing everyday tasks. We have decided to utilise the smart phone as the tool to achieve our goal as many users already carry these devices at all times. Recent analyses have proven that smart phones have the potential to create new habits consisting of brief usage sessions [11]. In principle, our goal was to capitalise on that potential by establishing a set of triggering contexts (in our case driven mainly by location) that would promote the desired behaviours. We have conducted semi-structured interviews with potential users and constructed severla user journeys and personas to aid the design.

To engage the user in environmental activities, Vertoid uses a set of environmental challenges that suggest possible actions that might help reduce greenhouse-gas emissions. Location tagging assures the challenges are posted at appropriate locations. The tasks may range from simple ones, like replacing a light bulb, to more complicated, like replacing the furnace filter. Whenever possible, a specific amount of carbon dioxide that can be saved by completing the challenge is indicated. Some challenges concern changing habits and others are designed to incline the user to make a single contribution. Each task is associated with a specific location type. Our aim was to increase the chances for an immediate completion of the tasks by asking the user to manipulate objects in their direct physical proximity.

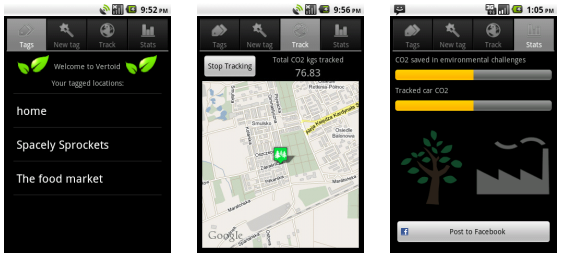
The application keeps track of the declared contributions and can always provide an overview of the current progress of the user. The users can also use the phone to track the carbon dioxide produced during car travel by activating *Vertoid* while driving. The personal statistics are also easy to share on social networks.

IV. Implementation

In order to evaluate the *Vertoid* concept, a high-fidelity prototype was implemented on the Android mobile platform. Here, we present the key features of *Vertoid*.

The tag list (Figure 1(a)) — Technical limitations require the users to declare their home and work locations as well as public places they frequent. This is needed only once. The main purpose of the list is to enable the user to verify which locations have already been tagged. There is a possibility to delete a given tag by using the context menu.

The map view (Figure 1(b)) — this screen enables recording carbon dioxide emissions while driving. The current position of the user is displayed on a map and tracking can be toggled on and off.



(a) The tag list screen (b) The map view during car tracking (c) The statistics screen

Fig. 1. Screen shots showing the most used screens in *Vertoid*

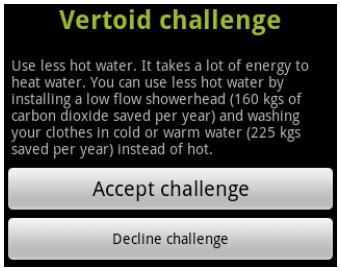


Fig. 2. The challenge prompt. *Vertoid* triggers environmental challenges based on user location

The statistics screen (Figure 1(c)) contains a visualisation of all the data accumulated during the usage of *Vertoid*. The user's status as to saving and generating carbon dioxide is presented as progress bars and waning pictures of a factory and a tree. A Facebook share button is provided.

Environmental challenges are *Vertoid*'s core feature. Whenever a user enters a location defined previously, a *Vertoid* notification appears in the Android notification panel. When reviewed, the notification scales up to a challenge prompt (an example is provided in Figure 2). The user can accept or reject a given challenge. The appearance of a new challenge is signalled by a vibration and challenges appear only once per visit to a location.

V. Evaluation

A. Methodology

We have conducted a limited-scope field study with 16 (9 male and 7 female) participants who were asked to try using the application in their everyday lives. Study subjects were recruited on a voluntary basis and consisted mainly of students. We looked for regular smart phone users already familiar with the Android operating system who expressed interest in actions against global warming. A detailed demographic profile of the participants is presented in Table I. The first user evaluation activity was conducting semi-structured interviews with all the participants to ensure their prior familiarity with smart phones and the intent to pursue environmental activities to some extent. The inteviews included a section where we discussed everyday actions and their impact on global warming. While the participants were quite enthusiastic about helping the

TABLE I
BASIC INFORMATION ON THE PARTICIPANTS AND THE STUDY. WE ASKED THE PARTICIPANTS TO SUBJECTIVELY RATE THEIR SMART PHONE USAGE FROM 1 — VERY SELDOM TO 5 — MORE THAN 10 TASKS PER DAY

Property	max	min	$mean$
Age [years]	33	19	24.73
Usage duration [weeks]	8	4	5.27
Smart phone usage [see caption]	5	3	4.10

common cause of reducing greenhouse gas emissions, their awareness to what one can do to help was rather limited. This created an opportunity for exploring *Vertoid*. We also recorded basic demographic data on the participants. We have then installed the application on the users' personal Android phones and provided a brief overview of the functionality with a practical walk through. Our initial concern was that the usability of the program might have affected its persuasive potential. We used expert evaluation from the start of the development, but a simple user test was required. Consequently, each user was asked to complete a simple questionnaire based on Nielsen's usability heuristics [12] after two weeks of use. We asked the users to rank the qualities of the application on a 1 to 5 scale. Short descriptions of the qualities were provided. We concluded that the usability of the application did not affect its possible impact as the users rated Vertoid (on average) 4.10 for clarity, 3.82 for appearance and 4.28 for error handling. We believe that these ratings are satisfactory for a prototype application. The participants had the opportunity to use *Vertoid* on their phones for periods from 4 to 8 weeks (the varying period lengths are a result of limiting the intrusiveness of the study by avoiding scheduling conflicts).

After the unsupervised usage period, the participants were invited for an interview once again. As our investigation was largely exploratory, we looked mainly for qualitative feedback. However, we gathered input on the frequency of use. In our preliminary talks, we have determined that some of the participants were reluctant to share their logged data as it contained their frequented location. This is the motivation behind relying on reported usage accounts rather than logging.

In order to evaluate the environmental awareness change caused by Vertoid, we included questions about green living in the interviews both before and after using the application. In the initial talk, we included both straightforward questions (*e.g.* "Do you try to maintain a sustainable lifestyle?") and indirect measures of green living ("How many incandescent light bulbs are there in your house?"). We asked similar indirect questions in the post-usage interview.

B. Results

Overall usage frequency varied significantly among participants. On average participants reported using *Vertoid* $\mu = 4.18$ times in a week with $SD = 2.36$. Such a discrepancy prompted us to investigate why some of the users refused to use *Vertoid* regularly. In Figure 3 we show usage frequency distribution among the participants.

Those of the participants who reported using the application

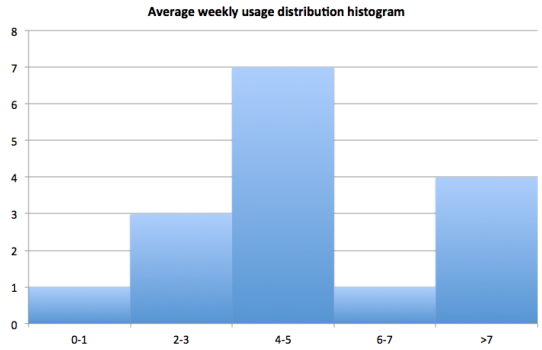

Fig. 3. The histogram shows participant counts and usage frequency intervals in times used per week for the field study.

only sporadically described the experience as interesting, but lacking the impact potential. *"A few lines of text cannot convince me to do additional housework."* remarked one participant. Two participants did not tag their frequented locations citing privacy issues, so they only received notifications in a predefined set of locations shipped with the installation. Even though 7 (33%) of the users explicitly stated that they did not use the application more than once a week, they still claimed that they wanted to improve their daily routines to make their lives more sustainable. On the other hand, those who reported using *Vertoid* regularly noted that the number of challenges was quite high (*"I never realised you could have so many tips on green living"*). All of the users who read at least one of the challenges (95%) reported learning new facts through the challenges. Those who used location tagging reported that it worked properly and the triggered challenges were relevant to the space. Accounts of the shopping experience with *Vertoid* provided us with additional insights. It surfaced that the coarse positioning was inadequate in the shopping areas while it worked at home and at work. For example, users were annoyed to receive suggestions about buying local produce once they have passed the vegetable section, but they did not mind being reminded to change to fluorescent light bulbs while not within reach of a lamp. Generally, we can conclude that the cues were quite successful when they concerned short, immediate actions performed with objects close to the user, *e.g.* choosing nationally locally meat.

We have observed a difference between declared environmental engagement and real actions taken everyday. Users often overestimated their efforts in living a green lifestyle despite being unaware of the simple actions that help. In the post-usage interview, we noted a slight increase in the knowledge of easy ways to reduce greenhouse gas consumptions. Figure 4 illustrates the subjective and objective pre-study awareness level as measured by our questionnaires and the results of a similar objective test after using *Vertoid*. We believe that the observed increase in awareness may suggest that mobile contextualised cues have cause a long-term effect.

VI. DISCUSSION

Overall, we believe that our exploratory field study confirmed the persuasive potential of location-aware mobile cues

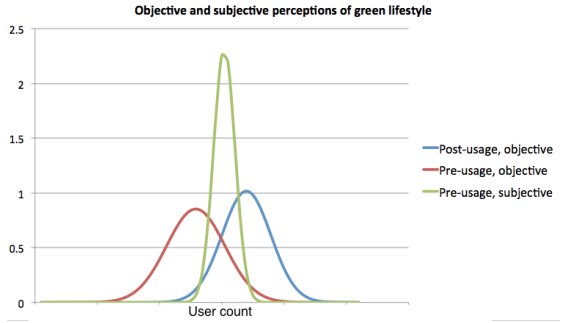

Fig. 4. User environmental awareness levels as measured by our questionnaire. The plot contains values declared by the participants and pre- and post-study results obtained with our questionnaire.

for stimulating environmental awareness. Those of the participants who decided to use *Vertoid* regularly reported positive experiences and were inclined to put some of the suggestions into practice. This was not the case for those using the application only sporadically. We can attribute this difference to the fact that *Vertoid* may constitute a significant intrusion to everyday life that must be consciously accepted by the user. As a consequence, we may speculate that context-aware mobile cues may affect everyday acrtion to a degree that requires conscious acceptance of the intrusion prior to delivering the cues, *i.e.* they are effective for users who want to change, but seek the means to achieve the goal. In a way, the field study differentiated between those who spoke of environmental matters as this was "a good thing to say" and those who were ready to take action.

We have consciously employed a user-driven design approach in creating *Vertoid* in order to embrace the practicality of everyday lives and focus on user accounts. This is supported by the fact that most known theory-driven methods revolve around health and well-being (discussed to a large extent in [13]). Using a design-oriented approach affects our insights as to the long-term effect of the application. The long-term experience of using *Vertoid* is a complex research question due to the mobile field setting and we cannot use theoretical means for modelling the answer. We have completed an exploratory study that clearly confirms the potential of mobile cues to become an effective behavioural change technology. Qualitative feedback from the participants seems to confirm that some of them learnt new ways to lead a more environmentally-friendly life and integrate some of the suggestions into everyday habits. Thus, we see an emerging need for studying this research context further to clearly determine if providing contextualised suggestion can lead to real changes in patterns of daily life. Long-term field studies are required, but these will only be possible if sensing techniques that will enable more accurate context recognition are made available. Recent advances in embedding information in physical objects like near field communication can be explored for opportunities to provide more relevant suggestions.

VII. Conclusions

In this paper we have presented the design, implementation and an exploratory field study of a mobile application that investigates the potential of contextualised mobile cues for persuading users to lead a more environmentally-friendly lifestyle. We have implemented a high-fidelity prototype and ran a field study that resulted in a better understanding of the persuasive effect of the application. *Vertoid* received positive feedback from most of the 16 study participants. Usage intensity varied significantly, but those participants who reported using the application on a everyday basis concluded that it was a useful addition to their everyday routines and created new opportunities for a greener lifestyle. We have observed that the location-based challenges functioned satisfactorily at home and at work. We see new potential emerging from increased accuracy at shopping places for an enhanced experience. We hope to explore the potential of context-awareness for persuasion further by employing more advanced sensing methods and long-term studies.

Software Systems Development & Applications

SSD&A is a FedCSIS conference area aiming at integrating and creating synergy between FedCSIS events that thematically subscribe to the discipline of software engineering. The SSD&A area emphasizes the issues relevant to developing and maintaining software systems that behave reliably, efficiently and effectively. This area investigates both established traditional approaches and modern emerging approaches to large software production and evolution. Events that constitute SSD&A are:

- ATSE'13 – 4th International Workshop Automating Test Case Design, Selection and Evaluation
- IWCPS'13 – International Workshop on Cyber-Physical Systems
- PBDA'13 – Performance of Business Database Applications
- WAPL'13 – 4th Workshop on Advances in Programming Language

4th International Workshop Automating Test Case Design, Selection and Evaluation

TRENDS such as globalisation, standardisation and shorter lifecycles place great demands on the flexibility of the software industry. In order to compete and cooperate on an international scale, a constantly decreasing time to market and an increasing level of quality are essential. Software and systems testing is at the moment the most important and mostly used quality assurance technique applied in industry. However, the complexity of software systems and hence of their development is increasing. Systems get bigger, connect large amounts of components that interact in many different ways on the Future Internet, and have constantly changing and different types of requirements (functionality, dependability, real-time, etc.). Consequently, the development of cost-effective and high-quality systems opens new challenges that cannot be faced only with traditional testing approaches. New techniques for systematization and automation of testing are required.

Even though many test automation tools are currently available to aid test planning and control as well as test case execution and monitoring, all these tools share a similar passive philosophy towards test case design, selection of test data and test evaluation. They leave these crucial, time-consuming and demanding activities to the human tester. This is not without reason; test case design and test evaluation are difficult to automate with the techniques available in current industrial practice. The domain of possible inputs (potential test cases), even for a trivial program, is typically too large to be exhaustively explored. Consequently, one of the major challenges associated with test case design is the selection of test cases that are effective at finding flaws without requiring an excessive number of tests to be carried out. This is the problem which this workshop wants to attack.

This workshop will provide researchers and practitioners a forum for exchanging ideas, experiences, understanding of the problems, visions for the future, and promising solutions to the problems in automated test case generation, selection and evaluation. The workshop will also provide a platform for researchers and developers of testing tools to work together to identify the problems in the theory and practice of software test automation and to set an agenda and lay the foundation for future development.

Topics

Topics include (but are not limited to):

- techniques and tools for automating test case design:
  - model-based,
  - combinatorial.based,
  - optimization-based,
  - etc.
- Evaluation of testing techniques and tools on real systems, not only toy problems.
- Benchmarks for evaluating software testing techniques

Requirements on automatically generated random test cases

Thomas Arts
Quviq AB

Alex Gerdes
Quviq AB

***Abstract*—Developing, for example, a simple booking web service with modern tools can be a matter of a few weeks work. Testing such a system should not need to take more time than that. Automatically generating tests from specified properties of the system using the tool QuickCheck provides professional developers with the required test efficiency. But how good is the quality of these automatically generated tests? Do they cover the cases that one would have written in manual tests? The quality depends on the specified properties and data generators and so far there has not been an objective way to evaluate the quality of these QuickCheck generators. In this paper we present a method to assess the quality of QuickCheck test data generators by formulating requirements on them. Using this method we can give feedback to developers of such data generators in an early stage. The method supports developers in improving data generators, which may lead to an increase of the effectiveness in testing while maintaining the same efficiency.**

I. Introduction

THIS paper provides a solution to a problem originating from the use of property-based testing of a simple, but realistic web service developed and used by a telecommunication company. Property-based testing [1] is a technique with which one describes properties of a software system using QuickCheck. QuickCheck has many implementations, for example [2], [3]. The general methodology is that one writes properties of the software under test, from which QuickCheck automatically generates test cases to validate these specified properties.

It has been shown that property-based testing increases efficiency and effectiveness of software testing [4]. Prowess [5], a recent EU STREP project, addresses the challenge to reduce time spent on testing, whilst increasing software quality, in order to quickly launch new, or enhancements of existing, web services and internet applications. In this paper we do not evaluate property-based testing, but focus on one particular challenge in using this technique. The use of property-based testing requires the definition of data generators that control QuickCheck's random data generation. There are many ways to define such data generators, and it requires some skills and experience to define a data generator with good data distribution. We explore how we can help developers to measure the quality of their data generators.

A danger in using QuickCheck is that we no longer see the generated test data. In fact, we would not want to see it, because QuickCheck can generate many test cases. As a result, we may be tricked into a false sense of security by a large number of passing tests, but fail to notice that the distribution is badly skewed. Even if we observe it by using QuickCheck's possibility to collect statistics on the test data, we would need an expert to judge whether the provided data is good test data.

We address the manual interaction of judging test data by capturing the expert knowledge in formal requirements. These requirements are used to automatically assess the quality of the test data generators. In this way, the generators can be developed with limited involvement of experts.

A clear example of the problem of judging the quality of data generators came to our attention when testing a web service created by a telecommunication company. Telecommunication systems often use special purpose hardware, which is rather expensive to build. This raises a cost issue for testing such systems; unlike commodity PCs, one cannot simply put as many machines in a test lab as one would like to. Hardware becomes a resource and more efficient use of this resource lowers the total production cost. When sharing resources, one needs a booking system. In our case, the interoperability requirements were to fit the already in-house built continuous integration and other test and deployment tools. Based on these specific requirements and experience with purchasing this kind of heavily integrated software in the past, this booking system was decided to be build in-house by spending a few weeks of effort. This resulted in a simple web service used by several sites in the world described in more detail in Sect. III.

Unit level testing of this system was performed following the existing literature [6], [7] and revealed that it is hard to judge the quality of the generated test cases. One can be mislead in believing that the system is well tested, although the randomly generated test cases do not cover the interesting test cases. We identified the need for assessing the quality of the generated test cases. In Sect. V we describe how we can express requirements on QuickCheck generators that we use to assess the quality of the generated test data.

After successfully using our method in this proprietary first application, we have evaluated the method in a different context. We have used the method to asses the data generators that we use to test our second application: the open source scheduling web application Dudle[8]. In Sect. VI we describe the requirements with which we validated the data generators for testing Dudle.

Although this paper describes the application of our method for two particular applications, the techniques we describe for

Partially supported by the EU STREP project Prowess, grant 317820

978-83-60810-53-8/$25.00

formulating requirements on generated test cases are generally applicable to many applications of this kind.

II. QUICKCHECK

QuickCheck [2] is a tool that tests universally quantified *properties*, instead of single test cases. QuickCheck generates random test cases from each property, tests whether the property is true in that case, and reports test cases for which the property fails. QuickCheck also "shrinks" failing test cases automatically, by searching for similar, but smaller test cases that fail as well. The result of shrinking is a "minimal"[1] failing test case, which often makes the root cause of the problem easy to find.

The original Haskell QuickCheck has inspired a number of different versions for a wide range of programming languages such as C++ [9], Java [10], or ML [11]. The work in this paper is based on the use of QuviQ QuickCheck. QuviQ QuickCheck[2] [3] is a commercial application that includes many advanced features, such as model-based testing using a state machine model [12]. State machine models are tested using a QuickCheck library, which invokes call-backs supplied by the user to generate and test random, well-formed sequences of API calls to the software under test.

An example of a QuickCheck property is shown below. This property is used to test a timeline datatype. A timeline is considered an ordered list of intervals and an interval is an ordered pair of dates. The property uses data generators for an interval (`interval()`) and for a timeline (`timeline()`). The software under test provides a function `add` that, given an interval and a timeline, should add this interval to the timeline, provided the interval does not overlap with an already existing interval. After successfully adding the interval, it should be a member of the newly created timeline.

```
prop_add() ->
  ?FORALL({I, T},
          {interval(), timeline()},
     begin
       case catch add(I, T) of
           {'EXIT', {overlap,_}} ->
             is_overlap(I, T);
           NewT ->
             member(I, NewT)
       end
     end).
```

The functions `is_overlap` and `member` are provided by the software under test as well.

At a unit testing level, one could express a number of such general properties for API functions. This would already be effective in finding a number of defects, but the problem is that it is hard to know when one has provided enough properties to cover the implementation. This problem has been addressed in literature [6] for datatypes. Based on this approach, the solution for the timeline example would be: create a model implementation, a generator for a timeline in which all possible constructors are used in the generation, and one property per operation. This solution, however, does not address the problem of generating data with a good distribution.

Let us consider how to write data generators for an interval and a timeline, which are used in the property above. A simple way to construct a timeline would be to generate a random number of intervals and put those in a timeline. If an interval consists of two completely random dates, the first less or equal to the second, then the size of the interval may be huge and the possibility to get overlapping dates in a timeline increases quickly. In this case, generating a timeline becomes problematic, since it must not contain overlapping intervals. We therefore should put the generation of intervals and dates under control and steer it in the right direction. For example, if we only randomly pick the first date and then add a random (small) number of days to this date to generate an interval, then we may end up with timelines that contain far more intervals. But the possibility of negative testing, i.e., testing that overlapping intervals are rejected, decreases.

Using QuickCheck, one needs to control the randomness in the generators. The problem we address in this paper is *not* to come up with different generators that are better or worse for certain kind of testing, the problem is to know whether the generated test cases provide a good coverage of the things you want to test.

III. APPLICATION 1: BOOKING WEB SERVICE

The booking web service is a tool used internally within a testing organisation at a telecommunication company to manage and enable efficient sharing of hardware equipment. Specialised hardware in the telecommunication industry is usually associated with profound costs, and efficient sharing of those resources is fundamental to achieve a cost-effective environment. It is also becoming more commonplace to configure larger networks of nodes. Those are setups that take longer time to install and configure, and re-using them between teams saves a considerable amount of time for testers.

The web service serves two main use cases with different needs: manual use of the test equipment and automatic use of the test equipment. In the first use case, engineers want to search the labs for hardware that they need for their tests. When they find what they need, they reserve the hardware for some days or a couple of weeks. Engineers can return to the service for additional information or to extend their bookings. The second use case is a fully automatic use of the test equipment during the continuous integration process. Every time a new software package is delivered, a few different sets of suites are run, organised as short, medium, and long term, each suite defined to run on a specific network setup. Every time this activity starts, the web service will be queried for available hardware of the proposed topology. Any network that contains this topology is accepted, and that network will be configured to disconnect the unwanted hardware. All networks not containing the proposed topology will not be considered. If there are no networks available that satisfy the request, then

[1] In the sense that it cannot shrink to a failing test with the shrinking algorithm used.

[2] We use QuickCheck from here on to denote this version

continuous integration will pause for some time and retry again some time later.

The web service is built in Erlang [13], based on a Mnesia database, and a YAWS front-end [14]. At the core of the application it uses a timeline data structure to manage bookings. This data structure represents a calendar in which certain intervals are blocked (the days that equipment is booked).

Keeping an efficient regression suite is important. Implementing a small booking system is a relatively small task compared to implementing other telecommunication software. It took less than five weeks to implement the first version of the functionality. However, as the system evolved over time, as is common in industry, it had to be adapted to new and changing requirements many times over. The first implementation, for example, was used with a single lab only, having users all at the same location. The system today has evolved and users can now be found in a handful of locations around the world. The software has had to retain its integrity over several adaptations like this.

Even though these small scale tools are not business critical, the consequences for an organisation can still be severe when they malfunction. In the case of the booking web service, it would have only modest effects on the engineers since their sole use of it is to find and book new equipment. The already booked nodes will not be affected, and thus tests can be carried on as normal. However, the global usage puts stress on the availability, and small errors at any time will most likely create annoyances or delays for someone, somewhere.

The effects are more severe for the automatic testing since it is continuously dependent on up to date information of hardware availability. It was decided that it should not occupy any resources when not running because the total number of hardware that would idle between runs would have an unacceptable impact on the lab size.

The web service shows a small and limited, but practical example of a software entity ubiquitously found in industry. These kind of systems are not business critical in themselves, but their cumulative effect on the business process as a whole is. Testing them sufficiently to ensure their quality will therefore be important to keep the bigger machinery running smoothly.

IV. Testing datatypes

The booking web application consists of a number of components, of which the implementation of the timeline datatype is central. This datatype is used to store, compare and remove time intervals for bookings. Since testing datatypes with QuickCheck is well documented [6], [7], we just need to follow the methodology described: create a generator using the constructors of the data type, create a model implementation of the datatype, and write one property for each operation on the datatype.

The timeline datatype represents a calendar in which certain intervals are blocked (the days that equipment is booked). A timeline can be constructed and manipulated using the following functions:

`new`	create an empty timeline,
`add`	add an interval to a timeline,
`delete`	delete a specific interval from a timeline,
`after_`	remove all intervals before a certain date from the timeline; used to prune old bookings,
`tail`	remove the first interval of a timeline.

According to [6] we should use all these operations in the timeline generator.

In addition to these operations, we also define functions to compare timelines, extract elements from a timeline, such as an particular interval, and to check whether two intervals overlap:

`equals`	check whether two timelines are equal,
`empty`	check whether a timeline is empty, i.e., does not contain any interval,
`member`	check whether a particular interval is already in the timeline,
`overlap`	check whether a given interval overlaps with any of the intervals in the timeline,
`valid`	check whether the intervals in a timeline are chronologically ordered and do not overlap,
`get_overlap`	return the first interval in the timeline that overlaps with a given interval,
`head`	return the first interval in a timeline,
`nth`	return the n^{th} interval in a timeline,
`overlap`	check whether two given intervals overlap.

Following the method mentioned earlier, we now need to create a generator for timeline data structures, and a model of a timeline that can be constructed with corresponding operations. We can then define a QuickCheck property for each operation, which applies the operation to a timeline and the corresponding operation to a model of that timeline, and validates if the resulting timeline conforms to the resulting model. For example, we define the following property for the `add` operation:

```
prop_add() ->
  ?FORALL(
    {I, SymT}, {interval(), timeline()},
    begin
      T = eval(SymT),
      case catch add(I, T) of
        {'EXIT', {overlap, _}} ->
          is_overlap(I, model(T));
        NewT ->
          equals(model(NewT),
                 model_add(I, model(T)))
      end
    end).
```

A random interval `I` and a timeline `SymT` are generated by the generators `interval()` and `timeline()` respectively. The timeline generator generates a symbolic timeline, that is, a value generated by this generator is a list of symbolic calls to constructor operations. Symbolic values allow us to inspect how an actual value is constructed. Whenever we need the actual value, we evaluate the symbolic value using the `eval` function. We also want to perform negative tests and check if a proper error message is produced. When an exception is

raised, we validate if it is raised for the right for the right reason, in this case if the generated interval overlaps with the generated timeline. If no exception is raised, the model of the newly obtained timeline should be equal to the model of the generated timeline to which we add the interval via the corresponding model operation.

The model and properties are easy to come up with following the aforementioned method, but the tricky parts are the generators for intervals and timelines. Decimal numbers [6] and ordered sets [7] can be generated from a simple recursive generator or grammar description, since there is little dependency between values generated in different recursive calls. However, in our case we have an invariant on the generated timeline, namely that intervals should be non-overlapping. This makes the data generation severely more difficult. The first contribution of this paper is *a method to evaluate the data distribution* for datatype generators that need to meet some requirements. The second contribution is *a timeline generator that performs well* with this evaluation.

A. Interval generator

We want to test the timeline functions on random input and need data generators for the arguments of those functions. Many functions take an interval as argument. We represent an interval as a pair of two triples: year, month and day. A naive approach would be to construct an interval using two (ordered) random generated dates. Using QuickCheck one would generate such a triple with the `choose` generator and use the `?SUCHTHAT` macro to filter dates that the Erlang `calendar` module rejects as valid date.

```
ymd() ->
 {choose(2012, 2013),
  choose(1, 12),
  choose(1, 31)}.

date() ->
  ?SUCHTHAT(Date, ymd(),
            calendar:valid_date(Date)).
```

A tuple of two such dates, however, does not provide good test data. We want the test data to typically be a few days, preferably around week, and containing month and year transitions. For example, 2012-12-28 to 2013-1-1 would make for a nice test case. We should create a generator that chooses such intervals with reasonable likelihood. As noted before, an interval generator that picks the date purely randomly would create intervals that are very large. Limiting the year to be either 2012 or 2013 reduces the number of extremely large intervals, but at the same time, choosing more than 4 non-overlapping random intervals in that domain is unlikely to happen with the uniform distribution of `choose`. We therefore steer the generation to make it more likely to select intervals that we are interested in by adding a few days to the date and discard dates that therewith become invalid.

```
interval() ->
  ?LET(D1, date(),
       ?LET(D2, larger_date(D1),
            {D1, D2})).

larger_date({Y, M, D}) ->
  ?SUCHTHAT(
    frequency(
      [{9, ?LET(Days, nat(),
                shift({Y, M, D}, Days))},
       {1, Date, date()}])
    Date > {Y, M, D}).
```

After picking the first random date, the second date is constructed by adding an arbitrary number of days to the date. Alternatively, in 10 percent of the cases we also allow a completely random date as second alternative, provided it is larger than the first date.

This is one attempt to get a good distribution of intervals in a timeline. The question is, how good? And are there any obvious cases that we do not test with such a distribution or cases that are unlikely to be generated in a run of hundred tests?

V. Testing Generator Requirements

We would like to be able to assess the quality of a test data, in order to convince ourselves that a generator is good enough. To assess the quality of a test data we propose to define *requirements* on values produced by such a generator. A requirement for a generator is a property that should hold for a certain percentage of the generated tests. So, we can specify that a minimum (or maximum) number of generated test values should adhere to a given property. We have extended QuickCheck with the possibility to define such requirements on generators in a convenient way. For example, a requirement on a generator for natural numbers between 1 and 10, may be that it should generate a 1 within say 12 tests. We can express such a requirement as follows:

```
req_has_one() ->
  Gen = eqc_gen:choose(1, 10),
  ?REQ_EXISTS(1, Gen, 12).
```

The `req_has_one` function returns a QuickCheck property that we can test, just as any other 'normal' property, with the `quickcheck` function:

```
1> eqc:quickcheck(req_has_one()).
OK, passed
true
```

Not surprisingly the generator meets this requirement. In case a generator meets a requirement, QuickCheck prints an acknowledgement and returns the value `true`.

A slightly larger example is the following requirement:

```
req_half_is_larger_than_five() ->
  Gen = eqc_gen:choose(1, 10),
  ?REQ_MIN(X, Gen, X >= 5, 50.0, 100).
```

This requirement demands from the generator that at least 50% of the generated values are equal or larger than 5. Running `quickcheck` on this requirement results in the following output:

```
2> eqc:quickcheck(req_half_is_larger_than_five()).
Failed! Only 46 percent meets the condition.
```

```
[6,4,1,9,2,8,9,1,6,2,7,2,10,9,3,9,8,5,6,1,2,
 ...
 2,4,3,2,5,3,10,2,8,2,5,5,9,4,1,9,2,10,8,5,8]
false
```

QuickCheck reports that the generator `choose(1, 10)` did not meet the `req_half_is_larger_than_five()` requirement. It shows the generated test data, which can be regarded as a counterexample, and the percentage of the data that did meet the requirement. Since the `choose` generator has a linear distribution, it is possible that we generate 50 numbers that are smaller than 5. The counterexample allows us to inspect the generated data. Using this information we can improve the generator, or, if we are satisfied with the data distribution, we could weaken the requirement.

We offer the following macros to construct requirements on QuickCheck test data generators:

`?REQ_EXISTS(X, Gen, N)`,
: check if a generator `Gen` will at least generate a value equal to `X` within `N` number of tests,

`?REQ_EXISTS_FOR(X, Gen, P, N)`,
: check if a value for which predicate `P` (that takes a value as argument and returns a Boolean value) holds, is generated within `N` tests,

`?REQ_BETWEEN(X, Gen, P, Min, Max, N)`,
: check if the percentage of the values for which `P` holds lies between `Min| and \erlang|Max`,

`?REQ_MIN(X, Gen, P, Min, N)`,
: same as `?REQ_BETWEEN` but only with a lower bound,

`?REQ_MAX(X, Gen, P, Max, N)`,
: same as `?REQ_BETWEEN` but only with an upper bound,

`?REQ(X, Gen, P, C, N)`,
: the above requirement macros are expressed in terms of this is general macro, which generalises the condition check (which takes an percentage as argument and returns a Boolean value).

The last argument, which specifies the number of tests, of all macros can be left out. If the number of test is not specified we use the default of a hundred tests. We can check individual requirements with the `quickcheck` function. In addition, we provide a function, named `req_module`, which checks all requirements defined in a module. The name of a requirement needs to be prefixed with `req_`.

QuickCheck already offers the possibility to *measure* the probabilities of different kinds of test data. This can be done by instrumenting a QuickCheck property to collect statistics during testing. For example, we might instrument a property as follows, to measure how often a one is generated by the `choose(1,10)` generator:

```
prop_has_one() ->
  ?FORALL(N, eqc_gen:choose(1,10),
          collect(N == 1, N < 11)).
```

The effect of the line `collect(N == 1, ...)` is to collect the value of `N` in each test, and after testing is complete, to display the distribution of the values collected. In this case, testing the instrumented property yields:

```
3> eqc:quickcheck(prop_has_one()).
.........................................
OK, passed 100 tests

89% false
11% true
true
```

The collected statistics show that `N` was 1 in 11% of the generated tests. This is already valuable information. However, we cannot use the collected data to give a judgement, nor can we let the property succeed or fail based on these statistics. As a consequence, an expert must (re)examine the result in order to check if a generator meets its requirements. Using the requirement macros defined above, we can. Note that the requirement functionality is not meant to replace the statistics collection functionality. Both are useful in their own right.

Interval generator: Let us now return to our running example. Using the above macros we can introduce some requirements on the interval generator, which we introduced in the previous section. For example, we can state that an arbitrarily generated list of intervals should consist of non-overlapping intervals in 75% of the cases:

```
req_non_overlap() ->
  ?REQ_MIN(Is, eqc_gen:list(interval()),
           non_overlapping_pair(Is),
           75.0).
```

The `non_overlapping_pair` function checks whether or not there is an overlap between one of the elements of `Is` with any of the other elements. When we check the requirement for the generator of intervals with two arbitrary dates (first smaller than the second), we get a requirement success rate of around 30%, thus in 70% of the generated lists of intervals, the lists contains overlapping intervals. Moreover, when we only generate lists containing five intervals, we seem to be unable to create any of these without an overlapping interval. However, for the smarter generator for intervals described above, we come close to a success rate of 80%.

A. Timeline generator

The problem of bad data distribution gets even more obvious if we follow the generator construction explained in literature, where we build a data structure by using the constructors defined by the datatype.

```
timeline() ->
  ?SIZED(Size, well_defined(timeline(Size))).

timeline(0) ->
  {call, ?API, new, []};
timeline(N) ->
  ?LAZY(oneof(
    [timeline(0),
     {call, ?API, add,    [interval(),
                           timeline(N-1)]},
     {call, ?API, tail,   [timeline(N-1)]},
     {call, ?API, delete, [interval(),
                           timeline(N-1)]}
    ])).
```

This generator creates an arbitrary timeline by recursively adding and deleting intervals from a previously defined timeline. We do this symbolically, which means that we build a data structure containing the calls to the API instead of calling the API directly. But this timeline generator does a very poor job. By deleting an arbitrary interval from the timeline it is most often the case that this interval is not present in this timeline. The software under test will in such case raise an exception. Exceptions are handled in the function `well_defined`, which takes a generator as input, and recomputes it if exceptions are raised under evaluation. When sampling this data generator, about 70% of all values created is the empty timeline, followed by timelines with one or at most two intervals in it. That does not make for good test data.

Lets improve the `timeline` generator. However, before doing so, we want to formulate requirements on the timeline generator we are trying to construct. A requirement that 2% of the test cases should have a symbolic timeline that after evaluation contains more than 10 intervals would be specified as follows:

```
req_length() ->
  ?REQ_MIN(SymT, timeline(),
           length(eval(SymT)) > 10, 2.0).
```

A requirement that any set of generated values should have at least one timeline with an interval that spans over a year border is specified as follows:

```
req_year_span() ->
  ?REQ_EXISTS_FOR(SymT, timeline(),
    lists:any(fun({{Y1, _, _}, {Y2, _, _}}) ->
                Y1 < Y2
              end, eval(SymT))).
```

Similarly, a requirement that checks if an interval is present that spans over a month, is defined as follows:

```
req_month_span() ->
  ?REQ_EXISTS_FOR(SymT, timeline(),
    [1 || {{_, M1, _}, {_, M2, _}} <- eval(SymT),
          M1 < M2] =/= []).
```

We have specified additional requirements on the timeline generator, but we omit the definition.

The symbolic representation of calls helps us to define requirements on the construction of timelines. Since the data generator has a structure in which we save which calls we apply instead of the final result, we can express a requirement that 10% of the generates timelines should have been build with both a `delete` and a `tail` in its construction. With those requirements and the above generator for timelines, we get the following result:

```
4> eqc_requirements:req_module(booking_eqc).
Failed! After 1 tests.
Requirement req_length failed:
  only 0.00% meets the condition.

Failed! After 1 tests.
Requirement req_consecutive failed:
  only 0.00% meets the condition.

Failed! After 1 tests.
Requirement req_mix1 failed:
  only 0.00% meets the condition.

Failed! After 1 tests.
Requirement req_year_span failed:
  only 0.00% meets the condition.

OK, passed 1 tests

false
```

The failure rate is 100% for all but the requirement that we should have an interval over the month border. This means that none of the generated values fulfils any of the other requirements.

By selecting existing intervals from the earlier generated timeline and only taking the tail from a timeline that contains at least one interval we can do much better. The improved generator is defined as follows:

```
timeline() ->
  ?SIZED(Size, well_defined(timeline(Size))).

timeline(0) ->
  {call, ?API, new, []};
timeline(N) ->
  ?LAZY(
  ?LETSHRINK(
    [SymT],
    [well_defined(timeline(N-1))],
    begin
      T = eval(SymT),
      frequency(
        [{50,{call, ?API, add, [interval(),SymT]}},
         {1, {call, ?API, after_, [date(),SymT]}}]
        ++
        [{5, {call, ?API, tail, [SymT]}}
          || T =/= []]
        ++
        [{5, {call, ?API, delete,
          [elements(T), SymT]}} || T =/= []])
    end)).
```

This generator performs much better and passes all requirements with good margins.

Specifying requirements provides the developers the tools needed to ensure that data generators meet the expectations on test cases that they would use in manually written unit tests. In a similar way as deciding which unit tests one should write, we now decide which particular data distributions provide valuable test data. After that, we specify one property per operation and check the result against a model. In this way, we do get the complete testing as described in literature plus an additional quality assurance on the generated test data. In practice, this has helped us to motivate the designers of the generators to realise the short-comings of early versions of the generators and to improve them iteratively.

VI. Application 2: Dudle

Dudle is an open source web service, which can be used to schedule a meeting or poll people for an opinion. It is a relatively small web service with a simple and well defined interface. In case of a schedule, users can vote for one or more time slots, and in case of a poll, users can choose several

options. Dudle has functionality for creating, deleting, editing a schedule or a poll. Participants can be invited via Dudle to take part in a schedule or a poll. And finally, the administrator of a schedule or poll can review the status in order to see which alternatives are preferred by the participants. Dudle is written in the programming language Ruby and can be deployed using a web server, such as Apache, via a common gateway interface (CGI).

We have tested the Dudle web service with QuickCheck, using the abstract state machine functionality. We maintain a model of the Dudle system while executing test commands, which are mapped to CGI-calls, and checking pre- and postconditions. We have developed a number of test data generators for this test, such as generators for a poll name, or a time slot. In this section we focus on a test data generator for a user name. We started out with a textbook case of a generator for random user names:

```
name() ->
  ?SUCHTHAT(
    Name,
    eqc_gen:non_empty(eqc_gen:list(eqc_gen:char())),
    not lists:member($\r, Name)).
```

We have constructed this generator in terms off standard QuickCheck generators. The `name()` generator produces a non-empty list of characters. We use the `?SUCHTHAT` macro to exclude user names containing carriage returns. To ensure that we pick equal names now and again we do not use this generator directly, but we use it to create a pool of names from which we choose.

We had to improve the user name generator, such that it generates more realistic user names. Dudle was not always able to handle peculiar user names, for example names containing newlines and spaces. We do not blame Dudle for this, instead, we blame our slightly naive generator. The improved version of the user name generator is defined as follows (where Erlang's notation for a character is preceded by a dollar sign):

```
name2() ->
  Gen = frequency([{100, choose($a, $z)},
                   {25,  choose($A, $Z)},
                   {25,  choose($0, $9)},
                   {5, $ },
                   {1, $-}, {1, $_}]),
  ?LET(Name,
       eqc_gen:non_empty(eqc_gen:list(Gen)),
       string:strip(Name)).
```

This generator also produces a non-empty list of characters, but the characters are selected more carefully. Instead of choosing random characters we now choose alpha-numeric characters and occasionally a slightly unusual character, such as a space or a dash.

We have used the above generator in testing Dudle and are quite satisfied with it. But does it actually produce the user names that we expect? That is, does it meet our implicit requirements? Lets find out and make these requirements explicit, and specify them using the macros from Sect. V.

We had the following implicit requirements in mind when we defined the user name generator:

1) at least 10% of the generated user names should contain an unusual characters, such as a dash,
2) we should not generate names with more than four spaces,
3) a quarter of the generated user names should be longer than 8 characters,
4) we want to generate user names containing both upper and lower case characters.

These implicit requirements can be translated to formal requirement using the requirement macros as follows:

```
req_unusual() ->
  Intersect =
    fun(Xs, Ys) ->
      [X || X <- Xs, lists:member(X, Ys)]
    end,
  ?REQ_MIN(Name, name2(),
           length(Intersect(Name, "-_ ")) > 0,
           10.0).

req_spaces() ->
  Spaces =
    fun(Xs) ->
      lists:filter(fun(X) -> X == 32 end, Xs)
    end,
  ?REQ_EXISTS_FOR(Name, name2(),
                  length(Spaces(Name)) < 4).

req_name_length() ->
  ?REQ_MIN(Name, name2(),
           length(Name) > 8, 25.0).

req_upper_lower_case() ->
  IsUpper =
    fun(X) ->
      X >= $A andalso X =< $Z
    end,
  IsLower =
    fun(X) ->
      X >= $a andalso X =< $z
    end,
  HasUpperAndLower =
    fun(Xs) ->
      length([X || X <- Xs, IsUpper(X)]) > 0
      andalso
      length([X || X <- Xs, IsLower(X)]) > 0
    end,
  ?REQ_EXISTS_FOR(Name, name2(),
                  HasUpperAndLower(Name)).
```

We have defined these requirements in the Dudle test module named `dudle_eqc`. We use the `req_module` function to test all requirements defined in the Dudle test module, which generates the following output:

```
5> eqc_requirements:req_module(dudle_eqc).
OK, passed 1 tests

Failed! After 1 tests.
Requirement req_unusual failed:
  only 7.00% meets the condition.

OK, passed 1 tests

Failed! After 1 tests.
Requirement req_name_length failed:
  only 8.00% meets the condition.

false
```

These results show that the `name2` generator does not meet two of the four requirements, namely `req_unusual` and `req_name_length`. The latter suggests that the length of the generated user names are too short. This may explain why the requirement `req_unusual` fails as well, since the unusual characters have a low probability of being generated. We adapt the user name generator such that it generates longer names:

```
name3() ->
  Gen = frequency([{100, choose($a, $z)},
                   {25,  choose($A, $Z)},
                   {25,  choose($0, $9)},
                   {5, $ },
                   {1, $-}, {1, $_}]),
  ?LET(Name,
       eqc_gen:non_empty(eqc_gen:longlist(Gen)),
       string:strip(Name)).

longlist(Gen) ->
  ?SIZED(Size,
         resize(Size*2, list(resize(Size, Gen)))).
```

Most of the generator is left as is, but we have replaced the standard `list` generator with our own `longlist` generator. The `longlist` generator produces lists that are double the size of lists generated by the `list` generator. Lets check the requirements again:

```
6> eqc_requirements:req_module(dudle_eqc).
OK, passed 1 tests

OK, passed 1 tests

OK, passed 1 tests

OK, passed 1 tests
true
```

The `name3` generator meets all the requirements. This example shows that testing requirements supports the development of good test data generators. Not only does testing requirements have added value for validating large complex generators, but also for simple straightforward generators, such as the user name generator. It is all too easy to overlook something, such as generating list of the proper length.

VII. Conclusions

From experience, strengthened by a scientific experiment [15], we know that it is difficult to write test cases that cover a good set of input data, both positive and negative data. Random generation of data makes testing immune to specific choices, but also introduces the possibility to generate data that does not cover border cases or specific inputs.

When QuickCheck data generators get more complicated to write and their distributions harder to grasp, one can get a false sense of trust by seeing many test cases pass. The actual generated data can be collected by built-in QuickCheck functions and printed as side-effect of testing. However, only presenting the data requires either domain experts to asses the statistics or forces engineers to subjectively judge whether the collected values are satisfactory.

In this article we contribute by showing how one can express and verify requirements on generators to convince oneself that the performed testing is sufficient. Interaction with domain experts is needed at the beginning of the test design, when the requirements on test data are stated. With data from testing two different web services, we have shown that with a naive approach to random data generation, we can easily produce test cases without the required quality. We have shown how we can make the quality requirements explicit and automatically verifiable. And finally, we have shown how to control the randomness so that the test cases we produce are of the required quality.

Mutation testing is a different way of judging the quality of a test suite. This is based upon introducing errors in the software under test and trying to find them by running the test suite. Mutation testing is a fundamentally different technique and requires code instrumentation with good mutants. It is further research how these techniques complement each other.

With the techniques presented in this paper, domain and test experts are able to write requirements to ensure that the tests they perform are of high quality. It allows for a high degree of automation by minimal intervention of domain experts and automatic feedback on the quality of the generated data.

A method for selecting environments for software compatibility testing

Łukasz Pobereżnik
AGH University of Science and Technology, Cracow, Poland

***Abstract*—Modern software is developed to work with multiple software and hardware architectures, to cooperate with various peer components and can be installed in many different configurations. In order to test it, all possible working environments needs to be created. This requires software and hardware resources like servers, networks and software licenses and most important: man-hours of qualified engineers that will have to configure and maintain them. Because resources are usually limited we have to choose a set of configurations with highest impact on quality of software under test. In this paper we present a method of measuring effectiveness of given software environment for discovering defects in software by introducing environment sensitivity measure. We also show how it can be used in simple algorithm used to select best configurations by using only a selected subset of them and progressively modifying it thougout software development process.**

I. Introduction and problem description

SOFTWARE usually does not work alone. It must have an environment that it works in. This environment can be composed from many components like: servers, operating systems, databases, remote services etc. Those components can also have other components that they rely on. Eg. database might need an operating system to work on. Those dependencies create a Component Dependency Graph (CDG) that describes an environment for Software under Test (SUT). Example of such graph is given on Figure 1. This graph shows only general structure of environment. Each component may also have a set of properties like type, version number, architecture type, permissions, locales etc.

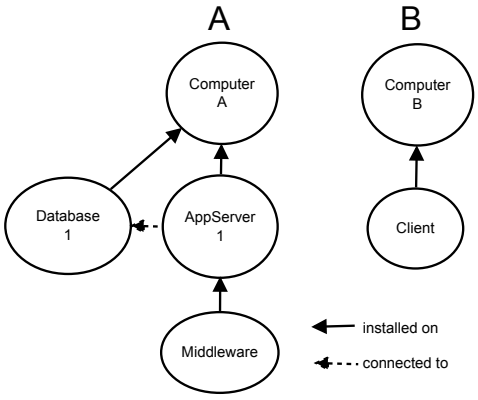

Fig. 1: Example of Component Dependency Graph (CDG) that shows dependencies between resources. Tree A represents environment for server application. Tree B is environment for client application.

Lets take a simple use case: an application working on two operating systems, with three database servers and two application servers. It will give about $2 \times 3 \times 2$=12 different environments to test. If we add another variable: 32-bit or 64-bit architecture, it will double possible environment configurations to at most 24. Adding new configurable element to environment tends to increase the number of possible setups exponentially. Not all configurations may be possible to create (for example some middle-ware may not be available for all operating systems), but it still is significant number of variants to test. Problems of generating test environments and possible solutions were mentioned in our other article [1].

There has been efforts to automate the process of creating those environments based on semantic description of CDG in [2] and [3]. Authors of those articles proposed to use virtualization to construct environments and then use snapshots to clone and then modify them to build other environments. This technique and additional simplifications allowed to reduce number of separate configurations from about 1200 to 160. However this is still to many environments to be build and maintained for everyday regressions tests or continuous builds.

In dissertation [4] same author came also to this conclusion and proposed a manual way to select subset of configurations based on testers' preferences. Decision on which configurations test software is in that case solely based on testers expert knowledge, without support of any analytical tools. In our research we tried to establish a method to measure how good is given configuration for testing and an algorithm to choose the best of them.

II. Selecting best environments for testing

As shown above number of possible environments can be quite high. This means that with limited resources we can only choose subset of them. One of the most popular methods is to use configurations that are most widely used by customers. However when number of software users is high, diversity of configurations may also be too high on and must also be limited.

We have to define what means that one configuration is better for testing purposes than the other and then create an algorithm for choosing the best of them. In our research we followed a common phenomena observed by testers: some of the software environments are causing more problems than the others - basically they fail more tests (or fail them more often). If configuration A is more problematic than configuration B that usually means that if we run tests on configuration A and

978-83-60810-53-8/$25.00

they will pass, so they will pass also on configuration B (with high probability). This means that we do not need to conducts tests on configuration B so frequently as on configuration A. Conclusion is that configuration A is better for testing than configuration B, because it allows to detect more environment related defects. In order to compare environments it is good to have a numerical metric that will allow to evaluate effectiveness of given configuration. It is also a requirement for many optimizing algorithms (especially evolutionary) to provide a fitness function to compare solutions.

A. Measure of environment sensitivity

In order to compare two environments for software testing we need to establish metric that would tell which configuration is better. Let a T be a set of n tests (test suite) consisting single tests t_i. Let T_k be a vector of test results executed in k iteration. Test can be either 1 (pass) or 0 (fail).

$$T_k = (t_1, t_2, t_3 ... t_n), t_i = 1 \vee 0 \tag{1}$$

E_j is an environment j. Testing function F_T is a function that assigns for each k iteration a vector of tests results T_k to environment C_j.

$$F_T(k, E_j) = (t_1, t_2, t_3, ..., t_n) \tag{2}$$

We can describe F_n for single iteration k in more convenient way as a matrix, where columns are tests and rows are environments (lets note number of configurations as m). t_{ji} is a result of test t_i on environment C_j.

$$F_T(k) = \begin{vmatrix} t_{11} & t_{12} & t_{13} \\ t_{21} & t_{22} & t_{23} \\ t_{31} & t_{32} & t_{33} \end{vmatrix} \tag{3}$$

First step in calculating sensitivity is to remove those tests that does not bring any information about environment differences. We remove those columns that satisfy condition:

$$\exists p \in [1, m] \forall x \in [1, n] \forall y \in [1, n] : t_{xp} = t_{yp} \tag{4}$$

This means that removed are only those tests that passed or failed in all configurations (remove columns of all 1 or all 0).

Then for each row vector we calculate how many times given test failed and normalize it by number of tests in vector (after removing some of them in first step).

$$Sens(C_j) = \frac{\sum_{x=1}^{n} (1 - t_{jx})}{n} \tag{5}$$

$$Sens(C_j) \in [0, 1] \tag{6}$$

Sensitivity value close to 0 means that given environment is not good for finding defects because all tests here pass. When sensitivity is 1 means that configuration is a good candidate for finding software errors because all tests fail on it whereas on at least one other configuration they pass. Of course, if all tests fail on given configuration we have to check if the problem is not with tests itself - for example there is a defect in testing code.

B. Properties of environment sensitivity

Let's define environment domination: environment A dominates environment B if:

$$\exists x : t_{Ax} < t_{Bx} \wedge \forall y \neq x : t_{Ay} \leq t_{By} \tag{7}$$

In other word: there is at least one test that failed on configuration A but passed on configuration B. This would mean that configuration A found a defect that was not discovered by configuration B.

Environment sensitivity has this property that:

$$A \; dominates \; B \Rightarrow Sens(C_A) > Sens(C_B) \tag{8}$$

This property is result of environment sensitivity definition. Let sum inequalities in second part of domination definition:

$$\sum_{k=1 \wedge k \neq i}^{n} t_{Ak} \leq \sum_{k=1 \wedge k \neq i}^{n} t_{Bk} \tag{9}$$

If we add $t_{Ai} < t_{Bi}$, weak inequality will become strong inequality:

$$\sum_{k=1}^{n} t_{Ak} < \sum_{k=1}^{n} t_{Bk} \tag{10}$$

Note that sensivity calculation requires removing tests that in every configuration failed or passed. This will also convert weak inequality into strong one. If we multiply both sides by -1 and add n:

$$n - \sum_{k=1}^{n} t_{Ak} > n - \sum_{k=1}^{n} t_{Bk} \tag{11}$$

Because $n = \sum_{k=1}^{n} 1$ then we can rewrite equation as:

$$\sum_{k=1}^{n} 1 - \sum_{k=1}^{n} t_{Ak} > \sum_{k=1}^{n} 1 - \sum_{k=1}^{n} t_{Bk} \tag{12}$$

$$\sum_{k=1}^{n} (1 - t_{Ak}) > \sum_{k=1}^{n} (1 - t_{Bk}) \tag{13}$$

Now divide both sides by n:

$$\frac{\sum_{k=1}^{n} (1 - t_{Ak})}{n} > \frac{\sum_{k=1}^{n} (1 - t_{Bk})}{n} \tag{14}$$

And now using environment sensitivity definition:

$$Sens(C_A) > Sens(C_B) \tag{15}$$

Introduction of environment domination allows to us to use existing multi-criteria optimization techniques to find Pareto-efficient solutions. This proof can also be used to quickly compare results of tests run on two configurations without calculating sensitivity itself. Of course it will only introduce order to the set of configurations but would not give any idea how much they differ.

C. Algorithm to generate configurations

Algorithm that will generate and evaluate environments must have several important properties:

1) Works on discrete solution spaces.
2) An ability to search unknown solution space (we have no additional information about local optima) .
3) Iterative schema of work, similar to iterative test execution.

Generating new environment and maintaining it is a costly operation. This means that algorithm must work with small data sets - typically 8-12 configurations. Tests should be run frequently, every code change or at least daily. This means that we may have enough iterations until we reach optimal solution. However we have to remember that each iteration means adding new configuration and this is a costly operation.

Algorithm 1 Simple algorithm for selecting most sensitive environments.

$E \Leftarrow GenerateAvailableEnvironments()$ {initial configuration pool}
$P \Leftarrow RandomSubset(E, n)$ {P represents current working set}
$P' \Leftarrow \emptyset$ {P' represents next set}
repeat
  $P'' \Leftarrow P'$ {P'' is set from previous iteration}
  $E \Leftarrow E - P$
  $R \Leftarrow RunTests(P)$
  $S \Leftarrow CalculateSensivity(R)$
  $S \Leftarrow SortBySensivity(S)$
  $P' \Leftarrow \emptyset$
  for $i = 0$ to k **do**
    $P' \Leftarrow P' \cup S[i]$
  end for
  $P \Leftarrow P' \cup RandomSubset(E, n - k)$
until E not empty and $P' \neq P''$

$GenerateAvailableEnvironments()$ creates a set of all possible environments we want to execute tests on. Function $RandomSubset(X, n)$ generates a random subset from set X of size n. Summarizing algorithm above: in each iteration we run test suite on n selected environments (working set). Using test results we calculate sensitivity for each of them. After that we select k best of them. From initial pool of environments we choose random ones to fill up working set so it will have n configurations again. Procedure is repeated until all configurations are used (initial pool is empty) or in next two consecutive iterations k best configurations is the same.

This algorithm tends to go though different solutions until it converge to optimal one. For environment compatibility testing this means that before we reach optimal set of configurations we will test much more of them and there is a possibility that we will find even more software defects, than using optimal set from the beginning.

III. Experiments

A. Direct application of environment sensitivity measure

To verify properties of environment sensitivity an experiment was conducted. We used a simple configuration with one operating system and a web browser installed on it. Operating systems used were Linux, Windows and Mac OS X. Browsers under test were Internet Explorer, Firefox, Chrome, Safari, Opera. Each browser was available in several different versions (depending on browser type). System used for experiment was built using small web server (Jetty) that was running a static web page. This web page was based on a popular HTML5 compatibility test site (www.html5test.com) and server both as test suite and application under test. Existing scripts were modified to send test results to data collection servlet running on the same web server (originally they were displayed on the screen). Schematic diagram of system used for experiment is shown on Figure 2.

When the test page was loaded it executed 242 true/false tests and sent results using JSON format back to server where they were stored in file along with information about browser and operating system type. The same page was run on each environment and test results were sent using separate script back to server that stored them for further analysis. Different configurations were provided by web browser compatibility testing cloud service (browsershots.org). We collected results for 46 different configurations. Expected number of environments should be higher, because some of the configurations has been not executed at all by the cloud (which is a defect in cloud service). However number of collected data is enough for analysis. In real life testing setups there are usually no more than several environments in constant use.

Sensitivity measure by definition is calculated relatively to other environments in tested configuration set. In most cases there is not enough resources (computing power, time, machines) to perform tests (and calculate sensitivity) for every environment in given configuration space. We wanted to check how much sensitivity measure will differ when it is calculated for small subset of configuration space against full configuration space. From all 46 environments we chosen randomly subsets of 5, 8 and 10 environments and calculated sensitivity for each configuration in it. We observed that sensitivity measure does not change more than 12 percent when it is calculated for a reasonable subset of initial test results (see Table I). If we use more than 8 environments it seems that average difference is less than 10 percent. We suppose that this behavior of measure is possible because the way environment reacts to tests is not dependent on other environments. This makes this sensitivity measure good candidate for fitness function in evolutionary programming.

B. Sensitivity measure as a fitness function

As stated before sensitivity measure can be used as fitness function so the next step was to check if proposed algorithm allows to quickly find best environments. Populations of sizes 8, 10 and 12 were tested. Each time algorithm was run 1000

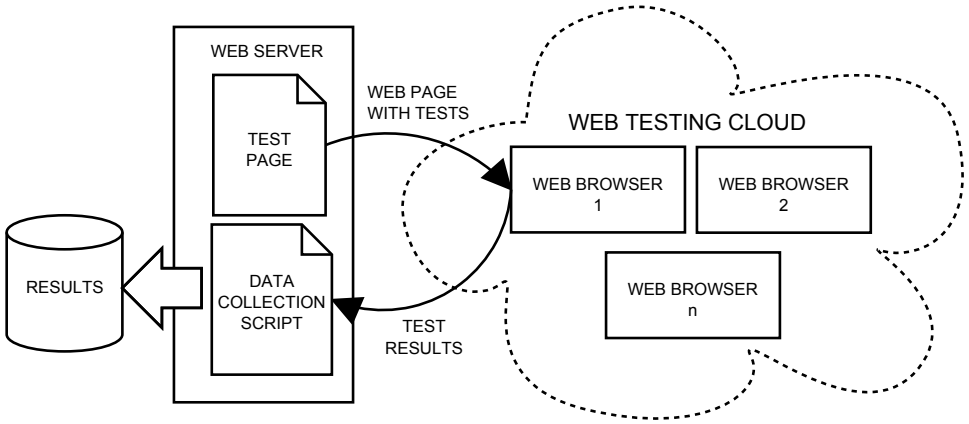

Fig. 2: Architecture of the system used for environment compatibility experiment.

TABLE I: Standard deviation of environment sensitivity calculated from random subsets from initial data.

	5 environments	8 environments	10 environments
100 random subsets	0.077	0.045	0.04
1000 random subsets	0.10	0.075	0.06
10000 random subsets	0.12	0.09	0.08

TABLE II: Averaged results after 1000 execution of environment selection algorithm. Difference is calculated against sensitivity calculated for all configurations together.

Population size	Max difference	Max iterations
n = 8, k = 4	15%	4.32 iterations
n = 10, k = 5	4.5%	4.09 iterations
n = 12, k = 6	3.8%	3.3 iterations

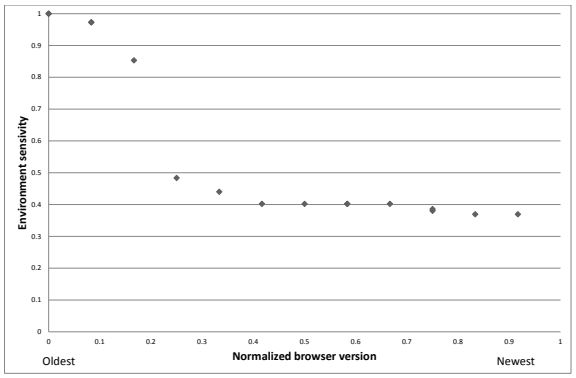

Fig. 3: Sensitivity of environment by browser version for Mozilla Firefox. Version numbers were normalized to be from 0 (oldest) to 1 (latest). You can see sudden improvement in HTML5 compatibility after third consecutive version.

times and results were averaged. They are presented in Table II. For population size of 10 algorithm delivered a stable set of environments in less than 5 iterations.

In Table III we can see browsers selected by algorithm in more than 10% of cases along with their average sensitivity. Columns Operating system, Browser type and Browser Version define environment. Frequency shows percentage of times given configuration was chosen in top k results in 1000 runs of algorithm (eg. 75% means that is was chosen in 750 times). Average sensitivity is arithmetic mean of sensitivity value calculated for environment in all runs. If we compare this table with sensitivity calculated for all environments in Appendix A Table IV they basically match each other.

C. Strategies for selecting environments for tests

Results also proved common sense that better to test on older versions of software because newer versions have lot of compatibility problems already fixed. This can be seen on Figure 3 and 4 where sensitivity of environment is presented versus browser version. We had to normalize version numbering to $[0, 1]$ because of different numbering schemes used by browser vendors. We can consider several strategies to reduce number of environments used for tests. Simplest one is to establish a cut off point below that every environment is discarded. On Figure 3 we see that good cut off point will be sensitivity with value 0.5 because it clearly separates set. However other good strategy will be to discard those some environments that have similar sensitivity value. From Figure 3 and Table IV we see that Firefox from version 6 to 15 have sensitivity between 0.3 and 0.4. This means that we can choose one or several of them based on own preference (or random choice) because they behave more or less similarly during tests.

Other important aspect is that environment sensitivity can provide an order of tests. If we start with environments with highest sensitivity and some tests will fail, we can stop, fix defect and start over again. In our test case, testing complicated web pages on latest browser versions will likely be successful,

TABLE III: Average sensitivity for environments using proposed algorithm (averaged after 1000 runs) for configuration set of size 10. Frequency show how many times given environment was chosen by algorithm in top k best. Only those configurations with frequency more than 10% are shown.

Operating system	Browser type	Browser version	Frequency	Average sensitivity
LINUX	FIREFOX	2.0.0.17	77%	0.960
LINUX	KONQUEROR	4.8	77%	0.889
MAC OS X	CAMINO2	2.1.2	76%	0.802
LINUX	FIREFOX	1.5.0.12	76%	0.983
WINDOWS	FIREFOX	2.0.0.12	74%	0.963
MAC OS X	SAFARI	4.0.5	50%	0.766
WINDOWS	CHROME	3.0.182.2	31%	0.777
WINDOWS	CHROME	4.0.223.11	24%	0.609
WINDOWS	OPERA	10.00	16%	0.388
LINUX	FIREFOX	7.0.1	12%	0.323
LINUX	FIREFOX	6.0.1	10%	0.326

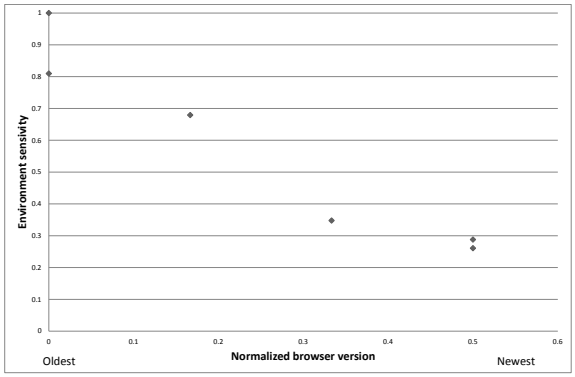

Fig. 4: Sensitivity of environment by browser version for Chrome. Version numbers were normalized to be from 0 (oldest) to 1 (latest). You can see improvement in HTML5 compatibility in latest versions. However it is not as steep as in Firefox browser.

because they are more HTML5 compatible. So better strategy will be to test on older versions and if they pass tests, then check on latest versions.

IV. Conclusions and future work

It seems that introduced environment sensitivity measure is a good way of measuring usefulness of environment for testing purposes. It provides analytical way to compare configurations and allows to use existing optimization techniques. For more complicated environments (that have several nodes in their CDG) we plan to use evolutionary algorithms. For presented browser testing case, cross-over and mutation operations were not feasible because they produced configurations that were not available in testing cloud. Introduction of environment domination (in Pareto sense) will allow to use existing methods used in multi-criteria optimization. Automated tests are usually run frequently in order to find out regression defects introduced during development. This causes tests to repeatedly oscillate between pass and fail states. We are now extending sensitivity model by introducing time line to take those changes into consideration and utilize historical information for more precise results.

We are also investigating possibility of using machine learning to correlate changes in application code base with historical test results to predict the best configuration and tests order to test on. This way when a new change is being introduced to software we can decide in which environment it should be tested in first place.

In our research we are planning to used multi-agent systems (See [5] and [6]) that will automatically deploy environments and optimize them for most efficient testing in terms of quality and resource consumption. Sensitivity is a useful measure to be used in algorithms that detect unusual behaviors like those mentioned in [7] and [8].

We are also considering introducing second measure based on probability that will cooperate with environment sensitivity that will allow us to better describe environment behavior and compare them in more than one category.

APPENDIX

In this section we present a table with sensitivity values calculated for different versions of popular browsers running on various operating systems. Sensitivity was calculated at once based on all test results from all available configurations.. In production it is usually not possible to keep so many testing environments, so only a small subset of them is used for daily testing and more of them are added when needed (for example before product release). You can compare results from this table with values from Table III.

TABLE IV: Sensitivity values calculated for all configurations (only non-zero values are shown). In this case sensitivity was calculated for all environments at once.

System	Browser	Browser version	Sensitivity
LINUX	FIREFOX	1.5.0.12	1.000
LINUX	FIREFOX	2.0.0.17	0.971
WINDOWS	FIREFOX	2.0.0.12	0.971
LINUX	KONQUEROR	4.8	0.902
MAC OS X	CAMINO2	2.1.2	0.821
MAC OS X	SAFARI	4	0.202
WINDOWS	CHROME	3.0.182.2	0.798
WINDOWS	CHROME	4.0.223.11	0.659

An Evaluation of Data Race Detectors Using Bug Repositories

Jochen Schimmel, Korbinian Molitorisz, Walter F. Tichy
Karlsruhe Institute of Technology (KIT), Germany
{schimmel, molitorisz, tichy}@kit.edu

***Abstract*—Multithreaded software is subject to data races. A large number of data race detectors exists, but they are mainly evaluated in academic examples. In this paper we present a study in which we applied data race detectors to real applications. In particular, we want to show, if these tools can be used to locate data races effectively at an early stage in software development.**

We therefore tracked 25 data races in bug repositories back to their roots, created parallel unit tests and executed 4 different data race detectors on these tests. We show, that with a combination of all detectors 92% of the contained data races can be found, whereas the best data race detector only finds about 50%.

***Index Terms*—Data Races, Unit Testing, Multicore Software Engineering, Empirical Study**

I. Introduction

ALMOST all race detection approaches are evaluated in source code, that is freely available or in productive use. But can these detectors also be effectively used during software development before delivery and prevent shipping errors? We conducted an empirical study to answer this question. For our experimental setup we browsed bug repositories of open source applications for reports of data races. For each report we tracked back the revision history to the point, at which the defect has been checked into the code repository for the first time. We used this revision to evaluate which of the data race detectors would have been able to find the race at the distinct moment where it was unintentionally inserted.

A first key finding was, that it was almost impossible to simply apply a race detector on our evaluation programs: The application of most race detectors was impractical and the true data races were outbalanced by the huge number of false positives. Furthermore, most data race detectors available consume too much memory and computation time. Results tend to be impressive when applied to small programs, but with increasing sizes of real world applications, race detection approaches become increasingly impractical. Our solution to this problem was to create parallel unit tests[1] for all programs: A parallel unit test calls two (or more) methods under test in parallel within separate threads. In contrast to regular unit tests, they do not contain assertions. A data race detector decides on the test result. It executes parallel test cases rather than the program itself. By writing such parallel unit tests, we divided the programs into smaller fractions and focused error detection on the relevant portions, that were small enough to be handled by the race detectors. As a consequence, we could successfully apply all four race detectors to the bug repositories and locate 92% of the data races.

This paper is structured as follows: In section II, we introduce the sample applications we used as benchmark for the data race detectors and present the bugs we found in the respective repositories. Section III presents the four data race detectors we evaluate. We discuss the results of our study in section IV and detail on parallel unit tests in section V. The paper concludes with related studies in section VI and a conclusion of the key findings.

II. Sample Applications and Bug Repositories

Apache Tomcat is a web server written in Java and uses Bugzilla as bug tracking system. In Tomcat, each web request is handled by a separate thread and all of them access common data. No or incorrect synchronization of the common data leads to program stalls or incorrect data. In Bugzilla we tracked down 23 reports of data races in Tomcat due to synchronization errors.

Spring is an application development framework library for Java and uses Jira to track bugs. Spring contains framework classes, that can be executed both sequentially or in parallel. We tracked 24 data race reports in the bug database caused by altered program semantics when executing the parallel versions of the framework classes.

Eclipse is an integrated development environment for Java and other programming languages and tracks bugs using Bugzilla. Eclipse executes long-running computations in background threads to keep the user interface responsive. We tracked 18 synchronisation errors in Bugzilla concering long-running background threads.

Defect Classification: We categorize the defects according to their root into four different error patterns: (1) Atomicity violation, (2) wrong usage of Java library, (3) if-race and (4) bad optimization. A data race may account to more than one of the four error patterns. However, some of the defects we found are specific and do not apply to any of these categories.

Atomicity violations are data races caused by incorrect granularity of synchonization. Here, different memory location have data- or control flow dependencies. They form a logical unit and may only be changed atomically or in a transaction. Even if each location might be synchonized separately, the acceess to the whole unit is not.

The Java library contains thread-safe classes, i.e. they can be used in multithreaded applications without additional locks.

The second error-pattern we define classifies code locations as defect in which classes are treated as thread-safe but that are not designed to be used like this.

Almost half of all errors we found are if-races: An if-race occurs, when a variable is checked for a certain value inside a conditional expression leading to a branch. In there, the variable is updated to a new value. For correct program semantics, both statements must be within the same lock because the thread could otherwise be interrupted in between and the variable is changed by another parallel operation.

The bad optimization pattern does not reflect a certain code design pattern, but rather describes different kinds of errors which come from the intention to improve program runtime but not its code behaviour. In fact, these code changes have unintended side effects. We could only identify these errors because of comments we found in the bug repositories.

We summarize our results in table I. One central finding is, that practically all data races can already be reproduced by a twofold parallel execution, although the programs may execute the parallel regions at a higher degree of parallelism. If the parallel regions execute in the wrong order at runtime, the defect manifests. 76% of all defects belong to this category. 20% require three or four operations, while only 4% require at least five operations in an unexpected order. With just one exception, we could successfully reproduce the defects using two threads. The column *Method sum* under *Program Details* shows, that roughly half of the data races are caused by a parallel execution of two different methods, whereas the other half is caused by parallel execution of the same method. This relates to the key finding by Shan Lu et al. [2], according to which most data races can be reproduced with only two methods. According to our finding, we can generalize the term of *two methods* to either depict the parallel execution of two separate methods as in task parallelism or to depict the parallel execution of the same method as in data parallelism.

III. DATA RACE DETECTORS

We present the four data race detectors used in our study. The selected detectors had to be freely available and were required to support Java code natively for comparability reasons. We included three dynamic and one static tool. Further studies should also include other prominent tools available such as Helgrind+ [3] or Racer-X [4].

MTRAT: Multi-Thread Run-time Analysis Tool for Java (MTRAT) is a dynamic detection tool for data races and deadlocks developed by IBM [5]. MTRAT uses a combination of the happens-before and lockset race detection algorithms. For this work, we used its Eclipse plugin for Windows in order to define which classes of an application to instrument. MTRAT can also instrument libraries at bytecode level, except for Java core libraries. For self-written code, MTRAT returns the line numbers where the error occured; for errors in libraries, only the class name is returned. MTRAT captures the execution path and makes the data race reproducable. Unlike other race detectors, it is unable to identify alternative control flows. For us to work with MTRAT, we manually wrote test cases, that induced the problematic control flow. Thus, the investigation of complex programs such as Eclipse is not feasable due to slowdown limitations.

ConTest is another dynamic tool developed at IBM alphaworks [5]. ConTest inserts sleep and yield instructions heuristically into Java bytecode to create different thread interleavings. When re-executing an application, ConTest varies the thread

scheduling to provoke data races and deadlocks. ConTest is available as an Eclipse plugin. It offers numerous options to adjust the interleaving heuristics. In contrast to other race detection tools, ConTest does not identify data races, it only provokes different interleavings, so ConTest raises the chance for a data race to occur. The developer finally has to identify the race by invalid program behaviour using assertions.

Jinx is a commercial tool to find errors in multithreaded applications [6]. It supports programs in Java, C/C++ and .NET-languages. Jinx is a dynamic race detector and executes a program several times, altering thread schedules. When a race is detected, Jinx can replay the problematic schedule. Like ConTest, Jinx relies on programs throwing exceptions as soon as a data race occurs.

Jchord is an open source static data race detector [7]. Jchord is a command line tool which expects the Java classes under test as input; it will also detect errors within compiled Java libraries, such as the Java core libraries.

IV. Results

Table I summarizes all 25 bugs and the data race detection results of all 4 evaluated tools. The column *Bug-ID* references the respective bug tracking system. We evaluated each of the race detectors with the same unit tests as program input. For ConTest and Jinx we had to extend the parallel test cases to include exceptions and assertions. We found, that by executing 9 defects could even be found without any data race detector. We call this extension *enriched parallel unit tests*. The results are shown in column *enriched PUT*.

MTRAT is unaware of atomicity violations and cannot find defects due to wrong library usage, as it does not check the Java core libraries. To verify the library limitation, we used an open source implementation of the Java library. With this change MTRAT would have found all 9 library defects. MTRAT exhibited false positives on one occasion only. According to its heuristics, MTRAT could have found 15 data races, 13 were in fact found.

ConTest alternates thread interleavings, so its results are not reliable. ConTest can only find data races, when they actually occur. We therefore executed ConTest 10 times and measured if the race was reported at least once. Another weakness is, that ConTest reports races on the basis of hand-written exceptions or assertions that fail, so we extended our benchmark to use enriched PUTs. With this, ConTest could identify 9 additional defects. A third drawback of ConTest is the lack of information to resolve the defect: It only executes the test case. It does not provide any information about what caused the data race or at which code line.

As Jinx is also unreliable we used the same reproduction logic and used our enriched PUTs as input. Jinx offers several *intensity levels* to improve defect detection, that showed no noticeable difference in our experiments. Jinx is able to detect errors due to wrong library usage, atomicity violations and did not produce false positives, but found only 36% of the errors. With 9 defects, the enriched PUTs found as many errors as Jinx, but 2 of them were only found by Jinx. The slowdown of Jinx is within a few seconds, so it may be used as a supportive tool.

Jchord is a static race detector. It can be applied to the regular evaluation applications, but we used it on our test cases for comparability reasons. Also, this extension reduced the execution time drastically: With the regular test cases Jchord required 4 minutes on average and in 4 cases it crashed with out of memory exceptions. With enriched PUTs each test case executes within a few seconds; From the remaining 21 bugs, 13 were found. Jchord is unable to find atomicity violations and was the only tool to produce a significant number of false positives. For 6 test cases it reported more than 10 false positives. This severly lowers its benefit for real-life scenarios.

V. Parallel Unit Tests

Our evaluation shows the efficiency of data race detection supported by parallel unit tests. If parallel unit tests are available, they can be used as input for different race detectors. Combining all 4 detectors, we could identify 92% of the bugs. A combination of the two best race detectors MTRAT and ConTest still found 84%. This shows that parallel unit tests may be a veritable approach to ease data race detection. Some race detectors like CHESS [8] are specificially designed for parallel unit tests. However, writing sound parallel unit tests is hard. Therefore, the exploration of automatic generation of parallel unit tests is an active research topic [9, 10]. The parallel test cases we wrote for this study conform to this research: A parallel test case is a test method calling at least two program methods in separate threads; the test method exits as soon as the threads have returned. A parallel test method does not alter the thread schedule or influence the program execution in any way - this is left to the data race detector that executes the parallel test method. Parallel unit tests do not contain assertions or throw exceptions deliberately, the decision whether a race is found or not is completely left to the detector. As we showed, some race detectors break with this definition of a parallel unit test, as they require assertions in the test case. If a parallel test case contains assertions to detect the presence or negative effects of data races, we call it enriched.

Figure 1 shows a sample with a parallel test case and an enriched version. The test case executes *inc()* concurrently in two threads. After they return, the test exits. The results and side effects of the test are not evaluated, this is left to the execution environment, i.e. the race detector. In the second case, the enriched test case waits for both methods and will report an error if the value of *val* is not 2. This test is able to detect malicious race behaviour, but it depends on the concrete thread schedule and the race detector influences the probability to provoke unintended behaviour. Using enriched PUTs, complexity is transfered from detector design to test development; this may be a good approach for bugs that are hard to detect, like atomicity violations. Here, semantic information on the programmer's intention is required to identify an error. Even in our small sample, we show that MTRAT cannot find them, whereas detectors using enriched tests such

```
class CInc {

private int val;

public void inc() {
  val++;
}

public int getVal() {
  return val;
}

}
```

(a) The sample class CInc.

```
class IncrementTest  {
static CInc inc = new CInc();

public static void Main() {
  Thread t1 = new Thread(
    new Runnable() {
    public void run() {inc.inc();}
  });
  Thread t2 = new Thread(
    new Runnable() {
    public void run() {inc.inc();}
  });
  t1.start(); t2.start();
}
```

(b) A parallel test case for CInc.

```
class IncrementTestX {
static CInc inc = new CInc();

public static void Main() {
  Thread t1 = new Thread(
    new Runnable() {
    public void run() {inc.inc();}});
  Thread t2 = new Thread(
    new Runnable() {
    public void run() {inc.inc();}});
  t1.start(); t2.start();

  try { t1.join(); t2.join(); }
  catch (InterruptedException e) { }
  if (inc.getVal() != 2)
    System.err.println("Error!");
}
```

(c) Enriched parallel test case for CInc.

Fig. 1. Code excerpt of the Bank Account Sample with its instrumented versions.

as Jinx can. Nevertheless, developing enriched, sound parallel test cases is harder than usual parallel test cases and to our current knowledge, no automatic generation approaches exist.

VI. Related Work

Bug evaluation has been performed before: Shan Lu et al. [2] evalute 105 synchronisation bugs from large applications for bug patterns. In contrast to our work, no data race detectors have been evaluated. In [11] and [12], different Java race detectors are evaluated. However, the used defects are from artificial sample applications, not from real bug repositories. They indicate that static race detectors produce too much false positives and are hard to use. In [13], programs written in C/C++ are evaluated.

VII. Conclusion

In this work, we searched bug repositories of four large Java applications for historic data races reported by users. We then tested 4 well-known data race detectors with the program revisions which contained the bugs for the first time. Seen individually, each of the four data race detectors found about 50% of the bugs. Together, the detectors found 92% of these bugs. In order to efficiently use the detectors, it is necessary to write specific test cases for data race detection. Our results indicate that a good, test based detection infrastructure combining different race detection approaches may help to find most data races early. However, writing good parallel test cases is hard and time-consuming. We therefore see our results as a motivation to automatically generate parallel unit tests. Different works heading in this direction have been mentioned. For future work, we plan to extend this study to more evaluation programs and other race detectors. As a combination of different tools seems promising, it would be interesting to know if a certain combination of detection strategies leads to optimal results. Furthermore, we want to search for data races using generated test cases from the works presented above.

Acknowledgment

The authors would like to thank Yana Stoeva for her support with this project.

Test City metaphor as support for visual testcase analysis within integration test domain

Artur Sosnówka
West Pomeranian University of
Technology, ul. Żołnierska 49,
71-210 Szczecin, Poland
Email: arsosnowka@wi.zut.edu.pl

***Abstract*—the majority of formal description for software testing in the industry is conducted at the system or acceptance level, however most formal research has been focused on the unit level. This paper shows formal test selection and analyzes criteria for system or integration test based on visualization analysis for low level test cases. Visual analysis for low level test case selection is to be based on inputs from available Test Management system. The paper presents a use case for visual metaphor as a base for analysis testware for a test project in the industry.**

I. Introduction

Software development is dealing with growing complexity, shorter delivery times and current progress made in the hardware technology. Within the software lifecycle the biggest, however not directly seen part, is the maintenance. Number of used systems in the corporation is continuously increasing. During time progression users get trusted to the used software, so tolerated number of deviations is decreasing. As soon as software is put in the production environment, every big change or even small adaption of the source code can cause potential danger in the best case monetary in the worst case image or even human being losses. Nevertheless the maintenance is very often provided during the whole period through different groups of technicians or business partners. This makes the task of programming, understanding and maintaining of the source code for the system and its testware more complex and difficult. Testware management, especially for the high (HLTC) and low level test cases (LLTC) [8], which are focusing on old but still valid functionality keeps going to be not affordable, or omitted on purpose. This causes increasing maintenance costs to the limit, when new development can produce less cost and even be easier to implement than creation of the new functionality within the old system.

Required quality of the software is very often to be reached through quality assurance activities on several levels, starting from unit test, through system, integration and ending on acceptance tests. Artifacts produced during the test process required to plan, design, and execute tests, such as documentation, scripts, inputs, expected out-comes, set-up and clear-up procedures, files, databases, environment, and any additional software or utilities used in testing are named, according to ISTQB, testware [8]. Detection of the problems within a testware can save much effort and reduce necessary maintenance costs. Number of executed tests in the first or second year of software maintenance is not being a disruptive factor for the test projects. As soon as software is coming into the last phase, associated teams are very often moved to the other development projects or taken out of the company (e.g. consultants are being moved from customer to customer). To prove necessary quality after performed adaptations, growing complexity of the system is demanding high professional skills and understanding from people and organizations taken over the responsibility for the system.

Software quality is according to definition:

1. The degree to which a system, component or process meets specified requirements [21].
2. Ability of a product, service, system, component, or process to meet customer or user needs, expectations, or requirements [22].
3. Degree to which the system satisfies the stated and implied needs of its various stakeholders, and thus provides value [23].
4. Degree to which a system, component, or process meets customer or user needs or expectations [21].
5. The degree to which a set of inherent characteristics fulfills requirements [24].

Above given definition is obligating quality assurance teams to perform planned and systematic pattern of actions to provide adequate confidence to the product or item that it conforms to established technical requirements [2]. Execution of needed actions to provide at least same quality during the whole maintenance phase is a big cost factor. According to survey-analysis presented during the iqnite 2011 conference in Düsseldorf [19], almost 60% of the software projects are spending between 20 and 30% of its budget on Quality Management (QM) and testing activities.

Especially big and complex systems are providing large number of functions and demanding even larger number of objects within the testware. To provide 100% fulfillment the test team has to ensure that each function is not affected through the code adaptation and its site effects. Adaptation of the system demands adaptation of testware to fulfill quality requirement for the current system.

Even best managed testware, after few years of usage, is not free of objects which are old, obsolete, duplicated or

978-83-60810-53-8/$25.00

there are no HLTCs or LLTCs covering demanded functionality. Those objects are causing additional management effort and its existence does not increase expected quality needs.

Often developers and managers believe that a required change is minor and attempt to accomplish it as a quick fix. Insufficient planning, design, impact analysis and testing may lead to increased costs in the future. Over time successive quick fixes may degrade or obscure the original design, making modifications more difficult [7] and finishing in not acceptable, low quality of the system.

As long as we are accepting loose of the software and testware quality, its transparency, increasing maintenance costs, decreasing test efficiency, and continuous testware erosion is not a subject. However, in time of financial crisis and decreasing IT budgets, there is none of the project which can come over this dilemma. In the next chapters we would like to show results from pilot project which has been executed in the industry in order to prove usefulness for the approach of the visualization metaphor for testware reorganization.

II. Related Work

Since the early days of software visualization, software has been visualized at various levels of detail, from the module granularity seen in Rigi [13] to the individual lines of code depicted in SeeSoft [3]

The increase in computing power over the last 2 decades enabled the use of 3D metric-based visualizations, which provides the means to explore more realistic metaphors for software representation. One such approach is poly cylinders [20], which makes use of the third dimension to map more metrics. As opposed to this approach in which the representations of the software artifacts can be manipulated (i.e., moved around), our test cities imply a clear sense of locality which helps in viewer orientation. Moreover, our approach provides an overview of the hierarchical (i.e., package, test object) structure of the systems.

The value of a city metaphor for information visualization is proven by papers which proposed the idea, even without having an implementation. [15] Proposed this idea for visualizing information for network monitoring and later [14] proposed a similar idea for software production. Among the researchers who actually implemented the city metaphor, ([9]; [1]; [18]) represented classes are districts and the methods are buildings. Apart from the loss of package information (i.e., the big picture), this approach does not scale to the magnitude of today's software systems, because of its granularity.

The 3D visual approach closest in focus to ours is [10], which uses boxes to depict classes and maps software metrics on their height, color and twist. The classes' box representations are laid out using either a modified tree map layout or a sunburst layout, which split the space according to the package structure of the system. The authors address the detection of design principles violations or anti-patterns by visually correlating outlying properties of the representations, e.g., a twisted and tall box represents a class for which the two mapped metrics have an extremely high value. Besides false positives and negatives, the drawbacks of this approach is that one needs different sets of metrics for each design anomaly and the number of metrics needed for the detection oftentimes exceeds the mapping limit of the representation (i.e., 3). The detection strategies [12] were introduced as a mechanism to formulate complex rules using the composition of metrics-based filters, and extended later [11] by formalizing the detection strategies and providing aid in recovering from detected problems.

III. Visualization Metaphor

A visualization metaphor is defined as a map establishing the correspondence between concepts and objects of the application under test and a system of some similarities and analogies. This map generates a set of views and a set of methods for communication with visual objects in our case - test cases [6].

Lev Manovich has said: "an important innovation of computers is that they can transform any media into another". This gives us possibility to create a new world of data art that the viewer will find as interesting. It does not matter if the detail is important to the author; the translation of raw data into visual form gives a viewer possibility to get information which is the most important just for him. Hence, any type of visualization has specific connotations, which may become metaphoric when seen in context of a specific data source. Metaphor in visualization works at the level of structure, it compares the composition of a dataset to a particular conceptual construct, and the choice of any visualization is always a matter of interpretation.

Numerous currently existing visualization systems are divided into three main classes:

→Scientific visualization systems [4];

→Information visualization systems [5];

→Software visualization systems [16]

Although all visualization systems differ in purposes and implementation details, they do have something common; they manipulate some visual model of the abstract data and are translating this into a concrete graphical representation.

In this paper we are not aiming to present all possible visualization metaphors, as this is not the focus for our research. We would like to show basic and easy to understand "City metaphor" which is helpful for representation specific test data and allow easier test reorganization. After some of the previous research work which is however not in focus of this paper we settled our first attempt to the metaphor which is very widely presented in [17] and is a part of his PhD [17]. In its research and implementation for software source code classes are represented as buildings located in city districts which in turn represent packages, because of the following reasons:

→A city, with its downtown area and its suburbs is a familiar notion with a clear concept of orientation.

→A city, especially a large one, is still an intrinsically, complex construct and can only be incrementally explored, in the same way that the understanding of a complex system increases step by step. Using an all too simple visual

metaphor (such as a large cube or sphere) does not do justice to the complexity of a software system, and leads to incorrect oversimplifications: Software is complex; there is no way around this.

→Classes are the cornerstone of the object-oriented paradigm, and together with the packages they reside in, the primary orientation point for developers.

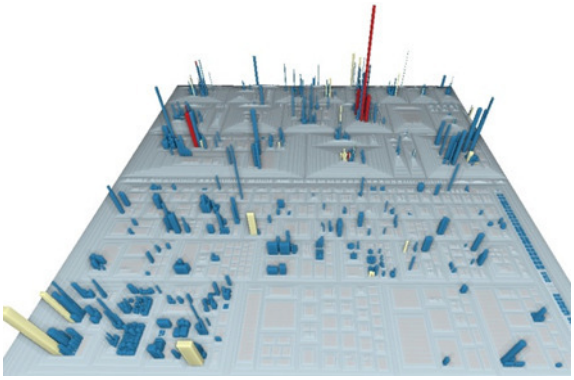

Fig. 1 Example of "Software City" representation of JBoss application server.

In our attempt we perform mapping between available LLTC and its basic metrics, perform testware reorganization and at the end provide easy to understand and manage overview about the current state of testware.

A. Test metrics

To be able to perform data visualization, defined set of the static and dynamic data has to be prepared. Based on the available information's for LLTC we are extracting following basic metrics, which we use for later mapping:

→Amount of LLTC
→Execution status for available LLTC
→Last modification date/age
→Number of executions

Dependent on the metrics type, those are to be taken as a data export through the available API from the test management tool or statistical data taken from the support or test organization.

Fetched metric can be mapped into the chosen visualization metaphor as:

→Data physical properties (color, geometry, height mapping, abstract shapes)
→Data granularity (unit cubes, building border or urban block related)
→Effect of Z axis mappings on the image of the city
→Abstraction of data and LOD are key issues
→Resulting "data compatible" urban models are much larger than the original VR urban models.

IV. Test Reorganization

In this paper we would like to show how useful can be usage of visualization based on the "Test City" metaphor. We would like to show how to perform test reorganization based on the very basic set of metrics available in the test project.

For our experimental work we have established a new system interacting with several Test Management applications placed on the market. The base idea of the system is an automation extraction and pre-evaluation of several different test metrics. Those metric are imported via available API connections from the Test Management tool and evaluated to get required set of metrics. The test metrics are provided as a text file, e.g. CSV (Comma Separated Values), and imported into visualization framework. Used visualization framework is based on the existing solution presented in [17] and allows us perform necessary analysis. The analysis result is taken as an input to the Test Management tool for Test-Set creation and evaluation.

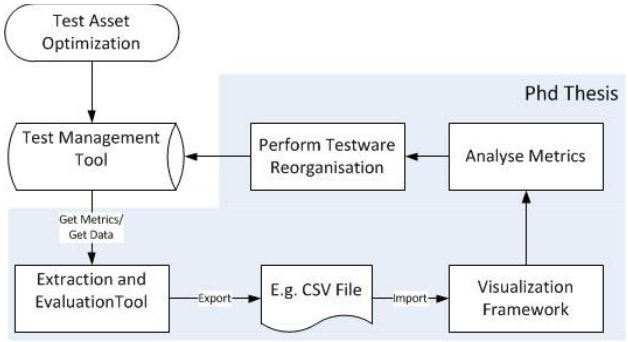

Fig. 2 - Block Structure created analysis system.

Within our research for one test project that contains over 4000 LLTC, we have performed analysis for basic and extended test metrics.

Visualization results for this test project with testware structure shown in the tables 1 and 2 are shown in the Figure 3, 4, 5 and 6. Parameters have been based on following test metrics:

1. Test execution age → mapped to the color.
2. Number of executions → mapped to the height.
3. Modification age → mapped to size.

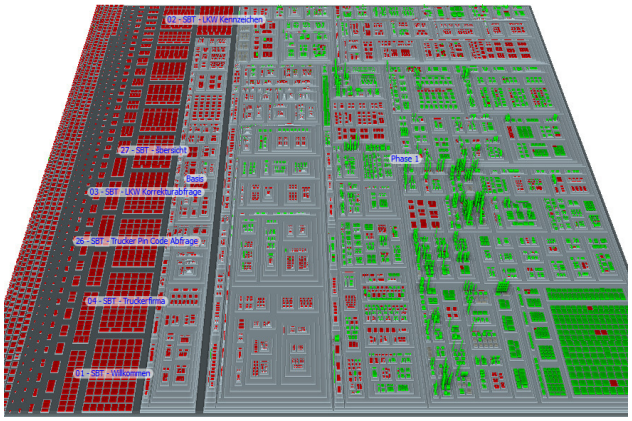

Fig. 3 Test-City based on LLTC for Test Project

To provide real reference to the analysed testware, the districts (as a square group) of the Test City are mapped to the structure created by test teams and managed with help of the Test Management system (e.g. Test folder or Test object).

Looking at the possible analysis for testware visualization according to the Figure 3 we can provide following input for the improvements:

1. There is a large number of old LLTC which has been executed later than threshold set to 370 days (e.g. red buildings – left site in the Figure 3). Most of them had a small height which gives as an information about low number of executions. Those LLTC shall be either archived, or completely removed from the Testware. LLTC not modified for longer than 1 year and rarely executed is with very high probability obsolete.

2. There are other areas in the middle and the top, which has to be taken as well under investigation (red buildings). Based on the height we can assume, most of them are obsolete; however moving to the archive is better option than leaving them within the testware.

3. Each green building is representing LLTC been most likely commonly used in the last 370 days. Large number of high and green buildings allows us to assume area of regression tests. Those LLTC has been used in the last period to assure certain quality of the product and shall not be moved to the archive or adapted within the first phase for testware reorganization.

Below, the tables shows the visualized artifacts in numbers.

Using a visualization we are able to show up hotspots within the testware domain. In order to localize objects within the testware we are focusing the interesting area with help of built in zoom function. Please see Figure 4 for an example

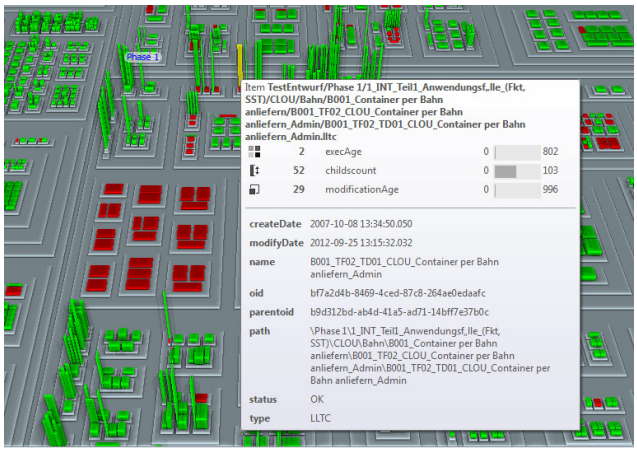

Fig. 4 Zoom on interested LLTC for Test Project

TABLE II.
TESTWARE QUANTITY FOR GIVEN TEST PROJECT

Object type	Quantity
LLTC	18473
Executions	38182

Without having a deep knowledge about the current testware and objects details we can provide the test managers with exact information regarding that LLTCs. Presented and used metrics are very basic but are giving very good start for testware reorganization and have been taken as a feedback for involved test managers.

TABLE I.
TESTWARE QUANTITY STRUCTURE

Execution Age	LLTC	(%)
0	11519	62,36
1-370	6526	35,33
>370	428	2,32

A. Reorganization results part 1

Based on the given output testware reorganization hase been performed. After finishing the first part we have executed testware domain processing and present the results. As an outcome for our work we have presented new Test-City shown in the Figure 5.

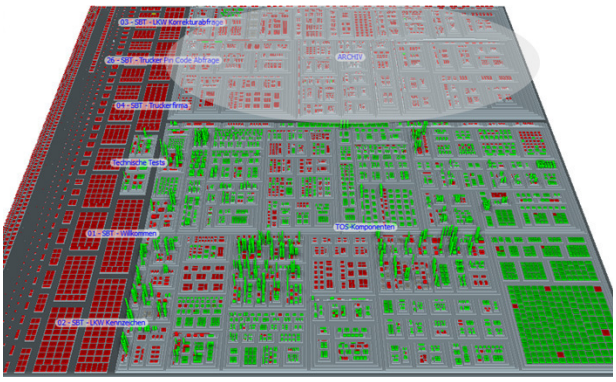

Fig. 5 Test City after first reorganization

There is a marked area where big part of obsolete LLTC has been moved. Most of the buildings are small and red colored, which shows correctness for our attempt.

Below the area we can see large district with several parcels of building which are green colored and relatively high. This allows us to assume commonly used regression tests.

Recursive execution our analysis has gave as result Test-City presented in Figure 6.

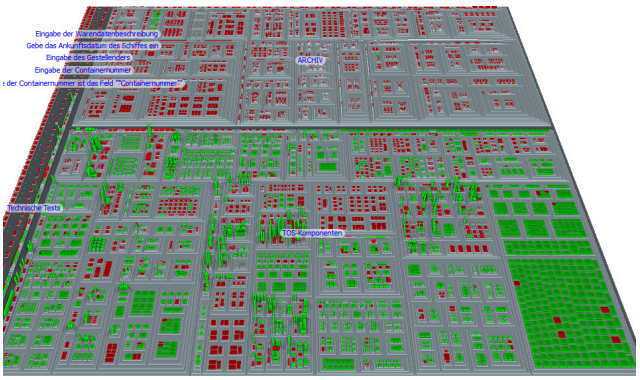

Fig. 6. Final structure for LLTCs within Test Project

There is visible well organized structure within the domain. Current analyze state has been taken as end Phase with used metrics. Deeper analysis can be performed based on other set of metrics which will allow even smaller size of testware database afterwards.

V. Feedback from Test Managers

Created results have been presented to the involved experienced Test managers within the organization and their feedback has been checked. Following results has been achieved:

→There is no false positives, all ugly layouts represents real problems
→No false negatives, no beauty layout should be ugly
→Unique global overview on the testware landscape
→Identify of hotspots ("there was always a question")
→Identify cluster of issues (e.g. regression test)
→Identify cluster of stagnation

The feedback has proven our first impression we got by looking at the testware visual representation. Even if the system looks well-organized, in spite of the numerous disharmonious artifacts: we see a districts, where the test which were executed more than 365 days ago are localized and districts of increased number of high building, even skyscrapers, in which several very important and common tests are defined.

The skyscrapers are giving us the impression how many of existing LLTC have been executed very often. Their color shows execution age as an important factor for testware reorganization.

Within very short time we were able to locate and show large number of obsolete and suspicious LLTCs. Identified hotspots and pain points based on very basic test metrics has been confirmed by the personal working for longer time with the testware, even without our deeper knowledge for the system itself. Necessary data for LLTC adaptation and/or reorganization has been exported based on zooming information at interesting areas/districts given to the test managers and used for next iteration.

Testware reorganization has been done within integration test domain and has brought minimization of used LLTC within a database. This saves in long term necessary maintenance costs and gives well overview about the current testware status.

VI. Conclusion

Test case management, test analysis and test creation are the most important tasks within the whole test management process. It is very hard to concentrate the analysis on small set of the LLTC as it is not getting potential win against the requirement spectrum. Possible loss of testware quality can be threated only as additional cost factor and each activity steering against is helping to keep those on expected level. Performed visualization has shown, how easy in use and efficient can be presented method for testware analysis. Finding an obsolete LLTC based on available metrics is very comfortable and does not require deep system knowledge, even if analyzed system seems to be very complex. This saves needed time, resources and allows problem presentation not only on technical but as well on management level. Presented results have been used for further deeper analysis and reorganization activities.

Additionally we have observed person performing analysis is tending to point its view on maximum two metrics in time and not searching for further information on the third one. This behavior was partly driven via visualization framework and its available mapping attributes and partly human laziness.

Our future directions will focus on the points listed below:

1. Extension for more APIs to Test Management tools available on the market.
2. Comparison for analysis outcome when using same metrics but different Visualization Metaphors.
3. Visualization for metrics within the timeline.
4. Extend number of evaluated metrics, especially to find out duplicate tests.

International Workshop on Cyber-Physical Systems

PROLIFERATION of computers in everyday life requires careful investigation of approaches related to the specification, design, implementation, testing, and use of modern computer systems interfacing with real world and controlling their environment. Cyber-Physical Systems (CPS) are physical and engineering systems closely integrated with their networked environment. Modern airplanes, automobiles, or medical devices are practically networks of computers. Sensors, robots, and intelligent devices are abundant. Our life depends on them. Cyber-physical systems transform how we interact with the physical world just like the Internet transformed how we interact with one another.

The event is a continuation and extension of 2006-2010 Real-Time Software FedCSIS workshops. The objective of the workshop is to assemble and develop a community with main interest in cyber-physical systems.

Topics

Due to an extensive scope of the topics, the workshop will accept papers in the following areas:

- Control Systems
  - embedded/networked/intelligent
  - wireless sensing/actuation
  - adaptive/predictive
- Scalability/Complexity
  - modularity
  - design methodology
  - legacy systems
  - tools
- Interoperability
  - concurrency
  - models of computation
  - networking
  - heterogeneity
- Validation and Verification
  - assurance
  - certification
  - simulation
- Cyber-security
  - intrusion detection
  - resilience
  - privacy
  - attack vectors
- Applications of CPS
  - robotics
  - transportation
  - military
  - medical
  - consumer
  - manufacturing
  - power systems
- CPS Education
  - curriculum development
  - web-based laboratories
  - academic courses
  - pedagogy issues

***Abstract*—To effectively cope with correctness issues of concurrent and timed systems, the use of formal tools is mandatory. This paper proposes an original approach to modeling and exhaustive verification of Java-based concurrent systems which relies on the popular UPPAAL model checker. More precisely, a library of UPPAAL timed automata (TA) reproducing the semantics of major Java concurrent and synchronization mechanisms was developed, which fosters a smooth transition from specification down to implementation. The library includes such common control structures like semaphores and monitors, both classic and Java specific. The paper describes the developed TA library and shows its practical use by means of examples. Finally, an indication of on-going and future work directions is drawn in the conclusion.**

I. INTRODUCTION

CURRENT and prospective availability of powerful multi-core (in the CPU) and many-core (in the Graphical Processing Unit or GPU) computing architectures, and the growing acceptance of Java as a key technology for building time-dependent embedded systems, challenges software developers to the construction of concurrent programs which can greatly benefit from the high-performance computing potential of such parallel machines. Concurrent algorithm design, though, is a well-known difficult task due to human inability to check, either through peer-review or by experimental tests, the correctness of a parallel program where multiple threads of control evolve simultaneously according to complex interleaving of their actions. Race conditions, deadlocks, starvations and so forth are common risks deriving from an improper use of locks.

The work described in this paper argues that to properly design and implement concurrent and time-dependent software systems, the use of formal tools is mandatory which can enable a *reasoning* on concurrency, which is of utmost importance both in an educational or industrial context. This paper describes current status of a research project on modeling and verification (M&V) of concurrent and timed systems which was preliminarily proposed in [1]. The approach is centered on Java as the target implementation language and UPPAAL [2], [3] as a popular, mature and efficient timed automata (TA) [4] based toolbox, which makes it possible to model check complex systems [5], [6]. Although the developed concurrent structures are Java-based, they can easily be ported to other concurrent languages as well. More precisely, this paper describes current shape of a UPPAAL catalog of concurrent control structures, which was significantly improved and expanded with respect to the initial version reported in [1].

This paper contribution can be related to the solutions proposed e.g. by Hamberg & Vaandrager in [7] and to the well-known approach FSP/LTSA [8]. Our work shares with [7] the use of the UPPAAL model checker and some common semaphore and monitor control structures. However, the catalog described in this paper is original, more general and efficient, and fosters different concurrent programming styles. In addition, proposed mechanisms were mainly inspired by Java concurrency features. The FSP/LTSA approach is based on a process algebra specification of a concurrent system (FSP or Finite State Processes), automatically transformed into an equivalent Labelled Transition System (LTS) expression which is model checked in the toolbox LTSA (LTS Analyzer). A system specification must finally be implemented into Java. However, the FSP specification language does not favor the expression of FIFO based concurrent control structures (e.g. of a semaphore). Moreover, FSP/LTSA adopts a discrete time model which can complicate the verification of realistic models. A semantic gap exists between an FSP specification and a corresponding implementation in Java of a system model. Obviously, in general, an implementation cannot be proved to be a faithful concretization of a specification, but a reduction in the above semantic gap, as proposed in this work, can *help* achieving a correct implementation.

The paper is structured as follows. First basic concepts of UPPAAL are summarized. Then a running modeling example is introduced. The paper goes on by describing the developed TA catalog for modeling concurrent Java programs. Then the library is practiced through the chosen example. The discussion puts into evidence a general approach for modeling a Java thread-safe class. Finally, an indication of on-going and future work is given in the conclusion.

II. AN OVERVIEW TO UPPAAL

A system [2] is the parallel composition of multiple timed automata modeled as *template processes*, which can have parameters, can be instantiated, and consist of *atomic actions*. Parallel composition means that UPPAAL is capable of analyzing all the possible action interleavings of the component processes.

978-83-60810-53-8/$25.00

TA synchronize to one another by CSP-like channels (*rendezvous*) which carry no data values. Asynchronous communication is provided by broadcast channels where a single sender can engage in a synchronization with a (possibly empty) group of receivers. The sender of a broadcast signal in no case is blocked. Locations (states) of an automaton are linked by a set of *edges* (transitions). Time is handled by means of *clock* variables. Clocks can only be reset and compared against to a nonnegative integer constant. All the clocks of a model increase automatically at the same rate of advancement of the (hidden and dense) system time. UPPAAL extends basic TA with integer (and boolean) variables and arrays of integers, clocks and channels. Declarations can be global (shared by all the TA in a model) or local to a TA. In latest versions of the toolbox, C-like functions and structures are permitted.

Edges can be annotated by three (optional) components: (i) a *guard*, (ii) a *synchronization* action (? for input and ! for output) on a channel, and (iii) an *update* consisting of a set of clock resets and variable assignments. The update of an output command is executed before that of the matching input command.

A clock *invariant* can be attached to a location as a *progress* condition. The timed automaton can remain into the location as long as its invariant gets not violated. UPPAAL offers also *committed* and *urgent* locations which must be exited immediately (without passage of time), and *urgent channels* whose synchronizations must be fired as soon as possible. Committed locations have priority with respect to urgent locations.

UPPAAL consists of a graphical editor, a simulator and a verifier (model checker). The simulator executes a specification and visually documents the reached execution state by traversing the model state graph. The simulator is useful for model debugging and for examining a diagnostic trace (counter example) built by the verifier. For exhaustive property assessment, the verifier must be used which tries to build the reachability graph of the model, where execution states are organized into equivalence classes based on *time zones* (clock inequalities system).

Safety (e.g., absence of deadlocks) and bounded liveness (e.g. an end-to-end time constraint) properties can be verified by reachability analysis using a subset of TCTL formulas [2]. Admitted formulas (see below) refer to local state properties, i.e. boolean expressions over predicates on locations and integer variables and clock constraints.

$E <> \varphi$ means "*Possibly* φ" (a state can be reached in which φ holds).

$A[]\ \varphi$ means "*Invariantly* φ" (in all states φ holds).

$E[]\ \varphi$ means "*Potentially Always* φ" (a path exists where φ holds in all reached states).

$A <> \varphi$ means "*Always Eventually* φ" (equivalent to: $not\ E[]\ not\ \varphi$).

$\varphi - - > \psi$ means "φ *always leads to* ψ" (equivalent to: $A[]\ (\varphi\ imply\ A <> \psi)$).

III. A MODELING EXAMPLE

A classic yet representative concurrent example which can be modeled and verified using UPPAAL is the Dining-Philosophers problem (see e.g. [9], [10], [11]). N philosophers (e.g. $N = 5$), seat around a table which has a never ending big plate of spaghetti. Philosophers are equipped by a own plate and a single fork (at its left). Philosophers spend their life by thinking and, when they become hungry, try to get the two forks at its left and its right so as to take some spaghetti and then switching to eating. A thinking phase consumes from 2 to 10 time units. An eating requires from 4 to 12 time units. Forks are kept by the philosopher for the whole duration of its eating. When the philosopher finishes eating, it puts forks (hopefully after cleaning them) on the table and turns to thinking again. The availability of forks can now make some adjacent colleague get them and pass to eating as well. The problem is to ensure that the system is live (no deadlock occurs) and that it is bounded the waiting time a hungry philosopher experiments before achieving the forks (absence of starvation).

Fig. 1 shows a "native" model for philosopher i, which directly depends on the basic UPPAAL features. A global array of boolean `fork`, initialized to all true, holds the status of the fork resources. Forks relevant to the i-th philosopher have indexes i (left) e $(i + 1)\%N$ (right). Adjacent philosophers have identifiers respectively $(i + 1)\%N$ (left colleague) and $(i + (N - 1))\%N$ (right colleague).

The model is safe: a philosopher either picks both forks or none, but it is incorrect from the point of view of starvation. A hungry philosopher waits for forks in the `WAITING` location. When the fork status changes, a signal over the broadcast channel `check` is sent which allows all interested philosophers to review their status and possibly switch to the `EATING` location. On a system with N instances of the basic TA, the following queries can be issued:

```
1. A[] !deadlock                          (satisfied)
2. A[] forall(i:pid) Philosopher(i).EATING imply
   !Philosopher((i+1)%N).EATING &&
   !Philosopher((i+(N-1))%N).EATING       (satisfied)
3. Philosopher(0).THINKING-->Philosopher(0).EATING
                                          (not satisfied)
```

Query 2. confirms only not adjacent philosophers can be eating simultaneously. Native UPPAAL models tend to be concise and efficient (in space and time) for model checking. However, a native model has to be intuitively implemented e.g. in Java, relying on the reasoning on the problem solution allowed by model analysis. Ultimately, the action vocabulary of the source model (atomic actions, broadcast signals etc.) has to be transformed in the vocabulary of the target language (synchronized blocks and wait/notifyAll operations, or semaphores etc.). All of this can create problems in achieving a correct implementation. To shorten the semantic gap between modeling and implementation, source model design can be driven by implementation aspects. The following describes a library of UPPAAL TA which furnishes reusable templates for common concurrent control structures.

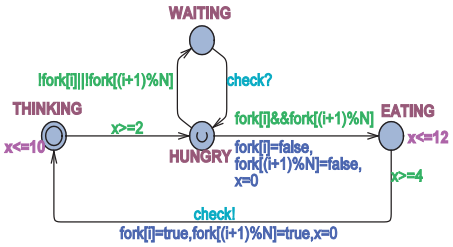

Fig. 1. A UPPAAL native model for the problem of Dining-Philosophers

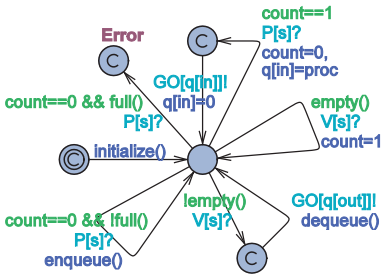

Fig. 2. BINARYSEMAPHORE automaton

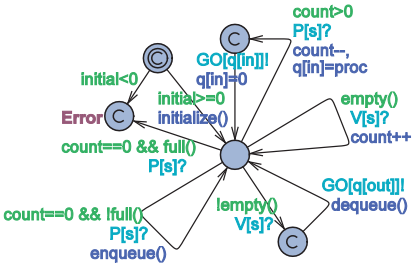

Fig. 3. SEMAPHORE automaton

IV. A TA CATALOG FOR CONCURRENT SYSTEMS

An original library of UPPAAL TA was developed which includes classic binary/counting semaphores, Java inspired semaphore, built-in monitor structure of Java, lock/condition monitor of Java, Hoare monitor, Active Oberon inspired monitor [12], exchangers, barriers etc. Other synchronizers can be added.

A. Semaphore structures

Fig. 2 and 3 respectively show a binary semaphore and a counting semaphore automata whose design tries to balance ease of use with efficient analysis.

Semaphore processes in Fig. 2 and 3 are strong in that they ensure FIFO management of waiting processes. Template parameters include the unique id of the semaphore, the initial number of permits and the expected queue size. A violation of the queue size determines the `Error` location is entered and the verification is deadlocked. Classic `P/V` operations are implemented as channel arrays `P[.]/V[.]` whose dimension mirrors the number of semaphores used in the model. A `P` operation to a semaphore `s`, is requested by a synchronization `P[s]!`. The requesting process is assumed to follow the pattern (see also Fig. 10) of putting into a global (`meta`) variable `proc` its unique process id at the time of `P[s]!`. Variable `proc` is used only during the atomic action of `P[s]!`, with the receiving semaphore which frees it immediately by storing the `proc` value in a local variable. Being a meta variable, `proc` does not contribute to the state part of the model. A further channel array `GO[.]`, whose dimension is the number of processes in the model, is used for blocking the requesting process until the semaphore assigns a permit to it. As a consequence, a `P[s]!` operation issued by process `p` should always be followed by `GO[p]?` synchronization. It is worth noting that the use of `GO` is implicit in the operation `P` in a programming language, but in UPPAAL it serves the purpose of transforming a *strict rendezvous* (`P[.]!`) into an *extended rendezvous* which terminates when the semaphore completes the handling of the `P` operation and allows the requesting process to unblock. A `V[s]!` request never blocks the requesting process and normally does not require the `proc` mediation.

With respect to the proposal in [7], our semaphores use less variables. For instance, the identity of the requesting process during a `P` operation which finds green a binary semaphore, is temporarily stored in the surely empty internal queue of the semaphore. The modeler often experiments that even by dropping one single redundant variable can avoid state explosion during the construction of the state graph, thus facilitating model checking.

Fig. 4 portrays the `JSemaphore` automaton which was inspired by the behavior of `java.util.concurrent Semaphore` class. Differences from classic semaphores concern the possibility of acquiring/releasing atomically a number of permits greater than 1. In addition, a `fair` parameter can be used to request a FIFO behavior of acquire requests. The use of `JSemaphore` rests on the channel arrays `Acquire[.]`, `Release[.]`, `PermitsAvailable[.]`, `GO[.]`, and the use of two global variables: `proc` and `perm`. The `perm` variable stores, at the time of an `Acquire[s]!` or `Release[s]!`, the number of involved permits, and contains the number of available permits of the semaphore following a `PermitsAvailable[s]!` operation. A `GO[p]?` synchronization must follow an `Acquire[s]!` or a `PermitsAvailable[s]!` command. More precisely, it is at the time of `GO[p]?` unblocking that `perm` is filled of the semaphore permits number.

It should be noted that both classic and Java specific semaphore TA are useful in practical concurrency modeling. Whereas a burst of release operations on a `JSemaphore` instance used as a mutex, will increase the permits number arbitrarily, in the case of a `BinarySemaphore` a burst of `V`'s can never augment the internal count beyond 1.

B. Monitor structures

Although widely used, semaphores are often viewed as a low level concurrent abstraction mechanism, where a misuse

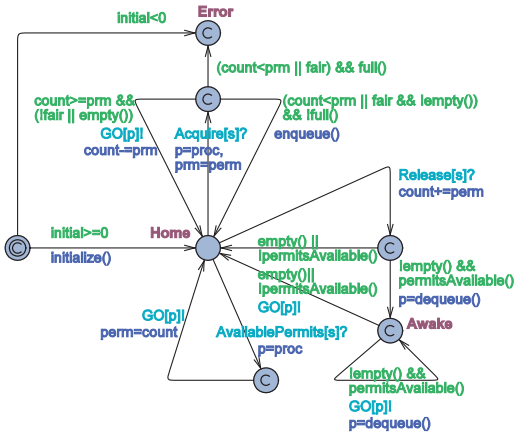

Fig. 4. JSEMAPHORE automaton

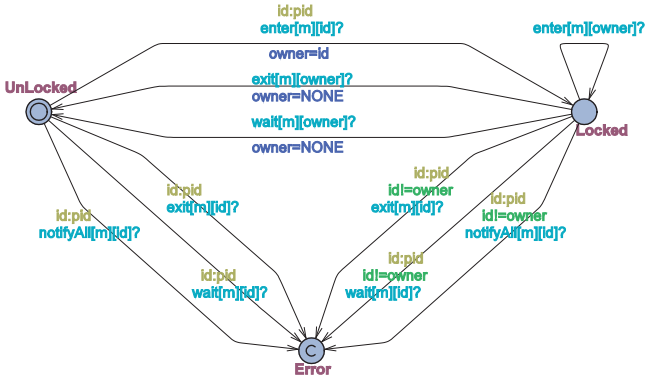

Fig. 5. JMONITOR automaton

of `P/V` operations can easily lead to a deadlock. Monitors, on the other hand, represent a higher level concurrent control structure which naturally acts as a guardian of an abstract data type, e.g. encapsulated into a Java class. Monitors are a key for achieving thread-safe classes by offering control over: mutual exclusion among methods (synchronized blocks or critical sections of code) and suspension/signaling from within a critical section. Different kinds of monitors are defined in the literature, which are characterized by different programming styles and guarantees/obligations which are assigned to both processes and the control structure.

Java adopts the Lampson&Redell [13] monitor structure with broadcast signaling, where suspended processes in a synchronized block are responsible of re-checking a condition in a while-loop to see, at each awaking, if the condition requires coming back to waiting or instead the process can go on because the condition is satisfied. Broadcast signaling is not blocking for the signaler process. An awaken process has to compete in reacquiring the lock for it to actually resume execution.

The Hoare monitor (e.g. [9], page 234) has a different signaling mechanism: when a process (*signaler*) changes the status of the data structure so that a (possibly) waiting process (*signalee*) on a condition can be awaken because the condition holds, control is immediately transferred to the signalee (together with the lock) which is thus the only process which can then proceed. The signaler, on the other hand, is put to wait on an urgent queue from where it gets unblocked as soon as the monitor is up to become free.

A discussion about Lampson&Redell vs. Hoare monitors can be found in [9] at page 240 where it is argued, besides any runtime implication and number of context switches, that Lampson&Redell monitor can be superior in the most general case.

An example of a monitor which facilitates the developer by transferring responsibilities from the programming level to the control structure, was adopted in the Active Oberon language [12]. Here the programmer has only to deal with the logic of conditions which, as long as they do not hold, prescribe a process has to wait. Signaling and process awaking is hidden in the control structure.

In the following, a series of developed monitor TA is presented.

Fig. 5 depicts the `JMonitor` automaton which allows to model concurrent objects according to the Java built-in monitor. A monitor instance can be operated using such channel arrays as `enter[mid][pid]`, `exit[mid][pid]`, `wait[mid][pid]`, `notifyAll[mid][pid]` which accommodate for the possible existence of multiple monitor instances in a model. Types `mid` and `pid` respectively are integer sub-ranges of unique identifiers for monitors and processes used in the model. For instance, `enter[m][p]!/exit[m][p]!` are used by a process `p` to explicitly enter/exit to/from a synchronized block based on monitor identifier `m`. Similarly, `wait[m][p]!/notifyAll[m][p]!` serve respectively to suspend the requesting process p until its condition holds (in a while loop), and to awake all the processes suspended on monitor `m`.

Every Java object owns a lock which can be used as a monitor. The lock holds one implicit condition, whose meaning is only known to the modeler/programmer. The lock object is associated with a *wait-set* where both entering processes which find the lock closed, or processes within a synchronized block (based on the lock object) but whose condition prescribes waiting, are put (although the two kind of waiting processes are clearly distinguished to one another) and suspended. Processes which are suspended for a `wait` operation can only be awaken by a `notifyAll` operation which does not free the lock. Other processes awake as the lock/monitor is up to be abandoned (at an `exit` or `wait` operation). In the proposed implementation, the wait-set is purposely realized implicitly. Processes requesting `enter` simply are blocked if the monitor is already locked.

Processes which execute `wait` are supposed to move into a location (see `WAITING` in Fig. 11) from which they can only exit following a relevant `notifyAll` signal. Towards

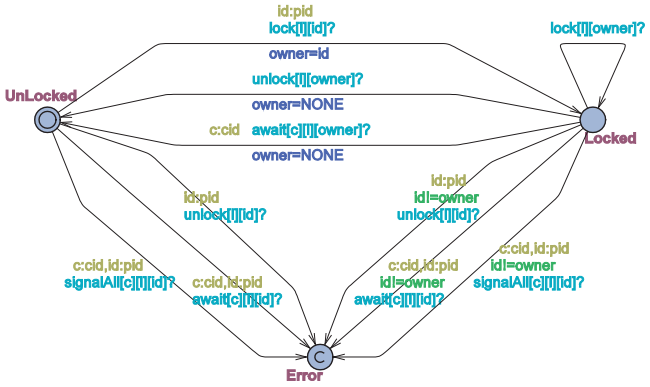

Fig. 6. LOCK automaton

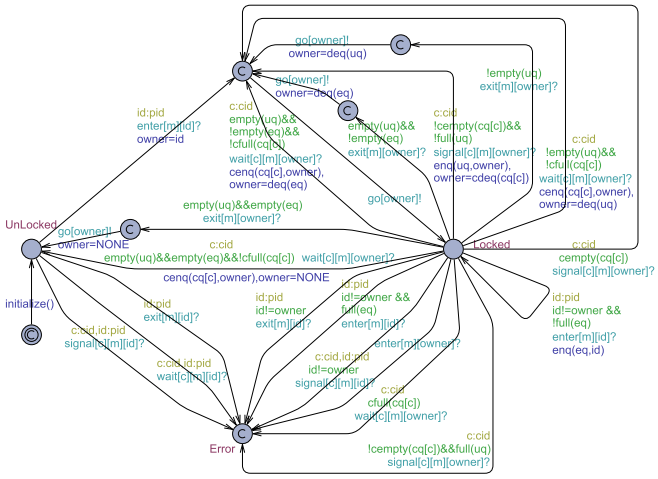

Fig. 7. HOAREMONITOR template

this, channels `notifyAll[.][.]` are declared as broadcast channels.

The automaton in Fig. 5 maintains the identity of the monitor `owner`, which is used both to realize reentrancy and to check for erroneous operations, which in Java correspond to raising an `IllegalMonitorStateException`.

The implicit realization of the wait-set complies with the Java specification and lets processes which try to enter the monitor and awaken processes to be handled non deterministically and thus without any privilege. The design pattern also requires that an awaken process from a wait location has to explicitly compete in reacquiring the lock (this operation is hidden in the Java `wait()` method of class `Object`). The design pattern makes it possible to implement also a *timed wait*. In this case, from the wait location (now provided of a clock invariant) the process can also exit when the clock goes beyond a given time limit (*timeout*), thus competing for the lock before checking the condition.

In reality the Java built-in monitor also offers a `notify` operation to awake *one* unspecific process suspended in the wait-set. For generality reasons the automaton in Fig. 5 only implements the `notifyAll` (broadcast) operation because, as discussed e.g. in [14] at pages 181-183, the use of `notify` can cause what is known as the `Lost-Wakeup-Problem`.

Since Java 5, the `java.util.concurrent` package also provides a refinement of the built-in monitor through the lock/condition control structure. In this version, it is possible to introduce both a lock object and a certain number of condition objects linked to the lock object. As a consequence, processes can be suspended on the different conditions and the signaling mechanism can be directed to all the processes waiting on a certain condition.

Fig. 6 depicts the Lock automaton which realizes the locking mechanism (and its reentrancy) and also handles the relevant conditions.

Monitor operations are captured by two dimensional `lock[lid][pid]`, `unlock[lid][pid]` array channels, whose first dimension is related to the sub-range of lock unique identifiers used in a model, and whose second dimension is tied to the process unique identifiers, and three dimensional `await[cid][lid][pid]`, `signalAll[cid][lid][pid]` array channels where the first dimension consists of the unique condition identifiers of a given lock identifier.

As in the case of the `JMonitor` automaton, the enter wait-set and condition wait-set are realized implicitly, as well as `signalAll[cid][lid][pid]` channels are declared as broadcast channels.

The same conventions discussed for `JMonitor` apply here: a waiting process on a condition `c` is supposed to wait into a suitable location of the automaton, from where the process can exit following a `signalAll` or a timeout. It then has to compete for reacquiring the lock and is in charge of re-checking the relevant condition.

As it is common, the Hoare monitor can be achieved on top of semaphores, in particular binary semaphores. If N are the conditions of the monitor, $N + 2$ semaphores are to be used: one as mutex, another for the urgent mechanism of signalers and N for conditions. In Fig. 7, a slightly different but equivalent and more efficient automaton implementation is proposed which rests on $N + 2$ queues. The monitor can be used through the matrices of channels `enter[mid][pid]`, `exit[mid][pid]`, `wait[cid][mid][pid]`, `signal[cid][mid][pid]`, `go[pid]` where `mid`, `cid` and `pid` are respectively the integer sub-ranges of monitor unique identifiers, relevant condition unique identifiers, unique process identifiers. The pattern of use does not necessarily depend on the while-loop required by built-in Java monitor. A process waiting on a condition is, in general, guaranteed that the condition holds when it is signaled. The monitor is assumed to be not reentrant. As a rule, a synchronization on the `go[.]?` channel must follow each invocation (!) of `enter`, `exit`, `wait` or `signal` operation.

A simplification of the Hoare monitor is provided by the Active Oberon monitor (see Fig. 8) where the signaling operation is removed. The burden (and the risks) of proceeding by an awaken process whose condition cannot possibly hold,

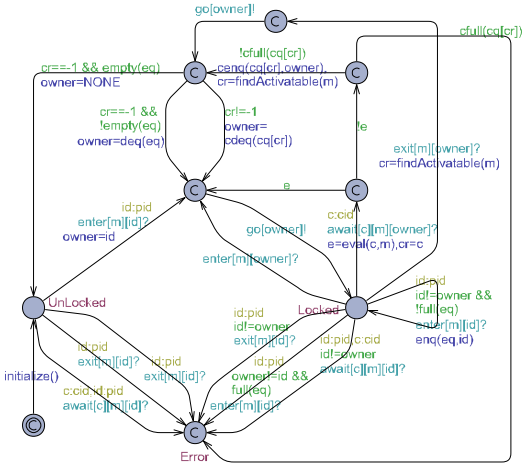

Fig. 8. AOMONITOR template

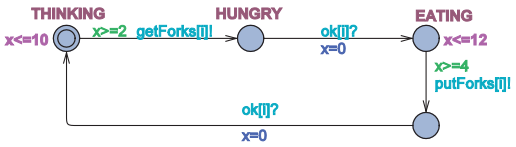

Fig. 9. The PHILOSOPHER automaton

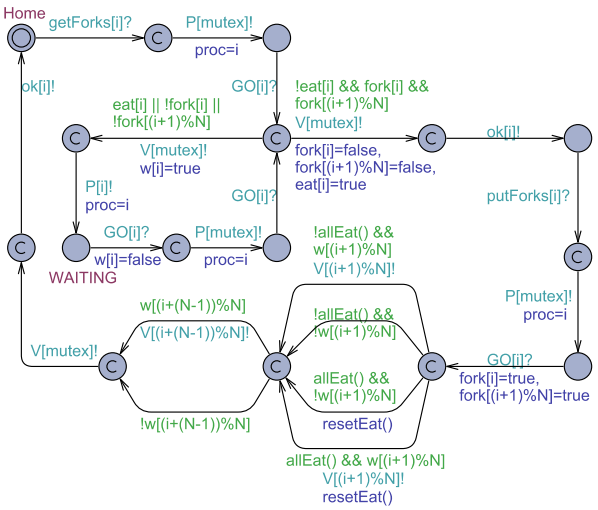

Fig. 10. Manager automaton based on semaphores

are eliminated by the control structure which manages an implicit signaling and the transfer of the lock to an awaken process. Therefore, the resultant modeling/programming style becomes more concise with respect to the Hoare monitor.

The `AOMonitor` automaton (Fig. 8) is supposed to be reentrant. Its use depends on the matrices of channels `enter[mid][pid]`, `exit[mid][pid]`, `await[cid][mid][pid]`, `go[pid]`. A `go[.]?` synchronization is required after each invocation (!) of `enter`, `exit` or `await` operation. Any waiting room is realized as a FIFO queue.

The modeler has to introduce a global `bool eval(cid,mid)` function, model specific, which receives a condition id and its monitor id and returns true if the logical boolean expression which is associated with the given condition of the given monitor, holds; otherwise `eval()` returns false.

The `findActivatable(mid)` function used in Fig. 8 scans the list of conditions of the given monitor and returns, if there is one, the identifier of the first condition which is found satisfied; the function returns -1 if the search fails. The result of `findActivatable` is used to transfer the control (together with the monitor lock) to the oldest process waiting on the given condition.

In order to avoid starvation, the control structure maintains the last index of success on the list of conditions so as to start the next lookup from the next position and cyclically.

V. PUTTING THE LIBRARY INTO ACTION

Usefulness of the developed library was assessed through several examples. In the following, the use of the library is demonstrated by applying it to the Dining-Philosophers problem. Modularity issues suggest separating the application processes from the details of concurrency control which in Java are embedded into a thread-safe class. Therefore it is convenient to organize the Philosopher model as shown in Fig. 9 and introducing a `Manager` model which exposes a suitable interface to philosopher processes and hides the synchronization constraints. In particular, the channel arrays `getForks[pid]`, `putForks[pid]` e `ok[pid]` are assumed to define the `Manager` interface. Since each philosopher can block in the manager model, N identical instances of the `Manager` are created, each one corresponding to a distinct philosopher. All the manager instances, though, share global data e.g. the boolean array `fork[.]` about free/occupied status of forks. Both `Philosopher` and `Manager` have one single parameter i (of type `pid`) which furnishes the identity of the philosopher. Following a `getForks[i]!` or `putForks[i]!` operation, the philosopher expects an `ok[i]?` synchronization confirming that the requested operation was carried out. Again, in a Java implementation the `ok` signal is redundant because the extended rendezvous is automatically provided by `getForks/putForks` methods of the `Manager` class.

A. Manager based on semaphores

In Fig. 10 is depicted a `Manager` automaton which uses $N+1$ binary semaphores.

One semaphore is used for mutual exclusion (`mutex`, initialized to 1). The remaining N semaphores, one per philosopher, are waiting rooms or conditions (always kept to 0). Condition identifiers coincide with philosopher identifiers. The model in Fig. 10 uses two further boolean arrays: `w[pid]` and `eat[pid]`. The former serves to know if a

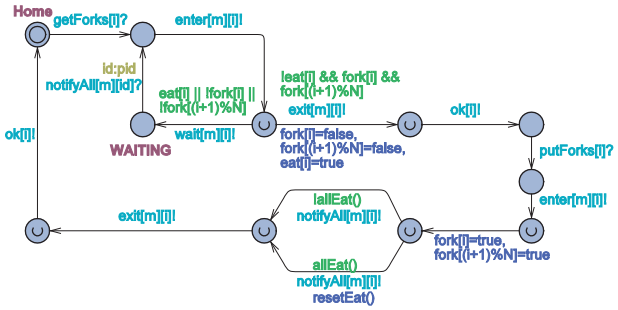

Fig. 11. Manager automaton based on Java monitor

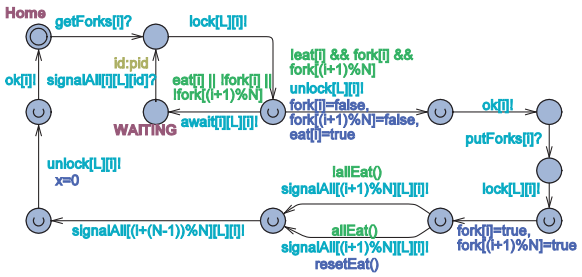

Fig. 12. Manager automaton based on lock/condition monitor

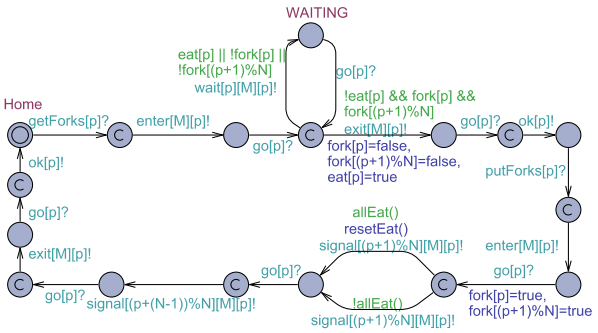

Fig. 13. Manager based on the Hoare monitor

given philosopher is waiting for forks. The latter is used for implementing a simple strategy for avoiding starvation. Philosophers are supposed to eat at turns. A turn finishes when all philosophers have eaten. A `getForks` request is not responded either because some fork is unavailable or the philosopher has already eaten in the current turn. The latest philosopher who eats resets the array `eat` so as to start a new turn.

All the three queries suggested in section III, are now satisfied. Query 3 concerning proving absence of starvation deserves some further comments. It is a liveness property. UPPAAL is most apt to verify safety and bounded liveness properties. General liveness can be difficult to assess. In a normal location, in fact, an automaton can stay an arbitrary amount of time. To help checking liveness properties, Urgent/Committed locations or urgent channels should be used. In Fig. 10, the use of committed locations was preferred.

A bounded liveness property for the model of Fig. 9 and Fig. 10 concerns the worst case amount of time a philosopher stays in the `WAITING` location of its manager, waiting for the other colleagues to complete the current turn. Using $N = 5$ philosophers, and adding a decoration clock y to the `Manager` model, which is reset at each `getForks[i]?` request, the following query was issued to the UPPAAL verifier:

```
A[] Manager(0).WAITING imply Manager(0).y<=64
```

The query was found satisfied, but changing the upper bound to 63 the query no longer holds. This result corresponds to a $(10-(2+4))*(N-1)$ remaining thinking time for the other partners, and then a $12*(N-1)$ worst case eating time of remaining colleagues.

As a final remark, except for the `GO[pid]` and `ok[pid]` channels which are required only in the UPPAAL models, the automata in Figures 9 and 10 can directly be expressed in Java code.

B. Manager based on JMonitor

Using the built-in Java monitor, a `Manager` model like that shown in Fig. 11 can be achieved. With respect to the semaphore based solution, it requires less space and time for the analysis.

A similar model to that in Fig. 11 was built using the lock/condition monitor, which is slightly more efficient due to reduced partial order following a signaling operation. The new model is portrayed in Fig. 12.

It should be noted that since enter/lock requests can be delayed by the monitor being already locked, such operations should not exit from urgent locations. In addition, because of broadcast signaling, there is no need to pay for the `w[pid]` boolean array used in the semaphore based solution.

C. Manager based on Hoare monitor

It was interesting achieving a Hoare monitor based model for manager, to compare expressiveness and guarantees during signaling with Java built-in or lock/condition based versions. The model is portrayed in Fig. 13. As expected, this particular example does not allow to exploit the normal guarantees of the Hoare monitor: i.e. that a signaled process waiting on a condition is sure its condition holds when awaken by a signal. In fact, putting forks is only a partial fulfillment for the precondition of adjacent philosophers to be able to get forks. As a consequence, without going to put much burden on the signaler processes, the right solution consists in envisioning the while-loop also in a signalee so as to come back to waiting if the precondition for awaking does not actually hold. Without the while-loop, UPPAAL confirms the model is incorrect.

Model of Fig. 13 is more expensive in terms of space and time for verification with respect to models in Fig. 11 and Fig. 12. This is due to the use of queues for conditions and related bookkeeping data.

D. Manager based on Active Oberon monitor

This version of the `Manager` model is illustrated in Fig. 14.

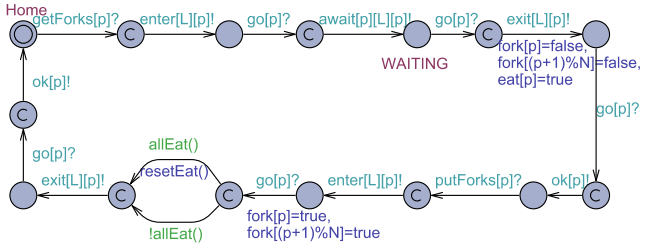

Fig. 14. Manager automaton based on the Active Oberon monitor

The following is the `eval()` function which was prepared for working with the Dining-Philosophers problem:

```
bool eval( cid c, mid m ){
  if( !eat[c]&&fork[c]&&fork[(c+1)%N] )
    return true;
  return false;
}//eval
```

The solution in Fig. 14 is the most concise and easy to follow from the modeler/programmer point of view. Its analysis performance, though, is similar to the Hoare monitor version because the model has almost the same data requirements.

Verification experiments with $N = 5$ philosophers were carried out on a Win 8, 12GB, Intel Core i7-3770K, 3.50GHz. To figure out efficiency of the various models, the query which checks for the absence of deadlocks lasts in the worst case in about 25sec with a RAM peak of about 100MB.

VI. Conclusion

The UPPAAL library of timed automata (TA) proposed in this paper is effective for modeling and verification (M&V) of Java-based concurrent and timed programs. It includes both semaphores and monitor control structures. The Java built-in monitor or its refinement based on lock/condition are often preferable both from the M&V perspective and the implementation viewpoint. The Active Oberon monitor offers the most concise level for modeling and implementing a thread-safe class.

Being not primitive in Java, Hoare monitor and Active Oberon monitor classes were achieved on top of semaphores. By the way, a `BinarySemaphore` class was also realized which is weakly bisimilar to the automaton in Fig. 2.

A nondeterministic point e.g. in the Hoare monitor class accompanies the implementation of the `wait` operation which in general must free the lock and put the requesting process to sleep. Whereas UPPAAL atomic actions hide the problem (e.g. through a committed location), in a concrete implementation the alea point could be handled by ensuring that before relinquishing the lock the wait operation starts a new time-slice. This could be achieved by using the Thread `yield()` method. However (see discussion in [15] at page 287) the `yield()` method can often behave as a no operation. A better provision could be a `Thread.sleep(1)` if 1 millisecond is the time resolution of the underlying operating system.

The library is currently in use in an undergraduate course on systems programming and the response of students is positive.

A major benefit of the catalog and of the UPPAAL model checker rests on the possibility of favoring a *reasoning on concurrency*.

On-going and future work are geared to:

- Optimizing the library so as to improve the efficiency of model checking activities.
- Extending the library with other concurrency control structures, e.g. based on the concept of software transactional memory [14] which delivers a different and attractive style of concurrent programming.
- Extending the approach based on the UPPAAL model checker to M&V of lock-free concurrent objects [14] which are often perceived as a grand challenge for an exploitation, in parallel and embedded software systems, of the computing potential of current and future multi-core/many core machines.

***Abstract*—In the last few years hybrid automata have been widely applied in the modeling and verification of hybrid systems, but their related formal verification techniques usually rely on un-implementable assumptions to which a concrete control strategy cannot adhere. For this reason, once a hybrid model of the system has been proved to be correct with respect to the desired properties, it would be valuable to derive a correct-by-construction implementable control strategy for such a model. This work discusses a new methodology and a corresponding tool-chain that allows to synthesize an implementable control strategy for the class of hybrid automata named Lazy Linear Hybrid Automata (LLHA). LLHA model the discrete time behavior of control systems containing finite-precision sensors and actuators interacting with their environment under bounded delays.**

I. Introduction

HYBRID systems are dynamical systems whose behaviors cannot be characterized faithfully using either discrete or continuous models. They consist of a discrete part that operates in a continuous environment, and for this reason, they are sensitive not only to time-driven phenomena but also to event-driven ones. The presence of mixed dynamics makes the formal treatment of this kind of systems considerably hard.

Hybrid automata (HA) [1] are a powerful formalism for modeling hybrid systems. It extends the usual definition of finite state automata with continuous variables that evolve according to dynamics characterizing each discrete state. In the last few years, a wide spectrum of algorithmic techniques has been studied to solve the problems of simulation and verification for hybrid automata. Current state-of-art tools can verify hybrid systems with complex nonlinear dynamics [2], [3], or linear systems with a large number of continuous variables [4], thus becoming of interest also for real test-cases and application domains.

Another phase of the design flow where the interplay of continuous and discrete behaviors makes things complicated is the refinement and implementation phase. Indeed, formal verification techniques for hybrid automata usually rely on un-implementable assumptions, such as the *synchrony hypothesis*, i.e., the capability of performing any computation in zero time units and forcing a change in the dynamics of the hybrid system with no delays. As a consequence, the verification results on the correctness of the ideal model of the system cannot be directly applied to a real implementation [5].

For this reason, new semantics for hybrid automata, which do no rely on synchrony or other unrealistic assumptions, have been proposed in the literature [6], [7]. By formally verifying the correctness of the system using such semantics, it is possible to synthesize an implementable control strategy for the analyzed hybrid system, i.e., determine the *performance and latency bounds* to be satisfied by any conservative concrete hardware/software device that implements the system.

In [6], [8], the authors propose the Almost-ASAP semantics, a formal semantics that imposes a controller to react within a bounded delay, i.e., Δ, when a synchronization or a control action has to take place. The authors use reachability analysis [1] to look for the largest value Δ for which the controller is still correct w.r.t. the properties that the original instantaneous model has to enforce. Such a Δ-relaxed controller represents an implementable control strategy if $\Delta > 0$. The main limitation of this approach is that the problem of synthesizing such a value Δ may not be decidable.

The work in [7] proposes a similar approach for synthesizing implementable control strategies. The authors try to derive an implementable control strategy from the original instantaneous model by shrinking the guards of the latter so that, by assuming bounded reaction delays for synchronization and control actions, all behaviors of the former are non-blocking (i.e., shrinkability problem). This means that all timing requirements satisfied by the instantaneous control strategy, such as critical deadlines, are strictly respected by the derived one. The authors have shown that deciding the shrinkability problem can be checked in EXPTIME.

This work focuses on the problem of automating the synthesis of implementable control strategies for a relevant class of hybrid automata, named *Lazy Linear Hybrid Automata* (LLHA). Such a kind of automata takes into account all the typical implementation aspects (e.g., discrete time behaviors, finite precision of sensors and clock, sensing and actuation delays), thus, once they have been proved correct, they provide an implementable control strategy for the hybrid system.

The paper is organized as follows. Section II introduces the fundamental definitions and semantics of LLHA which motivate the assumptions at the base of the proposed methodology for synthesis of implementable control strategies described in Section III. Section IV describes some case studies to which the methodology has been applied. Finally, Section V is devoted to concluding remarks.

II. BACKGROUND

In the following the class of LLHA is described. A LLHA is meant to be a model of a closed-loop system consisting of a digital controller interacting with a continuous environment [9]. The controller samples the state of the continuous environment at periodic discrete-time instants. The state of the environment consists of the values of the continuous variables as observed by the sensors. These values are digitized with finite precision and reported to the controller that may decide to switch the state of the environment. In such a case, the controller generates suitable output signals that, once transmitted to the actuators, will effect the desired change. Sensors will report the values of the current variables and actuators will change the evolution of the continuous variables with bounded delays.

A. The LLHA formal definition

Definition 1 (Lazy Linear Hybrid Automaton)**.** A finite precision Lazy Linear Hybrid Automaton (LLHA) is a tuple $\langle X, Q, init, inv, flow, E, jump, Act, P, D, \epsilon, B\rangle$. The components of a LLHA are as follows:

- *Variables*. A finite set $X = \{x_1, \ldots, x_n\}$ of real-valued variables. $\dot{X}$ stands for the set $\{\dot{x_1}, \ldots, \dot{x_n}\}$ of dotted variables and X' stands for the set $\{x'_1, \ldots, x'_n\}$ of primed variables.
- *Control modes*. A finite set Q of control modes. $Q_0 \subseteq Q$ denotes the set of initial modes.
- *Initial condition*. A labeling function $init$ that assigns to each control mode $q \in Q_0$ an initial predicate. The initial predicate $init(q)$ is a convex (non-)linear formula over the variables in X.
- *Invariant condition*. A labeling function inv that assigns to each control mode $q \in Q$ an invariant predicate. The invariant predicate $inv(q)$ is a convex (non-)linear formula over the variables in X.
- *Flow condition*. A labeling function $flow$ that assigns to each control mode $q \in Q$ a flow predicate. For each $i \in \{1, \ldots, n\}$, let $\dot{X}^i_q \subset \mathbb{Q}$ be the set of legal flow rates for the variable x_i in the control mode q. The flow predicate $flow(q)$ is of the form $(\dot{x}_1 \in \dot{X}^1_q) \wedge \ldots \wedge (\dot{x}_n \in \dot{X}^n_q)$.
- *Control switches*. A set E of edges (q, q') from a source mode $q \in Q$ to a target mode $q' \in Q$.
- *Jump condition*. A labeling function $jump$ that assigns to each control switch $e \in E$ a predicate. Each jump predicate $jump(e)$ from the control mode q to q', is given by the conjunction of a guard and a reset condition. The *guard* is given by a convex (non-)linear formula over the variables in X. The *reset* condition is given by the identity predicate over the variables in $X \cup X'$ (e.g., $x'_i = x_i$).
- *Actions*. A finite set Act of actions that the automaton uses either for internal synchronization or for synchronizing with other communicating automata. An edge labeling function $action : E \to Act$ assigns an action to each control switch.
- *Period*. P represents the sampling interval of the controller, i.e., control mode switches take place at times T_0, T_1, T_2, ... where $T_{k+1} = T_k + P$.
- *Delay parameters*. $D = \{g, \delta_g, h, \delta_h\} \subset \mathbb{Q}$ is the set of delay parameters such that $0 \leq g \leq g + \delta_g < h \leq h + \delta_h \leq P$, where g denotes the actuation delay, h denotes the sensing delay and δ_g, δ_h represent the uncertainty in actuation and sensing delay, respectively.
- *Precision*. ϵ_i is the precision of measurement of variable x_i.
- *Range*. $B_i = [B_{i_{min}}, B_{i_{max}}] \subset \mathbb{R}$ is the allowed range of the variable x_i such that $B_{i_{min}}$, $B_{i_{max}} \in \mathbb{Q}$ and $B_{i_{min}} < B_{i_{max}}$.

To keep the notation compact, in what follows, $q \xrightarrow{a,\varphi} q'$ is used to denote that there exists a control switch $e = (q, q')$ with $q \neq q'$, $a = action(e)$ and $\varphi = jump(e)$ in A.

Unlike the conventional definition of linear hybrid automata [10], invariants and guards in LLHA can be non-linear (i.e., polynomial). The flows in linear hybrid automata are represented using rectangular formulas which denote closed intervals of the form $[l, r] \subset \mathbb{R}$ with $l, r \in \mathbb{Q}$ and $l < r$. Under the assumption of finite precision, in a LLHA such rectangular formulas denote finite sets of rational values modeling the rate of change of the different continuous variables.

B. The LLHA formal semantics

Let A be a lazy linear hybrid automaton as defined above. The following definitions are required to specify the behavior of A in terms of a transition relation.

Definition 2 (Valuation for continuous variables)**.** Let $X = \{x_1, \ldots, x_n\}$ be a set of continuous variables. A valuation V for the variables in X is a member of $\mathbb{R}^n$ such that V assigns a real value $V(i)$ to each variable x_i.

Definition 3 (State of a LLHA)**.** A *state* of a lazy linear hybrid automaton A is a triple $(q, V, \hat{q})$ where q, $\hat{q}$ are control modes and V is a valuation. q is the control mode holding at the current time instant and $\hat{q}$ is the control mode that held at the previous time instant. V captures the actual values of the variables at the current instant. The state $(q, V, \hat{q})$ is feasible if and only if $V(i) \in [B_{min_i}, B_{max_i}]$ for every i.

Intuitively, the state of a LLHA stores information about current and previous control modes (i.e., q and $\hat{q}$, respectively) due to the fact that, as a result of a mode change, the change of rates of continuous variables will occur with bounded delays. As a consequence, the evolution of continuous variables in a mode q will depend not only on the flow predicates of q, but also on the flow predicate of the previous control mode $\hat{q}$.

The initial state is, by convention, the triple $(q_{init}, V_{init}, q_{init})$. It is assumed without loss of generality that the initial state is feasible. Let S_A denote the set of states of A.

For convenience, in what follows, it is assumed that the rate of change of continuous variables is constant in each control mode. Thus, each flow predicate $flow(q)$ can be described

by vector $\rho_q \in \mathbb{Q}^n$ that specifies the rate $\rho_q(i)$ at which each variable x_i evolves when the automaton is in the control mode q.

Definition 4 (Transition relation of a LLHA)**.** $\Longrightarrow \subseteq S_A \times (Act \cup \{\tau\}) \times S_A$ is such that:

- Let $(q, V, \hat{q})$, $(q', V', \hat{q}') \in S_A$ be states and $a \in Act$. Then $(q, V, \hat{q}) \overset{a}{\Longrightarrow} (q', V', \hat{q}')$ if and only if $\hat{q}' = q$ and there exist a control switch of the form $q \overset{a,\varphi}{\longrightarrow} q'$ in A and $t_1 \in \mathbb{Q}^n$, $t_2 \in \mathbb{Q}^n$ such that $\forall i \in [1, n]$, $t_1(i) \in [g, g+\delta_g]$, $t_2(i) \in [h, h+\delta_h]$ and the following conditions are satisfied:
  1) Let $v_i = V(i) + \rho_{\hat{q}}(i) \cdot t_1(i) + \rho_q(i) \cdot (t_2(i) - t_1(i))$ for each i. Then $(\langle v_1 \rangle, \ldots \langle v_n \rangle)$ satisfies φ and each $\langle v_i \rangle$ represents the digitized value of the variable x_i that has been rounded using the value of ϵ_i.
  2) $V'(i) = V(i) + \rho_{\hat{q}}(i) \cdot t_1(i) + \rho_q(i) \cdot (P - t_1(i))$ for each i.
- Let $(q, V, \hat{q})$, $(q', V', \hat{q}') \in S_A$ be states. Then $(q, V, \hat{q}) \overset{\tau}{\Longrightarrow} (q', V', \hat{q}')$ if and only if $q' = \hat{q}' = q$ and there exists $t_1 \in \mathbb{Q}^n$ and $\forall i \in [1, n]$, $t_1(i) \in [g, g + \delta_g]$ such that:
  1) $V'(i) = V(i) + \rho_{\hat{q}}(i) \cdot t_1(i) + \rho_q(i) \cdot (P - t_1(i))$ for each i.

The lazy semantics of linear hybrid automata means that if a control mode switch took place at time T_k, then the delay in actuating a change in flow rates lies between $[T_k + g, T_k + g + \delta_g]$. Similarly, a control decision made at time T_k is based on the variables values read by the controller at some time in the interval $[T_{k-1} + h, T_{k-1} + h + \delta_h]$. The parameters δ_g and δ_h represent the bounded uncertainty in actuation and sensing delay, respectively. The precision ϵ_i depends on the accuracy of the sensors measuring x_i from the continuous dynamical system. Guards and state invariants are evaluated on the digitized values $\langle x_i \rangle$ of the variables x_i that have been rounded using the value of ϵ_i. The parameter B, instead, reflects the range of values which can be taken by a state variable associated with a fixed width register.

From the semantics defined above, it is possible to derive the notions of trajectory of a LLHA and the reachability relation between states.

Definition 5 (Trajectory of a LLHA)**.** Let A be a lazy linear hybrid automaton and let $(q, V, \hat{q})$ be a state of A. A trajectory of A from $(q, V, \hat{q})$ is a sequence of states $(q_i, V_i, \hat{q}_i)$ with $i > 0$, such that $(q_0, V_0, \hat{q}_0) = (q, V, \hat{q})$ and $(q_{i-1}, V_{i-1}, \hat{q}_{i-1}) \overset{\alpha}{\Longrightarrow} (q_i, V_i, \hat{q}_i)$ for some $\alpha \in Act \cup \{\tau\}$.

Example 1. Figure 1(i) sketches a lazy linear hybrid automaton A with two control modes q_1 and q_2. Let i and j be such that $i, j \in \{1, 2\}$ and $i \neq j$. Each invariant condition $inv(q_i)$ is defined as a subset I_i of $\mathbb{R}$ and the LLHA can stay in the control mode q_i if the valuation of the variable x satisfies the invariant condition. The jump condition of a control switch $e_{ij} = (q_i, q_j)$ is specified by a guard set G_{ij} and a reset function that, by definition of LLHA, is always

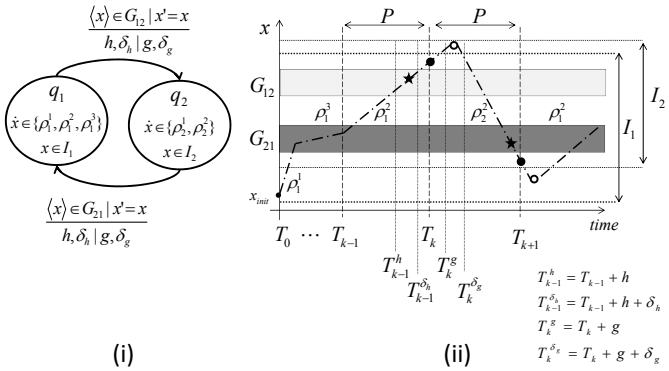

Fig. 1. Lazy linear hybrid automaton example.

the identity function. The control switch e_{ij} is enabled only if the digitized value $\langle x \rangle$ detected by the sensor belongs to G_{ij}. Moreover, sensing and actuation delays (i.e., h, δ_h and g, δ_g, respectively) are associated to the control switch. Finally, each flow condition $flow(q_i)$ constrains the evolution of the continuous variable x to one of the possible rates ρ_i^n allowed in the mode (e.g., $\{\rho_1^1, \rho_1^2, \rho_1^3\}$ in q_1).

Figure 1(ii) sketches part of a trajectory of such a LLHA starting from the initial state (q_1, x_{init}). In the example, the trajectory keeps following the dynamics $flow(q_1)$ until the time instant T_k. In fact, the control switch e_{12} is not enabled as soon as the trajectory reaches the guard set G_{12} because of the semantics of LLHA: a jump condition can be evaluated only at periodic time points and by considering the digitized values detected by the sensor at some instant (marked with $\star$) in the interval $[T_{k-1}^h, T_{k-1}^{\delta_h}]$. As shown in the figure, at T_k, the invariant condition of the mode q_1 is still satisfied, thus, the LLHA can either switch to q_2 or continue with the dynamics of q_1. Let assume that the automaton performs a control switch (marked with $\bullet$) and moves to q_2. When the LLHA switches from q_1 to q_2, it resets the continuous variable x according to the predicate specified by the jump condition, i.e., the identity function. Thus, in this case, the trajectory starts from the same state reached at T_k. Notice that the trajectory keeps following the dynamics of q_1 due to the presence of an actuation delay (i.e., g, δ_g) on the control switch. In fact, only at some time (marked with $\circ$) in the interval $[T_k^g, T_k^{\delta_g}]$ the trajectory changes according to the rates specified by the flow condition of q_2 (i.e., $\dot{x} \in \{\rho_2^1, \rho_2^2\}$). Then the trajectory follows that flow rate until the invariant I_2 is violated or the jump condition G_{21} is satisfied allowing the automaton to jump back in the mode q_1.

Definition 6 (Reachability relation between states of a LLHA)**.** Let A be a lazy linear hybrid automaton. A state $(q, V, \hat{q})$ reaches a state $(q', V', \hat{q}')$ if there exists a finite trajectory of states $(q_i, V_i, \hat{q}_i)$, with $0 \leq i \leq n$, such that $(q_0, V_0, \hat{q}_0) = (q, V, \hat{q})$ and $(q_n, V_n, \hat{q}_n) = (q', V', \hat{q}')$. $\mathcal{RC}(q, V, \hat{q})$ is used to denote the set of states reachable from $(q, V, \hat{q})$. $\mathcal{RC}$ is used to denote the set of all the possible states reachable from the initial ones.

III. Synthesis of Implementable Control Strategies for LLHA

The main contributions of this work can be summarized as follows:

- it proposes a Bounded Model Checking (BMC) [11] formulation for the problem of synthesizing implementable control strategies for LLHA that reduces such a problem to the state reachability problem on LLHA. A previous BMC formulation has been given in [12]. While that work assumes that precision and delay parameters are given, the present paper models them as parameters that must be synthesized. Then, by verifying the safety properties as reachability queries, it is possible to identify values for such parameters which make the control strategy implementable, i.e., the control strategy is able to handle the continuous plant by following discrete-time and finite-precision behaviors.
- it proposes a synthesis procedure that, starting from a set of feasible values for the different parameters, identifies for each of them the maximum values which enable a LLHA to satisfy its required safety properties.

The following sections describe all the details of the proposed approach.

A. Problem definition

The synthesis of an implementable control strategy for a LLHA consists of determining if there exist legal values for the sampling period (i.e., P), and upper bounds for sensing and actuation delays (i.e., $T_{SD} = h + \delta_h$ and $T_{AD} = g + \delta_g$, respectively) for which the control strategy modeled in the LLHA is able to satisfy the safety properties that the hybrid system has to ensure.

Let A be a LLHA such that $\mathcal{S}_A$ is the set of the possible states, $\mathcal{INIT}$ be a predicate that constrains the initial state, $\mathcal{TR}$ be the transition relation that models the lazy behavior of A and φ_{safe} be a function that tests whether the safety properties for the hybrid system hold in a given state. The synthesis problem summarized above can be formalized by a Quantified Boolean Formula (QBF), i.e., a formula in which propositional variables can be either quantified existentially or universally, as follows:

$$\begin{aligned}&\exists P, T_{SD}, T_{AD}, \forall\, n \in \mathbb{N}, \forall S_i \in \mathcal{S}_A : \mathcal{INIT}(S_0) \wedge \\ &\bigwedge_{i=0}^{n} \mathcal{TR}(S_i, S_{i+1}, P, T_{SD}, T_{AD}) \rightarrow \bigwedge_{i=0}^{n} \varphi_{safe}(S_i)\end{aligned} \tag{1}$$

Intuitively, the formula states that there exist suitable values for P, T_{SD} and T_{AD} for which at any step i, the state S_{i+1}, reachable from a previous state S_i, satisfies the safety property φ_{safe}.

An efficient way to solve this problem consists of deriving from Formula (1) a BMC problem on A. Such a BMC problem focuses on identifying the existence of *bad states*, i.e., states S_i violating the safety properties and reachable from the initial state of A:

$$\begin{aligned}&\mathcal{BMC}(A, \varphi_{safe}, n, P, T_{SD}, T_{AD}) \equiv \mathcal{INIT}(S_0) \wedge \\ &\bigwedge_{i=0}^{n} \mathcal{TR}(S_i, S_{i+1}, P, T_{SD}, T_{AD}) \wedge \bigvee_{i=0}^{n} \neg\varphi_{safe}(S_i)\end{aligned} \tag{2}$$

The identification of suitable values for the parameters n, P, T_{SD} and T_{AD} which cause the unsatisfiability of Formula (2), will prove the validity of Formula (1) w.r.t. the chosen P, T_{SD} and T_{AD}. Notice that, given the values for n, P, T_{SD} and T_{AD}, the satisfiability of Formula (2) may be proved or disproved by applying a Satisfiability Modulo Theory (SMT) [13] decision procedure on its propositional part.

Notice that the transition relation $\mathcal{TR}$ in the $\mathcal{BMC}$ formula may be unrolled a finite number n of times, where n is the *reachability diameter* [14] of the LLHA, i.e., the minimal number of steps for reaching all its reachable states. Thus, the formula checks if a bad state $S_{i \leq n}$ is reachable from the initial state S_0. Unfortunately, such a number n may require a very high number of copies of the transition relation in the $\mathcal{BMC}$ formula making the verification unfeasible due to memory problems.

Due to lack of space, the symbolic BMC encoding will be described in an extended version of the paper. In what follows a synthesis procedure is proposed for identifying the maximum suitable values of sampling period (P), sensing and actuation delays (T_{SD},T_{AD} respectively) to let the LLHA A satisfy the safety specification φ_{safe}.

B. Synthesis procedure

The definition of the BMC formula described in the previous section is based on a set of parameters whose values affect the correctness of the LLHA model. The synthesis engine aims at identifying the maximum values of such parameters for which the discrete-time and finite-precision behaviors specified by the LLHA are able to satisfy φ_{safe}.

In particular, the parameters reported into the formula $\mathcal{BMC}$ are the following:

- *sampling period* P. It specifies the periodicity at which it is possible to evaluate the guards for performing a mode switch;
- *sensing delay upper-bound* T_{SD}. It specifies the maximum delay admitted for notifying the controller that a mode switch can be performed (i.e., sensor latency);
- *actuation delay upper-bound* T_{AD}. It specifies the maximum delay admitted for changing the rate due to a mode switch (i.e., actuator latency).

At the moment, the precision ϵ of the observed values is not explicitly modeled as a parameter. Instead, it is assumed that it is fixed at some suitable level of granularity and that the constant values reported in the predicates that model guard and invariant conditions have been scaled accordingly to be represented as integers[1].

[1]Remember that the underlying structure used for the symbolic representation of variables is the bit-vector.

For reducing the time required in identifying the suitable values for the parameters summarized above, the user is asked to specify a desired sampling period P that the control strategy has to adopt. Then a synthesis procedure will automatically retrieve the maximum values for T_{SD} and T_{AD} that preserve the safety of the model according to the specified sampling period.

The procedure identifies the intended values by using a bisection method on a finite interval of feasible values for the parameters. According to the LLHA semantics, the actuation delay has to be smaller than the sensing delay and the sensing delay has to be smaller than the sampling period. Thus, it is necessary to search the suitable values of T_{AD} and T_{SD} in some intervals $\mathcal{I}_1 = [a, b]$ and $\mathcal{I}_2 = [c, d]$ such that $b < d$ and $b + d < P$. This is due to the fact that, in the BMC encoding, the upper bound T_{AD} for the actuation delay is considered as the most distant time instant from a sampling period T_i at which a control switch has occurred and, as a consequence, its starting search space should be given by the interval $[0, b]$. Similarly, in the BMC encoding, the upper-bound T_{SD} for the sensing delay is considered as the most distant time instant from a sampling period T_j, subsequent to T_i, at which a control decision may be taken. Thus, the starting search space for T_{SD} should be given by the interval $\mathcal{I}_2 = [0, d]$.

Algorithm 1 reports the pseudo-code implementing the synthesis procedure for parameters, and $BMC^n(P, T_{AD}, T_{SD})$ denotes the BMC encoding of the transition relation of the LLHA A unrolled n times (n is the reachability diameter).

At each step, the procedure divides the current subintervals of $[a, b]$ and $[c, d]$ in two by computing their midpoints mid_1 and mid_2. Then, using a SMT solver (i.e., $\mathcal{SMT}$), it verifies whether the formula $BMC^n(P, mid_1, mid_2)$ is valid by fixing $T_{AD} = mid_1$ and $T_{SD} = mid_2$. Now, according to the verification results, the method registers the current midpoints as candidate solutions and selects the subintervals to be used in the next step. In particular, if mid_1 and mid_2 make the formula valid, they become *candidate* maximal values for T_{AD} and T_{SD}, resp., and the new intervals of search will be $[mid_1, b]$ and $[mid_2, d]$, i.e., the procedure will check the validity of the formula on new values greater than the current midpoints. Otherwise, the procedure has to look for smaller ones. At first, it checks the formula validity by reducing only the current value for actuation delays. It computes the new candidate for T_{AD} (i.e., mid_{new}) and, by preserving the previous candidate mid_2 for T_{SD}, verifies the validity of the formula $BMC^n(P, mid_{new}, mid_2)$. If the verification returns a positive answer, then mid_{new} and mid_2 are recorded as new candidate maximal solutions for T_{AD} and T_{SD}, resp., and the new intervals of search will be $T_{AD} \in [mid_{new}, mid_1]$ and $T_{SD} \in [mid_2, d]$. On the contrary, the non-validity of the formula underlines that also a smaller sensing delay is required. For this reason the search continues on the intervals $[a, mid_1]$ and $[c, mid_2]$. In this way the intervals that contain the satisfying values of the parameters are reduced in width at least by 50% at each step. The process is continued until the maximum number N of iterations is reached.

```

IV. Experimental Results

This section reports the results obtained by applying the proposed LLHA parameter synthesis approach on four case studies. All experiments have been performed on a workstation with Intel Xeon 2.53 GHz processors and 16GB RAM. The hybrid models of the case studies have been described by means of the CIF [15] language. The *cif2uclid* tool has been implemented to automatically derive, from such models, the LLHA descriptions and the corresponding BMC encodings which have been automatically synthesized into equivalent SMT formulas by using the UCLID [16] modeling environment. Several SMT solvers have been used to verify the models and identify the maximum values for the sensing and actuation delay parameters appearing in the LLHA models. In particular, for each case-study the performances of the following SMT solvers have been compared: Beaver [17], Boolector[2] [18], and Yices [19]. Notice that any available SMT solver could be used as verification and parameter synthesis engine.

[2]MiniSat and PicoSat have been used as the underlying SAT engines.

A. Train-Gate Controller

The train gate controller ensures that the gate is closed when the train is approaching it. The train is assumed to move at a constant speed v on a circular track of length $d_{far-away}$ and the gate begins to close at a constant angular speed u when the train is at d_{max} distance from the gate. Once the train has moved d_{max} distance away from the gate, the gate begins to open again. The system is shown in Figure 2. The distance d of the train is measured in meters, the angle a of the gate in degrees and the time in seconds. The set of parameter values used in the running example is as follows: $v = 20m/s$, $u = 10°/s$, $d_{far-away} = 20000m$, $d_{max} = 400m$ and $d_{safe} = 160m$.

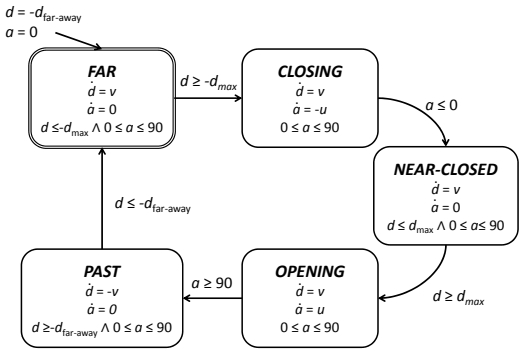

Fig. 2. LLHA model of the Train-Gate controller.

The system is considered safe, i.e., the train is never closer to the gate than d_{safe} unless the gate is completely closed, only if the following safety property is satisfied: $-d_{safe} \leq d \leq d_{safe} \rightarrow a <= 0$.

Such a property is used during the synthesis phase for identifying the maximum values for the sensing and actuation delay parameters (T_{SD} and T_{AD}, respectively) that are reported into the LLHA modeling the system. In particular, the parametric LLHA has been automatically generated by using a digitizing precision $\epsilon = 10^{-3}$ and a control switch period $P = 10^{-2}s$. Then, the parameter synthesis approach has determined that the coarse values for the sensing and actuation delays which ensure the correctness of such a LLHA are $T_{SD} = 4 \cdot 10^{-3}s$ and $T_{AD} = 2 \cdot 10^{-3}s$. The time required for synthesizing such values is reported in Table I.

TABLE I
SYNTHESIS TIMES USING DIFFERENT SMT SOLVERS.

$\mathcal{SMT}$	T_{SD} **s-Space**	T_{AD} **s-Space**	**# Bisect.**	**Time (s)**
Beaver	$[0; 5 \cdot 10^{-3}]$	$[0; 4 \cdot 10^{-3}]$	15	123.336
Boolector	$[0; 5 \cdot 10^{-3}]$	$[0; 4 \cdot 10^{-3}]$	15	101.544
Yices	$[0; 5 \cdot 10^{-3}]$	$[0; 4 \cdot 10^{-3}]$	15	49121.94

In particular, column $\mathcal{SMT}$ reports the name of the compared SMT solvers; columns T_{SD} *s-Space* and T_{AD} *s-Space* report the initial search spaces used for identifying suitable values for the sensing and actuation delays, respectively. Column *# Bisect.* shows the maximum number of bisection iterations allowed for synthesizing the parameter values and, finally, column *Time* reports the total time (in seconds) spent for the synthesis process.

B. Room Heating Controller

The room heating controller ensures that the temperature of a room is kept into a comfort interval by turning *on* and *off* the heater installed into the room. Figure 3 depicts the model of the system. Intuitively, the automaton is composed by two control modes *on* and *off*, representing the status of the heater. The variable x denotes the room temperature (measured in $°C$). When the heater is *off*, the temperature of the room falls according to any rate specified by the rectangular constraint $\dot{x} \in [-b, -a]$. Instead, when the heater is *on* the temperature of the room rises following any rate specified by the constraint $\dot{x} \in [b, c]$. The heater is turned on as soon as the falling temperature reaches x_{low}: the automaton moves to the control mode *on* and the temperature rises starting at a value $x \leq x_{low}$. The heater is turned off as soon as the temperature reaches x_{high}: the automaton moves to the control mode *off* and the temperature starts falling again at a value $x \geq x_{high}$. This control strategy guarantees that the temperature of the room will remain between x_{min} and x_{max} starting at the initial temperature x_{init} such that $x_{low} < x_{init} < x_{high}$. The set of parameter values used in the running example is as follows: $a = 2 \cdot 10^{-1}$ $°C/s$, $b = 3 \cdot 10^{-1}$ $°C/s$, $c = 4 \cdot 10^{-1}$ $°C/s$, $x_{min} = 17.8°C$, $x_{low} = 18°C$, $x_{high} = 22°C$, $x_{max} = 22.5°C$ and $x_{init} = 19°C$.

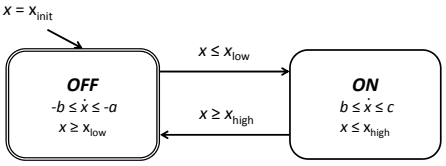

Fig. 3. The LLHA model of the room heating controller.

The property $x_{min} < x < x_{max}$ is used for synthesizing the maximum values of the sensing delay T_{SD} and the actuation delay T_{AD} in the parametric LLHA modeling the finite-precision lazy heating controller. Such a model has been generated from the one depicted in Figure 3 by choosing a digitizing precision $\epsilon = 10^{-4}$ and a control switch period $P = 10^{-2}s$. The synthesis procedure found that the values $T_{SD} = 11 \cdot 8^{-3}s$ and $T_{AD} = 10 \cdot 10^{-3}s$ guarantee that the lazy controller keeps the temperature into the comfort bounds (i.e., x_{min} and x_{max}). The time required for synthesizing such values is reported in Table II.

C. Watertank Controller

The watertank system is centered on a water tank, which is characterized by an uncontrolled outbound water flow, while the inbound water flow is controlled by the aperture of a valve. The controller acts on the aperture of the valve y in order to keep the water level x in a safe interval $x_{min} < x <$

TABLE II

$\mathcal{SMT}$	T_{SD} s-Space	T_{AD} s-Space	# Bisect.	Time (s)
Beaver	$[0; 4 \cdot 10^{-2}]$	$[0; 3 \cdot 10^{-2}]$	15	343.888
Boolector	$[0; 4 \cdot 10^{-2}]$	$[0; 3 \cdot 10^{-2}]$	15	1584.864
Yices	$[0; 4 \cdot 10^{-2}]$	$[0; 3 \cdot 10^{-2}]$	15	90903.836

TABLE III
SYNTHESIS TIMES USING DIFFERENT SMT SOLVERS.

$\mathcal{SMT}$	T_{SD} s-Space	T_{AD} s-Space	# Bisect.	Time (s)
Beaver	$[0; 5 \cdot 10^{-2}]$	$[0; 4 \cdot 10^{-2}]$	15	531.56
Boolector	$[0; 5 \cdot 10^{-2}]$	$[0; 4 \cdot 10^{-2}]$	15	2413.02
Yices	$[0; 5 \cdot 10^{-2}]$	$[0; 4 \cdot 10^{-2}]$	15	107236.98

x_{max}. The system model is shown in Figure 4. The water level is measured in deciliters, the valve aperture in degrees and the time in seconds. The set of parameter values used in the running example is as follows: $a = 1dl$, $b = 2dl$, $c = 4dl$, $d = 7dl$, $v = 20°/s$, $x_{high} = 850dl$, $x_{low} = 550dl$, $y_{min} = 0°$, $y_{max} = 360°$, $x_{max} = 870dl$ and $x_{min} = 540dl$.

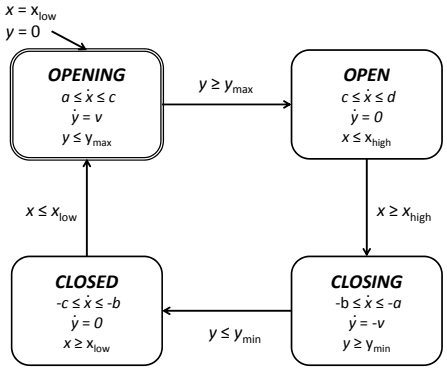

Fig. 4. LLHA model of the watertank controller.

In the model, the water level begins to increase according to a rectangular constraint $\dot{x} = [a, c]$ when the valve starts to open at constant angular speed v. As soon as the valve reaches its full aperture, the incoming flow reaches its maximum value, filling faster the water tank. Once the water level crosses an upper threshold x_{high}, the valve starts to close in order to avoid a water overflow. Once the valve is completely closed, no inbound water flow is present and the water level keeps decreasing. When the water level reaches its lower threshold x_{low}, the valve begins to open again.

The property $x_{min} < x < x_{max}$ is used for synthesizing the maximum values of the sensing delay T_{SD} and the actuation delay T_{AD} in the parametric LLHA modeling the finite-precision lazy watertank controller. Such a model has been generated from the one shown in Figure 4 by choosing a digitizing precision $\epsilon = 10^{-3}$ and a control switch period $P = 10^{-1}s$. At the end of the synthesis phase, the verification has determined that the values $T_{SD} = 23 \cdot 10^{-3}s$ and $T_{AD} = 11 \cdot 10^{-3}s$ guarantee that the lazy controller keeps safely the water level into the x_{min} and x_{max} bounds. The time required for synthesizing such values is reported in Table III.

D. Automated Highway Control System

Automated Highway Control System (AHS) is an arbiter which ensures that there is no collision between cars running on a highway by imposing legal speed ranges. The linear hybrid automaton representing the case of four cars is shown in Figure 5. This example is a small variant of the original model reported in [20]. The distance between cars is measured in km, time in hours and speeds in km/h. The set of parameter values used in the running example is as follows: $rl = 20km/h$, $b = 30km/h$, $c = 40km/h$, $d = 50km/h$, $e = 60km/h$, $ru = 70km/h$, $f = 100km/h$, $\alpha_{min} = 2 \cdot 10^{-3}km$, $\alpha_{max} = 1km$ and $\alpha'_{min} = 5 \cdot 10^{-4}km$.

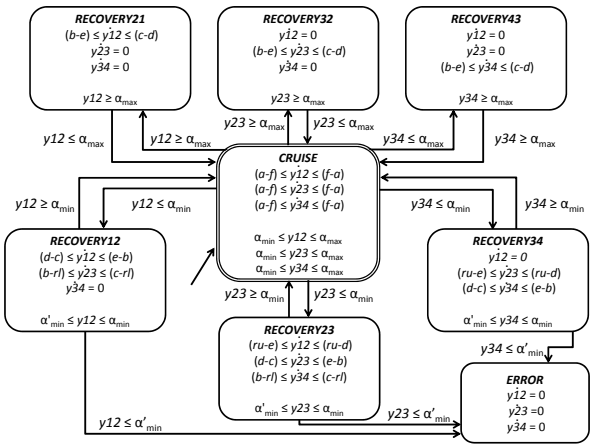

Fig. 5. LLHA model of the Automated Highway Control System.

To avoid collisions, the arbiter specifies speed limits (i.e., $[a, f]$) for each vehicle. When two vehicles i and j come within a distance $y_{ij} \leq \alpha_{min}$ of each other, there exists a possible collision event. The arbiter asks the approaching car to slow down by reducing the speed into the interval $[b, c]$, and asks the leading car to speed up by keeping a speed into the interval $[d, e]$; it also requires that all other cars not involved in the possible collision slow down to a constant recovery mode velocity rl for cars behind the critical region and ru for cars in front of the critical region. When the distance between the two vehicles involved in the possible collision exceeds α, the arbiter model goes back to the dynamics of the cruise mode. Moreover, the arbiter keeps all the vehicles below a maximal distance α_{max} of each other. When two vehicles i and j exceed such a distance (i.e., $y_{ij} \geq \alpha_{max}$), the arbiter asks the leading car to slow down by reducing the speed into the interval $[b, c]$ and asks the approaching car to speed up by keeping a speed into the interval $[d, e]$; it also requires that all other cars keep the current distance constant (i.e., speeding up for cars behind the critical region and slowing down for cars in front of the critical region). When the distance between the

two vehicles decreases below α_{max}, the arbiter model goes back to the dynamics of the cruise mode.

The only safety property to be satisfied by the model is that the control mode is never the *error* mode.

Again, once the parametric LLHA model has been extracted by choosing a digitizing precision $\epsilon = 10^{-5}$ and a clock period $P = 10^{-2}$, the safety property is used as a constraint for identifying the coarse values of the sensing and actuation delay parameters (T_{SD} and T_{AD}, respectively). In this case study, the synthesis phase determined that the values $T_{SD} = 218 \cdot 10^{-5}h$ and $T_{AD} = 112 \cdot 10^{-5}h$ guarantee the safety of the system, i.e., the lazy controller is able to avoid cars' collision. The time required for synthesizing such values is reported in Table IV.

TABLE IV
SYNTHESIS TIMES USING DIFFERENT SMT SOLVERS.

$\mathcal{SMT}$	T_{SD} **s-Space**	T_{AD} **s-Space**	**# Bisect.**	**Time (s)**
Beaver	$[0, 5 \cdot 10^{-3}]$	$[0, 4 \cdot 10^{-3}]$	15	1472.75
Boolector	$[0, 5 \cdot 10^{-3}]$	$[0, 4 \cdot 10^{-3}]$	15	1844.05
Yices	$[0, 5 \cdot 10^{-3}]$	$[0, 4 \cdot 10^{-3}]$	15	188523.11

V. CONCLUSION

The development of methodologies for the synthesis of implementable control strategies for models based on hybrid automata is a new and valuable research area. This work focused on defining a new methodology which enables the synthesis of implementable control strategies for the interesting subclass of lazy linear hybrid automata. To support the methodology, a tool, i.e., *cif2uclid*, and a synthesis procedure were implemented in order to provide a complete toolchain for synthesizing the implementable control strategy in a systematic way. *cif2uclid* is able to extract from a hybrid model a corresponding parametric-LLHA description, that is automatically synthesized into an equivalent SMT formula by using the UCLID modeling environment. The verification of such a formula retrieves constraints for the parameters which guarantee that the control strategy is implementable, i.e., the verification retrieves the performance and latency bounds which make the control strategy realizable by a concrete hardware/software device. The synthesis procedure may use any available SMT solver.

The proposed procedure for the automatic synthesis of parameters that guarantee implementability of control strategies is supported by a complete toolchain and improves the state-of-art with respect to previous proposals, however scalability of the overall approach is still a serious issue, when the objective is to study test cases of industrial strength. This may require from one side further restrictions to the class of allowed hybrid automata, still preserving enough expressivity for practical purposes, and from the other side advances in the computational engines and how they are used (for instance, gaining efficiency by using incrementally the SMT solvers).

Towards deductive-based support for software development processes

Radosław Klimek
AGH University of Science and Technology
al. A. Mickiewicza 30, 30-059 Krakow, Poland
rklimek@agh.edu.pl

***Abstract*—The work relates two initial disciplines of the Rational Unified Process (RUP), i.e. Business Modeling and Requirements Engineering, to support them in an integrated way through deductive-based formal verification using temporal logic. On the other hand, Cyber-Physical Systems (CPS), which should be an effective orchestration of computations and physical processes, need careful development and formal verification to ensure they influence software reliability, trustworthiness and cost in a positive way. A method for building both business models and requirements models, including their logical specifications, is proposed and presented step by step. Applying the presented concepts bridges the gap between the benefits of deductive reasoning for correctness analysis and the difficulties in obtaining complete logical specifications.**

I. Introduction

CYBER-Physical Systems (CPS) are understood as integrations of computation with physical processes [1] and often refer to embedded systems. A CPS is designed as a network of interacting elements with physical input and output and focus on both technology and mathematical abstractions. CPS need to improve the development processes, in order to raise the level of abstraction, and to formally verify designs. On the other hand, the Rational Unified Process (RUP) provides a disciplined approach to assignment of tasks and responsibilities within software processes. Most iterations within RUP phases result in an executable deliverable. RUP consists of perspectives, disciplines, etc. [2]. The work focuses on the first two disciplines which are Business Modeling (BM) and Requirements Engineering (RE). BM involves higher level managing people. RE involves higher level software engineers. BM facilitates discovering RE. On the other hand, considering BM and RE together can result in a synergic effect. Formal methods enable the precise formulation of important artifacts, eliminating ambiguity during the software development process [3]. Deductive inference enables the analysis of infinite computation sequences and is an essential part of everyday life and scientific work. On the other hand, the important question for deductive approach is the lack of automatic methods for obtaining logical specifications understood as (large) sets of temporal logic formulas. Thus, the automation of this process seems justified and particularly important.

The motivation for the work is the lack of tools for deductive-based formal verification of RUP-like processes. Another motivation is the lack of tools for automatic extraction of logical specifications from software models. The contribution of the work is a method for automatic generation of logical specifications considered as sets of temporal logic formulas. Relatively simple yet illustrative examples of the approach are provided.

Work by Morimoto [4] contains a survey of formal verification methods for business processes. It discusses automata, model checking, communicating sequential processes, Petri nets, Markov networks, and all these issues are discussed in the context of business process management and web services. Work by Brambilla et al. [5] contains some aspects of workflows and temporal logic, but formulas are mostly created manually and formal verification is not discussed widely. In work by Kazhamiakin [6], a method based on formal verification of requirements using temporal logic and model checking approach is proposed, and a case study is discussed.

II. Basic assumptions

The idea of workflow patterns is crucial for this work. They constitute a kind of primitives to enable development of software models and modeling logical specifications. A set of temporal logic formulas is linked to every pattern. The basic issues related to temporal logics and their syntax and semantics are discussed in many works, e.g. [7]. The considerations in this work are limited to the *linear-time temporal logic* LTL, and attention is focused on the *propositional linear time logic* PLTL. The *elementary set* $pat()$ of formulas over atomic formulas a_i, where $i > 0$, which is also denoted $pat(a_i)$, is a set of temporal logic formulas $f_1, ..., f_m$ such that all formulas are syntactically correct. The example of an elementary set is $pat(a, b, c) = \{a \Rightarrow \Diamond b, b \Rightarrow \Diamond c, \Box\neg(a \wedge b \wedge c)\}$ which is a three-element set of formulas created over three atomic formulas. The *logical expression* W_L is a structure similar to the well-known regular expressions and allows to express the complex and nested workflow model in a literal notation. For example, $Seq(Split(a, b, c), Cond(d, e, f))$ shows the sequence of a parallel split followed by conditional execution of some tasks, and the meaning of all patterns is intuitive and not formally defined.

Every pattern has a predefined and countable set of linear temporal logic formulas. Thus, all acceptable patterns constitute a set of *predefined design patterns* Π. The example of such a set for business models is shown in Fig. 1. Software workflows should be modeled using predefined patterns only.

978-83-60810-53-8/$25.00

Most elements of this predefined set, i.e. comments, two temporal logic operators, classical logic operators, are not in doubt. The slash allows to place more than one formula in a single line. The $entry$, or shortly en, and $exit$, or shortly ex, expressions are collections of atomic formulas which describe, informally speaking, the potential logical entry points end logical exit points for a particular pattern. The entry and exit formulas represent a pattern as a whole. f_1, f_2 etc. are atomic formulas for a pattern. They constitute a kind of formal arguments for a pattern.

The *logical specification* L consists of all formulas derived from the logical expression W_L using the algorithm $\mathcal{A}$, i.e.

$$L(W_L) = \{f_i : i \geq 0 \wedge f_i \in \mathcal{A}(W_L, P)\} \quad (1)$$

where f_i is a PLTL formula. The generation algorithm $\mathcal{A}$ has two inputs. The first one is a logical expression W_L which is a kind of a variable, i.e. it varies when a model (workflow) is subjected to any modification by software engineers. The second one is the predefined set P for business models or for activity models which is a kind of constant, i.e. it is once defined and then widely used. The output of the algorithm is a logical specification understood as a set given by a formula 1. However, generation of logical specifications is not a simple summation of formula collections from predefined design patterns. The algorithm ($\mathcal{A}$) is as follows:

1) at the beginning, the logical specification is empty, i.e. $L = \emptyset$;
2) the most nested pattern or patterns are processed first; then, less nested patterns are processed one by one, i.e. patterns that are located more towards the outside;
3) if the currently analyzed pattern consists of atomic formulas only, the logical specification is extended, by summing sets, by formulas linked to the currently being analyzed pattern $pat()$, i.e. $L = L \cup pat()$;
4) if any argument is a pattern itself, then the logical disjunction of its $entry$ and $exit$ formulas is substituted in the place of the pattern as an argument.

III. Business modeling

Business modeling BM allows to understand the structure and behavior of the organization in which a system is to be deployed. It also ensures stakeholders to have a common understanding of the target organization. *Business Process Modeling Notation* BPMN is a standard graphical notation provided by the Business Process Management Initiative (BPMI) for the modeling of business processes. BPMN is becoming the dominant modeling notation, bridging the gap between business process design and process implementation. The main goal of BPMN is to provide a notation that is understandable by all business users, from business analysts to technical developers, and finally, to business people who will manage and monitor those processes [8]. An important parts of BPMN are 21 patterns which are introduced by van der Aalst et al. [9]. Gradually building in complexity, process patterns were broken down into six categories: Basic Control Flow Patterns, Advanced Branching, Structural, Multiple Instances, State Based, and Cancellation. For example, the basic control flow patterns are divided into five particular patterns: Sequence, Parallel Split, Synchronization, Exclusive Choice, and Simple Merge, the meaning of which is defined in terms of temporal logic formulas in Fig. 1.

```
                                /* ver. 27.04.2013
/* Basic Control Patterns
Sequence(f1,f2):
entry=f1 / exit=f2
f1 => <>f2 / ~f1 => ~<>f2 / []~(f1 & f2)
ParallelSplit(f1,f2,f3):
en=f1 / ex=f2,f3
f1 => <>f2 & <>f3 / ~f1 => ~<>f2 & ~<>f3
[]~(f1&(f2|f3))
Synchronization(f1,f2,f3):
en=f1,f2 / ex=f3
f1 & f2 => <>f3 / ~f1 | ~f2 => ~<>f3
[]~((f1|f2)&f3)
ExclusiveChoice(f1,f2,f3):
en=f1 / ex=f2,f3
f1 => (<>f2 & ~<>f3)|(~<>f2 & <>f3)
~f1 => ~<>f2 & ~<>f3
[]~(f2 & f3) / []~(f1&(f2|f3))
SimpleMerge(f1,f2,f3):

f1|f2 => <>f3 / ~f1 & ~f2 => ~<>f3
[]~(f1&f2) / []~((f1|f2)&f3)

/* ..... [other] Business Patterns
```

Fig. 1. A predefined set of patterns P for BPMN models

Let $\Pi_1 = \{Sequence, ParallelSplit, Synchronization, ExclusiveChoice, SimpleMerge, ...\}$ be a predefined set of patterns for business models, with aliases Seq, $Split$, $Synch$, $Choice$, and $Merge$, respectively. The meaning of patterns is formally defined in Fig. 1. Although the above set contains only some patterns to present the main ideas of the work, other workflow patterns together with their temporal logic formulas could be defined in future research.

The business model for flight dispatch is considered below. The BPMN model is shown in Fig. 2. When the decision to realize the flight is taken, then some processes are carried out concurrently. Some of them relate to the preparation of the aircraft and the crew, while others – to passenger handling and loading of baggage. Taking off must be preceded by a permission to start with all of its internal actions. Every business process should be decomposed into a business use case and a series of activities. The logical expression W_L is

$$Seq(Split(Initiate, Split(PreFlightPreparation, AircraftPreparation, PassengerHandling), FlightCoordination), Synch(Synch(CrewPreparation, BaggageLoading, AircraftTaxiing), PermissionStart, TakingOff))$$

or after the substitution of propositions (business processes) as capital letters of the Latin alphabet: A – Initiate, B – PreFlightPreparation, C – AircraftPreparation, D – Passenger-Handling, E – FlightCoordination, F – CrewPreparation, G – BaggageLoading, H – AircraftTaxiing, I – PermissionStart, and J – TakingOff. A logical specification L for the above logical expression is built in such a way that patterns are processes in the following order: most nested $Split$, most

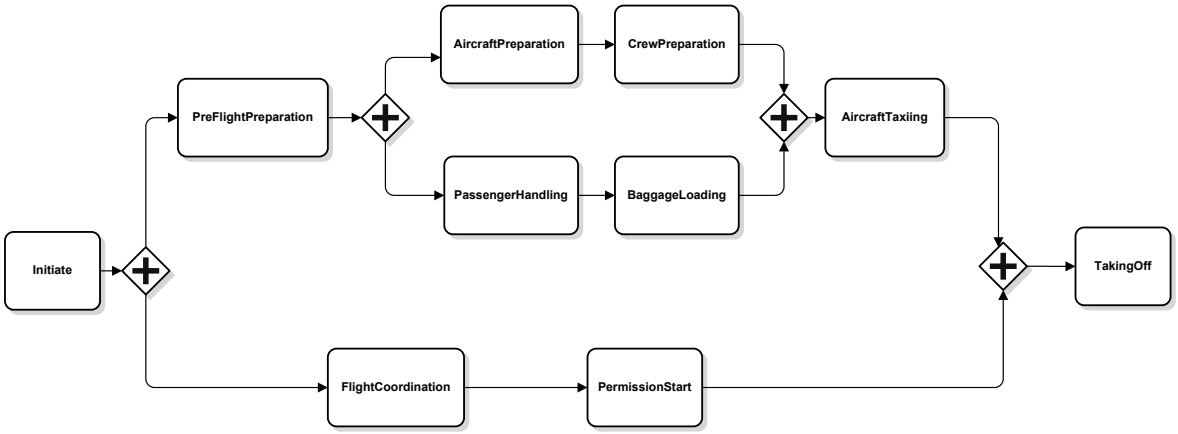

Fig. 2. A business model for a flight dispatch

nested $Synch$, outer $Split$, outer $Synch$, and Seq. The resulting logical specification contains formulas

$$\begin{aligned} L = \{&B \Rightarrow \Diamond C \wedge \Diamond D, \neg B \Rightarrow \neg\Diamond C \wedge \neg\Diamond D,\\ &\Box\neg(B \wedge (C \vee D)), F \wedge G \Rightarrow \Diamond H, \neg F \vee \neg G \Rightarrow \neg\Diamond H,\\ &\Box\neg((F \vee G) \wedge H), A \Rightarrow \Diamond(B \vee C \vee D) \wedge \Diamond E,\\ &\neg A \Rightarrow \neg\Diamond(B \vee C \vee D) \wedge \neg\Diamond E,\\ &\Box\neg(A \wedge ((B \vee C \vee D) \vee E)), (F \vee G \vee H) \wedge I \Rightarrow \Diamond J,\\ &\neg(F \vee G \vee H) \vee \neg I \Rightarrow \neg\Diamond J,\\ &\Box\neg(((F \vee G \vee H) \vee I) \wedge J),\\ &(A \vee C \vee D \vee E) \Rightarrow \Diamond(F \vee G \vee I \vee J),\\ &\neg(A \vee C \vee D \vee E) \Rightarrow\\ &\neg\Diamond(F \vee G \vee I \vee J),\\ &\Box\neg((A \vee C \vee D \vee E) \wedge (F \vee G \vee I \vee J))\} \end{aligned} \quad (2)$$

Formal *verification* is the act of proving the correctness of a system. Liveness and safety are a taxonomy of system properties. *Liveness* means that the computational process achieves its goals (something good eventually happens). *Safety* means that the computational process avoids undesirable situations (nothing bad ever happens). The liveness property for the model can be

$$A \Rightarrow \Diamond J \quad (3)$$

which means that **if the initiation is executed then sometime in the future the aircraft take off**, or formally $Initiate \Rightarrow \Diamond TakeOff$. When considering the property, the entire formula to be analyzed using, for example, the semantic tableaux method is

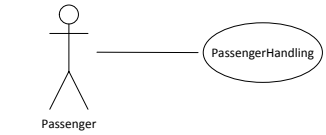
$$C(L) \Rightarrow (A \Rightarrow \Diamond J) \quad (4)$$

where $C(L)$ is a logical conjunction of all formulas that belong to the logical specification L, c.f. formula 2. In a similar way, safety formulas are considered, e.g. $\Box\neg(\neg PermissionStart \wedge TakingOff)$ or even formula $\Box\neg(PermissionStart \wedge \neg CrewPreaparation.c \wedge \neg BaggageLoading.c)$ the meaning of which seems understandable, and the $.c$ suffix means the logical condition associated with an activity. However, the presentation of a full inference tree for these cases exceeds the size of the work. In the case of the semantic tableaux method for logical reasoning, when the falsification of the semantic tree is received, the open branches are obtained and provide information about the source of the error. This is another advantage of the method.

IV. Requirements modeling

Once the business model is built, a requirements model is developed. The transition between the models is done in such a way that a single business process is mapped to a single business use case [2]. A business use case is always actor-centric. A business use case *scenario* is a description that illustrates the behavior from the actors's point of view. Every scenario allows to identify and extract atomic activities. Afterwards, the *activity diagram* enables the modeling of workflows for atomic activities using predefined workflow patterns. It supports choice, concurrency and iteration. The activity diagram shows how an activity depends on others. Nesting of activities is permitted. The following design patterns for activities are introduced [10], [11]: *sequence*, *concurrent fork/join*, *branching* and *loop-while* for iteration. Thus, the predefined set of patterns for activity workflows is $\Pi_2 = \{Sequence, Concurrency, Branching, LoopWhile\}$, and aliases are: Seq, $Concur$, $Branch$, and $Loop$, respectively.

The business use case "PassengerHandling" is discussed below. This is one of the processes received from a business model shown in Fig. 2. The use case scenario is in Fig. 3. The use case scenario is in Fig. 4. When the passenger holding a valid ticket arrives at the airport, the airport check-in, i.e. counter or self, must be made to confirm the passenger's presence, and then a boarding pass is issued. When the passenger has hold baggage, then it must be registered. (In Europe) when the passenger is outside the non-Schengen countries, then border and custom controls need to be performed. The last step before boarding is the security control. Not to introduce the simple branching (if-then) as another pattern for the activity



Use Case: PassengerHandling
Preconditions: Passenger has a valid ticket without check-in
Scenario: 1. Passenger's "Check-in"or"SelfCheck-in" 2. If necessary then "HoldBaggage" 3. If non-Schengen then "BorderControl" and "CustomControl" 4. Passenger's "SecurityControl" 5. Passenger's "Boarding"
Postconditions: Passenger completed all formalities related to the flight

Fig. 3. A business use case (top) and its scenario (bottom)

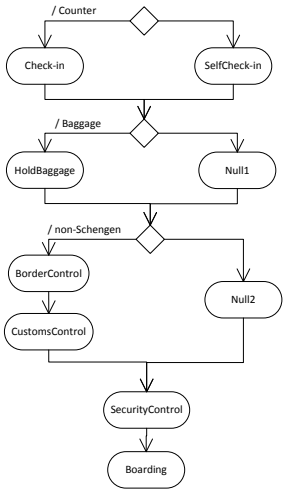


Fig. 4. An activity diagram for the scenario from the Fig. 3

diagram, the empty activity ("Null") is introduced instead a full branching (if-then-else). The Null activity does not consume time, i.e. after reaching the activity it is always immediately completed.

After the substitution of propositions (atomic activities) as small letters of the Latin alphabet: a – Counter, b – CheckIn, c – SelfCheckIn, d – Baggage, e – HoldBaggage, $n1$ – Null1, f – nonSchengen, g – BorderControl, h – CustomControl, $n2$ – Null2, i – SecurityControl, and j – Boarding, then the expression W_L is

$$Seq(Seq(Branch(a,b,c),Branch(d,e,n1)),\\ Seq(Branch(f,Seg(g,h),n2),Seq(i,j)))$$

A logical specification L for the above logical expression is build in the same way as it is shown in the previous section. An example of the liveness property for the model can be

$$e \Rightarrow \Diamond j \tag{5}$$

which means that **if the hold baggage for a passenger is registered then sometime in the future the passenger is boarding**, or more formally $HoldBaggage \Rightarrow \Diamond Boarding$.

V. Conclusion

A method for a deductive-based support developing software models for the first two RUP disciplines is proposed. Also, a method for automatic generation of logical specifications is defined.

Future works might result in development of CASE software which supports deduction-based formal verification of software development processes for CPS systems. Considering Concurrent Communicating Lists [12] is encouraging for strengthen and join these directions of research.

***Abstract*— The paper discusses mutual relationships of safety and security properties in cyber-physical systems (CPS). Generally, safety impacts the system's environment while environment impacts security of a CPS. Very frequently, safety and security of a CPS interact with each other either synergistically or conflictingly. Therefore, a combined evaluation of safety and security that considers their interrelationships is required for proper assessment of a CPS. Bayesian Belief Networks (BBN) can be used for this evaluation where factors related to safety and security of a CPS are assumed to be randomly distributed. The result of this evaluation is an assessment that is non-deterministic in nature but gives a very good approximation of the actual extent of safety and security in a CPS. Using a case study of a SCADA system in an oil pipeline control, the authors present a BBN approach for assessing mutual impacts of security and safety violations. This approach is compared with the Non-Functional Requirements approach (NFR), used previously, which is largely qualitative in nature. This study demonstrates that the BBN approach can significantly complement other techniques for joint assessment of safety and security in CPS.**

I. Introduction

MODERN industrial computer systems are a complex combination of hardware and software. In addition, with the proliferation of the Internet, they are all becoming interconnected, which gave rise to the term cyber-physical systems (CPS), reflecting the fact that embedded computers are interfaced to physical devices and make them accessible in the cyberspace.

The ease of interconnectivity raises a number of previously unknown issues in the design and operation of safety-critical CPS, which are now exposed to security vulnerabilities and related threats. Thus, relevant problems are being addressed by respective professional communities. For example, recent discussions between aviation professionals engaged in the work of RTCA Special Committee SC205 [1] dedicated to the software aspects of airborne systems certification (safety focus) and SC216 [2] dealing with aviation systems security, brought us an interesting perspective. The two committees came up with two sets of guidelines for industry developing aviation systems discussing these issues somehow independent from each other.

Thus, industry faces enormous challenges when designing and implementing software-intensive safety and security related systems exposed to abundant networking environments. The critical observation of this paper is that some aspects of integration of complementary views existing in specific domains are inadequate and exhibit lack of required system and process thinking.

The paper presents a perspective on joint, integrated treatment of safety and security properties in cyber-physical systems, with a potential for quantitative analysis of their interrelationships to provide software assurance, i.e., to achieve a required level of confidence that software systems and services function in the intended manner, are free from accidental or intentional vulnerabilities, provide security capabilities appropriate to the threat environment, and recover from intrusions and failures [3]. Our conjecture is that security and safety can be addressed jointly to measure their mutual impact on system trustworthiness and on each other.

The rest of the paper is structured as follows. Section 2 outlines some previous studies on joint treatment of safety and security, Section 3 introduces the case study of an oil pipeline control system, Section 4 discusses our approach, based on Bayesian belief networks, and Section 5 derives some conclusions.

II. Safety and Security

A. Common Perspective

From the technical perspective, in cyber-physical systems, critical system properties, such as security, safety, reliability, etc., cannot be treated in isolation from each other. In industrial applications, with a control system in charge of the technological process, typically safety was considered a critical property. Computer systems were

This project has been funded in part by a grant SBAHQ-10-I-0250 from the U.S. Small Business Administration (SBA). SBA's funding should not be construed as an endorsement of any products, opinions, or services. The second and third authors gratefully acknowledge the AFRL 2011 and 2012 Summer Faculty Fellowships, in Rome Labs.

designed such that the behavior of computer software or hardware would not endanger the environment in a sense that equipment's failure would cause death, loss of limbs or large financial losses.

On the other hand, the security of industrial computer control systems was typically limited to the physical plant access and off-line protection of data. With the miniaturization of computing devices, growing sophistication of control, and with the advent of the Internet, multiple functions of industrial control systems have become accessible online, which opened doors to enormous security threats. Thus, to increase trustworthiness of industrial computer systems, security concerns have to be taken into account and the mutual relationships of safety and security have to be studied and reconciled.

B. Background

Several industries have attempted to address related issues, for example, railways [4], chemical [5], off-shore [6], automation [7], nuclear [8], and industrial control [9]. Since the publication of a seminal paper by Burns et al. [10], around three dozen papers have been published discussing jointly safety and security issues, recently summarized in [11]. Since then, a more comprehensive review of related issues has been published [12].

Boyes, based on his 25 years of industry experience, discussed the problems of vulnerability of critical infrastructure due to the increasing interactions with external networks [13]. The question posed is whether or not the safety system built on top of the control system is not only safe but also secure. He identified situations when security violations may lead to safety violation and thus related incidents resulting even in some fatalities. He observed that security issues must be considered in safety implementation in any process plant, just as safety issues must be considered when administering conventional information technology security issues.

However, there seem to be only a few studies that aim at assessing both properties in a comprehensive manner, including an impact, which one might have on another in the same system. For example, the OCTAVE (Operationally Critical Threat, Asset, and Vulnerability Evaluation) framework [14] provides a checklist-based approach to evaluate safety and security in an organization; however, explicit analysis of tradeoffs between these properties is left to the judgment of evaluators.

Metrics-based approaches can be used to compute safety and security quantitatively: for example, Fenton's [15] causal/explanatory model which uses factors to determine metrics can perhaps be applied in the context of cyber-physical systems as well. Likewise, ATAM, the Attribute Tradeoff and Analysis Method [16], develops a utility tree to capture factors involved in analyzing a design. Again, the tradeoff analysis is mostly implicit. The NFR Approach, where NFR stands for Non-Functional Requirements, allows explicit joint analysis of safety and security properties [17]-[18], by using a goal-orientation. This approach is essential for the current research and described in detail in the next section.

III. NON-FUNCTIONAL REQUIREMENTS APPROACH

The Non-Functional Requirements (NFR) approach is a goal-oriented technique that can be applied to determine the extent to which specific objectives are achieved by a design. The NFR considers properties of a system such as reliability, maintainability, and usability, and could equally well consider functional objectives and constraints for a system. Thus the NFR approach can be applied to evaluate whether a specific design satisfies safety and security requirements for the system.

The NFR approach uses a well-defined ontology that includes softgoals, contributions, and propagation rules [17]. The graph that captures the softgoals, their decompositions, and the contributions is called the Softgoal Interdependency Graph (SIG). The approach relies on a qualitative assessment based on the concept of the contribution "satisficing" positively or negatively the softgoals resulting in determination of the network softgoals to be satisficed or denied.

Subramanian and Zalewski recently applied the NFR [18] to evaluate safety and security of an example cyber-physical system: a typical oil pipeline control SCADA based system (Figure 1) at the Center for Petroleum Security Research (CPSR) [19]. Such system consists of the Master Station and Remote Terminal Units (RTU) connected directly to field instruments measuring pressure and rate of flow of the oil. The field instruments also contain shutoff valves that can change the rate of flow or the pressure. The RTU's communicate with a central master via Ethernet, satellite, cable, cellular phones, or fiber optics.

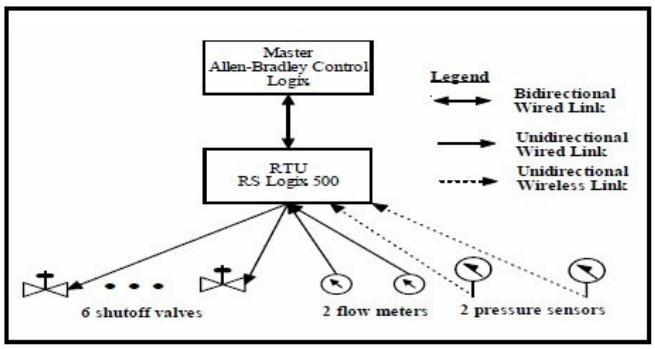

Fig. 1 Example of application (oil pipeline flow control)

In the selected example, safety requirements combine operational and maintenance safety. For operational safety, pressure, structural integrity, and correct distribution are

monitored. For maintenance safety, the flow must be diverted to alternate line, leaving the flow-free portion of the pipeline not monitored for operational safety. Security requires that only authorized personnel are to control the system, all events are logged for audit, and encrypted data are used for wireless transmissions.

The results of the study [18] showed that the NFR approach is effective in joint qualitative assessment of security and safety properties, allowing for simultaneous evaluation of impacts lower level variables might have on these system level properties. In the current project, we are using the same case study and apply the technique known as Bayesian Belief Networks (BBN) to address issues of mutual relationships of safety and security, and their impact on each other.

IV. Bayesian Belief Network Approach

A. Background

A Bayesian Belief Network (BBN) is a graphical model representing the conditional probability distribution of a set of random variables. The technique has been used in the last two decades in multiple industrial applications for decision making under uncertainty, including safety assessment [20]. Since its theoretical background has been well described elsewhere [21], in this paper we provide only a brief overview of BBN principles.

The BBN is based on a formula for belief updating from evidence (E) about a hypothesis (H) using conditional probability measurements of the prior truth of the statement updated by posterior evidence:

$$P(H|E) = (P(E|H) * P(H)) / P(E) \qquad (1)$$

The BBN is described by a directed acyclic graph of nodes and arcs. The nodes can assume specific states with apriori defined likelihood or with a certainty (if there is evidence of their actual state). The arcs represent relations among the variables in terms of likelihood of being in a specific state depending on a state of their ancestors.

An arc from node A to node B means that variable B depends directly on variable A (and A is called a parent of B). If the variable represented by a node has a known state then the node is said to be observed as an evidence node. A node can represent a variable, a measured parameter, or a hypothesis.

A Bayesian network is specified by an expert providing an initial assessment of likelihood that the nodes are in a specific state as well as the likelihood of descendant node being in a specific state, assuming states of its parent nodes. The network is then used to perform inference after some evidence about the state of specific nodes is entered. The predictive mode allows the user to determine likelihood of the outcome, i.e., top-level node being in certain state, assuming specific evidence one may have on its preceding nodes. The network allows also use a diagnostic mode of reasoning. Introducing the evidence of a resulting event leads to estimates regarding the causes of this event.

There are several tools supporting development of BBN with a list compiled in [22]. MSBNx has been used in this project [23].

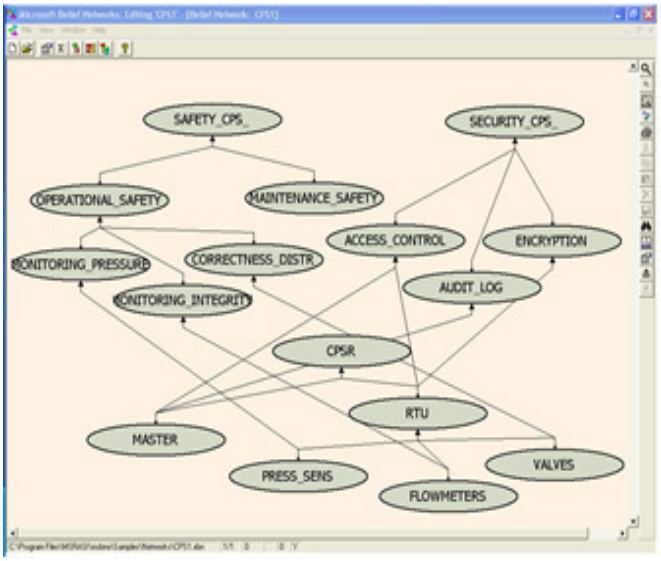

Fig. 2 BBN of the example CPS - oil pipeline control

B. Preliminaries

A BBN model was built for a case study of an oil pipeline control. In reality, safety may be affected by valve fault, pump failure, pressure build-up, leakage, blockage of pipes, and other factors. Security may be affected by lack of authentication and authorization, excessive privileges, wireless transmissions, lack of encryption, connection between the enterprise IT and SCADA networks, lack of audit logs, improper personnel training, poor physical security and the like. However, we consider only a few of these factors to illustrate our ideas. Figure 2 shows a diagram presenting the belief network with safety and security as the top nodes. Here, safety depends on both operational and maintenance safety. Operational safety, in turn, depends on correct monitoring of the pressure (depending on proper work of the pressure sensors) and integrity of the pipeline (depending on correctness of the pressure meters), as well on correctness of flow distribution (proper operation of shutoff valves). Security depends on controlling access, maintaining audit logs, and assuring encryption of transmission. Both Master Controller and RTU's are responsible for access control. Master maintains audit logs while RTU sends data, which may or may not be encrypted. Correct operation of the entire system depends on correctness of the hierarchy of underlying hardware and software.

The computation is initialized with the likelihoods reflecting the probability of correct (State 0-YES) or incorrect (State 1-NO) operation. The dependency relations have been also initialized by assuming that incorrect operation of the parent node impacts the descendant node. Two cases were analyzed: all components operated with a specified likelihood of correctness: 90% and 99%.

The example dependency relationships for top-level safety and security nodes are shown in Figures 3 and 4. Likelihood level of the system security and safety properties are determined by dependency relationships based on the specific evidence of the state of the events affecting these properties.

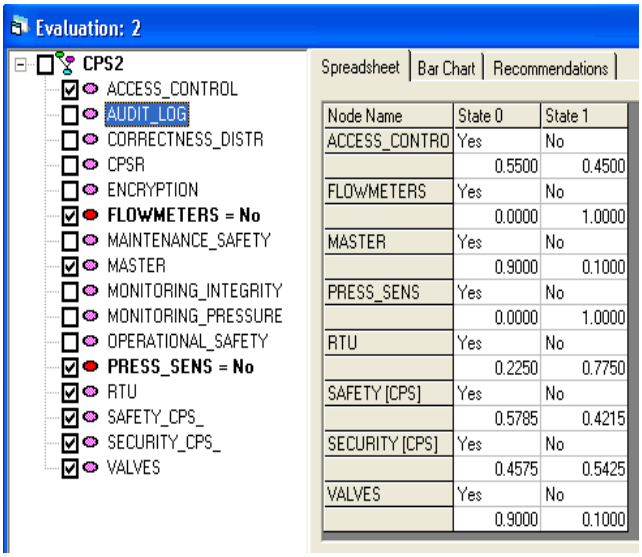
C. Modeling

Several experiments were conducted to assess the impact of specific base elements evidence on the likelihood of the system safety and security represented by top nodes. The results of selected experiments are depicted in Figures 7-9. These three examples show the BBN results when there is failure evidence of elements impacting safety (sensors), impacting security (audit log and encryption), and impacting both (valves and encryption) – all under assumption that likelihood of all other elements being operational is 90%.



Node Name	State 0	State 1

	0.9000	0.1000

Fig. 7: An example scenario - safety impact: pressure and flow sensors not working (Table 1, case #3, 90% likelihood).

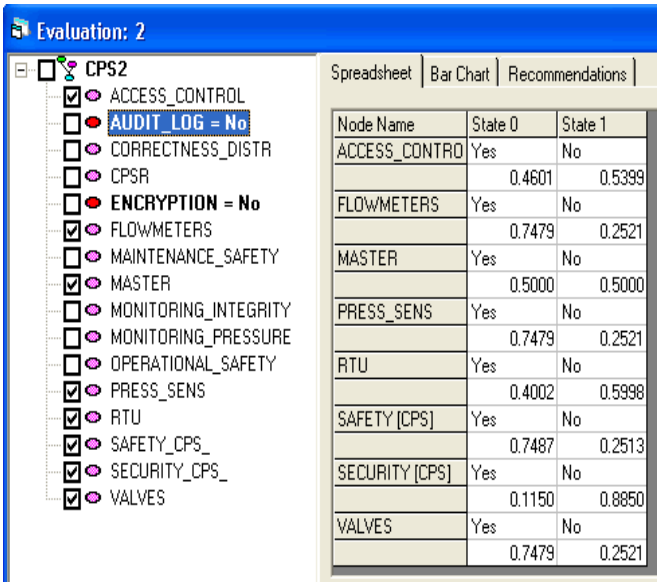

Fig. 8: An example scenario - security impact: audit log and encryption not operational (Table 1, case #8, 90% likelihood)

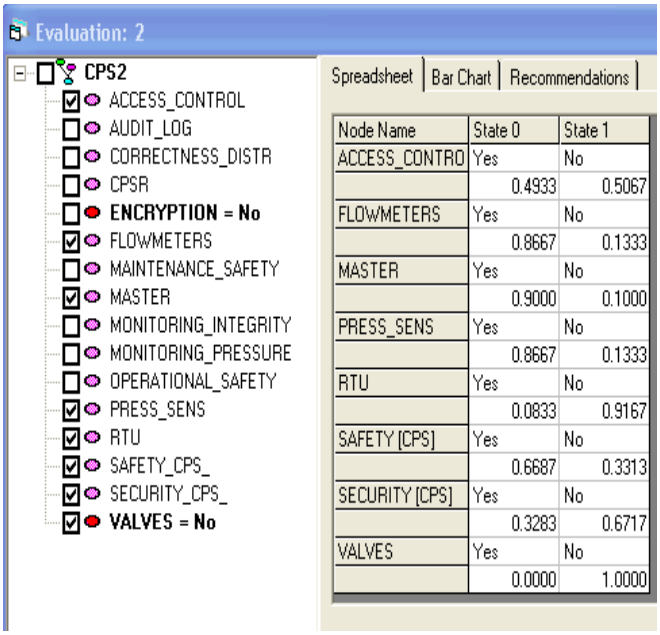

Fig. 9: An example scenario - combined impact valves and encryption not operational (Table 1, case #9, 90% likelihood).

Table 1 illustrates a subset of experiments. After capturing a nominal case (#1), evidence of failing the system components as well as evidence of not operational encryption and audit logs is introduced. Additionally, as presented in the last two rows, the impact of having evidence of a complete failure of safety on security, and vice versa, is analyzed.

Row 1 in Table 1 presents probability levels of safety and security assuming "nominal" values of likelihood of all base events, i.e., when there is no specific evidence and they are defined only by their original probabilities (two scenarios are considered, assuming either 90% or 99% likelihood of correct operations). Consecutive rows present results of deviation from the nominal state and the effect of evidence of these deviations on safety and security. It can be observed that with an evidence of failures or malfunction the probability of a safe/secure operation of the system deteriorates often two-fold.

Using Table 1 one can also compute likelihood of extended scenarios. As an example of a scenario where loss of security negatively impacts safety, consider the case where the RTU in the field was physically tampered which leads to the failure of valve control and thereby permits higher than normal amount of fluid to accumulate in the pipeline. The probability of such compound event can be evaluated from Table 1 as follows:

P(safety violation physical tampering with valve control) = P(safety impact due to security failure)* P(valve failure)

The computation results in probability of safety violation due to a physical tampering destroying the valve control: 0.4668 (0.6907*0.6759) or 0.5811 (0.8357*0.6954), for 90% and 99% scenarios respectively. It is assumed that other evidence is unknown, i.e., the likelihood of correct operation of all remaining components is as specified by the scenario.

TABLE 1: RESULTS OF HYPOTHETICAL SCENARIOS FOR TWO CASES OF THE BASE COMPONENTS OPERATIONAL LIKELIHOOD.

	90% likelihood		*99% likelihood*	
CASE	***Safety***	***Security***	***Safety***	***Security***
#1. nominal	0.8264	0.7452	0.8732	0.8455
#2. valve fails	0.6759	0.5599	0.6954	0.6155
#3. flowmeter & valve fail	0.5785	0.4575	0.5876	0.4993
#4. flowmeter, valve & pressure sensor fail	0.4876	0.3552	0.4876	0.3831
#5. master controller fails	0.8264	0.3552	0.8732	0.3816
#6. encryption fails	0.7487	0.3600	0.8543	0.4350
#7. audit log not operational	0.8264	0.3572	0.8732	0.4372
#8. audit log & encryption fails	0.7487	0.1150	0.8543	0.2047
#9. valve fails & encryption fails	0.6687	0.3283	0.6946	0.3568
Impact				
Safety violation	0	0.6907	0	0.8357
Security violation	0.7893	0	0.8652	0

Additionally, conditional probabilities may also be deduced from Table I. For example, for the scenario where

the valve fails and a security violation occurred, one would wish to deduce the probability that the valve failed due to such security incident. Then:

P(valve failed | security violation) =
P(valve failed and security violation)/P(security violation)

Assuming unknown evidence with 90% scenario, the computation results in the conditional probability 0.7094 (0.5599/0.7893). With 99% scenario, the conditional probability is 0.7114 (0.6155/0.8652).

As shown, BBN's can be used for estimating probabilities of unknown events based on probabilities of known events. As can be expected, the better the data used for modeling BBN, the more trustworthy the computed probabilities. This in turn requires a more accurate modeling of factors affecting both security and safety, which form the basis for BBN's.

The proposed approach allows not only to specify numerical values for safety and security (in terms of their likelihoods), but also allows for quantitative assessment of a relationship between safety and security as well as that of an impact of the status of the system components on safety and security.

An obvious challenge is to identify not only the likelihoods of events at specific nodes representing the system components but also the initial likelihoods of dependency relations between them. These can be derived from failure rates of equipment available, for example, from the military handbook [24] or from industry studies such as [25]. Likelihood estimates can also be obtained from incident rates related to safety and security such as rates of deliberate acts of sabotage and vandalism or the rates of deliberate software attacks [26]. Additionally, the proposed analysis could be conducted, expo facto on a system in which a failure has already occurred to provide some validation evidence and means for calibrating the data.

V. Conclusion

The driving force behind the presented research is that security and safety properties in cyber-physical systems are mutually dependent and influence each other. It is, therefore, natural to seek methods of measuring their mutual impact and assessing their susceptibility to related events and changes in values of basic variables.

In this paper we studied the relationship of safety and security using Bayesian Belief Networks. For a case study of an oil pipeline SCADA based control system, the BBN technique was applied to determine the impact of failures in low-level equipment on the overall security and safety of the entire system and evaluate safety and security in case of equipment or software failures. It turns out that the method proves useful for applied purposes and is comparable to the NFR approach applied previously.

The NFR is a qualitative approach evaluating the safety and security of a cyber-physical system given known factors of a system's configuration (including components and connections). It applies propagation rules to assess NFRs such as safety and security. In contrast, the BBN uses likelihood estimates of a system's configuration to evaluate quantitatively the achievement or denial of safety and security of cyber-physical systems; likelihood estimates can include failure rates of system components and connections or could be likelihood of incidents impacting safety and security. It needs to be noted that [18] describes a qualitative technique to evaluate safety and security. As a result of this evaluation we can conclude to what extent (good or bad) safety and security have simultaneously been achieved in the system. In this paper we have attempted quantitative evaluation of achievement of safety and security in a system using probabilistic computations from BBN.

Therefore, evaluations of safety and security obtained from BBN are rooted in data collected in the field and can be used for both predictive and diagnostic purposes. These data can be used for re-evaluation of contributions in the NFR approach and vice versa, assessments from NFR can be used to re-evaluate critical aspects using the BBN approach. Thus, both these techniques can be used in a complementary manner to iteratively reassess safety and security of cyber-physical systems.

In future work, it would be interesting to include in this study the Safety Case approach [27]. It is based on a graphical Goal Structuring Notation (GSN), similar to NFR, to represent entities and relationships used in the safety argument. Such GSN may be another base to model with BBN's.

***Abstract*—This paper presents object-oriented design of library meant for modeling and simulating Timed Colored Petri Net models. The approach is prepared to integrate TCPN models with crucial parts of larger applications implemented in object-oriented languages. The formal models can be tightly joined with applications allowing the latter to interpret states of the formal model in their domain of responsibility. This approach allows less error-prone and more pervasive use of formal methods to improve quality of software created with imperative languages.**

***Index Terms*—Petri nets, simulation, object-oriented, integration.**

I. Introduction

TImed Colored Petri Net (TCPN) is a flavor of Petri Net formalism designed by K. Jensen [6]. It is suitable for modeling and analysis of distributed and concurrent systems. Since in Colored Petri Nets (CPN) tokens can carry values (*colors*) of specified types (*colorsets*) models created using CPN are more compact and thus more clear. Consequently, CPN can be conveniently used to analyze large systems. Time extension of Timed Colored Petri Net enables analysis of time relationships e.g. efficiency.

Petri net based model can be formally analyzed to prove its properties as described e.g. in [9] and for CPN in [6]. The models can also be simulated, to observe behavior of modeled systems. Both approaches are used, to derive conclusions about the analyzed systems [1], [11], [15], [14]. This approach, however, is rarely used in business applications (e.g. in banking, trade, accounting). The first reason, certainly, being complexity and scale of this kind of software. Secondly, for the sake of special competences required for modeling and analysis and thus cost of this process.

Certainly, large applications could benefit from formal-based analysis or from incorporating formally-verified modules. Especially, that most of contemporary systems are not only concurrent, but also distributed and thus significantly complex. However, majority of these systems are implemented using imperative languages that are hardly susceptible to formal analysis, with Java as pervasively used example.

It is however, possible to incorporate formalisms-based approach into larger applications, also the ones implemented using imperative languages [2], [12]. This results in crucial parts of a system that can be formally verified, or directly steered by a formal model, minimizing possibility of errors.

To make this approach more pervasive it is however necessary to prepare libraries designed for programming languages commonly used in business applications and enabling convenient incorporation of formalisms. In this work we present an approach to enable TCPN-based modeling using Java – one of most frequently used object oriented programing languages. We present object-oriented design of library we have implemented to support modeling and simulation of Timed Colored Petri Nets as a part of larger systems. This first approach assumes that TCPN model should be correctly simulated. Formal analysis of TCPN models is considered as possible future work.

II. Related Work

There is great variety of Petri net flavors and there is also great variety of computer tools designed to create and analyze Petri net models. An extensive list is maintained e.g. by University of Hamburg[1]. For Jensen's Timed Colored Petri Nets there are two important software packages: *Design/CPN* [3] and newer, rewritten in Java: *CPN Tools* [7], [10]. Both of them have GUI to create Petri net models and both implement algorithms enabling simulation and formal analysis. Also both tools provide interfaces for external communication, that allow various levels of integration using various programming languages.

Design/CPN has interface called COMMS/CPN [5]. It allows to communicate with simulator while Petri net is being simulated. It is a message passing interface with small set of functions that allow to establish connection, send and receive messages. The functions should be called from Standard ML code being part of Petri net model (e.g. guards). There is Java/CPN interface, that facilitates establishing communication with COMMS/CPN from Java software.

The newer CPN/Tools has two kinds of interfaces forming Access/CPN framework [17]. The first one, available for Standard ML and more tightly connected with the model is *designed with state space analysis in mind*. It is worth mentioning, that this interface is meant to be formalism independent, not strictly connected to TCPN. The second part of Access/CPN is *Java CPN Model Interface*. It allows to

[1]http://www.informatik.uni-hamburg.de/TGI/PetriNets/tools/db.html

978-83-60810-53-8/$25.00

create or import model created using CPN Tools. It also supports TCP/IP based communication with running simulator.

The presented TCPN design and analysis tools certainly provide interesting interfaces that can be used in selected applications. The message passing communication allows to steer TCPN simulator and respond to some events. It is however a low level communication solution. It also does not allow for tight coupling of TCPN models with applications: TCPN model should be implemented using Standard ML programing language, and Petri net side of communication should also be programmed in Standard ML. It is not possible to implement guards and inscriptions directly in object-oriented language and pass objects as token values.

Petri Net Kernel [16] is a Java library designed to support implementation of various types of Petri nets. It can also be adapted for Timed Colored Petri Nets and in fact was exploited in our research done so far [12], [13], [14]. This general purpose tool has an important disadvantage: token values in Colored Petri Nets are represented by `String` objects. This approach has certain justification: in Java `String` objects are immutable, as tokens in Petri nets. Consequently, design of the programing language ensures one of important assumptions of the formalism. This has, however, two important disadvantages. First, in applications where tokens should carry values more complex than strings, it is not convenient to develop `String` representation of each possible value to pass it to the model and then parse it to an object when its being collected. Second, the performance loss resulting from necessity of parsing the strings is significant.

III. Challenges of Object-oriented Design for TCPN

Library designed in this work should enable modeling and correct simulation of TCPN models. The simulator should be able to run automatically without requiring user interaction and efficiency of simulation must be sufficient for practical applications.

Tight integration of a model as a part of a larger application should be possible, in order to allow subsequent states of a model to be automatically interpreted by an application in its domain of responsibility. In order to limit the effort required by integration, model of Petri nets should be created using classes and objects of Java. Additionally, the library should put possibly small restrictions on objects that are traversing TCPN models in the form of *tokens* and on implementation of TCPN *guards* and *inscriptions*.

Petri net formalism, however, puts restrictions on behavior of its models. The one that strongly affects the design of the library and presents significant challenge, concerns behavior of tokens. Tokens in TCPN are immutable similarly to symbols in functional languages. Presented solution must correspond to this demand, to ensure correct behavior of TCPN model. This requirement must be reconciled with the need to put almost arbitrary object as token value, as mentioned above.

IV. Object-oriented Representation of TCPN

This section presents object-oriented design of the library together with solutions to major problems.

A. Elements of the TCPN Graph

The bipartite graph of Timed Colored Petri Nets consisting of two types of vertexes: *Places* and *Transitions* and of *Arcs* joining the vertexes is described by the natural entities used in object-oriented design.

Places are represented by objects of class `Place` holding `String` attribute describing `name`, `Class` attribute called `type` and describing type of the place and `marking` attribute described by a class implementing `IMarking` interface.

Transitions are described by two attributes: `name` of class `String` and by *guard* used to determine if the transition can be fired. *Guard* is implemented as a reference to an object implementing `IGuard` interface which defines only one method called `guard`. The method gets binding as an argument and returns a `Boolean` value to indicate the guard result.

In this work we distinguished *input arcs* (from a place to a transition) and *output arcs* (from a transition to a place) and described them separately. For simplicity, we assumed that *input arcs* will be used only to define number of tokens used in firing a transition, more complex operations can be performed on *output arcs* using not only basic expressions but also functions. This assumption does not limit expressiveness power of TCPN and considerably facilitates simulation process.

Input arcs are objects of class `InputArc` and hold references to the places being their sources. The `InputArc` class objects have also `inscription` attribute describing tokens that should flow through this arc while firing transitions. The inscription is a `String` in the format analogous to the one defined by K. Jensen [6] and describing count of tokens and variables.

Output arcs are represented by objects of class `OutputArc` and containing references to their destination places and inscriptions. The inscriptions are represented by objects implementing the `IExpression` interface that defines method called `process`. The method receives binding of the transition being fired as an argument, and returns collection of tokens (class `Token`) that should be put in the output place as a result of transition firing. The `process` method can perform any desired operations on tokens and their contents. `BasicOutputArcExpression` class provides means to define simple expressions analogous to the ones used for input arcs.

The references between subsequent elements of TCPN join transitions with their input and output arcs, while the arcs store references to their source or destination places. This solution allows to conveniently access required information while firing a transition by simulator. Parser for arc inscriptions provided as strings is an implementation of finite automata.

B. Tokens

Tokens indicating state of a Petri net model are represented by generic class `Token`. Type of the class parameter corresponds to the type of the token used in Petri nets. It also determines type for the `value` field that holds the token value. This way any class can be used as token type, according to the requirements. Token timestamp is represented by `timestamp` field of the `Token` class.

Consistent simulation of a Petri net requires token values to be controlled by the net only. In Java this is not easy to achieve, since objects are passed to and from methods by reference, not by value. Consequently, it might happen that one object is referred by more than one token as its value or a user could modify value of an object during simulation interfering with the simulation algorithm.

The TCPN designed by K. Jensen are described using functional programing language. This solves the previously mentioned problems by natural means of this paradigm: the tokens are immutable, as are symbols in functional programming. To emulate this behavior in Java, we decided that the following requirements are crucial: (1) TCPN simulator can be trusted to deal with the tokens respecting Petri net principles. (2) By design we must ensure that the user will not be able to breach the rules of TCPN simulation, despite his or her lack of knowledge concerning these principles. (3) For efficiency reasons objects should be copied as rarely as possible.

In order to meet the above requirements, we clone token values (using deep cloning described in [4]) when they enter simulator structures and when they are about to leave these structures. Thus, the compromise ensures correct simulation, regardless of how the token values are processed outside of the TCPN structures, concurrently preserving reasonable efficiency overhead.

C. Marking

Simulation of TCPN consists on subtracting and adding tokens from and to the markings of Petri net places, therefore proper implementation of marking is crucial for efficiency of the simulator. The structure used for implementation of marking must enable efficient search and verification of existence of tokens of known values. In case of Jensen's timed nets the structure should also enable efficient consideration of token timestamps. As stated in [8] the marking can be a composite structure consisting of more than one data structures holding tokens and of consistent interface allowing to operate on the marking as a whole and designed for Petri net simulator.

The implementation corresponding to the above mentioned requirements is placed in `BasicMarking` class. During simulation of a timed net at the given moment only these tokens from a marking are important, that have timestamps not greater than current simulation time. Therefore, conforming to the solution described by Mortensen et al. in [8], we decided to divide tokens in a marking into two separate structures. The tokens, that can be used in current firing of a transition (i.e. with timestamps not greater than current simulation time) are stored in `activeTokens` field. The tokens with timestamps indicating that they can be used later are placed in `waitingTokens` field. These fields refer to objects of different classes, implementing different data structures. The `activeTokens` data structure is an implementation of hash table with support for storing multiple values for a single key. The hash function in this structure uses token values as keys. Thus tokens with given values can be found efficiently while firing a transition, this being a key of efficient TCPN simulation. When simulation clock is advanced selected tokens from `watingTokens` in each place must be moved to the `activeTokens` structure. To perform this operation efficiently, the `waitingTokens` structure is a priority queue sorted by tokens timestamps (`TokenComparator` class is responsible for proper comparison of the tokens in the queue).

The `BasicMarking` class implements `IMarking` interface and the `BasicMarking` can be easily substituted by different implementation of marking implementing the same interface, which ensures all required methods are provided by the implementation. Each marking must implement `getDistinctTokens` returning list of tokens from the marking used to generate bindings while simulation. Boolean method `containsToken` allows to verify if the given token exists in the marking. Method `getToken` removes from the marking a token holding given value and returns this token. Methods `putToken` and `putTokens` enable adding tokens to the marking. During simulation `getNextTime` method is used to determine the least value of the clock that would release new tokens from `waitingTokens` to `activeTokens` in this marking. Finally, `setTime` method is called while each change of simulation clock.

D. Petri Net Structure

The structure of TCPN model is stored in an object of class `CPNet`. The user is supposed to create TCPN model by creating `Place`, `Transition`, `InputArc` and `OutputArc` objects together with guards and inscriptions implementing `IGuard` and `IExpression` interfaces. For efficiency of simulation it is however vital, to provide various information about the net as quickly as possible, without the need to repeatedly exploit computationally intensive graph algorithms. Therefore, after user provided the model, the `CPNet` class performs additional processing in order to cache data concerning model structure and efficiently provide required information for the simulator.

On the basis of the list of transitions provided by the user the `CPNet` class creates list of all places in the model (as Java `ArrayList`). Additionally it caches Petri net structure in an array analogous to graph incidence matrix. The internal structures are filled by method `init` of class `CPNet` that should be called after the `CPNet` object is provided with the list of objects representing TCPN transition.

The proposed solution allows to reconcile requirements concerning efficient access to different aspects of TCPN model while simulation, with the need to ensure consistency between different representations. Obviously the structure of the Petri net cannot be changed after the call to the `init` method.

V. Simulation Data Structures

Variables are represented in different ways, depending on the context. In the arc structures they are represented as objects of class `Var` containing `String` attribute `name` and `Integer` attribute denoting quantity of tokens to be removed from a place. In a *binding* the variables are represented as their names of class `String`. Similarly to [6] variable's range is limited to arcs connected with one transition and their type must be consistent with type of places their arcs are related to.

Bindings are entities assigning variables to their values during simulation. Subsequent bindings are stored in `HashMap` objects with the key being the variable name and value of class `Token`. Thus, during simulation access to variable values connected with a binding is both convenient and efficient. The `HashMap` is encapsulated in the `Binding` class that exposes two methods: `get` to obtain tokens assigned to a variable and `insert` to set binding between a variable and a token.

VI. Integration Interface

The goal of this work was to enable integration of Petri nets with software implemented using imperative programing language. Designed approach enables this integration in two possible ways.

Firstly, crucial elements that create Petri net model and that are part of its behavior, can be objects used in the other parts of application. Tokens can carry objects of arbitrary classes as their values. Transition guards and arc inscriptions can be implemented to depend on application logic.

Secondly, the presented solution is equipped with event listener interface. The listeners can be registered to be called before and after events concerning changes in markings, transition firing, and changes of simulation clock.

VII. Summary

In this paper we presented object-oriented approach to modeling and simulation using Timed Colored Petri Nets. Petri net model with all its components, including token values, guards and inscriptions, should be implemented in object-oriented programming language. The concept was implemented as library in the pervasively used Java.

The approach allows one to integrate Petri net model in a larger application and let it benefit form the formalism-based simulation. The integration can be done while the model is implemented, by joining its components with components of the larger system. It can also be tightened by the use listener interface that allow to implement code responding to specific events occurring in Petri net model. Consequently, the enclosing software can influence behavior of the formal model. Concurrently, the Petri net can steer behavior of the software that can interpret events from the model and apply them in the software's domain of responsibility.

The design of the approach ensures not only tight and convenient integration with object-oriented software. It also ensures that the rules of TCPN simulation are preserved. Thus, the software can benefit from the formal rules, governing behavior of modeled processes and from their correctness.

The presented solution includes TCPN simulator, that allows execution of created model. Care was taken, to ensure efficiency of TCPN simulation that allows practical applications. Necessary optimizations were designed and implemented and if required, additional solutions can be developed.

***Abstract*—Verification is one of the essential topics in research of cyber-physical systems. Due to the combination of discrete and continuous dynamics, most verification problems are undecidable and need to be dealt with by various kinds abstraction techniques. As systems grow larger and larger, most verification problems are difficult even for purely discrete systems. One way to address this problem is the use of interactive verification. Recently, this approach has also been considered by cyber-physical verification tools like KeYmaera and other classical theorem provers.**

Important requirements for the interactive verification are a precise and readable modeling language as well as the possibility to decompose the system into smaller subsystems. Here, tools like KeYmaera and PVS still need further improvement. On the other hand, these modeling aspects are both addressed within the language Quartz as it provides a complete programming language for cyber-physical systems with standard data types and programming statements as well as a precise compositional semantics that is well-suited for compositional verification.

In this paper, we take the advantages of two different tools, the Averest system and KeYmaera, for the interactive verification of cyber-physical systems. This way, we combine modeling and verification capabilities of Averest and the verification capability of KeYmaera, in order to provide a basis for powerful tool set for the interactive verification of cyber-physical systems.

I. Motivation

CYBER-physical systems are systems that combine discrete and continuous dynamics. The environment of embedded reactive systems often consist of continuous behaviors that are determined by the laws of physics. Formal verification is already hard for discrete systems because of the size of the transition systems, and most verification problems for cyber-physical system are even undecidable, due to the combination of discrete and continuous dynamics.

Inspired by the success of model checking [1] in hardware verification and protocol analysis, there has been increasing research on developing techniques for the automated verification of cyber-physical systems. The main line of research concentrates on model checking of finite abstractions of restricted subclasses of the general model. Most techniques proposed so far in this area either rely on bounded state reachability or on abstraction refinement techniques [2–4]. While the first approach suffers inherently of incompleteness, the latter approach often introduces unrealistic behaviour that may yield spurious errors being reported within the analysis.

Despite the theoretic achievements in research, only a few tools are available to verify non-trivial cyber-physical systems. Tools like e.g. PHAVer [5], HyTech [6], Charon [7, 8] focus on the continuous dynamics. They lack typical program statements and data types.

Furthermore, current tools often require an explicit enumeration of the discrete state space. Although the discrete state space typically consists of only finitely many states, the number of these discrete states can become too large to be handled properly by current computers [9].

HySAT [10] and MathSAT [11, 12] are built based upon a SAT-solver that calls a linear program solver for conjunctions of the linear continuous-part constraints. As this technique requires to encode the whole problem space first, the size of the handleable problems is quite small. BACH [13, 14] provides a convenient GUI to construct rectangular hybrid automata with linear location invariants together with a powerful bounded reachability checker for these systems. Another tool, HybridSAL relation abstracter [15, 16] abstracts the discrete and continuous dynamics of the hybrid system automatically to infinite state discrete transition systems that can be model checked by SAL tools [17].

An alternative approach to verification is based on interactive theorem provers. An approach based on higher-order logic [18] for specification and verification of hybrid control system is described in [19]. A verification framework is presented in [20] to strike the balance between the expressiveness of theorem proving and the efficiency and automation of the state exploration techniques. In order to assist in the deductive verification of hybrid systems, [21] presents a tool implemented as a part of STeP [22]. Deductive methods are used in [23] to deal with the parallel composition of hybrid systems, the operational step semantics and a number of proof-rules within PVS [24] have been formalized as well. KeYmaera [25, 26] is an automated and interactive theorem prover for specification and verification logics for differential dynamic logics for hybrid system. It integrates numerous techniques for automated theorem proving, combining deductive, real algebraic, and computer algebraic prover technologies.

Recently, a new language for modeling, simulation, and verification of cyber-physical systems has been developed in our research group [27]. This language is an extension of the synchronous language Quartz that is derived from the Esterel language. Originating from a programming language for discrete systems, there is a rich set of data types, and many

978-83-60810-53-8/$25.00

statements for expressing discrete behaviors in a convenient way. In particular, generic statements and module hierarchies allow one to describe large parametric systems in a concise way. Thus, the modeling capabilities of Quartz are in many cases better than in comparable languages. Like Quartz, also the extension to cyber-physical systems has a precise formal semantics that defines unique behaviors for given input traces. For this reason, the language lends itself well for formal verification. In particular, Quartz programs can be translated to equivalent symbolic transition relations, and thus provide a sound basis for formal verification. The determinism of the language is also very important for simulation, since it allows one to reproduce once observed behaviors. Based on the programing language Quartz, the *Averest* toolset has been developed. Besides of transformations, hardware/software synthesis, a symbolic model checker and other tools, the Averest toolset has recently been extended by a technique for interactive verification [28]. However, up to now these interactive verification techniques are restricted to the discrete component of Quartz, models with hybrid components cannot yet be dealt with.

In this paper, we therefore propose a new approach for the interactive verification of cyber-physical systems by interfacing the Averest toolset and KeYmaera. While the overall verification task remains within the interactive Averest prover, assertions for the continuous components can be verified with the help of KeYmaera. Thus, the advantages of both systems – the modelling and verification capabilities of Quartz especially w.r.t. the discrete component and the verification capabilities of continuous components within KeYmaera – can be combined in order to result in a powerful tool for the interactive verification of cyber-physical systems. Due to the underlying synchronous language this approach will be very well suited for compositional verification that is a great challenge in the context of cyber-physical systems.

The outline of the paper is as follows. In Section II the synchronous language Quartz and the hybrid language used by KeYmaera are briefly introduced. Then, Section III gives a detailed overview of the interfacing of Averest and KeYmaera for applying interactive verification. The paper will be concluded with the application of the interactive verification to a widely known example in section IV.

II. Preliminaries

In the following, we give a brief overview over the synchronous language Quartz, its hybrid extension for modeling cyber-physical systems and the KeYmaera language.

A. The Synchronous Language Quartz

Quartz is a synchronous language that is derived from the Esterel language. The execution of a Quartz program is defined by so-called *micro and macro steps*, where a macro step consists of finitely micro steps whose maximal number is known at compile time. Macro steps correspond to reaction steps of reactive systems, and micro steps correspond with atomic actions like assignments of the program that implement these reactions. Variables of a synchronous program are *synchronously updated* between macro steps so that the execution of the micro steps within a macro steps is done in the same variable environment of their macro step. This synchronous update is important for avoiding data races, and therefore to ensure determinism.

The language offers many data types like booleans, bit-vectors, signed and unsigned integers that may be bounded or unbounded, real numbers, as well as compound data types like arrays and tuples. Modules are declared with an interface that determines inputs and outputs, and a body statement that may use additional local variables. In the following, we list some of the possible statements to describe the examples given in this paper. A complete definition of the language is found in [29] for the discrete case, and in [27] for the hybrid extension.

Provided that S, S_1, and S_2 are statements, ℓ is a location variable, x is a variable, σ is a boolean expression, and α is a type, then the following are statements (parts given in square brackets are optional):

- $x = \tau$ and $\texttt{next}(x) = \tau$ (assignments)
- $\texttt{assume}(\varphi)$, $\texttt{assert}(\varphi)$ (assumptions and assertions)
- $\ell : \texttt{pause}$ (start/end of macro step)
- $S_1; S_2$ (sequences)
- $S_1 \parallel S_2$ (synchronous concurrency)
- $\texttt{if } (\sigma) \ S_1 \ \texttt{else} \ S_2$ (conditional)
- $\texttt{do} \ S \ \texttt{while}(\sigma)$ (loops)
- $\{\alpha \ S\}$ (local variable)

the `pause` statement defines a control flow location ℓ – a boolean variable being true iff the control flow is currently at ℓ : `pause`. Since all other statements are executed in zero time, the control flow only rests at these positions in the program, and thus the possible (discrete) control flow states are the subsets of these locations.

There are two variants of assignments that both evaluate the right-hand side τ in the current macro step: Immediate assignments $x = \tau$ transfer the value of τ to the left-hand side x directly, while delayed assignments $\texttt{next}(x) = \tau$ assign the value in the next macro step.

If the value of a variable is not determined by assignments of the current of previous macro step, a default value is used according to the declaration of the variable. To this end, declarations of variables consist of a *storage class in addition to their type*. There are two storage classes, namely `mem` and `event` that choose the previous value (`mem` variables) or a default value (`event` variables) in case no assignment determines the value of a variable.

In addition to the statements known from other imperative languages (conditionals, sequences and loops), Quartz offers synchronous concurrency $S_1 \parallel S_2$ and sophisticated preemption and suspension statements (not shown in the above list), as well as many more statements for the comfortable descriptions of reactive systems. There is also the possibility to call once implemented modules and to store modules in packages to support the re-use in the form known from software libraries.

Our Averest system provides algorithms that translate a synchronous program to a set of guarded actions [29], i.e.,

pairs (γ, α) consisting of a trigger condition γ and an action α. Actions are thereby assignments $x = \tau$ and $\texttt{next}(x) = \tau$, assumptions $\texttt{assume}(\varphi)$, or assertions $\texttt{assert}(\varphi)$. The meaning of a guarded action is obvious: in every macro step, all actions are executed whose guards are true. Thus, it is straightforward to construct a symbolic representation or extended finite state machine (EFSM) of the transition relation in terms of the guarded actions (see [29]).

While time in synchronous languages is given in the abstract form of macro steps, cyber-physical systems require the consideration of physical time. In order to combine these inherently different concepts of time, the computational model of macro steps is endowed by a continuous transition that takes place between the immediate and delayed assignments of the macro step. During the continuous transition, which consumes physical time, variables of the new storage class `hybrid` change their values according to the new *flow assignments* `x` $\leftarrow \tau$ or `drv(x)` $\leftarrow \tau$ (that equate variable `x` or its derivation on time `drv(x)` with the expression τ).

The continuous transition of the macro step starts with the variable environment determined by the immediate assignments as initial values. To distinguish between the 'discrete' value and the changing value during the continuous transitions, a new operator `cont(x)` is introduced: `x` always refers to the discrete value of a variable, whereas `cont(x)` refers to the (changing) value during the continuous evolution. For memorized and event variables `x` and `cont(x)` always coincide as these variables do not change during continuous evolutions.

The continuous actions may only occur in special statements of the form `flow` S `until(`σ`)` where S is a list of flow assignments and σ is a so-called *release condition* that terminates the continuous phase defined by the flow statement. Figure 1 depicts a program fragment together with the corresponding EFSM. Starting from location ℓ_1, the immediate assignment `x = 0.0` is executed so that the continuous transition starts with initial value `x = 0.0`. The derivation of `x` is then 1 during the continuous transition, and the continuous transition terminates as soon as the continuous value of `x` is 1. Then, the control flow will move to ℓ_2. However, it may be the case that another flow-statement runs in parallel, and that its continuous transition terminates before `x = 1.0` holds. In this case, the control flow moves to ℓ_2', and it will be restarted from there in the next macro step.

B. KeYmaera: Hybrid Programs

KeYmaera is a verification tool for hybrid systems that combines deductive, real algebraic, and computer algebraic prover technologies [26]. It is an automated and interactive theorem prover for a natural specification and verification logic for hybrid systems. In this section, we give an incomplete overview of the syntax and semantics of KeYmaera programs. Statements not needed in the remainder of the paper will be omitted here, for more detailed information consider [25, 26].

The relevant program statements of KeYmaera are summarized in Table I. During a discrete transition, all right hand sides of the actions $x_i := \tau_i$ are computed in parallel and

SYNTAX OF KEYMAERA (INCOMPLETE)

1	$x_1 := \tau_1, \ldots, x_n := \tau_n$	Discrete jump set
2	$\{x_1' = \tau_1, \ldots, x_n' = \tau_n, H\}$	Continuous evolution
3	$\alpha \,;\, \beta$	Sequential composition
4	if(ϕ) then α else β fi	Deterministic choice
5	$< \alpha > \phi$	Existential operator
6	$[\alpha]\phi$	Universal operator
7	$[[\alpha]]\phi$	Universal Path operator

assigned in a second step, which essentially corresponds to the delayed actions of synchronous languages. Continuous transitions are defined by the differential equation systems $x_i' = \tau_i$ of the variables and the evolution domain H, which is defined by a set of location invariants. Continuous evolutions *may* be terminated at any point of time, they *must* be terminated at the latest, when location invariants would be violated. Thus, continuous transitions are always non-deterministic. As stated in line 3, KeYmaera provides sequential composition. The statement if-then-else in line 4 provides a deterministic choice, that depending on the condition ϕ either executes α or β.

Further statements such as loops and non-deterministic choice will not be considered here. Thus, the only non-determinism provided in the presented fragment of KeYmaera lies within the continuous transition, as all other statements in Table I are deterministic.

The formulas from line $5-7$ are used for verification. $< \alpha > \phi$ is an existential operator that evaluates to `true` iff ϕ holds after at least one valid run of the hybrid program α. Analogously, $[\alpha]\phi$ is an universal operator that evaluates to `true` iff ϕ holds after all valid runs of the hybrid program α. $[[\alpha]]\phi$ is a universal path operator that holds true iff during all runs of the hybrid program α the condition ϕ is satisfied.

III. INTERFACING AVEREST AND KEYMAERA

Due to the combination of discrete and continuous dynamics, most verification problems are undecidable for cyber-physical systems. Even the simple reachability problem is undecidable for most families of cyber-physical systems and the few

decidability results depend on strong restrictions of either the discrete or continuous component.

An interactive verification approach is pursued by the tool KeYmaera that is especially suitable for verifying parametric hybrid systems [26, 30]. Unfortunately, like most tools for cyber-physical systems, KeYmaera focuses on the continuous component, e.g. only real-valued variables can be modelled. Furthermore, the tool still lacks good capabilities for modelling the parallel composition of systems.

Recently, our research group proposed a new verification approach for discrete Quartz programs (see Figure 2), which is based on the Averest system. Assuming that the system is given as a Quartz program, the user determines rules based on the program structure which are then verified on the intermediate code format AIF, that essentially is a set of guarded actions. By rule applications, the guarded actions are decomposed into smaller AIF files. The proof goals can also be decomposed flexibly, so that the compositional reasoning could be used for verification by the AIFProver, meaning that already proved goals/assertions of some program fragments can be used as assumptions for the remaining program fragments. At the moment, this approach only supports discrete Quartz programs.

In this section, we propose a way to integrate the continuous component of Quartz programs into that framework by interfacing the tool KeYmaera with AIFProver as depicted in Figure 2. As already mentioned in the preliminaries, Quartz and the underlying language of KeYmaera differ in major points (especially the discrete semantics) which makes it difficult to translate complete Quartz programs to KeYmaera. Thus, we will interface Averest and KeYmaera such that proof rules that depend on continuous transitions will be proved by KeYmaera while the overall verification remains within the Averest.

A. General Idea

Recall that continuous transitions of Quartz programs and KeYmaera programs are based on quite different semantics.

In Quartz programs, continuous evolutions *must* terminate at exactly the first point of time, where an active release condition evaluates to true. The continuous assertions given in the form of constraints (which essentially correspond to location invariants) do not influence the control flow of the Quartz program and may be used only for verification purposes. Thus, continuous transitions in Quartz programs are completely deterministic. Contrary to that, continuous transitions of KeYmaera programs are non-deterministic. They *must* be terminated before active location invariants would be violated, they *may* be terminated at any point of time before that. There is no equivalent to our release condition.

In the following, we explain the general idea of how to adapt continuous transitions in Quartz to KeYmaera and still provide the required semantics. Assume for simplicity to have a continuous transition (compare Figure 4) with only one active release condition in the form of $\phi(t) \leq 0$ together with the proof goal σ that shall hold true at the end of the continuous transition, i.e. when the transition terminates according to its release condition $\phi \leq 0$. Assume furthermore, that the release function ϕ satisfies the condition, that it will have a zero-crossing in finite time and that the first zero-crossing point is a 'real' crossing point instead of only a 'zero-touching' point as depicted by the straight line in Figure 3. Then it holds, that for $0 \leq t \leq t_0$ the invariant $\phi \geq 0$ holds, while the same invariant will be violated for $t > t_0$. Thus, adding this invariant to the KeYmaera program as the evolution domain of the continuous transition enforces the transition to terminate at t_0 at the latest while not changing the transition otherwise.

Now, in order to enforce KeYmaera only to consider *one* path, where the continuous transition terminates at time t_0, the proof goal σ at the end of the KeYmaera program must be changed to $\phi \leq 0 \rightarrow \sigma$. According to our assumption w.r.t. the release function ϕ we know that at least one path exists where the continuous transition terminates at t_0. Thus, $\phi \leq 0 \rightarrow \sigma$ evaluates to true iff σ holds on thepath we are interested in.

B. Transformation

Figure 5 shows the transformation of the continuous transition of a macro step to an equivalent KeYmaera program according to the ideas in the previous subsection. The left-hand side of the figure depicts the continuous transition of the macro step together with the given assumptions and proof goals (assertions). The corresponding KeYmaera program (for ease of notation without variable initializations) on the right-hand-side is described in detail below. The transformation of the continuous transition is divided into four parts:

- *Initialization*
  Already obtained assumptions by the interactive verification together with known initial values of the variables are gathered in the assumption ψ_{assume}. Furthermore, a new location label $s := -1$ is introduced that is used for bookkeeping whether the continuous transition has been terminated because of the release-conditions or prematurely.
- *Continuous transition*
  The differential equations of the hybrid variables can be translated one-to-one. $\Psi := \bigvee_i \sigma_i$ is the disjunction of all active release conditions and states the termination criterion for the continuous transition. As already sketched previously, a set of location invariants $\hat{\Psi}$ needs to be added, that is determined by the active release conditions Ψ:
  For ease of notation assume that each single release condition σ is a conjunction of basic expressions of the form $f(x_0,..,x_n) \leq 0$ or $f(x_0,..,x_n) = 0$. If disjunctions occur, these can be dealt with in the same way as several release conditions in parallel. Define now for the first case
  $$\hat{f}_i := f(x_0,..,x_n) \geq 0$$
  and for the latter case
  $$\hat{f}_i := f(x_0,..,x_n) \begin{cases} \leq 0: & f(x_0,..,x_n) < 0 \textit{ initially} \\ \geq 0: & f(x_0,..,x_n) > 0 \textit{ initially} \end{cases}$$
  Then, the release condition σ is replaced by $\hat{\sigma} := \bigvee \hat{f}_i$, as the continuous transition must be terminated only, when all of the basic expressions evaluate to true.
  Several release conditions in parallel correspond to a disjunction of these conditions, as it is only necessary that at least one release triggers. Thus, the location invariants determined by each single release condition must hold true in parallel, i.e. $\hat{\Psi} := \bigwedge_i \hat{\sigma}_i$
- *Termination of the continuous transition*

  Lines $7-10$ define the control flow of the program for the next macro step. Depending on the fulfillment of the active release conditions Ψ, new values of the location variables are determined.
  By definition, the continuous transition terminates due to the release conditions iff $\Psi := \bigvee_i \sigma_i$ evaluates to true. Thus, the arc from line $7-9$ will be executed iff the continuous transition terminates because of the active release conditions. For ease of notation, this information is stored in the location label s, that is either set to 1 or 0, regarding to the termination condition.
- *Proof goal assertion*
  The proof goal ψ_{assert} of the Quartz program must evaluate to true iff the considered path terminated the continuous transition according to the active release conditions. Thus, it must be proved that $s = 1$ holds which is enforced by the KeYmaera proof goal $s = 1 \rightarrow \psi_{assert}$

C. Correctness

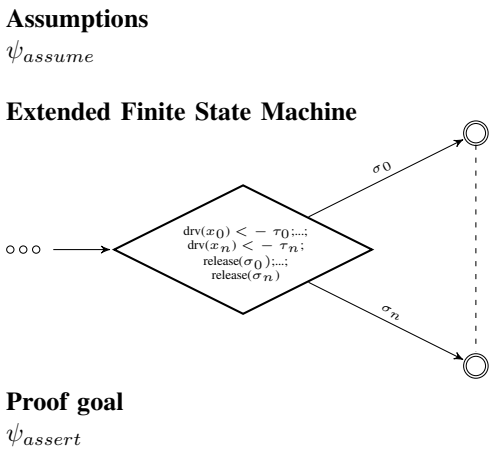
In this section, we present how to use the transformation given in the previous subsection for the interactive verification. The main difficulty lies within the different semantics of KeYmaera and Quartz, namely the difference between determinism (Quartz) and non-determinism (KeYmaera). These difficulties have been dealt with by the introduction of the location invariants $\hat{\Psi}$ together with the additional location label s. The following theorem now states the correctness of transfering the proof results within KeYmaera back to the Quartz language.

Theorem. *Consider a continuous transition in Quartz as given in Figure 5 together with assumptions and proof goals (assertions). Assume furthermore, that the release functions of the continuous transition provide a real zero-crossing (see Figure 3) and that the continuous transition will be terminated in finite time t_0. Then, the following holds:*

1) *The continuous evolution of the variables given by the differential equations are analogous to the ones in Quartz.*
2) *The continuous transition of the KeYmaera program must be terminated at the time $0 \leq t \leq t_0$ and after executing the KeYmaera program, $s = 1$ holds iff $t = t_0$, otherwise $s = 0$.*
3) *If the goal $s = 1 \rightarrow \psi_{assert}$ is proven in KeYmaera, then ψ_{assert} holds after the continuous transition in Quartz.*

Proof.

1) Obvious.
2) The continuous evolutions of the hybrid variables are equivalent within Quartz and KeYmaera. By assumption t_0 is the first point of time where an active release condition evaluates to true. Thus, the location invariants as defined in the previous section are satisfied for all times $0 \leq t \leq t_0$. Furthermore, according to the assumption that the release conditions satisfy the condition as depicted in Figure 3, at least one of the location invariants will be directly violated for $t > t_0$.
   Thus, the duration of the continuous transition of the KeYmaera program can be any time t with $0 \leq t \leq t_0$. The arc given in lines $7-9$ will be executed iff at least one release condition evaluates to true, i.e. if the continuous transition of KeYmaera terminates at time $t = t_0$. This yields that after executing the program $s = 1$ holds iff $t = t_0$, otherwise $s = 0$.



```
1.  \problem {
        /* Initialization */
2.      \ [ ψ_assume
3.      (       s = −1
4.  → \ ⟨
        /* Continuous transition */
5.      {   x_0' = τ_0, ..., x_n' = τ_n,    Ψ̂   } ;
        /* Control flow assignment*/
6.      if( Ψ )    then {
7.          if(σ_0) then l_0 := 1 fi ; ... ;
8.          if(σ_n) then l_n := 1 else ℓ_n = 0 fi ;
9.          s := 1
10.     } else {   s := 0   }    fi
11. \ ⟩
        /* Proof goal assertion*/
12.     ) ( (s = 1)→ ψ_assert )
13. }
```

Fig. 5. Continuous transition in Quartz together with the corresponding KeYmaera program

3) Since by assumption the continuous transition in Quartz terminates at finite time t_0, according to 2), there exists exactly one path satisfying $s = 1$ after executing the KeYmaera program, which corresponds to the continuous transition in Quartz. Thus, if the condition $s = 1 \rightarrow \psi_{assert}$ can be proven by KeYmaera, then ψ_{assert} holds after the continuous transition within Quartz.

■

The first assumption, that the release functions have the form as given in Figure 3 is not a severe restriction, as this is the realistic behaviour in most cases and can be checked in advance. The second assumption, that the continuous transition terminates in finite time can directly be checked by KeYmaera, by simply exchanging the proof goal to the existence of a path satisfying $s = 1$ at the end (compare line 5 in Table I).

If one is interested in proving the continuous assertions of Quartz programs, this can be achieved by replacing the proof goal with the universal path operator as depicted in line 7 in Table I.

IV. Interactive Verification

In this section, we apply the framework as depicted in Figure 2 to an adaptation of the well-known bouncing ball example. While the bouncing ball itself is a standard example with relatively simple continuous dynamics, the parallel composition of a number of balls is difficult to model for most tools as without a suitable compositional semantics the model suffers severely from state space explosion.

Figures 6 and 7 depict the Quartz code of N parallel balls, where N is an arbitrary parameter and the balls start from arbitrary heights. In the main module the observer `n_sum` counts the overall number of bounces of *all* balls, whereas the module `Ball` models an individual ball.

The correctness of the implementation of this observer is proved in two steps: In the first step, the correctness of the counters of each single ball is proven. As the module `Ball` works independently of the rest of the program and is stable under parallel composition, this goal can be achieved by only considering that submodule, disregarding of the number of parallel balls (for more information on the stability of Quartz programs under parallel composition compare [27]). In the second step, the only proof goal is the correctness of the overall observer, i.e. that for all times `n_sum` is defined as the sum of the single observers.

A. Verification of a Single Counter

In Quartz programs, it is possible to have several variable values for the same physical point of time, as the semantics of the language does not only consist of physical but also of logical time. Therefore, the event of the ball hitting the floor cannot simply be described by $h \leq 0$. A good alternative is given by 'the ball reaches the floor during a continuous transition, the starting point may be in the air or directly after a bounce'. The latter part is defined by $\sigma :=$ `h=0 and v>0 or h>0`, whereas reaching the floor during the continuous transition is defined by `cont(h)<=0 and cont(v)<0`. To prove the correctness of the event description, it suffices to show, that during any continuous transition satisfying σ, this condition holds as an invariant for all points except the termination point of the continuous transition. Thus, the event of hitting the floor can only be triggered at the end of but not during the continuous transition. In terms of Quartz, the first property is expressed by σ`-> constrainSM(cont(`σ`))`. The corresponding KeYmaera proof for the only flow statement is depicted in Figure 8.

Define now `NEXTSTEP(`ϕ`)` as a macro for the macro step following one, where a given condition ϕ holds. Then, in a second step the global invariant `NEXTSTEP(h>0 and cont(h)<=0)->next(n)= n+1` is proven. Here, KeYmaera must prove that the release condition `cont(h)<=0 and cont(v)<=0` implies the condition `h>0 and cont(h)<=0`, which is obviously the case and omitted here. The rest of the proof rules will be done by the AIFProver.

```
module Ball(real ? init_h, ? init_v ,int n,) {
   hybrid real h, v;
   h = init_h ; v = init_v ;
   loop{
      flow {
         drv(h) <- cont(v);
         drv(v) <- -9.81;
      } until(cont(h) <= 0 and cont(v) <= 0);
       next(v) = -v/2.0;
       next(n) = n + 1 ;
       flow {} until(true);
   }
}
```

Fig. 6. Hybrid Quartz Module One Ball

```
import BounceBall.*;
macro N = ?;
module NBalls([N]real ? InitH){
    hybrid [N]real h, v;
    [N]int n; int n_sum;
    for(i=0..N-1) {h[i] = InitH(i); v[i] = 0.0; }
    /* n parallel balls */
        {for(i=0..N-1) do || Ball(h[i],v[i],n[i]);}
    ||
        loop{
            n_sum = sum(i =0..N-1 ) n[i];
            pause;
        }
}
```

13.	fi
14.	$\setminus]$ (($s = 0$) $\rightarrow$ ((σ))
15.	}

Fig. 8. KeYmaera Program for only Flow Statement

B. Verification of the Overall Counter

The verification of the overall counter is very simple, as the single counters work correctly. As the counters are discrete variables, it suffices to show that it holds globally `n_sum = n[1] + ... + n[N]`, which is easily done by the AIFProver.

V. Conclusion

Quartz is a powerful synchronous language for the modelling of cyber-physical systems with non-trivial discrete dynamics. This language provides possibilities for the interactive verification of purely discrete programs based on the program structure. In this paper, we presented how to combine the modelling and discrete verification capabilities of Averest with the verification capabilities of KeYmaera. To that end, we interfaced KeYmaera and Averest and showed the capabilities of this tool combination by interactively verifying a non-trivial example.

***Abstract*—Systems whose functionality and services span over multiple, interconnected application domains have become known as cyber-physical system (CPS) and currently receive much attention in research and practice. So far, CPS still come with a variety of development-process-related and technical challenges. These challenges include the interaction between the different domain-specific systems and possible conflicts between their requirements, as well as the choice of appropriate modelling concepts.**

This paper makes two main contributions: First, we show how such an inter-domain development-process can be structured, beginning with a a model-based requirements engineering approach. In order to illustrate the concepts, this paper provides a continuous example scenario, developed within a group of the respective domain experts, that outlines the future of mobility using technologies currently under development in the ARAMiS project. The intention is to allow for an analysis of interaction and possible interference between domain-specific scenarios as well as the analysis of the relation between derived domain-specific scenarios and the global, cross-domain scenario. Second, we provide an analysis of the realisability of the scenario steps according to a set of quality criteria and estimate the respective time horizon, derived from interviews with experts from different domains.

The described scenario allows the reification of goals and requirements of CPS for the mobility domain. Moreover, it makes apparent the need for connecting CPS of different domains. Our validation research provides an accompanying resource for future analysis of the interaction between domains and the relation between their requirements as well as teaching requirements engineering in the domain of CPS.

I. Introduction

ADVANCED features in the mobility domains of automotive, avionics and railway require high-performance computing technologies for complex processing or increased networking, as current technologies used in control devices run up against their performance limit. Future control units will have to perform a greater number of more elaborate functions simultaneously.

One class of such systems with the challenge of integrating different system types are cyber-physical systems (CPS). CPS are integrations of computation and physical processes. Lee [6] defines CPS' as embedded computers and networks that monitor and control physical processes, usually with feedback loops where physical processes affect computations and vice versa. The functionality provided by CPS enables us to realize complex business processes, or complex logistic services as in world-wide travelling.

a) Problem: Today there are typically no or only few shared domain-spanning development artefacts. As a result, domain-spanning RE artefacts are not or only in few cases documented. This results in system functionality which may be adequate for the individual domains, yet cross-domain topics of interests and analyses of interaction and mutual interference between multiple domains are neglected. Furthermore, as domain-specific requirements are located in each individual domain, there is no possibility to link requirements between different domains or associate a common rationale on the CPS level.

b) Contribution: Our comprehensive CPS scenario spans over the relevant mobility domains (automotive, railway, avionics) such that cross-domain topics of interest permit the analysis of interaction and mutual interference possibly arising between domain-specific scenarios as well as the analysis of the interplay of each domain-specific scenario with the global, cross-domain scenario. Furthermore, we provide an analysis of the realisability of the scenario steps according to a set of quality criteria and estimate the respective time horizon.

II. Background & Related Work

A. Systems of Systems (SoS) & Cyber-Physical Systems

The software engineering community has developed methodologies to cope with the engineering process of large systems. The term **S**ystem **o**f **S**ystems (SoS) was introduced to characterize such large systems. Shenhar[10] defines SoS as "a large widespread collection or network of systems functioning together to achieve a common purpose". SoS thus stand out because of their composed nature, their large scale, their decentralized control mechanism, their evolving environments, and their large number of stakeholders.

One class of systems of systems with the additional challenge of integrating different system types are cyber-physical systems (CPS). CPS are integrations of computation and physical processes. Lee [6] defines CPS' as embedded computers and networks that monitor and control physical processes,

978-83-60810-53-8/$25.00

usually with feedback loops where physical processes affect computations and vice versa. This leads to complex functionality that spans a variety of application domains. A helpful overview with a body of knowledge and links to further reading is provided on http://cyberphysicalsystems.org/.

From a more technical point of view, [3] characterises a CPS as system with embedded systems, which may directly record physical data using sensors and affect physical processes, evaluate and save recorded data, is connected with one another and in global networks via digital communication facilities and uses globally available data and services.

Vincentelli et al. [9] and Gezgin et al. [4] discuss the challenges of designing CPS and propose to use contract-based design. Dillon et al. [2] present a case study that presents a framework to link a CPS to the web of things. Lin et al. [7] offer a case study on intelligent water distribution by the integrated simulation of CPS. Huang et al. [5] perform a case study on CPS for real-time hybrid structural testing.

All of these works focus on design and/or implementation instead of requirements and do not provide a case study that reflects and describes the complexity of a large CPS. This is the gap the paper at hand intends to fill.

B. The ARAMiS project

The German academy of technical sciences (acatech) has recently completed a study on the perspectives in CPS research, development, and application [3]. This study serves as scientific basis for the publicly funded research project ARAMiS: Automotive, Railway, and Avionics in Multicore Systems (see http://www.projekt-aramis.de/). The main goal of ARAMIS is to provide for the technological basis for improving safety, efficiency, and comfort in the mobility domains of automotive, railway, and avionics by using multicore technology. The insights gained in the project build the indispensable foundation for the successful integration of embedded systems to cyber-physical systems. The structure and decomposition of the ARAMiS systems of systems, the CPS', is depicted in Fig. 1.

III. The ARAMiS CPS Case Study

A. Methodical Approach

The CPS scenario was developed in a combination of top-down and bottom-up approaches in the following phases: We sketched the scenario in a creative workshop and described the initial storyline (top-down). Then the scenario was reviewed in various workshops with domain experts and the storyline was extended with domain-specific contents (bottom-up). In the next phase, the scenario was specified according to the project-wide reference artefact model [8]. In another series of workshops, an assessment scheme was defined to evaluate the realizability of the individual scenario steps and the assessment was performed by a group of domain experts. Finally, concrete requirements were derived from the scenario steps and the assessment results to provide a rationale and an explicit relation to the domain-specific case studies.

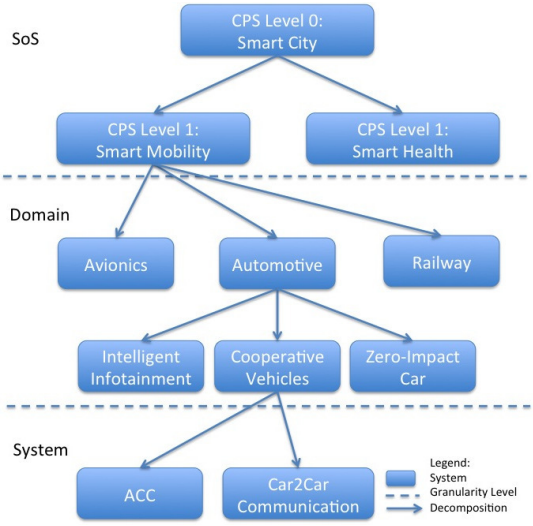

Fig. 1. The ARAMiS structuring and decomposition of SoS

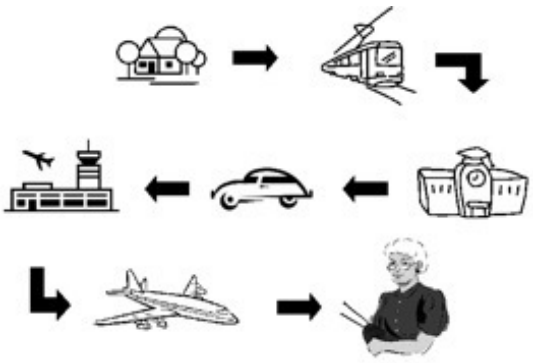

Fig. 2. Overview of the journey

B. Scenario Description

The scenario's starting situation is as follows: Ms Rosemarie Weber plans to spend the next Christmas break with her two children at her mother's, Ms Pauline Mayer. The Weber family lives in Munich, Ms Mayer lives in Sandvika near Oslo. Ms Weber's intention is to pick up her children from school and from there to travel directly to her mother.

Ms Weber enters departure time as well as from and to locations, a maximum cost amount for the entire route as well as passengers' names in the Travel Management Service (TMS) of her smart device. The mobile device is connected to various providers and to Ms Weber's private cloud, and makes suggestions for the trip. In the following, the individual steps of the envisioned scenario are described.

1) Leaving Home: Ms Weber accepts the TMS's suggestion with the proviso that the car be hybrid and capable of autonomous driving. The TMS issues a ticket for Ms Weber's ride in the urban railway, a car reservation according to her preferences, and three flight tickets from Munich to Oslo; name and age of the passengers as well as Ms Weber's possibly further preferences are stored in the cloud.

2) Local transportation (from home to school): Shortly before departure Ms Weber gets a notice on her handheld device about the current status of the local transportation train. As the train is delayed, she takes the opportunity to call and have a little chat with her mother. Afterwards she leaves her home; as she and her children will be away longer, the home is automatically locked, energy saving mechanisms of all devices are enabled, lights are switched off and the home security is activated. Finally she reaches her train on time.

3) At School: Due to the cancellation of the day's last lesson, Ms Weber's children are allowed to go earlier to their day-care centre nearby. This occurred once Ms Weber already set off to school, and she is informed via her smart device of the new location where to pick up her children. At the day-care centre, the children join their respective project teams, organized to collaboratively do their homework. The younger child's group is not yet done with the homework by the time Ms Weber arrives at the day-care centre. Spontaneously, the group members decide to stay a little longer and complete their task. Given that Ms Weber and her children have a plane to catch, the homework group resolves to keep in touch with the leaving child by means of the videoconferencing support put at disposal by the infrastructure.

4) Car-Sharing (from school to airport): For the route connecting the school with the airport the TMS booked an e-mobility car of a car-sharing provider. Ms Weber picks up her dedicated car in front of the school. The car has her driver profile already preloaded, so that the seat and entertainment system is automatically adjusted to her preferences. In addition, the discussion of her child's homework group is streamed to the in-vehicle infotainment (IVI) system and distributed to the corresponding rear-seat screen. As Ms Weber and the two children enter the car, the navigation system starts and suggests the most efficient route to the airport. The IVI offers Ms Weber to book the "premium lane" on the autobahn, which includes a guaranteed arrival time at the airport as an option. The car leaves the parking slot automatically and integrates itself in the traffic flow. The traffic lights are taken into account in two ways. On one hand, there is a coarse-grained traffic dynamics reduction that is triggered by the (smart city) backend in communication with all connected cars. On the other hand, there is direct communication between traffic lights and cars that provides fine-tuning with more precise local information, including an analysis of movements in front of the car. During the drive on the autobahn, the car is being automatically alerted by car-to-car communication about an approaching rescue vehicle on the "premium lane". The car informs Ms Weber, immediately changes lanes, and reduces its speed. In this car-to-car communication, the rescue coordination center informs the rescue vehicle about the accident location to ensure quick appearance with the most up-to-date traffic information.

Back on the "premium lane" the car's speed is controlled by the supervisory TMS. The TMS detects unconnected cars and monitors them using cameras. The performance of unconnected cars is taken into particular consideration during traffic control and planning. Suddenly the car in front brakes, but the collision can be avoided as the optimum evasive maneuver is initiated by the TMS and applied to all connected cars. Unconnected cars are considered accordingly in the scenario; see Figure 3. Thereby, the emergency brake application is calculated within the vehicle and the information is forwarded to the backend. By Car-to-X communication, the braking maneuver is also broadcasted to other vehicles in the direct neighbourhood. This information about braking maneuvers is collected in the backend, to issue a general warning to the traffic section in case the traffic is prone to producing a traffic jam or an accident.

Fig. 3. Avoidance of collision

Close to the airport an Unmanned Aerial Vehicle (UAV) registers heavy rain at position "A (48.456303,12.148819)" with wind direction SE. This information is sent to the TMS, which communicates the upcoming weather situation to every intelligent Road-Side Unit (RSU) within a suitable radius. These RSUs collate the information received with the data they locally sense (wind, rain). The TMS analyses if there is a risk of aquaplaning, in which case a number of actions are taken: unconnected cars are warned using traffic signs, cars equipped with advanced navigation systems are informed in real-time through the system, cars with car-to-x (C2X) close-range communication capabilities receive the warning through nearby RSUs (802.11p) and adapt to the slippery road, and autonomous driving convoys lower speed automatically. Ms Weber arrives at the airport; the car stops and parks in front of the departure entrance according to the flight details, which are sent to the car through the TMS and frequently updated. Ms Weber and her children get out of the car, and label and dispatch their luggage using the automatic check-in counter at the entrance. The car drives autonomously to the parking deck for e-mobility cars of the respective car-sharing provider.

5) Flight (Munich towards Oslo): At the gate, the flight is announced and Ms Weber and her children embark the plane and take their reserved seats. After the boarding is completed, the aircraft takes off in the direction of Oslo.

When the plane has reached a certain height and changes to cruise flight mode, the passengers are allowed to use their personal electronic devices to connect to the wireless passenger network on-board. After reading the digital version of the on-board magazine and ordering drinks and duty free perfumes, Ms Weber starts to watch a TV series and the younger child connects to the school working group via a video conference tool using his tablet device and re-joins the video session that was already joined in the car to the airport; the security of the data exchanged is guaranteed. After twenty minutes into the flight, Ms Weber is informed on her personal

smart device that someone rang the bell at her home. She tabs on the notification on the screen and the video and audio signal from her home's door camera is transmitted to her smart device. She informs the calling neighbour that they will be in Norway for the next few days and wishes him a nice holiday season. Meanwhile the pilot notices a warning on the weather RADAR and is informed by air traffic control that there was a major incident on an oil platform with a huge fire and catastrophic leaking into the North Sea. To ensure the safety of the passengers, the flight is dynamically re-routed by SESAR, but can still reach Oslo with the available fuel. The system organizes the new flight routes of all the planes in the airspace and schedules them to safely reach their airports. To warn the passengers of the expected turbulences, the pilot switches on the seatbelt signs in the passenger service unit and makes afterwards an announcement to all cabin loudspeakers in order to inform the passengers of the redirection. Ms Weber's TMS is informed of the redirection and the plane's estimated arrival time in Oslo. Right after the customer service system prompts her if she would like to notify anybody of the incident, Ms Weber receives a call from her mother, Ms Mayer. The old lady has a headache and would prefer not to drive to the airport to pick them up. So instead of using the customer service system, Ms Weber uses the TMS to change her final destination to Sandvika and the system automatically chooses the next available train to Sandvika and reserves seats in the family wagon in order to ensure that Ms Weber and her children are able to reach their final destination.

6) Railway (Oslo to Sandvika): Once Ms Weber and her children occupy their train seats, she discretely discusses via chat with her mother about Christmas presents for the children. The children notice an attendant talking to a senior passenger. The man's pacemaker detected an irregularity in his heart rhythm; therefore, the Telemedicine System (TS) automatically intervenes: It notifies the train personnel as well as the man's cardiologist. The attendant is guided through the immediate actions to be taken by his smart device. An ambulance with the adequate equipment and remedies is sent to the next train stop, which is to be reached within 20 minutes. The man's health is thus properly nursed.

Ms Weber and her children finally arrive at their destination, where the grandmother cheerfully welcomes them.

C. Model of the Scenario

The scenario was modelled according to the ARAMiS artefact model [8] in the tool Enterprise Architect, which is used project-wide for requirements and system modelling. For this purpose, we developed a profile that provides the modeling elements for the defined content items, such that all requirements documents across the project follow the same template structure and use the same elements.

Figures 4 and 5 depict two exemplary illustrations from the model, namely excerpts of the usage model and the functional hierarchy. There are 23 use cases in Figure 4 which describe the journey in detail and about the same number of overall system user functions in Figure 5 which represent the system-sided realization of these use cases. The use cases were also the basis for the realisability assessment in Section III-D. The models were realized in collaboration among the partners from the various domains and detailed further on the respective domain-specific system levels. Further details of the model can be found in [1].

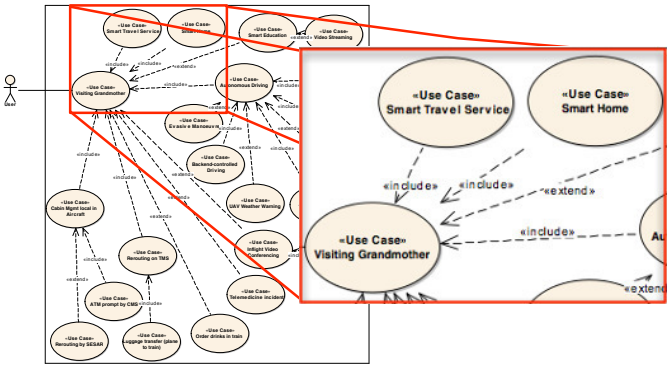

Fig. 4. Use Case Model of the CPS Scenario

D. Technology Realisability Assessments

When describing a future scenario like the CPS scenario, the probably most interesting aspect to assess is the time horizon of the technical realisability of the different parts of the scenario. We performed such an assessment in a number of workshops and in iterations with domain experts. An overview of the results is depicted in Fig. 6 and 7. The domain experts agreed on a list of quality characteristics, for example infrastructure criteria and quality of service criteria, that were relevant to be assessed for judging the realisability of the CPS scenario. We distinguished 3 time horizons (colour-coded in the figures): available today (green), realisable within 5 years (orange), and realisable within 20 years (red). The assessment was performed for all 23 scenario steps in the top row of each table, and for each of the 14 quality characteristics in the first column of the tables. The rationale for each estimation is provided in additional documentation [1]. The time horizon resulting from the justification is coded by colour in the figures for an easy overview of the results. For example, the transmission of a driver profile to a rental car (2nd step "Driver Profil" in the table) and its necessary backend communication (car2backed) is already technically available. This may be implemented in rental cars within the next 5 years (resulting in colour orange), but to actually implement the service, a common data format for driver profiles would have to be standardised among the car manufacturers, which will presumably take considerably longer and is therefore estimated with 10-20 years (resulting in colour red).

IV. Conclusion & Future Work

This paper presented the ARAMiS cyber-physical systems scneario, including the methodical approach for developing the scenario, a storyline description, illustrative excerpts from

the requirements models, and an overview of the conducted technology assessment. It provides the rationale and the basis for the domain-specific developments in ARAMiS. For the research community, it offers a first available CPS case study of a fictitious system based on real facts targeted for the mobility domain. Therefore, it might serve as input for further research and as a resource for teaching, especially as it might be considered more on the Systems of Systems level, which is a good starting point to educate about CPS. Furthermore, as our paper also provides a preliminary assumption on the scenario parts' technical feasibility in the future, it provides the adequate basis to then go into details with further design-oriented case studies in the respective application domains.

Future Work: The next step is the explicit linking from the domain-specific scenario models back to the overall CPS scenario model in the project-spanning Enterprise Architect repository to allow forward and backward tracing and to provide the traceability for explicit rationale for every requirement in the domain-specific scenarios. The targeted outcome of the project is to provide a showcase that starts with the system of systems scenario at hand and details down to two or three specific use cases in the repsective mobility domains including the demonstrators that show the realization of the prototyped technologies.

Apart from the traceability analysis, we plan evaluation of the quality of the complete model repository to assess the advantages and drawbacks of a cross-domain reference model.

***Abstract*—Autonomous Ground Vehicles (AGV) require diverse sensor systems to support the navigation and sense-and-avoid tasks. Two of these systems are discussed in the paper: dual camera-based computer vision (CV) and laser-based detection and ranging (LIDAR). Reliable operation of these optical systems is critical to safety since potential faults or failures could result in mishaps leading to loss of life and property. The paper identifies basic hazards and, using fault tree analysis, the causes and effects of these hazards as related to LIDAR and CV systems. A Bayesian Belief Network approach (BN) supported by automated tool is subsequently used to obtain quantitative probabilistic estimation of system safety.**

I. Introduction

Light Detection and Ranging (LIDAR) combined with dual-camera computer vision (CV) are used as a primary technology for navigation representing a typical optical sensor systems for autonomous ground vehicles (AGV). Researchers at the National Institute for Standards and Technology [1], [2], [3], the U.S. Army [4], and Carnegie-Mellon University [5] have been using such systems to detect obstacles and navigate at ever increasing speeds. Obviously, AGVs combing physical and computing components are typical cyber-physical systems.

AGVs may also be equipped with other navigation technologies such as Inertial Measurement Units (IMU) or Global Positioning System (GPS) receivers; however, the accuracy provided by optically-based navigation controls is absolutely necessary for a safe and precise vehicle operation. Since GPS position errors may be in the range of several meters, GPS alone is not sufficient to safely control a vehicle in urban environment without endangering street signs, pedestrians, and other vehicles. Additionally, GPS reception is obstructed by tall buildings, making GPS unsuitable as a primary navigation tool in an urban environment. IMUs may be used to supplement GPS in low signal areas. However, as kinematic devices, IMUs quickly build up internal error, making them essentially useless for prolonged autonomous navigation. Due to these issues, it is necessary to navigate with a combined system which relies heavily upon optically-based sensor devices.

The paper specific focus is on dependability of the LIDAR and CV sensor systems. It is critical to analyze how the systems work jointly during normal operations and how they work separately under exceptional conditions. To encourage simplicity and maintain focus on the technology, the LIDAR and CV systems are viewed in a generic manner with no effort to model a specific brand of sensor platform. The increasing importance of these issues is realized as fully autonomous vehicles begin to find their way onto roads. Environmental sensing i.e., the capability of the AGV to recognize its location with respect to the environmental obstacles, is the major reason why LIDAR and CV systems are required. Since any unsafe AGV operation may result in violation of safety (property loss or harm to people), there is an evident need for safety analysis. The AGV is safety-critical, software intensive system and potential faults or failures could result in mishaps leading to loss of life and property. By analyzing the hazards posed by the system, the chance of mishap may be reduced or, in some cases, entirely eliminated.

The paper classifies the risk related to AGV operations and describes hazard analyses focusing on impact of LIDAR and CV systems on these operations. Fault Tree Analysis (FT) is used to identify undesirable events and sequences of events leading to top level mishaps such as pedestrian injury, vehicle damage, and external property damage. The Bayesian Belief Network (BN) was modeled based on the FT diagrams along with estimations of likelihood of the events and decision nodes. The presented model can be a good estimator of AGV optical navigation systems as a whole.

II. System Description

A. The AGV Sensor Systems

LIDAR and CV systems are optical sensor systems typically installed on AGV. Together with other sensors they are capable of providing kinematic information about a vehicle (position, velocity, acceleration) and physical information about surroundings (obstacles, road signs, pedestrians, etc). The information from the sensors feeds into a sensor integrator subsystem which filters and integrates data from all vehicle sensors. Detectable anomalies and erroneous data are typically filtered at this stage.

978-83-60810-53-8/$25.00

Having been filtered, the input data are packaged and sent to a state estimator which performs additional filtering and estimates the current state of the vehicle. This state data are then sent to the navigation module which acts as a high-level controller for the individual control algorithms related to degrees of freedom of the vehicle (velocity, heading, etc).

The navigation module (i.e., waypoint manager) handles high level control of the AGV's navigation. In the event of an optical sensor failure, the data passed on to the state estimator will be either corrupt or missing, generating a biased position estimate for the navigation module. The navigation module relies on this data to know where in the world the AGV is with respect to the waypoints, so a simple LIDAR failure could result in the navigation module thinking that the AGV is only 10 meters away from the target when in reality it is 100 meters away.

B. LIDAR

Regardless of measurement technique, all LIDAR units include the following (often redundant) components: laser, lens filter, receiver, power regulator, rotating mirror, position encoder, and onboard processors. As an example, Fig. 1 shows a LIDAR unit (by SICK) with panoramic scanning using rotating a mirror, allowing the laser diode to remain stationary. Detection is accomplished through a complicated combination of synchronizing hardware (including precision motors, and position encoders), and onboard processing capabilities. LIDAR systems typically use a lens filter to block wavelengths of light not identical to that emitted by the laser diode, thus passively reducing interference in the receiver and avoiding the additional complexity, software, circuitry, and cost associated with active filtering. Received laser signals are processed based on this synchronization data to produce a two or three dimensional point cloud. Any error in the system can obviously lead to incorrect depth or position calculations.

Despite being designed for an outdoor use, the high-precision moving parts and optics in modern LIDAR systems are very sensitive to shock. It is important to always place the device at safe, strategic locations around the vehicle. LIDAR should be placed at high clearance locations from the ground, minimizing the amount of vehicle parts obstructing the field of view. Precautions should be taken to protect the device. Foreign-object impact, shock, and vibrations resulting from crashes or rough terrain navigation could cause device failure.

The LIDAR optical filter is one of the most important components of the device. Any damage to the filter will adversely affect measuring accuracy. The LIDAR filter should be protected with a shroud to prevent or reduce impacts and scratches due to vegetation.

C. Computer Vision

Similar to the LIDAR, the CV camera system can produce a two dimensional image using a single camera (or a three dimensional image using dual camera system with two cameras arranged stereoscopically). Using two cameras also allows the failure of a single camera to degrade but not completely void the CV system functionality.

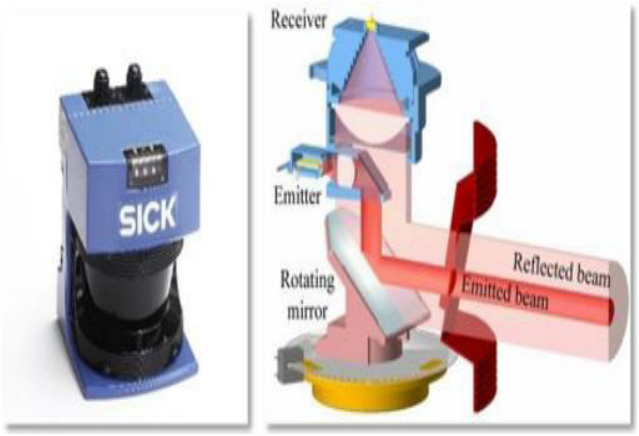

Fig. 1 Example LIDAR

Computer vision software is fundamentally bounded by image quality which is often related to the number of pixels. As each pixel must be processed at least once, the quantities of data and necessary memory may be overwhelming for a system with limited resources. With sufficient processing hardware it is possible to extract quantitative information from scenes, detect obstacles, or track targets using nothing but CV software.

Computer vision algorithms depend upon the video signal received from the camera device. Almost every camera generates some form of distortion which may degrade or even prevent a CV algorithm from operating properly. For this reason, it is necessary to properly calibrate camera and correct image distortion prior to using the image as a source for CV. Improper lighting typically affects both cameras at the same time due to overcast or night condition etc. High-intensity headlights and ambient light sensors on the cameras would be the mitigation technique.

LIDAR failure alone should not significantly degrade system performance. Cameras misalignment would occur if they are displaced by an impact or vibrate free (which can be mitigated with appropriate hardware, e.g., lock washers) and periodic maintenance. Optical receiver misalignment should be extremely rare and can only be caused by manufacturing defect or by physical stress on the device over time (i.e., vibrations from road).

III. Safety Assessment

A. Risks and Hazards

Incorrect operation of AGV may result in mishaps of various severity levels (Table I). One may identify risk as a measure of potential consequence of a hazard representing both the likelihood and the severity of something bad or undesired happening. During the hazard identification stage, hazards are classified according to their risks. A Preliminary Hazard Analysis (PHA) is the starting point to classify these hazards. As with most safety critical systems, the AGV system hazards can be classified in a qualitative manner, using pre-defined arbitrary categories known as risk classes computed as a product of severity and the likelihood of occurrence. For the AGV system, these levels are: negligible

(RV < 1), marginal (1 < RV < 10), critical (10 < RV < 100) and catastrophic (RV > 100).

TABLE I
MISHAP SEVERITY LEVELS

Severity Level	Description
1	No loss of any kind
2	Minor property loss (low cost hardware parts)
3	Major property loss, damage to the environment
4	Loss of critical hardware, human injuries, major damage to the environment
5	Catastrophic loss of life, loss of the entire AGV system, serious environment damage

From a safety standpoint, hazards become the source for safety requirements. Typically, loss of any system functionality may lead to a hazard (e.g., if the laser head of the LIDAR system stops rotating due to mechanical failure). The loss of functionality usually allows identifying a hazard. In turn, the hazard identification allows determining a control measure to be established to prevent or control this hazard. Finally, this control measure can be then converted into a safety requirement for the system and thus be considered in the system development lifecycle.

For the LIDAR example, there is a known hazard of losing the mechanical functionality of the laser rotor head due to wear or manufacturing defects. Typically, engineering department would design and test systems well enough to provide recommendations of conditions for safe operation of their product. Furthermore, manufacturers will typically add recommended maintenance checkups to prevent hazards from transforming into accidents and mishaps. Hazards are always dormant, that is, they exist harmlessly unless certain conditions and/or set of events occur, transforming the hazard into an accident or mishap. Hazards by themselves are not doing any harm unless some transformation takes place. For instance, an energy build-up (e.g., stress due to shaft miss-alignment) would be required for the electric motor that rotates the laser head to eventually give up and stop working. This process takes time. As time passes, wear and stress builds up on the weakest motor parts (with more critical defects). Eventually there will be enough wear and stress accumulated that a point of no return will be reached and a triggering event occurs. That is, at this point there is nothing else that can be done to prevent this hazard from transforming into some accident or mishap. As all this is happening, the system safety levels are gradually degrading from an initial "safe and controlled state" to a final "unsafe and uncontrolled state" leading eventually to a mishap. In all cases a hazard is a prerequisite to the final accident or mishap.

Since an AGV system is dependent on both LIDAR and CV subsystems to assure proper navigation and avoidance of obstacles, any hazards of either subsystem constitutes also a hazard for the AGV system. From this perspective, both LIDAR and CV are safety-critical. Any failure of these subsystems could propagate and lead to a disaster with severe consequences for the AGV. Preliminary list of hazards for LIDAR and CV subsystem, including also hazards and their severity levels is shown in Table II.

TABLE II
HAZARDS IDENTIFICATION

Item	Sub-item	Fault Condition	Hazard	Severity Level
LIDAR	Position Encoder	Fails to read position data	Mirror Motor Malfunction	4
	Electrical	Short circuit	Electrical Failure	4
	Electrical	Overvoltage	Electrical Failure	4
	Optical Receiver	Misalignment	Optical Receiver Error	3
	Optical Filter	Damaged	Optical Receiver Error	3
	Mirror Motor	Malfunction	LIDAR Failure	4
			laser Radiation	4
CV	Camera	Misalignment	CV Failure	3
	IR Filter	Missing	CV Failure	3
	Lens	Damaged	CV Failure	3
	Camera	Improper Lighting	CV Failure	3
Navigation Module	N/A	LIDAR Failure	Navigational Failure	4
		CV Failure	Navigational Failure	4
		Navigational Failure	Property Damage	5
			Vehicle Damage	5
			Pedestrian Injury	5

The most critical sequence of events is one that eventually leads to top level mishaps in the AGV system. Top level mishaps typically relate to loss of life, property or severe damage to the environment. The main goal of Safety Engineering is to prevent these mishaps from happening.

Generally, mishaps are not caused by single events. The accidents are almost always caused by a sequence of events that eventually take the system to an unstable and unsafe state causing the mishap. In the case of the AGV system there are three major top level mishaps: Critical Vehicle Damage, Pedestrian Injury, and Other Property Damage. Critical Vehicle Damage refers to a sequence of events leading to an accident in which the AGV is lost. This type of mishaps results from uncontrolled travel that leads to a physical contact involving substantial volume of kinetic energy between the AGV system and the physical world (i.e., crash or collision) which results in property loss. Pedestrian injury or fatality is by far the most undesirable top level mishap that may be caused by an uncontrolled travel of the AGV system. Other property damage refers to loss of property caused to third parties that are not a part of the AGV system. For instance, during collision with another vehicle the AGV system may cause damage to the other vehicle. All three above mentioned mishaps can be categorized at the highest severity level.

B. Fault-Tree Analysis

Based on the preliminary hazard identification presented in Table II, we may use Fault Tree Analysis (FTA) to show the chain of events that may lead to mishaps. FTA allows us not only to identify the set of events leading to top level mishaps but also determine the intermediate events that constitute a cause-effect chain [6].

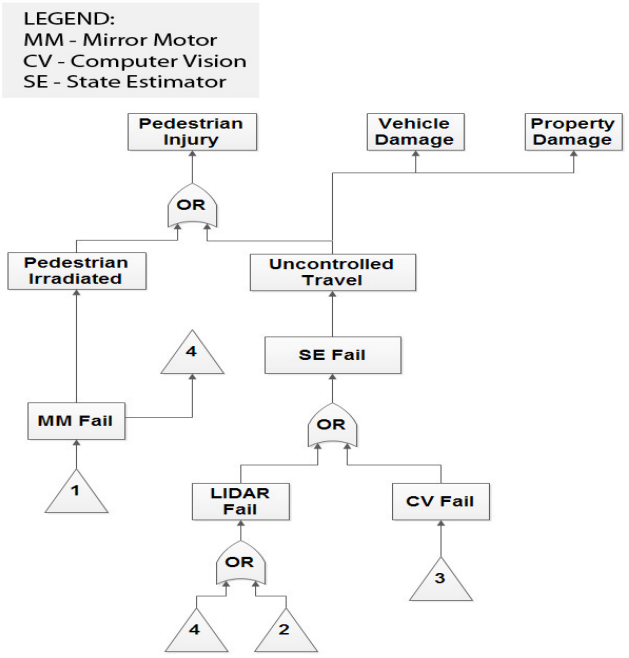

Figure 2 Top-level FTA for UGV

Fig. 2 presents top-level fault tree identifying three top-level mishaps and the LIDAR/CV contribution to these mishaps. LIDAR and CV subsystems fault trees are presented in Fig. 3 and 4. As Portinale [7] observed: "*Any FT can be transformed into a corresponding BN, by creating a binary BN node for each event in the FT, and by setting the probability of BN root nodes (corresponding to basic events in the FT).*" Thus, the cause-effect relations between the events are the basis of subsequent quantitative probabilistic analysis using a Bayesian Belief Network.

The FTA analyses show that any major mishap will involve the failure of one or more subsystem components. In the case of both subsystem components failing (CV and LIDAR) the resulting behavior of the AGV system will always reach a top level mishap scenario.

IV. Bayesian Belief Networks

A. Background

Bayesian Belief Networks have been widely used in Industrial Information Systems for solving variety of computational problems with insufficient information and excessive uncertainty [6, 8, 9]. Since the 18th century mathematician Rev. Thomas Bayes introduced the concept of updating probabilities based on new information, the method has been widely applied in probability and statistics. The basis for the

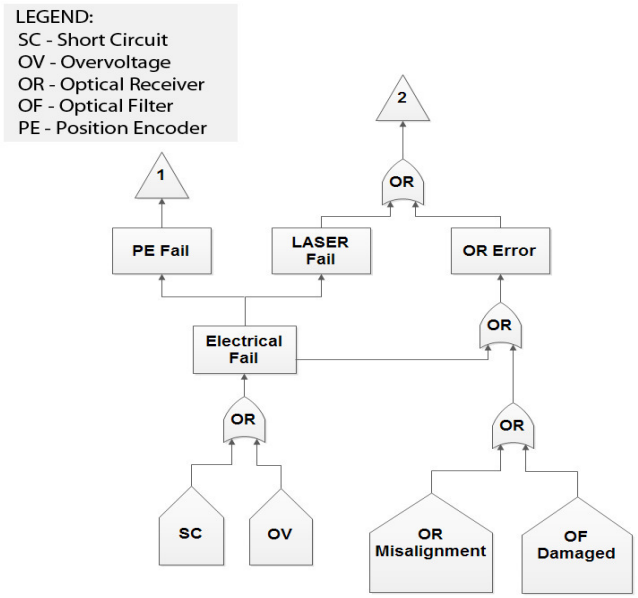

Figure 3 Low-level FTA for LIDAR

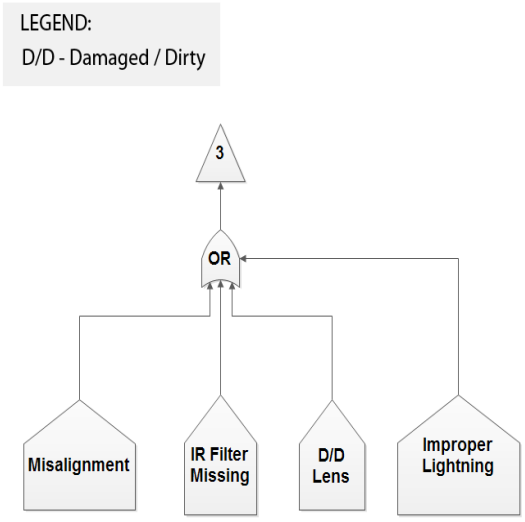

Figure 4 Low-level FTA for CV

method is the inversion formula for belief updating from evidence (E) about a hypothesis (H) using probability measurements of the prior truth of the statement enhanced by posterior evidence:

$$P(H|E) = (P(E|H)*P(H)) / P(E) \qquad (1)$$

A Bayesian belief network is a probabilistic graphical model. The belief network represents the joint probability distribution of a set of random variables with explicit interdependence assumptions. In this research a Bayesian network is defined by a directed acyclic graph of nodes representing variables and arcs representing probabilistic dependency relations among the variables [9].

An arc from node A to another node B indicates that variable B depends directly on variable A. If the variable represented by a node has a known value then the node is said to be observed as an evidence node. A node can represent any kind of variable, be it a measured parameter, a latent variable, or a hypothesis. Nodes are not restricted to representing random variables: this is what "Bayesian" is about a belief network.

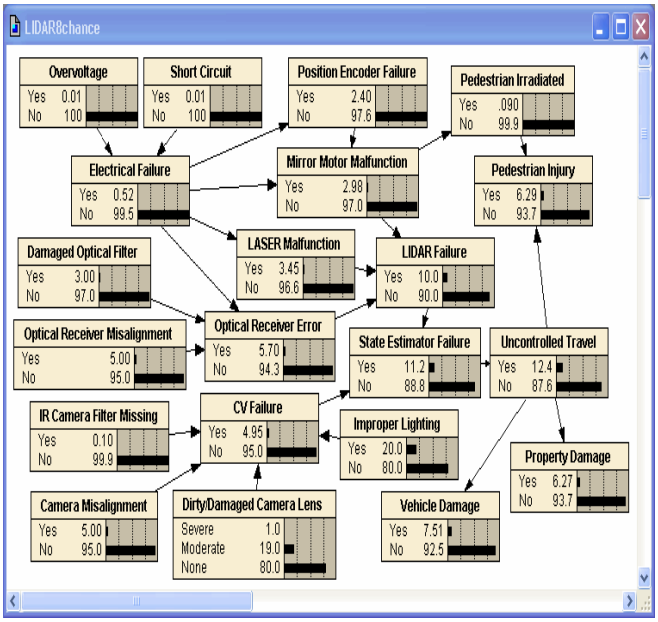

Figure 5 BN of the AGV System – a nominal scenario

The approach supports three types of reasoning. Predictive reasoning observes the causal evidence and updates the middle and upper layer nodes reasoning from a cause to the effects. Diagnostic reasoning observes the evidence of effects and updates the middle and the bottom layer causal variables, reasoning from an effect to the cause. The BN's also allow explanatory (inter-causal) reasoning, in which middle layer reasoning evidence is used to update both the causal and the effect variables.

B. Preliminary Modeling

There is a variety of tools supporting BN modeling: www.dsl-lab.org/ml_tutorial/software_bayesian_networks.html. The computations were done using Bayesian Networks generated by the tool Netica [10]. Based on the fault tree diagrams, along with assumption of base events likelihood (leaf nodes) and the conditional probabilities, it was possible to create a model which represents a good estimator of AGV optical navigation systems dependability. Using nominal likelihood values based on the system analyses and the available data, i.e., assuming no deterministic evidence about the status of the system components, we were able to assess the likelihood of top level mishaps and thus identify their criticality. Fig. 5 presents a screenshot of the tool in such nominal scenario.

From this nominal scenario the BN allows to introduce evidence of selected events and analyze the impact of this evidence on other events. The predictive reasoning property of BN allows us to introduce the evidence of base events (as an example: a camera misalignment) and observe the impact on intermediate events and ultimately on the top level mishaps (Fig. 6).

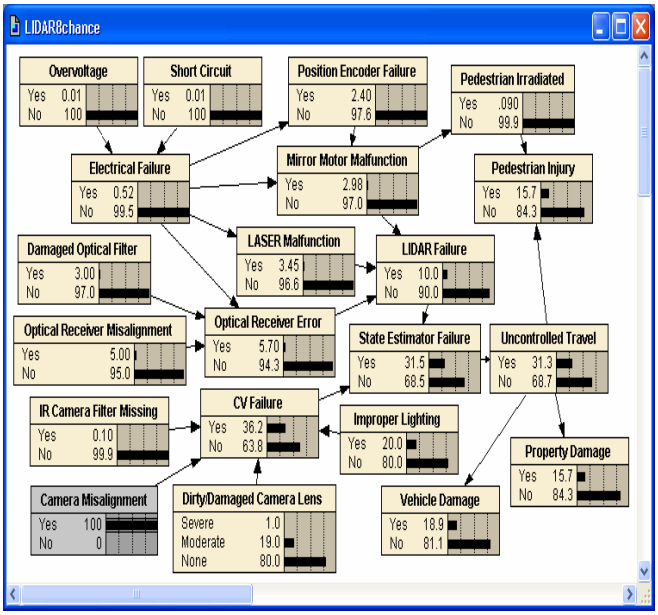

Figure 6 BN predictive reasoning – evidence of camera misalignment

Another scenario allows the presentation of the inter-causal reasoning property of the BN, i.e., analyzing impact of known evidence of intermediate events (e.g. malfunction of laser, mirror motor, optical receiver) up and down the causal chain. As an example, we show how introducing evidence of LIDAR failure results in over fivefold increase of pedestrian injury and property/vehicle damage probabilities (Fig. 7).

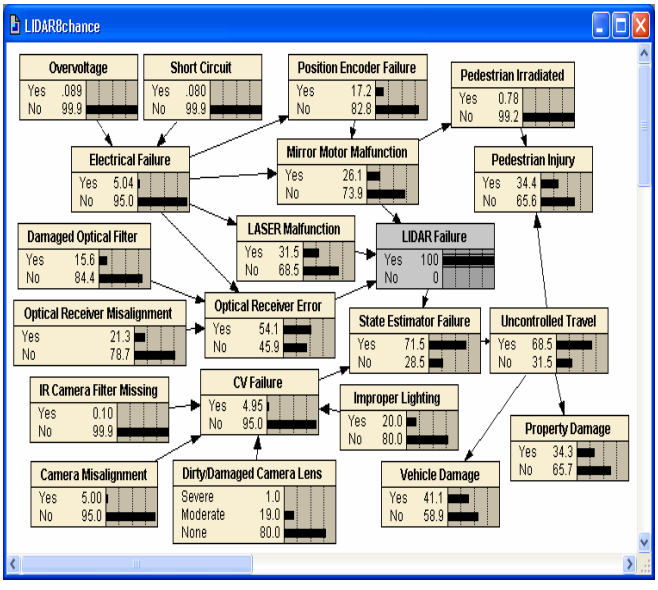

Figure 7 BN inter-causal reasoning – effect of the LIDAR failure

Similarly, the evidence of CV failure results in significant increase to the likelihood of top level mishaps (Fig. 8). Using the inter-causal reasoning one can also assess the poten-

tial causes of the malfunctions observing increased likelihood of causal events such as electrical failure, optical filter damage, or misalignment of the receiver.

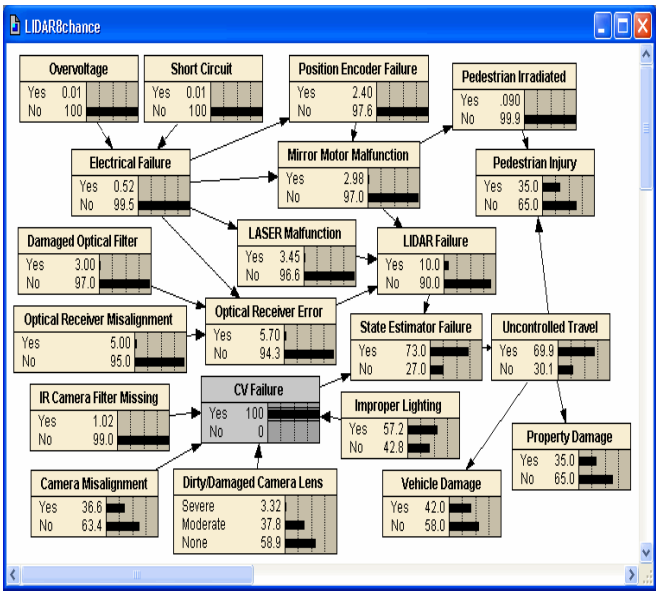

Figure 8 BN inter-causal reasoning – effects of CV failure

B. *Detailed Analysis*

Subsequently, a variety of scenarios were attempted to identify the impact of specific events and the criticality of top level mishaps. The model base probabilities are the best reasonable estimate numbers. Due to uncertainty built into the model, the top-level mishaps show relatively high likelihood of occurrence even with the evidence of correct operation and lack of any problems. The model thus implicitly accounts for unidentified hardware failures and other potential system defects that may cause uncontrolled travel. Table III presents partial results of the predictive and inter-causal reasoning modeling. In a nominal scenario (when all base nodes probabilities are "unknown" i.e. set to the assumed values based on the system analyses and available data), the probability of pedestrian injury is 6.29%. Given evidence of events such as overvoltage or damaged optical filter allows one to predict 200-400% increase in the likelihood of mishap. However, improper lighting or damaged camera lens increases the probability by less than twofold.

TABLE III
PREDICTIVE AND INTER-CAUSAL REASONING – IMPACT OF THE EVIDENCE ON PEDESTRIAN INJURY

Evidence	Pedestrian Injury Likelihood %	Impact (in relation to evidence unknown)
All base nodes "perfect"	***3.82***	***-39%***
All base nodes "unknown"	***6.29***	***0%***
All base nodes "bad"	***48.20***	***666%***
Improper lighting	9.07	44%
Severe damaged camera lens	9.76	55%
Camera misalignment	15.70	150%
Optical receiver misalignment	16.50	162%
Damaged optical filter	19.50	210%
Mirror motor malfunction	31.00	393%
Overvoltage	31.40	399%
LIDAR failure	34.40	447%
CV failure	35.00	456%
CV and LIDAR failures	47.70	658%

Using the predictive and inter-causal reasoning capabilities of Bayesian networks, it is possible to gain additional insight into improvements. For example, simply reducing the chance of inferior lighting is sufficient to remove catastrophic risks and substantially reduce the number of critical risks.

The BN also allows for a diagnostic reasoning (i.e., from effects to cause). For example, having evidence of pedestrian injury the BN estimates that the probability of mirror motor malfunction grows to over six times, CV failure five times, and state estimator failure nearly eight times its original value (Fig. 9).

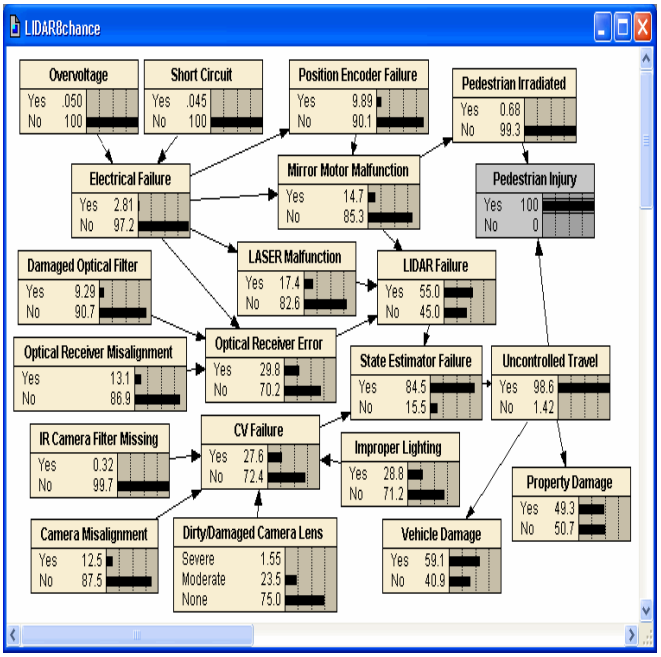

Figure 9 BN diagnostic reasoning – causes of pedestrian injury

Diagnostic reasoning is the most desirable in this research, since it allows making predictions on potential causes of mishaps, including quantitative assessment of risk. This, in turn, makes it possible to prepare for catastrophic events by minimizing their consequences or avoid them by paying closer attention to potential causes.

Using diagnostic reasoning it is possible to derive interesting statistics about the system, such as the rate of property and pedestrian damage in incidents of uncontrolled travel involving vehicle damage. Using available evidence it has been determined that vehicular damage will result in nearly

50% likelihood of property damage and pedestrian injury. It is also possible to estimate that, given the evidence of pedestrian injury, there is a 98.6% chance that it is caused by uncontrolled travel. Having evidence of vehicle damage, the reasoning allows us to estimate the likelihood of LIDAR failure to be 55% and CV failure 27.6%. However, with the evidence of no CV failure the likelihood of LIDAR failure increases to 70.8%. The proposed approach allows thus to analyze impact of given evidence on system in a variety of scenarios.

Table IV presents another partial result of the modeling. The columns present likelihood of the model events in two scenarios: when there is no evidence and when there is evidence of pedestrian injury. The LIDAR and CV failure show as the leading causes of potential pedestrian injury.

TABLE IV
DIAGNOSTIC REASONING – POTENTIAL CAUSES OF PEDESTRIAN INJURY

	No evidence of pedestrian injury	Evidence of pedestrian injury
Electrical failure	0.52	2.81
Damaged optical filter	3.00	9.29
Position encoder failure	2.40	9.89
Camera misalignment	5.00	12.50
Optical receiver misalignment	5.00	13.10
Mirror motor malfunction	2.98	14.70
Laser malfunction	3.45	17.40
CV failure	4.95	27.60
Improper lighting	20.00	28.80
LIDAR failure	10.00	55.00

Interestingly, and in accordance with the hazard table, the BN analysis shows that in the case of total state estimator and thus navigation failure, improper lighting bears a significant probability of being the reason, with CV and LIDAR being evidently on the top. The risk value corresponds equally well to LIDAR failures on the BN, with the laser malfunction as the primary cause. This correlation between the hazard table and the BN implies that the proposed approach provides reasonable base for quantitative assessment of system dependability.

V. CONCLUSIONS

This paper describes the analysis of autonomous ground vehicle system optical navigation components to identify hazards leading to potential safety violations and top level mishaps. We used safety analytical modeling techniques including Fault Tree analysis and Bayesian Belief Networks to better understand the sequence of events that could lead to a major accident or mishap. The quantitative analysis helps to determine the most important hazards that need to be mitigated or controlled. Analysis results confirmed the importance of the reliability and availability of the AGV sensor LIDAR and CV subsystems. Based on the analysis, specific mitigation measures can be recommended in order to reduce the risk of loss of life and/or property. These risk mitigations would lead to reducing the probability for subsystem and system malfunction.

By utilizing both Fault Tree Analysis and Bayesian Belief Networks it is possible to better determine what the sequences of events and their impact on the top level mishaps. From the FTA results it is clear that any major mishap will always involve the failure of one or more subsystem components. In the case of both subsystem components failing (CV and LIDAR) the resulting behavior of the AGV system will always reach a top level mishap scenario. Using predictive reasoning capabilities of Bayesian Networks, it was possible to gain additional insight into the system operation and identify the potential mitigation sources.

Future work would need to assure that the numerical values for the likelihood of events as well as the dependency relations between the nodes closely represent reality. A good source for these values would be published equipment failure rates (e.g. based on military handbook MIL-HDBK-217F 1995) or collected from industry studies related to safety incident rates [11].

Abstract— Systems engineers use SysML as a vendor-independent language to model Cyber-Physical Systems. However, SysML does not provide an executable form to define behavior but this is needed to detect critical issues as soon as possible. Action Language for Foundational UML (Alf) integrated with SysML can offer some degree of precision. In this paper, we present an Alf specialization that introduces the synchronous-reactive model of computation to SysML, through definition of not explicitly constrained semantics: timing, concurrency, and inter-object communication. The proposed specialization is well-suited for safety-critical systems because it is deterministic. We study one example already modeled in the literature, to compare these approaches with our one. The initial results show that the proposed specialization helps to couple complexity, provides better composition, and enables deterministic behavior definition.

I. Introduction

CYBER-Physical Systems (CPSs) are an integration of computational and physical processes [14]. The difficulty in modeling cyber-physical systems comes from the diversity of these systems. The most promising approach to mitigate this problem is developing expressive and precise modeling languages [8].

Accordingly, the Object Management Group (OMG) and the International Council on Systems Engineering (INCOSE) developed Systems Modeling Language (SysML) [20]; a general-purpose modeling language for systems engineering applications. SysML has demonstrated a capability for top-down design refinement for large-scale systems [11]; therefore, SysML is expressive, but the lack of formal foundations in the SysML results in imprecise models.

A major current focus in systems engineering is how to introduce precision in the approaches based on SysML through formal methods. This introduction can be a legal requirement when dealing with safety-critical systems; e.g., the IEC 61508 (Functional Safety of Electrical/Electronic/Programmable Electronic Safety-related Systems) defines formal methods as highly recommended technique for the highest safety integrity level; moreover, DO-178C (Software Considerations in Airborne Systems and Equipment Certification) addresses formal methods as a complement to testing. There are languages with a formal semantics such as Esterel [5] or the B-language [7]; nonetheless, there are no modeling languages with widespread use in systems engineering community that have the attraction of SysML [10].

This paper focuses on the evaluation of a formal foundation in SysML engineering approaches concerning behavioural definitions. Behavior is defined using SysML, and also using Unified Modeling Language (UML) [18], mainly by Activity Diagrams, Sequence Diagrams, and State Machine Diagrams, which do not have precise semantics given by OMG; and, in general, are not executable.

Behavioural definition could evolve with the Semantics of a Foundational Subset for Executable UML Models (fUML) [19]; this specification defines a formal semantics for an executable subset of UML. Moreover, OMG Action Language for Foundational UML (Alf) is the textual language for fUML [21].

On the contrary, there are research papers [4][22] stating that fUML and Alf are not suitable for behavioural modeling the safety-critical systems yet. The reasons can be classified as follows: (1) nondeterminism in the execution model [4]; and, (2) current tools do not allow the use of model-checking or theorem proving [22]. Hereafter, we will explore the reason (1) in detail.

fUML standard execution model is based on a model of computation (MoC), which is nondeterministic (we consider this in Section III.A). On the other hand, there is one MoC that can provide determinism, and can simplify the modeling and verification tasks; it is called synchronous-reactive [14].

The synchronous-reactive MoC can provide determinism using the fundamental model of time as a sequence of discrete instants and parallel composition as a conjunction of behaviors [3]. This MoC has been established as a technology of choice for specifying, modeling, and verifying real-time embedded applications [3], e.g. Esterel [5], Lustre (as well as, Lustre-based commercial Scade tool) [3], Signal [3], and Quartz [26] are languages also based on this MoC.

This work was supported by the Brazilian Coordination for Enhancement of Higher Education Personnel (CAPES) and German Academic Exchange Service (DAAD).

The synchronous-reactive MoC means that most of the statements are executed in zero time (at least in the idealized model). Synchronous computations consist of a possibly infinite sequence of atomic reactions that are triggered by a global logical clock. In each reaction, all inputs are read and all outputs are computed by all components in parallel. In the synchronous-reactive MoC, the communication and computation of values is done in zero time. Consumption of time must be explicitly defined with special statements, as e.g. the pause statement in Esterel [5] and Quartz [26].

Comparing a system described in the synchronous-reactive MoC against a system described following an asynchronous MoC for dual redundant flight guidance system, Miller et. al. [15] made the following observation: "the properties themselves are more difficult to state, were weaker than could be achieved in the synchronous case, and required considerable complexity to be added to the model to ensure that even the weakened properties were true". Furthermore, systems described by a synchronous-reactive MoC can be desynchronized [3] in a concrete solution that is then asynchronous, e.g. to generate Globally Asynchronous Locally Synchronous architectures (GALS) [15].

In this paper, we explore the causes of nondeterminism in fUML and Alf, and, present a deterministic specialization of Alf for CPSs modeling based on the synchronous-reactive MoC. This specialization removes deficiencies found by [2] [4] in fUML and Alf, and can be an alternative to define deterministic behaviors in SysML. The initial results show that the proposed specialization does not add complexity to the task of modeling CPSs using SysML, and enables a deterministic definition of the behavior.

The remainder of this paper is organized as follows: in Section II, related works are explored; in Section III, the relationships between Alf and other OMG specifications are explored; in Section IV, we present the initial approach; in Section V, we discuss the initial approach; finally, conclusions are shared in the last section.

II. Related Works

There is a large number of research papers about semantics for models defined using UML, and consequently, SysML. Hußmann [12] proposed the following classification for approaches concerning structural semantics: (1) naive set-theory, (2) meta-modeling, and (3) translation. This classification can also be used for the works focused on behavioural semantics.

Extending naive set-theory, Graves and Bijan [11] proposed one approach where behavior defined using SysML State Machine Diagrams is represented as a set of axioms in type theory. Graves [10] stated that SysML uses diagrams to model structure, and these diagrams can be encoded as axiom sets in OWL (Web Ontology language). The last work did not cover behavioural modeling, but it suggested that behavioural modeling should follow the same path of the structural modeling, i.e. behavior should be encoded as sets of axioms.

Alf [21], and the foundational subset for executable UML models (fUML) [19], combines the meta-modeling and an extension of set-theory, because the semantics of behavior is described operationally by fUML itself, and by a set of axioms (we consider this in Section III).

A broad set of researches adheres to translation through definition of a mapping between SysML and a formal language. Bousse et. al. [7] proposed a transformation from a subset of SysML into a subset of the B method; the selected subset of SysML covers behavioural definitions expressed by Alf. Afterwards, the resulting B method representation is proved by a specialized tool. Pétin et. al. [23] defined transformation from SysML requirements and SysML behavior (defined by State Machine Diagrams and Activity Diagrams, without use of fUML) into temporal logic and timed automata, respectively. Henceforth, the UPPAAL model checker is used to check safety requirements. Abdelhalim et. al. [1] defined a method that receiving State Machine Diagrams and Activity Diagrams (according to fUML) applies a transformation to Communicating Sequential Processes (CSP). Later, the method uses a model checker to verify the resulting CSP representation. This work focuses on maintaining the behavioural consistency between State Machine Diagrams and Activity Diagrams. Abdelhalim et. al. [2] refined their initial approach defining a subset of CSP to be used because difficulties emerge when non-trivial fUML inter-object communication mechanism is formalized. This work identifies patterns that are correct from the modeller's point of view and the system representation; however, when model checking the CSP representation of this model is performed, a state space explosion problem may occur. Perseil [22] suggested that a subset of Alf should be translated to PlusCal, which has precise semantics defined by a translation to TLA (Temporal Logic of Actions); later, the model checker from TLA would be used.

Some degree of semantics for models is a prerequisite for verification. Taking into account verification, there are a large number of research papers about the verification of UML, and consequently SysML, behavioural models, focusing on State Machine Diagrams, Sequence Diagrams and Activity Diagrams; nonetheless, a way to check the correctness of behavioural representations is still not agreed [24]. Planas et. al. [24] presented a method to verify correctness of behaviors defined using Alf through analysis of all possible execution paths. This method uses as input an UML model, and performs its checks directly on this model. This work states that translating UML behavioural models into other formalisms or languages could compromise scalability of these proposed methods.

However, few researches addressed the problem of nondeterminism, and its roots, in behavioural representations using fUML, and Alf.

Benyahia et. al. [4] showed that fUML, and also Alf, is not directly feasible to safety-critical systems because the MoC defined in the fUML execution model is nondeterministic. In spite of variation points provided by fUML, this work recognized that they are not powerful enough to change the MoC, and an alternative extension of the core execution model was presented to accommodate different MoCs.

III. OMG Specifications and MoCs

Execution and verification of models is the cornerstone of any Model-Driven Development (MDD). One prominent alternative for MDD is Model-Driven Architecture (MDA) [17] established by OMG. MDA defines three levels of abstraction: (1) Computational Independent Model (CIM) – focuses on the environment of the mission and mission's requirements; (2) Platform Independent Model (PIM) – defines requirements, structure and behavior for candidate abstract solutions; (3) PSM (Platform Specification Model) – describes concrete solutions.

An important OMG specification for PIM is Alf [21]. Alf is a textual surface representation for UML modeling elements. It is an action language that includes primitive types (including real numbers), primitive actions (e.g. assignments), and control flow mechanisms, among others. It is object-oriented, and it is an imperative language (like C and Java). Further, Alf has the expressivity of OCL (Object Constraint Language) in the use and manipulation of sequences of values, enabling an OCL-like syntax.

The execution semantics of Alf is given by mapping the Alf concrete syntax to the abstract syntax of fUML [19]. fUML abstract syntax is a subset of UML with additional constraints, so a well-formed model is one that meets all constraints imposed on its syntactic elements by the UML abstract syntax as well as all additional constraints imposed on those elements by the fUML abstract syntax.

Moreover, the execution semantics of fUML is an executable model written in fUML. However, instead of using Activity Diagrams, activities are written as equivalent code in Java; to support that, a mapping from Java to Activity is defined for core elements of activities (Base UML - bUML). The circularity is broken by the base semantics for bUML, which is specified in first order logic based on Process Specification Language (PSL). PSL (ISO 18629) provides a way to disambiguate common flow modeling constructs in terms of constraints on runtime sequences of behavior execution; desired behavior is specified by constraining which of the possible executions is allowed [6]. Fig. 1 shows relationships between these OMG specifications. In the following, "fUML execution model" refers to fUML and Alf.

SysML reuses a subset of UML 2 and provides additional extensions to satisfy the necessities of systems engineering, e.g. Requirement Diagrams [20]. SysML and Alf integrate seamlessly because Alf can be used in context of models not limited to the fUML subset [19].

Concerning the MoC provided by UML, one basic premise from this modeling language is that all behaviors are ultimately caused by actions executed by active objects [18], which is an instance of an active class (executed concurrently).

This establishes concurrent processes (active objects) but does not define a specific MoC because all BehavioralFeatures (e.g., Operations and Receptions) in UML allow three types of concurrency: sequential, guarded, and concurrent. Therefore, the semantics is unconstrained, which supports heterogeneous MoCs; in fact, it is one of the goals of the specification.

fUML constrains the concurrency for all BehavioralFeatures to the sequential type; as a result, the sole mechanism for asynchronous invocation in fUML is sending signals (SendSignalAction) to other active objects [19]. Further, the sending action is not blocking, i.e., an object sends a signal and continues its execution; it does not wait for a response, or an acknowledgment (nonblocking write). In contrast, the reception action is blocking, i.e., one computation running is blocked when it expects to receive a determined signal (blocking read). Moreover, the received signals are stored in an unbounded event pool for each active object, which is a FIFO (first-in first-out) in the fUML standard execution model (this is a variation point [19]). Consequently, the fUML standard execution model is characterized by concurrent processes (active objects) communicating with each other through unidirectional unbounded FIFO event pools, where writes to the event pool are nonblocking, and reads are blocking.

These fUML's characteristics are what the Kahn process networks have [13]. However, fUML standard execution model defines that signals coming from different active objects should be stored in the same target event pool. Allowing more than one process to write to an event pool (channel), the resulting process network is neither deterministic [13] nor a Kahn Process Network (in the strict sense). Consequently, the resulting process network can be described by active objects that receive (input) and emit

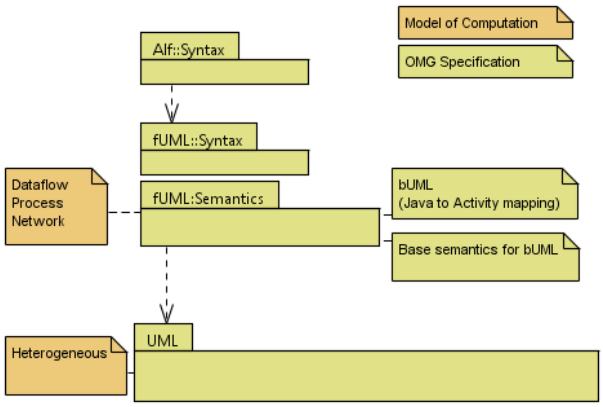

Fig. 1. Relationships between OMG specifications and MoCs.

(output) signals, and a set of firing rules (encoded in the behavior) defining when an active object should be fired; these characteristics are what the dataflow process networks have [13].

Nondeterminism can be a powerful modeling tool, but it should be used only when necessary [13]. Consequently, deterministic languages that allow nondeterminism remove it using precise techniques, e.g. the Quartz [26] compiler adds new control events to remove nondeterminism allowed by some statements.

Despite the nondeterminism of fUML MoC, it is designed to support a variety of different MoCs. This is pursued using two techniques: (1) defining explicit variation points, which are: event dispatching scheduling (used in the inter-object communication), and polymorphic operation dispatching; (2) leaving some semantics elements unconstrained that are: timing, concurrency, and inter-object communication.

IV. The Initial Approach

CPSs are often safety-critical systems [14]; hence executable models describing them must be deterministic: given a state $x(t_i)$ and an input $w(t_i)$ the system must generate the same output $u(t_i)$ for each reaction in state $x(t_n)=x(t_i)$ and input $w(t_n)=w(t_i)$.

The fUML specification states that there are a number of cases in which the UML indicates that the execution semantics in a certain area are nondeterministic [19]. In order to understand these nondeterministic areas, the next subsection discusses the roots of nondeterminism in the fUML execution model.

A. fUML and Nondeterminism

In order to analyze fUML's nondeterminism, behavior should be classified, which is done by UML [18] as: (1) intra-object behavior addresses the behavior occurring within classes; (2) inter-object behavior, which deals with how active classes communicate with each other.

The roots of nondeterminism in the fUML specification can be grouped as follows: (1) structural features manipulation – e.g. set one value to a property of an object; (2) conditions – fUML conditional clauses, e.g. defined using if or switch Alf statements; (3) token flow semantics – defines intra-object behavior semantics, e.g. how are tokens offered, and, consequently, in which sequence are nodes executed; (4) ObjectActivation – a key class responsible to bind inter-object behavior with intra-object behavior.

1) Structural feature manipulation

A property in a class, defined by a modeller, is a StructuralFeature in the meta-model of UML. Actions that write or remove values in a StructuralFeature can be nondeterministic. The nondeterminism occurs when a target property has multiplicity greater than 1, it is not ordered, and it does not have the uniqueness property; i.e., the property is a bag.

This nondeterminism can be a challenge for verification but it compromises neither the given definition of deterministic models nor the fUML MoC.

2) Conditions

Conditions are modeled in fUML using ConditionalNodes. ConditionalNode has an association with Clauses; each Clause can have an association with predecessor Clauses. The fUML execution model states that sequential evaluation is performed when the predecessor chain is defined.

Two statements in Alf map to ConditionalNodes in fUML: if, and switch. The statement if is mapped using predecessor clauses in fUML when the modeller uses the construct "if (*condition) else …"*, so the sequence of evaluation of clauses is deterministic; on the other hand, when the modeller uses the construct "if (condition) or …" the sequence of evaluation of clauses is nondeterministic. Finally, the statement switch is mapped without use of predecessor clauses in fUML so the evaluation of clauses is not deterministic.

As a result, the modeller has two options to produce a deterministic model, concerning conditions using Alf: (1) define conditions that are mutually-exclusive (assured by the modeller, or by an automated assistant); or, (2) use the Alf construct "*if (condition) else …*". A nondeterministic model is defined otherwise.

This nondeterminism compromises the given definition of a deterministic model, but it does not affect the fUML MoC.

3) Token flow semantics

fUML states that different execution traces for the same inputs in an identical environment (including same state) are allowed to be different [19].

For example, given two actions that are not directly or indirectly ordered by their relationships, the order of execution is determined neither by UML semantics nor by fUML execution model, as recognized by [4]. Other example, a ForkNode enables race conditions. Therefore, nondeterminism is established in the intra-object behaviors.

Some basic nondeterminism (coming from UML), in the token flow semantics, are removed by semantic mapping from Alf to fUML, e.g., a naive modeller can, using fUML, connect an OutputPin at two InputPins without using a ForkNode (it copies tokens). However, that construction is not possible in Alf, which generates a ForkNode for each local name [21].

This nondeterminism (if these different traces lead to different outputs or signals sent to other active objects) compromises the given definition of deterministic models, and can contribute to the nondeterminism in the fUML MoC.

4) ObjectActivation

ObjectActivation is the class defined in the execution model to handle the active behavior of an active object. It is responsible to bind inter-object behavior with intra-object

behavior because it, together with EventAccepters, offers the blocking read feature for fUML MoC.

Two associations of this class are important for analysis of nondeterminism: (1) eventPool - the list, without upper bound, of pending signals sent to the object handled by this object activation; (2) waitingEventAccepters - the set of event accepters waiting for signals to be received by the object handled by this object activation.

For example, an execution sequence (ES) for two active objects communication can be explained as follows: (1) an active object (A) reaches an AcceptEventAction (statement accept defined by Alf), this is a blocking read for a signal; (2) the corresponding ObjectActivation object registers an EventAccepter in the waitingEventAccepter; (3) another active object sends a signal, that matches (A) receptions, and the registered accept statement; (4) the ObjectActivation object inserts this new signal at the end of eventPool; (5) considering that eventPool had no previous signals, this signal is removed from eventPool, dispatched to respective accept statement, and EventAccepter is unregistered.

The step (5) is one of two explicit variation points from fUML, called event dispatching scheduling. The standard execution model provides the implementation described above, where events are dispatched from the pool using a first-in first-out (FIFO) rule.

The ObjectActivation is the key to understand how nondeterminism in the fUML MoC and in the token flow semantics is combined. Exploring the execution model of fUML, Fig. 2 shows an Activity Diagram for an active class. Further, Fig. 3 shows an Alf representation for the Activity Diagram presented in Fig 2.

In Fig. 2, there are two concurrent AcceptEventAction waiting for the same type of signal; they are designed to execute two different tasks using received signals. The ForkNode, together with the fact that the next two actions wait for the same signal, defines a race condition, where the output depends on the sequence of tokens offered. Considering that a signal sent by another active object arrived after the two EventAccepters were registered, and the execution sequence (ES) presented above; during the event dispatching phase (5), there are two registered EventAccepters. In this case, the execution model chooses nondeterministically one of these [19], dispatches the event to it, and unregisters it.

This nondeterminism compromises the given definition of a deterministic model, and contributes to the nondeterminism in the fUML together with fUML MoC.

B. Proposed specialization of Alf and fUML

The initial approach is described as follows: given the semantics defined by fUML, we specialize the explicitly unconstrained elements with the purpose of deterministic behavioural definitions using SysML and Alf. We chose to discuss the semantics in an informal way, and to present concrete additional Alf constructs for the specialization.

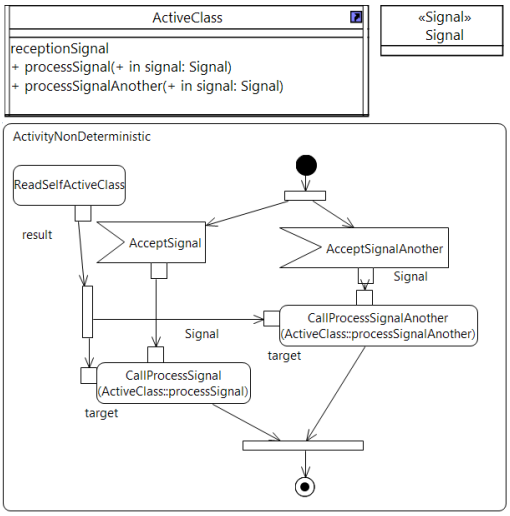

Fig. 2. fUML Activity diagram – nondeterministic.

These additional language constructs are defined using Annotation. According to Alf abstract syntax [26], annotation is a way to identify a modification to the behavior of an annotated statement. The applied approach allows us an early evaluation of the proposed specialization.

Therefore, a first concern is to introduce a synchronous-reactive MoC on fUML and Alf. A second concern is to specialize fUML and Alf, which means: do not change syntax parsing of Alf, but change its semantics.

The next three subsections explore the introduction of the synchronous-reactive MoC in Alf using unconstrained elements, and the variation points. The fourth subsection summarizes the proposal.

1) Timing

The behavioral semantics of UML only deals with discrete behaviors [18]. Accordingly, the timing semantics proposed divides the time scale in a discrete sequence of instants, each instant corresponds to one macro step as defined in the next subsection.

The annotation @delayed was introduced; it is the only way to assign new values to an already assigned variable in the current macro step. This annotation can be used in the assignments and in the SendSignalActions.

2) Concurrency

Concurrency can be achieved in Alf using two complementary techniques: (A) multiple active objects that, in general, imply the necessity of inter-object communication; or, (B) inside a given definition by the use of the annotation @parallel [21].

The alternative proposed is a combination of concurrency and synchrony (where computation and communication are instantaneous) through introducing the synchronous-reactive MoC to fUML and Alf. According to this MoC, a program can be defined by so-called micro and macro steps. Each macro step is divided into finitely many micro steps, which are all executed in zero time and within the same variable

environment. As a consequence, the values of the variables are uniquely defined for each macro step. Macro steps correspond to reactions of reactive systems, while micro steps correspond to atomic actions [26], e.g., assignments using Alf.

The demarcation of macro steps was introduced by the annotation @pausable; it is one of two ways to define demarcation between two macro steps. The second way is the use of the accept statement. This annotation is designed to be used with loop constructs (while, for, do while) but it can be also used with an empty statement of Alf. The semantics is: after each execution of the loop body, it waits for the next macro step. It follows that all concurrent behaviors run in lockstep: they execute the actions inside the loop in zero time, and synchronize before the next iteration.

The annotation @parallel can be used to define that all the statements in the block are executed concurrently. The block does not complete execution until all statements complete their execution; i.e., there is an implicit join of the concurrent executions of the statements [21].

Alf provides also an annotation called @isolated, it is defined in [21]: no object accessed as part of the execution of the statement or as the result of a synchronous invocation from the statement may be modified by any action that is not executed as part of the statement. Similar to this annotation, Alf provides the isolation expression through character $. Both options are not compatible with the synchronous-reactive MoC, where variables are uniquely defined for each macro step.

3) Inter-Object Communication and Event-Dispatching

Inter-object communication in Alf is performed by sending signals to other active objects. A signal is a specification of what can be carried; furthermore, a signal event represents the receipt of a signal instance in an active object [21]. A signal instance is identified by its contents.

Signals are based on the paradigm of message passing; furthermore, fUML provides a point-to-point (also known as unicast) message pattern. A signal is sent to a receiver (an active object) using a reference to it. In contrast, multicasting is required in many safety-critical systems, e.g., fault-tolerance by active redundancy [16]. Multicasting also supports the non-intrusive observation of component interactions by an independent object, and enables better composition [16].

```
                                                    //ACC0
//@parallel
{
    {
        accept( sig:Signal );                       //ACC1
        this.processSignal( sig );
    }
    {
        accept( sigAnother:Signal );                //ACC2
        this.processSignalAnother( sigAnother );
    }
}
```

Fig. 3. Alf representation for fUML Activity diagram – nondeterminitisc.

Multicasting is provided by the introduction of an active class called MessageDispatcher; it provides a service for multicast message exchange. Instances of this class work as bus transferring instances of signals between previously registered active objects, which generate events in the target active object. Every signal handled by MessageDispatcher has a specific identifiable sender, and zero or more receivers.

The set of receivers (active objects) is defined by existence of the reception for the sent signal. All signals generated in the current macro step are available instantaneously in the synchronous-reactive MoC. Further, signals not consumed during a macro step are lost. Delayed SendSignalActions are available in the next macro step.

It is possible to receive signals individually or as a set. Receiving a set of signals is important for those active objects that need to process all signals sent in the current macro step. However, individual signal receiving is fundamental for those active objects that should only process one signal sent to them. For this case (individual signal), the annotation @nonblocking was introduced; it is the only way to receive signals without blocking (nonblocking read).

In a macro step just one signal value (a signal is identified by its contents) is allowed for a given signal type, and MessageDispatcher; therefore, values of the signals for a given MessageDispatcher are uniquely defined for each macro step.

4) Summary

Table I summarizes the annotations available in the specialization of Alf. All other annotations available in Alf now are just comments, as well as, isolation expressions.

Considering that execution model of fUML has changed to accommodate proposed specialization, the semantics of Alf representation in Fig. 3 changes. As just one signal value in a macro step is allowed for a given signal type, and MessageDispatcher; the same signal instance is dispatched for those two parallel accepts, and computation follows in the same macro step concurrently.

The specialized semantics removes the nondeterminism indicated in section “IV.A.4 Object Activation” as described earlier. Also, it removes the nondeterminism indicated in section “IV.A.3 Token flow semantics” because the ordering of micro steps does not influence the semantics of a model. However, the new semantics does not remove the nondeterminism indicated in section “IV.A.2 Conditions”,

TABLE I.
ANNOTATIONS IN THE SPECIALIZED ALF

Annotation	Informal semantics
@delayed	Delayed assignment or SendSignalAction
@pausable	Macro step demarcation
@parallel	Computations on each block are carried out concurrently
@nonblocking	AcceptEventAction read nonblocking, makes optional signals available

which should be rejected by an interpreter for proposed semantics (when conditions are not mutually-exclusive).

With the proposed specialization, Fig. 3 can be changed without modification of the semantics: the two accepts (ACC1 and ACC2) could be removed, and a new one (ACC0) could be inserted before the concurrent block. This is referential transparency, which means syntactically identical expressions have the same semantics regardless of their lexical position [13].

5) Example

We evaluate the example from [4] but a case study with well-known CPS is [25]. Fig. 4 shows the Block Definition Diagram (BDD) for it. A PingPongSystem is composed by one Player1 and one Player2; both players are active classes. These two active classes communicate by exchanging signals Ping and Pong. The respective Alf representation for the behavior of each player is presented using comments.

In a given macro step, Player1 sends a delayed Pong (P11), and awaits for Ping (P12). In the next macro step, Pong is received by Player2 (P21), who sends a delayed Ping (P22). The game continues forever as showed in Fig. 5.

Fig. 5 shows the Internal Block Diagram (IBD) for the system, and the Alf representation for the main behavior. Player1 (S3) and Player2 (S2) are created passing an object of MessageDispatcher (S3); later, an infinite loop annotated with @pausable (S5), containing an empty statement, is used to define the evolution of time.

In contrast to [4], which uses static Association between the players, it is used Connectors that specify links between instances playing the connected parts only [18] (decoupling Player1 from Player2). The communication is provided by the instance of MessageDispatcher. The Alf specialization makes the example different concerning evolution of time, signal events, and communication. Therefore, this model is deterministic while [4] is nondeterministic.

V. DISCUSSION

Activity Diagrams are used frequently [1][4][2][23][24]; however, for significant activities, these diagrams quickly become large, intractable to draw and hard to comprehend [19].

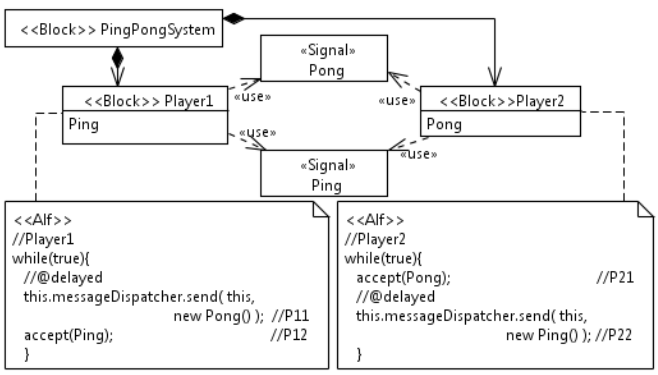

Fig. 4. BDD for the PingPongSystem.

State Machine Diagrams are another commonly used form of diagrams, especially suited for modeling state-based behavior [1][2][4][11][23][24]. However, UML, fUML, SysML, and Alf do not define precise semantics for state machines [9]. This is ratified by the Alf specification itself, which states that a normative semantic integration of state machines with Alf will be formalized later [21]. Indeed, environments of synchronous languages offer tools to visualize the resulting automata [3], e.g. Fig. 3 can be automatically transformed in a State Machine Diagram.

Transformation from SysML to other languages or formalism could bring some serious problems [12], and could compromise scalability [24]. However, we consider the certification process [22] more challenging because it is needed to assess the original model, and the translated model (or even the transformation itself). Nevertheless, these transformations are powerful, and can provide feedback for the fUML specification MoC. For example, [2] defines a pattern suitable of optimization called "fUML-Opti-Rule(2): Detecting unacknowledged signals" - an unacknowledged signal is one that has been sent from an active object to another active object, and then it (source object) continues sending further signals without waiting for an acknowledgment signal. This pattern is detected through model checking executed over a CSP representation, which is the result of a transformation of a fUML model [2]. Based on this feedback, the modeller should evaluate acknowledging those signals to reduce the state space of the corresponding CSP model. Although, this is a rendezvous that is common in CSP MoC; considering this case, fUML MoC needs more design effort than CSP MoC.

Concerning [10][11] which propose to encode SysML structure as a set of axioms, fUML and PSL [6] are well suited, hence axioms about structure and behavior can be combined and evaluated together.

The evaluation presented corroborates [4] concerning two points about fUML (and also Alf) as it is: (1) the execution model is nondeterministic; (2) it is not suitable for safety-critical systems. Nonetheless, Alf should be specialized to allow safety-critical systems modeling [22].

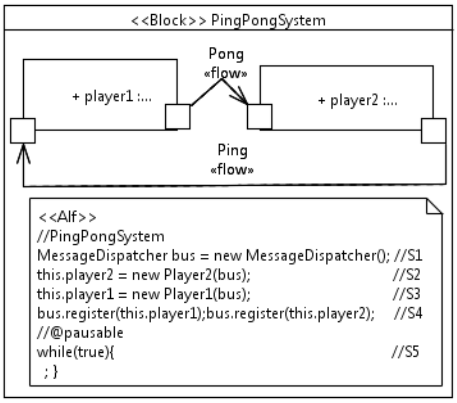

Fig. 5. IBD for the PingPongSystem (graphical view of flows).

The proposed specialization of Alf adheres the idea of introducing synchronous-reactive MoC during early stages of a system development [3]. The major drawback of this MoC is that the computer interpretation of the models is difficult [3]; further, polymorphism, reclassification, and dynamicity (actions: create, and destroy) can be even more challenging [3].

fUML states that every specialization must be defined using bUML; in fact, the initial approach presented here provides a complete description from the viewpoint of the modeller. It defines the semantics for three additional constructs for Alf that together with MessageDispatcher can transform Alf in a synchronous action language; however, the changes needed in the fUML execution model to support it must be defined.

VI. Conclusion

This paper shows the results of the proposed specialization of Alf, according to the synchronous-reactive MoC. It helps to couple complexity, provides better composition, and enables deterministic behavior definitions.

CPS is about the intersection of the computation, control and communication [14]. The initial approach focuses on the discrete computational and communicational aspects of CPSs. It can be composed with discrete control. A case study with a well-known CPS [25] shows that the initial approach can bring solid mathematical foundation from synchronous-reactive MoCs [3] to SysML executable models. We consider this as an intermediary step, located before a formal verification of executable discrete SysML models.

In summary, we believe that specializing well-known vendor-independent specifications (Alf and SysML) can provide an understandable and compact set of languages for modeling, analyzing and verifying of CPSs. Moreover, such a set of languages can enable formal verification for discrete parts of CPSs.

***Abstract*—Modern SCADA networks are connected to both the companys enterprise network and the Internet. Because these industrial systems often control critical processes the cyber-security requirements become a priority for their design.**

This paper deals with the network security in SCADA environment implemented by firewall devices. We proposed a method for verification of firewall configurations against a security policy to detect and reveal potential holes in implemented rule sets. We present a straightforward verification method based on representation of a firewall configuration as a set of logical formulas suitable for automated analysis using SAT/SMT tools. We demonstrate how such configuration can be analyzed for security policy violation that can be inferred from a security policy specification of an industrial automation system.

I. Introduction

SCADA (Supervisory Control and Data Acquisition) systems are commonly deployed to continuously monitor and control industrial processes to assure proper functioning, by automating telemetry and data acquisition. Historically, SCADA systems were believed to be secure because they were isolated networks: an operator console, or human-machine interface (HMI), connected to remote terminal units (RTUs) and programmable logic controllers (PLCs) through a proprietary purpose-specific protocol. Yielding to market pressure, that demands industries to operate with low costs and high efficiency, these systems are becoming increasingly more interconnected. Many of modern SCADA networks are connected to both the companys enterprise network and the Internet. Furthermore, it is common that the HMI is a commodity PC, which is connected to RTUs and PLCs using standard technologies, such as Ethernet and WLAN (see Fig. 1). Such configuration has exposed these networks to a wide range of security problems. The access to individual subnetworks are secured by firewalls that implement basic network security policy.

Securing networks properly by configuring firewall rules is difficult, time consuming and error-prone task. Wool has analyzed possible threats of incorrectly configured firewalls in [1] and called for methods that would help to improve the quality of firewall rules. The stated observation considers the complexity and the size of firewall rule sets as the main source of errors. He identified major source of difficulties in creating complex firewall configurations. Although Wool considered only a small set of relatively obvious errors, his survey demonstrated that a rule set having 1000 items includes more than 8 errors on average.

The approach described in this paper is close to the work done by Guttman [2], Bera, Ghosh and Dasgupta [3], and Al-Shaer et el [4]. Similarly we develop the method that is able to verify correctness and consistency of firewall configurations against network security policy given a set of simple policy rules. We show a simple translation of policies and firewall rules into logical formulas and describe the Satifiability Modulo Theory (SMT) verification method. The SMT tools employ algorithms for solving logical formulas with respect to combinations of background theories expressed in classical first-order logic with equality. In the present work we use Microsoft's Z3 tool that implements an efficient SMT decisions procedures.

Packet filters implement the basic level of security policies in the network. By restricting the accessibility of certain services, computers or subnetworks, we deploy rough but efficient security measures. Our network model deals only with IP addresses and services or ports. Therefore, the analysis does not reflect hardware or Operating Systems (OS) attacks. The contents of TCP/UDP packets are not examined, but it is possible to extend the description to support this. Our primary goal is to verify safety or resistance of the network with respect to the effect of dynamic routing. Therefore, this classification includes only basic categories of network security properties. Since it can utilize typical fields from IP, TCP, or UDP headers, namely source/destination IP address and service/port allows us to specify wide range of different communications to be analyzed in the network.

This paper is structured as follows: Section II discusses various packet filter representations. Section III presents representation of filtering rules in form of SMT formulas. In Section IV we define a verification method for a single firewall configuration. This is extended to the cascade of firewalls in Section V, thus providing a method for system-wide security policy verification. In Section VII we present a preliminary experimental results showing performance of the presented method. The paper concludes in Section VII by comparing presented method to related work and suggesting further development.

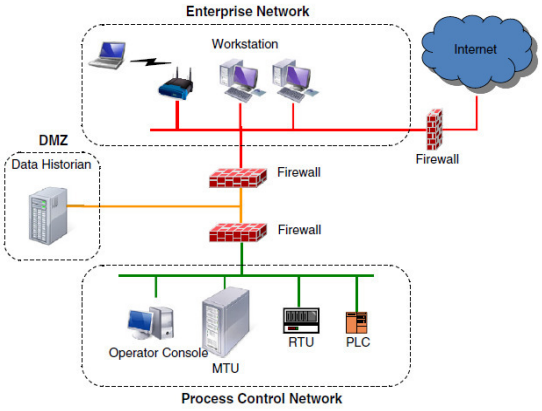

Fig. 1: An example of modern SCADA network.

II. Representation of Packet Filters

Firewall configurations are usually written in form of access control lists (ACL). An ACL format is easy to understand for network administrators and it is also suitable for machine processing. Nevertheless, for an efficient formal analysis this format may represent a problem because it admits conflicting rules. Conflicting rules are pairs of rules that match the same set of packets. These conflicts are solved at runtime by implementing first match semantics. However, certain classes of conflicts can signalize a configuration error, for instance, a rule that completely hides some other rules. Several methods to check conflicts in ACLs and constructing a non-conflicting *rule sets* were proposed, e.g. [5], [6], [7], [8].

Rules have multidimensional structure. Dimensions correspond to fields in a packet header, in particular, source and destination addresses, port numbers and a protocol type. Formally, we define a rule as a tuple $\langle src, dst, srv, act\rangle$, where *src* and *dst* are set of addresses, *srv* is a set of services, and *act* is an action.

A logical formula that is a translation of a simple rule $r = \langle s, d, v, a\rangle$ consists of a conjunction of all selectors. A selector is represented by a predicate that extracts required header field from packet p. Thus, for rule r the formula is written as follows:

$$src\_adr(p) \in s \wedge dst\_adr(p) \in d \wedge service(p) \in v.$$

A list of all possible selectors is shown in Table I A network-mask convention is adapted for representing a sequence of continuous addresses. For instance, address prefix 147.229.12.0/24 is a set of addresses ranging from 147.229.12.0 to 147.229.12.255. We can use the standard set operations, e.g., $src\_adr(p) \in 147.229.12.0/24$ or $dst\_adr(p) \in 147.12.28.0/24 \cup 147.12.30.0/24$. The latter can be expanded to $dst\_adr(p) \in 147.12.28.0/24 \vee dst\_adr(p) \in 147.12.30.0/24$, which allows us to use network-mask format for the canonical address representation.

Often, rule sets implicitly assume the existence of a default rule, which has the lowest priority and matches all packets not matched by any of the previous rules. For a single rule set of an ACL configuration we compute two logical filter representations. A *positive* filter represents all packets permitted by the ACL configuration. A *negative* filter represents all packets denied by the ACL configuration.

TABLE I: Network field selectors

Function	Description
$dst\_adr(p)$	Destination address of a packet p.
$src\_adr(p)$	Source address of a packet p.
$dst\_port(p)$	Destination port of udp or tcp datagram carried in packet p.
$src\_port(p)$	Source port of udp or tcp datagram carried in packet p.
$service(p)$	Service of a packet p.

III. Filter Representation

As proposed in [9] the output of reachability analysis and the input for consecutive security property analysis consist of a collection of reachability sets for forwarding paths in an analyzed network. There are various methods to calculate reachability sets. In this section, we discuss several issues related to these calculations. We overview the problem of efficient address encoding and rule set representation.

Guttman has described an approach to deal with abstract address scheme [2]. The abstract address is a symbolic name of a host or a subnetwork. This address scheme avoids dealing with huge IP address space, which consists of 2^{32}addresses. An abstract packet consists of an abstract source address, an abstract destination address, service identification, and a flow orientation. The flow direction represents the communication direction that is either client to server, or server to client. This approach leads to very reasonable complexity which is dependent on the size of the network and mainly on the number of interesting destinations and services. For an example, considering a network with N different distinguished addresses, S different distinguished services, then the abstract packet space of size will be $N^2 \cdot 2S$.

Different approach was proposed by Bera, Ghosh and Dasgupta in [3]. In their work, the IP address space is explicitly represented by bit variables. The bit variables $s_1, \ldots, s_{32}$ represents a source address, bit variables $d_1, \ldots d_{32}$ represents a destination address, and a vector of bit variables $v_1, \ldots, v_n$ of the appropriate length n, represents a service. A flow direction may be modeled separately by a single bit variable or encoded in the service vector. In this way, there is an explicit representation not only for each packet but also for each network represented in network-mask format.

Independently on whether we use abstract address representation or explicit representation, we construct logical formula for each rule in a filter. These are used in composition of formulas for positive and negative filters. Such formula can be encoded as a SAT instance using the Boolean reduction approach, which is defined in detail for explicit address scheme in [3]. If the abstract address scheme is used each abstract address has to be represented by a single Boolean variable.

These two approaches differ from the number of Boolean variables in generated SAT instances. While explicit represen-

tation requires the fixed number of variables, the number of variables used by abstract approach depends on the number of abstract addresses. On the other hand, the former may generate a large number of clauses while the latter tends to keep number of clauses smaller. It remains for future work to analyze and compare both approaches from the practical perspective on real data.

IV. SMT-BASED VERIFICATION METHOD

In this section, we describe an SMT-based verification method for validation of a network security policy. Given requirements on a packet flow and a filter specification in form of a rule set, we compute a subset of rules that violates these requirements. If the subset is empty than all requirements are satisfied.

First, we present the method to verify a single filter against a security policy. Later this method will be extended for verifying a cascade of filters. Checking if the specified packet flow p is permitted by a filter f it is enough to show that formula $\bar{f} \wedge p$ cannot be satisfied. For instance, assuming that s_0, s_1, s_2 are atomic propositions capturing abstract packet properties. Then filter $\bar{f}$ and a policy p are expressed as follows:

$$\bar{f} = \bigvee \begin{array}{l} s_0 \wedge s_1 \\ s_0 \wedge s_2 \\ s_1 \wedge s_2 \end{array}, \quad p = s_0 \wedge \bar{s_1}$$

In thi case, it is possible to find an assignment $s_0 = 1, s_1 = 0, s_2 = 1$ that satisfies $\bar{f} \wedge p$. While this gives us the required answer we would like to obtain more information to track the problem. To do so, we enrich the filter representation with information that refers to corresponding filtering rules.

$$\bar{f} = \bigvee \begin{array}{l} r = 0 \wedge s_0 \wedge s_1 \\ r = 1 \wedge s_0 \wedge s_2 \\ r = 2 \wedge s_1 \wedge s_2 \end{array}, \quad p = s_0 \wedge \bar{s_1}$$

where r is a bit vector that encodes a rule number. Using this annotation the answer contains information on deny rule that denied the analyzed packet flow, which is, $r = 1$.

To capture network security policy we employ Security Policy Specification Language (SPSL) as defined in [10]. This simple language allows us to express services available between different network zones. For network presented in Fig.1, such policy specification can be as follows:

```
zone ENTP [10.10.100.0/24];
zone DMZ [10.10.10.0/24];
zone PCN [10.10.200.0/24];
zone Inernet [*];

service HTTP = TCP [port = 80];
service SSH = TCP [port=22];
service TELNET = TCP [port=23];

policy p1 = deny [telnet,http]([ENTP],[PCN]);
policy p2 = deny [*]([Internet],[PCN]);
policy p3 = permit [http]([Internet],[DMZ]);
```

For instance, a specification of policy $p1$ can be converted to the following SMT representation:

```
01  (define-fun p_1 () Bool
02  ; deny [telnet,http]([ENTP],[PCN])
03     (and
04         (= (bvand dst_ip PCN_MASK) PCN)
05         (= (bvand src_ip ENTP_MASK) ENTP)
06         (or (and (= pt TCP)(= dst_pn HTTP))
07             (and (= pt TCP)(= dst_pn TELNET))
08         )
09      )
10  )
```

This policy denies telnet and http traffic to the Process Control Network. This is encoded by specifying source (line 5) and destination (line 4) address ranges of the packets that should be denied. Lines 6 and 7 describe protocol type and destination port numbers that correspond to telnet and http traffic, respectively. Addresses are encoded as bit vectors of size 32. Encoding constraints on addresses follows the general pattern:

```
(= (bvand x net_mask) net_addr)
```

Here, `bvand` is a standard bit wise AND operation on bit vectors. Port numbers are encoded as bit vectors of size 16. Using this direct encoding it is possible to directly express policy rules using a standard bit vector theory available in SMT tools.

We demonstrate the translation of ACL configuration to positive and negative filters using the following ACL snippet:

```
R  ip access-list extended paper-example
1   permit icmp any any echo-reply
2   permit icmp any any echo
3   deny   ip any 10.10.10.0 0.0.0.255
4   deny   ip any 10.10.11.0 0.0.0.255
5   permit  ip any any
```

These five rules permit any icmp echo and echo-reply traffic and forbid other traffic to target network. The translation to SMT yields four definitions of functions. Note that default permit rule is not translated.

```
(define-fun f1_r1 () Bool
; permit icmp any any echo-reply
    (and
       (= pt ICMP)
       (= dst_pn ECHO_REPLY)
    )
)
(define-fun f1_r2 () Bool
; permit icmp any any echo
    (and
       (= pt ICMP)
       (= dst_pn ECHO)
    )
)
(define-fun f1_r3 () Bool
; deny   ip any 10.10.10.0 0.0.0.255
    (and
       (= (bvor dst_ip #x000000ff) #x0a0a0aff)
    )
)
(define-fun f1_r4 () Bool
; deny   ip any 10.10.11.0 0.0.0.255
    (and
       (= (bvor dst_ip #x000000ff) #x0a0a0bff)
    )
)
```

Rules constraint only properties explicitly defined. Argument `any` is not represented as it expresses that the variable

is constrained by the valid range of the corresponding type, which is implicitly enforced by the type system of SMT. The translation of addresses and wild cards are according to the following pattern:

```
(= (bvor x wildcard) (bvor address wildcard))
```

To verify that ACL obeys a network security policy we need to obtain a representation in form of two partial filters. The negative filter, denoted as `f1_deny`, is a boolean formula that is satisfied for all denied abstract packets. Likewise, the positive filter, denoted as `f1_permit`, is a boolean formula that is satisfied for all permitted packets. We use this splitting to simplify the process of verification and finding counter-examples. The general method for computation of permit and deny filters is presented as Algorithm 1. We will explain the idea of this algorithm on an example of a deny filter. A list of ACL rules is processed in a reverse order. The deny filter formula is constructed in several steps. The immediate result of each step is denoted as f_d^i. Initially, f_d^0 is empty. The formula f_d^{i+1} is constructed as follows:

- If rule r is deny than its logical representation ϕ_r is added to formula $f_d^{i+1} = f_d^i \vee \phi_r$.
- If rule r is permit than its logical representation ϕ_r is combined with filter as $f_d^{i+1} = f_d^i \wedge (\neg\phi_r)$.

Note that in the algorithm the construction of a formula is slightly modified to improve compactness of the resulting formula. All consecutive rules sharing the same action is threated in a single step. Thus, in case of deny rule, we have $f_d^{i+1} = \bigvee f_d^i, \phi_{r_1}, \ldots, \phi_{r_n}$. The deny filter for ACL from the previous example is generated as follows:

```
01  (define-fun f1_deny () Bool
02       (and
03           (not f1_r1)
04           (not f1_r2)
05           (or
06               (and f1_r4 (= deny 4))
07               (and f1_r3 (= deny 3)))))
```

It can be seen that with deny rules there are annotations referring to ACL rules. The annotations allow us to infer information for counter-examples. The permit rule is computed in similar way. Line 8 contains a representation of permit all rule. Permit/Deny all rules match all abstract packets, thus logical representation is constant `true`.

```
01  (define-fun f1_permit () Bool
02       (or
03           (and f1_r1 (= permit 1))
04           (and f1_r2 (= permit 2))
05           (and
06               (not f1_r3)
07               (not f1_r4)
08               (and true (= permit 5)))
```

Policy verification is performed by checking formulas representing policy and filter by the SMT tool. For restricting policies, p_1 and p_2 it means to find satisfying valuation for $p_1 \wedge f_d$. In SMT syntax this is represented by the following code block:

```
(assert (and f1_permit p_1))
```

Algorithm 1 Computation of a permit filter

Require: An input access-control list L, represented as an ordered list of rules, $r_1, \ldots, r_n \in L$.

$$r_i \in \left[\begin{array}{l} action : \{permit, deny\}, pt : protocol, \\ src.ip : ip\_range, dst.ip : ip\_range, \\ src.pn : port\_range, dst.pn : port\_range \end{array}\right].$$

Ensure: A boolean formula representing the deny filter f_d.

```
f_d := true
R = L.Reverse
while R not empty do
  r := R.Pop
  if r.action = permit then
    p := true
    while r.action = permit & R not empty do
      p := p ∧ ¬φ_r
      r = R.Pop
    end while
    f_d := f_d ∧ p
  else
    d := false
    while r.action = deny & R not empty do
      d := d ∨ φ_r
      r = R.Pop
    end while
    f_d := f_d ∨ d
  end if
end while
```

```
(check-sat)
```

The answer of SMT is `unsat`, which means that the conjunction cannot be satisfied and hence the filter f_1 is correct with respect to policy p_1. In case of policy p_2 the result given by SMT is `sat` and a random model is provided, e.g., an assignment satisfying `(assert (and f1_permit p_1))` is as follows:

```
permit = 2, pt = ICMP, src_ip = #x0a0a6400,
dst_pn = #x0800, dst_ip = #x0a0a0a00
```

Such result contains diagnostic information telling us that policy is violated by ACL because permit rule 2 matches ICMP echo-reply packets originated from 10.10.100.0 and destined to 10.10.10.0. However, these packets should be denied according to the policy.

A cascade of filters is verified by applying essentially the same approach as described in previous sections. permit and deny predicates are computed for each filter. Then these filters are combined to a single formula representing the cascade of filters.

- $f_p^c = f_p^1 \wedge \ldots \wedge f_p^n$,
- $f_d^c = f_d^1 \vee \ldots \vee f_d^n$,

where $f_p^1, \ldots, f_p^n$ are permit filter predicates and $f_d^1, \ldots, f_d^n$ are deny filter predicates. Permit filter is combined using $\wedge$ operator as a packet is permitted if it passes all ACL on the

path. Contrary, a packet can be filtered by any ACL on the path and thus $\vee$ operator is used.

V. System-wide Analysis

In this section, we discuss an extension of a described method for verification of a security policy to system-wide scope. The main goal is to find a network states that violate the given security policy. Recall that security policy is a list of permitted and denied traffic between specified locations. Performing system-wide analysis amounts to check for every pair of network locations specified in a policy rule the permit or deny requirements on the traffic. As there can be multiple paths between these locations these have to be considered. Once we found that a path violates the policy rule it is reported to the user. Considering SCADA network as shown in Fig. 1. Then the topology of this network is capture by the following specification:

```
(declare-const path (Array Int Bool))

;path 1 = ENTP -> F1.1 -> F2.1 -> PCN
(define-fun fp1_permit () Bool
    (and f1_1_permit f2_1_permit))
;path 2 = ENTP -> F1.1 -> DMZ
(define-fun fp2_permit () Bool
    (and f1_1_permit))
;path 3 = PCN -> F2.2 -> F1.2 -> ENTP
(define-fun fp3_permit () Bool
    (and f2_2_permit f1_2_permit))
;path 4 = PCN -> F2.2 -> DMZ
(define-fun fp4_permit () Bool
    (and f_2_2_permit))

; checking violations for policy 1
(assert (or
    (and fp1_permit p1 (select path 1))
    (and fp2_permit p1 (select path 2))
    (and fp3_permit p1 (select path 3))
    (and fp4_permit p1 (select path 4))))
```

We use array to remark which paths violate the policy. The evaluation of SMT specification leads to finding a counter example in case of policy rule violation. The presented encoding brings any counter example depending on the run of SMT algorithm. However, it would be desirable if the produced counter example represent the largest subset of a rule set that violates a security policy. Using this approach the user is not confronted with an arbitrary counter example in case of policy violation, but with a counter-example that, if applied to path based policy checking, violates the greatest number of paths.

The idea of finding the greatest number of paths, which violates the policy rule is based on binary search procedure that guarantees to find the result in $\log_2 N$ steps. The search environment is initialized by introducing a counter array, which keeps the number of paths violating the policy rule. An index in the array is computed as follows:

$$\mathit{sums}\ [i] := \mathit{sums}\ [i-1] + \text{IF}\ path[i]\ \text{THEN}\ 1\ \text{ELSE}\ 0.$$

This initialization is encoded as follows:

```
(define-sort SumT () (Array Int Int))
(declare-const sums SumT)

(assert (= (select sums 0) 0))
```

```
(assert
  (forall ((i Int))
    (ite (select path i)
         (= (store sums i
           (+ (select sums (- i 1)) i)) sums)
         (= (store sums i
           (select sums (- i 1))) sums)
    )
  )
)
```

Note that it is better to unwind the forall statement to avoid dealing with quantifiers. The iteration consists of several steps for i by asserting the following:

```
(assert (= (select sums n) i))
```

Here, n is the total number of paths. Reading *sums* $[n]$ means to get a number of satisfied paths. The iterative steps are guided by the immediate results of SMT executions for the current instance.

VI. Results and Discussion

We experimentally implemented the proposed SMT-based method using Microsoft's Z3 tool. The results of execution of this method on problems of various size are shown in Table II.

The testing set of filtering rules consists of filters generated using the tool called ClassBench [11]. This generator is equipped with templates of filtering rules derived from a collection of real firewall configurations. The tool generates ACLs of different sizes and parameters. For our purpose, we generated filters for different templates, denoted as acl1-3 and fw1 and fw2. These templates differ by the number of conflicting rules. For every template a range of filters of various size was generated. We use rule sets generated for these templates as an imput to our tool that translated them to SMT specification, which was consumed by Z3 tool. We meassured time and memory requirements of the SMT method that checks rule set consistency.

Experiments were performed on a 2.53 Ghz Intel Core 2 Duo machine with 8 GB of RAM running Z3 version 4.3.1 in 64 bit mode. Table II contains results for different sizes of the problem. It can be seen that in most cases the time and memory consumption of the methods increases linearly with the number of rules in firewall configuration. The irregulairites are caused by the different number of conflicting rules in those samples.

VII. Conclusions

In this paper, we presented an approach for verifying ACL configurations by translating them to rule sets, which can be formally analyzed using SMT tools. The proposed method enables network administrators to observe the quality and correctness of firewall configurations, which improves the overall security in administered networks. This technique can be combined with other approaches supposed for securing industrial networks. The overview of security threats in industrial networks were presented by Alcaraz et el in [12] and later by Cardenas et el in [13]. These analyses emphasize the

TABLE II: Time and memory requirements of SMT procedure

Time[s]	10	100	1000	10000	100000
acl1	0.01	0.02	0.11	1.43	13.91

fw2	2.34	3.00	7.89	55.45	458.47

importance of a combination of reactive and proactive methods in order to secure the system against deception and DoS attack.

Description of network security properties is related to the classification of threats and intrusion. There are plenty of different network security problems, such as HTTP attacks, spam, TCP flooding, DoS attacks, Web server misuse, spoofing and sniffing etc. Protection of critical components and network infrastructure is identified as a key requirements for improving security in SCADA system by Hentea in [14].

Analysis of firewall configuration has been intensively studied. Namely, Guttmannin [2] proposed algorithm for computing reachibilty sets based on the firewall configurations. Bera et al in [10] proposed SAT-based methods for verification of security policy. Al-Shaer et al. [15] uses similar approach for representation of ACLs as permit and deny predicates. Their verification methods employ the BDD representation in model-checking procedure.

The network model presented in this paper deals only with IP addresses and services or ports. Therefore, the analysis does not reflect hardware or OS attacks. It also does not examine the contents of TCP/UDP packets. Therefore, this classification only includes selected categories of network security properties. Since it can utilize typical fields from IP, TCP, or UDP headers, namely source/destination IP address and service/port, it allows to specify wide range of different communications to be analyzed in the network.

In this paper we demonstrated the problem of automatic security analysis of IP based industrial networks. The presented verification method aims at validating network design against the absence of security and configuration flaws. The verification technique is based on the encoding problem into SMT instance solved automatically by the solver tool.

***Abstract*—Design of mobile robot control systems is a huge challenge, which require solving issues related to concurrent hardware access and providing high availability. Existing solutions in the domain are based on technologies using low level languages and shared memory concurrency model, which seems unsuitable for the task. In this paper a different approach to the problem of building a cyber-physical system for mobile robots control is presented. It is based on Erlang language and technology, which support lightweight processes, fault tolerance mechanisms and uses message passing concurrency model with built-in inter-process communication. Created system used a new, open-source robotic platform, which had been designed for scientific and educational purposes. Integrated system has been tested in several scenarios, proving flexibility, durability and high performance.**

I. Introduction

RECENT decades brought impressive growth in capabilities of autonomous mobile robots. Each year new wheeled, walking, swimming and flying devices are being created overcoming another limitations of mechanical devices. However, despite theoretical opportunities, mobile robots are still not widespread in industry or other commercial applications.

Each robotics system consists of two main layers: the hardware platform, which provides certain capabilities and has certain limitations, and the software controlling the hardware in order to fulfill particular tasks. It has been shown many times that even relatively low quality hardware can be used for solving sophisticated tasks if the software controls it correctly. This fact encourages further research on methods for building software systems for managing mobile robots.

Building a cyber-physical system responsible for controlling a robot is a huge challenge. Advanced robotic hardware platform is typically equipped with various sensors and effectors for determining the state of the environment and being able to modify it. The system has to interconnect all hardware devices and manage its functioning concurrently. The requirement of reliable, concurrent hardware access with real-time constraints makes the design and implementation of such systems an extremely hard task. It seems that further popularization of mobile robots in real-life applications depends on finding proper technologies and defining methods for rapid development of high quality cyber-physical systems for robotics applications.

Research in the domain of mobile robotics, which have been evaluated using real robots, has always been considered more valuable than the results obtained in simulation. Even solutions to relatively simple problems, like cooperative box pushing [1] or formation control [2], required a huge amount of work to verify using hardware. It seems that development of a control system dedicated for a particular robot and a particular task is definitely an inefficient approach.

Reusability of high level control software components can be achieved by using the software agents paradigm. Defining several layers of abstraction in a solution of a complex problem makes it possible to implement high level algorithms without depending on the specific hardware [3], [4].

Recent years brought some attempts to build an abstraction layer over hardware components, which should accelerate robot control software development. The Player/Stage [5] platform succeeded by the Robot Operating System [6] share the same idea: to provide a set of drivers for particular devices and a uniform method for accessing the hardware. Using a typical hardware with the ROS is definitely far simpler than creating hardware drivers from scratch.

There is no doubt, that the C++ language used by the ROS for implementing hardware drivers is the appropriate choice. However using the same language and technology for providing reliable and concurrent access to the hardware layer and for writing control applications may raise doubts. Shared memory concurrency model, used in C++, is based on pthreads library [7], which does not provide any high level constructs or high availability mechanisms. Error in any fragment of such application causes whole system failure which is an extremely undesirable feature in real-time mobile robot control programs.

In this paper a different approach to the problem of building cyber-physical system for mobile robots control is proposed. It is based on a message passing concurrency model adopted from the software agent paradigm. The model is applied in the hardware management layer in order to make the system more resistant to hardware failures. The implementation of the presented system has been created using Erlang language and technology [8], which provides built-in inter-process communication and failure recovery mechanisms.

The system has been tested on a new wheeled robotic platform developed in the Department of Computer Science, AGH University of Science and Technology. The platform will hopefully become very popular in educational and scientific applications. It is fully open-source, built of relatively cheap and common components, powerful and extendible. Documen-

978-83-60810-53-8/$25.00

tation is available at address http://capo.iisg.agh.edu.pl/.

In the following section the details on the hardware platform are presented. In the following section the complete Erlang-based cyber-physical system for controlling the robot is described. Finally results of preliminary experiments are provided.

II. Mobile Platform Hardware Design

The wheeled robotic platform required for testing the Erlang-based cyber-physical system for mobile robot control has to meet several requirements. It has to be equipped with relatively powerful on-board computer, capable of running Erlang virtual machine and Linux operating system. It has to provide precise velocity control and long lasting power source. One of the key features was extensibility – hopefully the system can be used in many different scientific applications, which may require different sensors and effectors. More over it should be relatively inexpensive.

Significant development and miniaturization of electronic components over last decades resulted in creation of several advanced commercial and open-source mobile robotic platforms. The platforms are designed with different applications in mind, like transportation, exploration of unknown or unsafe area, inspection of inaccessible places such as water pipes or in the buildings security.

Most of these solutions are designed to solve a particular problem. The most widespread group, which can be found in our homes, are cleaning robots, like Roomba, Scooba and Myrrh [11]. Although these robots are quite advanced, they are hardly extendible and it is hardly possible to use the platforms to other purposes.

Avatar III is an advanced platform, which belongs to a group of robots whose main task is to detect potential intruder[12]. This type of robots is characterized by very good parameters in comparison to experimental projects, but it still does not support flexibility in adding extensions.

There are several more flexible mobile platforms available, like Komodo [13] or much bigger Husky [14], which provide large spectrum of available extensions. However, it is hard to determine what kind of on-board computer do they use. Moreover, these solutions definitely do not meet the inexpensiveness requirement.

Designing a robotic hardware platform is a very complex task. Many unexpected problems have to be solved, making the process surprisingly slow. Final solution has to include designing a robot body, its components, power management, physical and electrical interfaces, integration with remote devices etc. Building individual components, like motor drivers or power distribution systems, requires a lot of time and expenses along with further design problems and delays.

In the presented platform simplicity was the key factor. For this reason the robot was built from off-the-shelf components integrated within suitable chassis. Beside of time saving, the most important advantage of this approach is the simplicity of building new units – off-the-shelf components are relatively easy to assemble. Another advantage of this solution is the possibility of independent testing of individual parts of the system which greatly simplifies failure diagnosis. On the other hand, ready-made parts often cause problems during integration because they were designed for other purposes. Selecting, testing and integrating proper components is probably the most important outcome of the presented work.

Designed mobile platform is composed of the following components:

- chassis,
- power supply
- control unit,
- motor drivers,
- sensors and other peripherals.

Selected chassis is a Lynxmotion A4WD1 four-wheel body, 30 cm long and width. The platform is shown in figure 1.

Fig. 1. Designed robotic platform based on A4WD1 chassis.

Power is supplied by two LiPo batteries connected in parallel with the nominal voltage level 14.8 V and single battery capacity 5000mAh, which is sufficient for several hours of continuous operation. Once the robot runs out of energy, batteries can be replaced without restarting the control unit.

The main robot control unit is Pandaboard [9]. Pandboard is a low-power low-cost single board computer based on the OMAP4430 dual core processor. Platform gives access to many of the powerful features of the multimedia processor while maintaining low cost. This will allow the user to develop software and use available peripherals in many configurations. The major components available on the PandaBoard, which can be used in the robot, are as follows:

- Power Management Companion Device,
- Audio Companion Device,
- Mobile LPDDR2 SDRAM Memory,
- HDMI Connector,
- SD/SDIO/MMC Media Card Cage,
- UART via RS-232 interface via 9-pin D-Sub Connector,
- LS Research Module 802.11b/g/n, Bluetooth, FM,
- Camera Connector,
- LCD Expansion Connectors,
- Generic Expansion Connectors,
- Composite Video Header.

The device runs Linux kernel with either popular distribution. The most basic task of the Pandaboard is to control the motor drivers – the RoboClaws [10].

The RoboClaw 2X15 Amp is an extremely efficient, versatile, dual channel synchronous regenerative motor controller. It supports dual quadrature encoders and can supply two brushed DC motors with 15 amps per channel continuous and 30 amp peak. With support for dual quadrature decoding it get greater control over speed and velocity is automatically maintains speed even if load increases. RoboClaw uses PID calculations with feed forward in combination with external quadrature encoders to make an accurate control solution. RoboClaw is easy to control with several built in modes. It can be controlled from a standard RC receiver/transmitter, serial device, microcontroller or an analog source, such as a potentiometer based joystick.

To control the speed of motor RoboClaw uses pulse width modulation (PWM). Pulse width modulation is a method of adjusting the current or voltage signals, which consists of changing the pulse width of constant amplitude, used in amplifiers, switching power supplies and systems control the operation of electric motors. PWM powers the system directly or through a low pass filter which smoothes the voltage waveform or current.

Because the Pandaboard and the RoboClaw works with different logic levels, a converter is required. For this purpose KAmodLVC [15] logic level converter has been used. KAmodLVC module is an 8-bit bi-directional converted voltage levels. The converter can be used to connect two digital systems operating with different voltages (like 1.8V and 5.0V in this case).

The basic orientation sensors embedded in the robot includes a gyroscope, accelerometer and magnetometer. The sensor can be used to determine the position of the robot in two planes. The diagram of components connections and relations is presented in Fig 2. The alignment of the components in the chassis is shown in Fig 3.

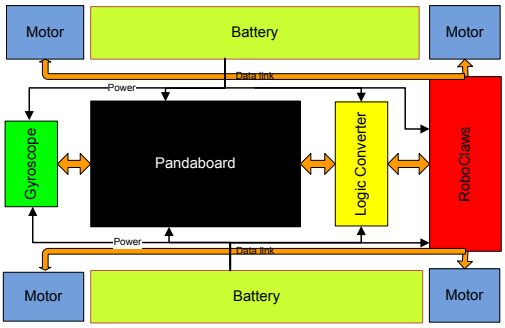

Fig. 2. The block diagram of the robot components.

The central point of control and communication is the Pandaboard. This board has several communication interfaces which are to control the robot effectors and to collect information from the sensors. Communication bus between Pandaboard and motor controller was realized using RS232 interface. For the purpose of control only lines RxD and TxD are used. There is no hardware flow control, because communication with the Pandaboard and RoboClaw is realized in inquiry respond method and it is always initiated by the Pandaboard. Therefore, if the control program waits for data from the controller it is not necessary to control rate. The data rate of this link is set to 38400bps.

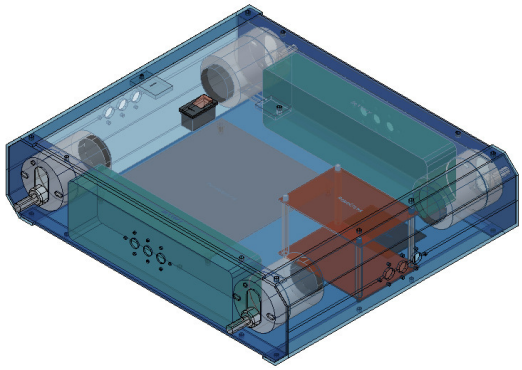

Fig. 3. Internal design of the robot components.

The orientation sensor uses serial I2C bus. To communicate with this bus the system uses duplex line Serial Data Line (SDA) and one-way line Serial Clock Line (SCL). Both lines are pull-up to power line so it is easy to detect transmissions collision using hardware. In robotic system this bus combines simplicity and functionality in one at a low investment of hardware and software to give the desired effect.

Robot communication with the surrounding environment is based on the built-in wireless card: Pandaboard WiFi. Each robot has its own unique MAC address so it is possible to communicate with the selected robot even if a group of robots is working in the same network.

Robot design provides an easy way for extending the range of sensors or effectors. It has been tested with ultrasonic sensors, laser rangefinders, cameras and Microsoft Kinect sensor. Further extensions are possible using various interfaces: USB, COM, I2C or SPI.

To determine the exact position of the robot can use the Global Positioning System (GPS) receiver or the more accurate indoor marker-based Hagisonic Stargazer [16] system. Stargazer uses markers placed on the ceiling and on the basis of their positions it can determine the location of the robot with high accuracy.

Ten units have been built so far for testing and further development purposes. The cost of all parts for a single unit does not exceed 900 USD, which is a very low price for the capabilities. The robot can develop speed of 3 m/s, it can put itself into vertical position by climbing a wall. It includes an on-board computer with 2-core CPU, running ordinary Linux OS and providing large variety of extension ports. It meets all defined requirements for testing the Erlang-based cyber-physical system for mobile robot control.

III. Control System Architecture

On the top of robot's hardware there is a need for a control software layer that allows users to interfere with it. Due to the fact that the robot was designed from scratch, control system was also chosen to be created from the ground up instead of using existing solution in order to fit the needs perfectly. Main aims of the software layer were to:

- provide high level, easy to use and consistent programming interface to low-level robot's peripherals,
- allow multiple client applications to run simultaneously on one robot, taking into account concurrency, timing, performance and other possible issues,
- allow users to write their client application in different programming languages,
- give an ability to put client application either on robot's on-board computer or on a separate network-reachable machine,
- ensure flexibility by allowing to add other external devices in the future.

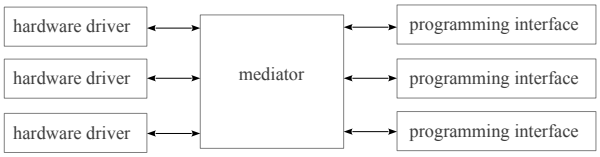

Fig. 4. Control system architecture schema

Control system has been divided into three parts (as shown on Fig 4):

- hardware drivers,
- mediator,
- programming interfaces.

Hardware drivers are standalone programs that interfere directly with robot's hardware. Being written in C++, they provide full compatibility with low-level Linux communication mechanisms.

Mediator connects hardware drivers and programming interfaces, handling communication between those two parts and controlling the whole system. It was developed in Erlang/OTP [8] due to the fact that Erlang was designed to be a solution for message passing and orchestrator applications.

Programming interfaces are libraries that end users include in their programs. They provide a consistent API to robot's hardware and can be implemented in virtually any language. There have been developed exemplary interfaces in Erlang and Java. This part of the system with be described in the next section.

System's internal communication has been based on Protocol Buffer [21] library, because it offers easy and reliable way of specifying and using custom binary protocols and has support for many popular programming languages.

A. Erlang in Embedded Systems

Erlang is a programming language created in 1986 at Ericsson Telecom AB to 'provide a better way of programming telephony applications' and "was designed for writing concurrent programs that 'run forever' " [17]. At that time telephony applications tackled atypical problems and so had unusual requirements. That applications were highly concurrent, had "soft real-time" constrains, had to be changed "on the fly" and—most importantly—had to be highly fault–tolerant, because "when the software that controls telephones fails, newspapers write about it".

Modern web servers have very similar requirements: high availability, ability to serve multiple concurrent clients, low latency and low downtime. As recent study shows [18], Erlang is well suited for such servers. It allowed writing Data Mobility server in $\frac{1}{3}$ of code and to obtain twice the throughput of C++ implementation. It's worth to note that the C++ server crashed when overloaded while Erlang just slowed down.

Since its birth, Erlang was designed as a practical tool. It is a dynamically typed, functional language with garbage collector to facilitate prototyping and ease programming. To greatly improve robustness, it implements language–level lightweight processes in shared–nothing architecture[23]. Communication is done exclusively with messages. Moreover, Erlang easily integrates with programs and libraries written in other languages. Finally it has a low memory footprint and people "successfully run the Ericsson implementation of Erlang on systems with as little as 16MByte of RAM. It is reasonably straightforward to fit Erlang itself into 2MByte of persistent storage"[24]. With all that in mind and with soft real-time characteristics of its scheduler, Erlang appears to be a perfect fit for modern embedded systems.

Embedded systems have to deal with hardware, but currently more and more sophisticated logic has to be implemented as well. Functional aspect of the language allows it to create great abstractions over hardware, algorithms and data structures. That is why it is considered that "Erlang programmers are not happy with design patterns as a convention, they want a solid abstraction"[20]. One positive effect of that is code reuse increases and the programmer can concentrate on the problem itself.

Interoperability is also very important in embedded world. Erlang has few methods for that. One of them is to write so–called "NIF"s – Native Implemented Functions. Another method is to use port drivers – communication method based on stdin/stdout streams. The latter has some advantages, most important of them is the separation of processes: even if the external program crashes for whatever reason (hardware failure or system bug), Erlang run–time is not harmed and can make attempt to recover.

In 2008 Erlang gained a SMP scheduler that allows it to scale on multiple cores/CPUs. This is a great feature, as it allows to fully use modern hardware like 64–core Parallella platform. In conjunction with multiple independent processes and message passing, this is a great advantage over most

programming languages. To compare briefly:

- Standard system processes are heavy – in practice it's not feasible to create more than few hundred of them. Erlang processes on the other hand are lightweight: each one occupies only 309 words of memory. Some tests showed that it's possible to run 136.000 Erlang processes on Raspberry Pi[19].
- Concurrency is *very hard* – while using low–level tools like locks, monitors and semaphores, programmer must deal with hard problems like deadlocks, process starvation, priority inversion. Using higher–level tools, exploiting scheduler that Erlang provides and using generic structures from standard libraries allows to avoid those problems most of the time and to facilitate reasoning about process' safety and liveness.

B. Mediator

Mediator is a central part of a system. It's a thin middleware that gives much flexibility:

- Abstracts messaging between components.
- Communicates with components using standard methods, so endpoints can be written independently in most modern languages.
- Supervises each component and takes actions in case of failures.
- It is a central part of a system – only one place where configuration needs to be done.

. During start, mediator reads configuration, creates supervision tree and spawns hardware drivers (Fig. 5). Next it runs a server for communication with, possibly remote, logic system.

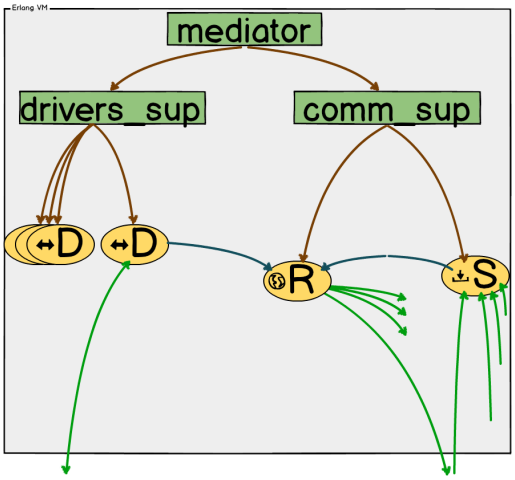

Fig. 5. Mediator is divided into: D – component mediating with software driver; R – central component, routing messages between components; S – server component, communicates with logic.

Communication with hardware drivers is done with Unix pipes. If a software or hardware has an error, mediator tries a simple yet effective tactic: restart and try again. After a number of failures in a row, it is assumed that such system is not recoverable. What is important, other subsystems are not affected and can continue to work, while defective system is turned off.

To communicate with logic, UDP protocol was chosen:

- Usually, if some part of transmission is lost, there is no need for retransmission as newer data will be available.
- UDP allows for communication locally and between computers in exactly the same way.
- When performed on localhost, packets could be lost only in case of UDP buffer overflow.
- UDP is fast and easier to use for programmers than TCP.
- Most modern programming languages have capability to communicate via UDP.

C. Hardware Drivers

As mentioned above hardware drivers are the part of the system that lays right next to robot's peripherals. There are different driver implementations for each type of supported device. They handle all low-level communication with external devices using hardware-specific protocols. This is also the only place were device logic is implemented.

Drivers are relatively simple programs spawned by the mediator and communicating with it using Unix pipes. Because software that interferes with hardware is always exposed to different kinds of failures, it is crucial to make the system as easy to recover from such issues as possible. Therefore drivers are designed as lightweight programs that can be quickly killed and restarted in case of any problems. This approach is, of course, not a perfect solutions for all types of possible exceptional situations (e.g. hardware malfunction), but makes system much more error-tolerant.

Due to the fact the drivers are separate and independent programs it is easy to add support for other devices, protocols and interfaces in the future.

All original requirements have been met in described robot's control system. The software is robust, error-tolerant, fast, flexible, perfectly suited to given hardware and ready to be used in future applications.

IV. Robot Programming Interfaces

Programming interfaces are the part of the system that end user uses directly. They communicate with the mediator using UDP sockets. Therefore client application can be run on any machine that has a network connection with robot, especially on the robot itself. UDP protocol has been chosen because it introduces small delays and low transmission overhead.

Programming interfaces can be implemented in any language that supports UDP sockets and has Protocol Buffer bindings. Thus it is possible to provide API in popular, easy to learn languages like Java or Python and allow less experienced users to work with the robot.

First implementation of programming interface was written in Java, which is a high-level, widely spread and well documented programming language that can be run on many different types of computers and other devices including

mobile phones and tablets. This fact extends the number of possible applications in which robot can be used.

Second implementation was written in Erlang. It's conceptually similar to Java's implementation, but it's written idiomatically to allow programmer fully benefit features of Erlang/OTP platform. Moreover, if mediator and logic are to be both running on the same unit, they can be run on one virtual machine, thus reducing memory usage. Finally, this allows fast prototyping and experimenting using REPL (Read–Eval–Print Loop, interactive environment with command line shell).

Apart from running programs on the robot there is a possibility of testing them in a simulation. The platform was integrated with ROBOSS simulation framework [22]. A model of a physical robot is described in XML and its visual representation in ROBOSS is shown on Fig 6.

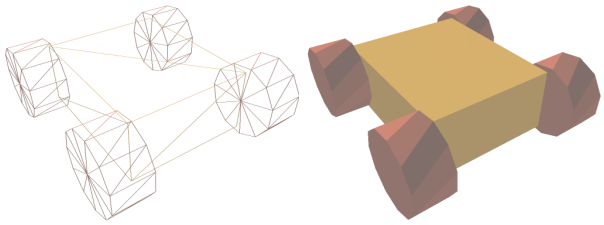

Fig. 6. Visualization of a robot model in ROBOSS simulation framework.

The use of custom Erlang module behaviour allowed to expose a simple interface which is implemented by specific Erlang modules (one for the simulation and one for the robot). As a result, the program containing logic can be run both in simulation and on the physical robot without any changes. The decision what target driver module should be used is made with regard to the configuration files.

V. Examples and Tests

In order to test the concept of building the Erlang-based cyber-physical platform and to prove that it can be used in solving real world problems, the system has been tested in a number of different applications. There were two basic groups of examples:

- on-board - when controlling program is running on robot's on-board computer,
- remote - when robot is controlled from other machine.

A. Basic Tests

In the first example robot was remotely controlled by user moving a joystick plugged into a standalone laptop computer connected to local wireless network. Moreover, real-time data read from 9DOF sensor was constantly transmitted back to the laptop and visualised on the screen as charts (see Fig 7). Therefore the user is able to see the immediate change of data charts while robot is moving.

This test showed that control software itself generates very small delays and provides enough performance to control robot manually. Actual latency is mostly dependent on WiFi

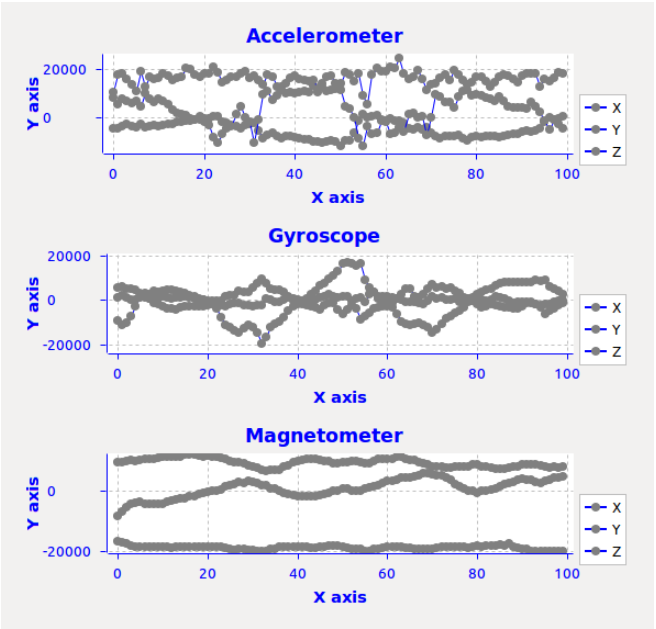

Fig. 7. Accelerometer, gyroscope and magnetometer sensors reading received from the robot during motion tests.

connection quality – some noticeable delays were observed on wireless router. This suggests that all time-critical decisions should be made on the on-board computer, while robot management or monitoring can be performed remotly.

To verify autonomous control algorithms using localization and motors controllers an advanced Trajectory Follower algorithm has been designed and implemented in Erlang. The algorithm was supposed to control robot's movements in order to reach specified locations in particular moments in time. A marker-based localization system (Hagisonic Stargazer) was used for finding current localization.

The algorithm is fully reactive. In an infinite loop it calculates most suitable control using localization and specified trajectory. The movements of the robot are smoothed according to specified algorithm parameters.

The Trajectory Follower is designed to be used both with physical robots and in a simulation. It is also desired to run on both remote and onboard nodes. Used simulation framework [22] is .NET based and this is why testing and running the trajectory follower in a simulation requires it working correctly on Windows operating system. Nonetheless, Windows OS is not required to run this component on the physical robot.

B. Trajectory Follower Algorithm

The entry point to the algorithm is a desired path to follow, expressed as a list of line segments and time constraints. On this basis, for each cycle of a control loop invoked by localisation update, desired robot speed is calculated. To preserve abstraction over the physical layer of robot, output of the algorithm is expressed as a pair of desired angular and

linear velocity. Those values are later converted to velocities on respective motors by a dedicated Erlang module, called driver.

In general, it is transparent to the driver whether it communicates with physical device or simulated robot, but it is responsible for translating control and localization. It must adapt abstract values to actual robot configuration: number of independent wheels or tracks, wheels distance and radius.

Velocity calculation algorithm is based on PD controller. Considered parameters – robot's angular distance d_α from the desired robot orientation and linear distance d_{track} from the followed trajectory, with respectful weights w_α, w_{track}, are used to obtain turn radius R:

$$\frac{1}{R} = w_\alpha d_\alpha + w_{track} d_{track} \quad (1)$$

The value of d_{track} can be treated as the P term while d_α can be treated as the D term in PD controller.

The input trajectory consists of successive path segments. The final R value is a weighted average of radiuses for corresponding segments. The number of segments taken into account and weight depend on the distance to them. Maximal cut-off distance is specified by $lookahead$ parameter in the configuration file.

Behaviour of the algorithm depends on two sets of settings: description of a robot and algorithm parameters. First one defines the name of the dedicated driver, robot's physical dimensions, localization update interval (in case of polling type of driver) and path to the simulation agent, if one is used. The latter one allows to modify weights of respective factors of PD controller, $lookahead$ parameter, maximal centripetal acceleration and maximal linear velocity.

The input can be also defined as a list of control points of Bézier splines which will result in much smoother path with no rapid turns. In this case the number of segments sampled from smoothed Bézier curve has to be defined. If the $lookahead$ parameter is too small, the robot can sometimes perform tougher turns. To ensure robot stability, centripetal acceleration of the robot must stay below certain limit.

C. Results

Example run performed in a simulation is shown in Fig 8.

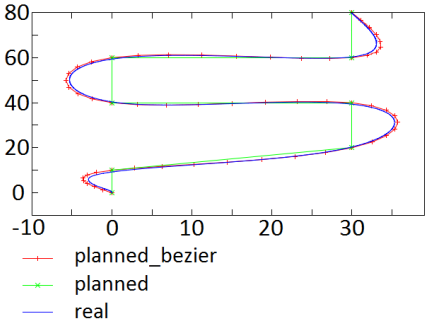

Fig. 8. Visualization of a run performed by a simulated robot. The input trajectory was smoothed with Bézier splines. Units in meters.

There was no difference or time overhead observed in communication while running the application from the remote and onboard node.

During the tests on a real robot, an issue with marker-based localization systems occurred. There were several strong light sources in the testing room. As a result, the robot tended to perform better runs with lights turned off. Exemplary run is presented in Fig 9. The robot managed to successfully read the destination within specified time, however, there is place for improvements. It is possible to reduce the noise and make measurements of localizer more precise by introducing a dead reckoning technique, i.e., applying Kalman filter.

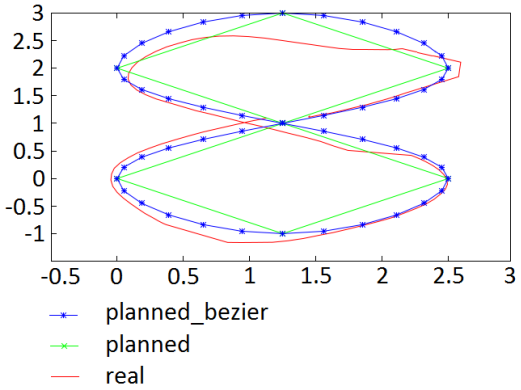

Fig. 9. Visualization of a run performed by a real robot. The input trajectory was smoothed with Bézier splines. Units in meters.

The system has demonstrated stability and performed well during the tests. It generated very small (unnoticeable) and constant delays even when several applications were using hardware components simultaneously. Erlang's functional nature seems to match high level abstraction what could be experienced during the design and implementation of the applications.

VI. Conclusions and Further Work

The implementation and performed test suggest that the Erlang language and technology is a suitable basis for building cyber-physical systems for mobile robots control. The developed system has been intensively tested in several applications. The results are promising and further work on this approach is definitely justified.

Mobile platform, which has been used for testing the approach, met all specified requirements. Designed robot is relatively inexpensive to build, offers good performance and is very easy to extend. Optional sensors and effectors will be introduced to the systems in order to increase its abilities and the range of applications. Hopefully the platform will become popular among robotics researchers.

Performance of Business Database Applications

MODERN business applications process large amounts of persistent data. Thus, a key aspect influencing the speed of such applications is the query processing time. This time can be optimized in a variety of ways, ranging from classic - such as automatic query rewriting or the usage of a variety of indexing techniques, through the variety of cashing techniques, automated database tuning, etc. On the other hand, application maintenance costs are closely related to the quality of the application architecture. Together, both those aspects lead to the search for optimization techniques that integrate with different intermediate layers and the use of alternative data persistence solutions. The development of graphics processing units and their unique computing power-price ratio also suggests searching for the acceleration of data processing based on GPUs. In addition to universal optimization techniques it is also worth looking into the use of domain knowledge in optimization mechanisms. The proposed workshop is planned to review the research on this broader query optimization process.

Topics

Topics include (but are not limited to):

- Extending the capabilities of object relational mappings
- Usage of the GPUs in query processing
- Indexing techniques
- Usage of metadata and domain knowledge in optimization processes
- Usage of fuzzy sets and rough sets in databases
- Cashing techniques
- Data snapshots
- Non-relational DBMS
- Column-oriented DBMS
- Hybrid DBMS
- Storage and analysis of time series
- Automated database tuning
- ETL optimization
- Business Intelligence optimization

***Abstract*—Persistent data of most business applications contain recursive data structures, i.e. hierarchies and networks. Processing such data stored in relational databases is not straightforward, since the relational algebra and calculus do not provide adequate facilities. Therefore, it is not surprising that initial SQL standards do not contain recursion as well. Although it was introduced by SQL:1999, even now it is implemented in few selected database management systems. In particular, one of the most popular DBMSs (MySQL) does support recursive queries yet. Numerous classes of queries can be accelerated using redundant data structures. Recursive queries form such a class. In this paper we consider four materialization solutions that speed up recursive queries. Three of them belong to the state-of-the-art, while the fourth one is the contribution of this paper. The latter method assures that the required redundant storage is linearithmic. The other methods do not guarantee such a limitation. We also present thorough experimental evaluation of all these solutions using data of various sizes up to million records. Since all these methods require writing complex code if applied directly, we have prototyped an integration of them into Hibernate object-relational mapping system. This way all the peculiarities are hidden from application developers. Architects can simply choose the appropriate materialization method and record their decisions in configuration files. All necessary routines and storage objects are then generated automatically by the ORM layer.**

I. Introduction

DATA models of numerous business enterprises encompass recursive data structures in the form of hierarchies and networks. They store data on e.g. railway networks, bill of material and product categorization. Their actual storage format can be chosen from a plethora of proposals [1]. There are various ways to query such data. Obviously, a dedicated 3GL client code can be written. Then, the data processing is done on the client side. In this case a significant amount of complex source code must be created, debugged and maintained. This usually causes a noteworthy increase of the budget and a shift in the delivery schedule. Therefore, a server side solution is called for. It was proposed as extensions to SQL, e.g. Oracle's CONNECT BY clause or recursive Common Table Expressions eventually adopted in SQL:1999. Such extensions have been implemented in numerous database systems [2]. Simultaneously the academia worked on optimization methods for such queries [3], [4], [5]. However, there are still database managements systems that do not support recursion in queries, e.g. MySQL. Since they are widely adopted and used, applications programmers often face the question how to query their recursive data. As noted above, they can choose to hardcode suitable logic in the application. In spite of deceptive simplicity of this solutions, it causes merely troubles: lower efficiency, increased cost and complexity, as well as reduced maintainability.

On the other hand, object-relational mapping systems (ORM) [6], [7] are a possible way to solve the above problem. They bridge the gap between data models of relational storage and object-oriented code [8], [9]. Besides this basic functionality, they also establish a thick abstraction layer that can be augmented with abundant features. In our research, we have prepared proof-of-concept extensions to Hibernate that realize recursive queries [10], [11], [12], partial aggregation [13] and functional indices [14]. In particular, we experimented with adding recursion on top of database systems that do not implement it directly [15]. In order to accelerate processing recursive queries in such a setting we proposed adding redundant data.

In this paper we describe another format of redundant data called *logarithmic paths*. Its advantage lays in its linearithmic size, while most state-of-the-art methods possibly lead to squared space complexity. We also describe our proof-of-concept implementation of this new method and three known techniques to build redundant data that facilitate recursive querying. They are *nested sets*, *materialized paths* and *full paths*. We show results of extensive performance experiments to verify the quality of these solutions. They have shown that there is no dominating method. All of them have advantages and disadvantages. We summarize them and present recommendations when each of them seems to be the most suitable.

The contributions of this paper are as follows:

- a novel (linearithmic in space) method to build redundant data that accelerate recursive querying,
- a proof-of-concept implementation of this method in Hibernate assisted with the implementation of three state-of-the-art methods,

Fig. 1. Example persistent data on the hierarchy of employees in a company.

- a thorough experimental evaluation of the performance of these four methods,
- an analysis of their quality and circumstances under which each of them is recommended.

The paper is organized as follows. In Section II we address the related work. Section III describes the integration of the proposed method with Hibernate object-relational mapping system. In Section IV we present the new materialization method that uses only linearithmic space. Section V reports the results of an experimental evaluation of four methods to build redundant data for recursive queries. Section VI contains recommendations when each of the considered methods is most suitable. Section VII concludes.

II. Related work

Recursive relationships between entities can be implemented with an additional database table or by a single foreign key in case of hierarchies (many-to-one association). If nodes and edges are stored in the same table, querying such data can be more efficient. There are numerous optimisation methods for recursive queries [3], [4], [5]. The survey [2] summarizes implementations of recursive queries in commercial and open-source database management systems.

As noted above, a single table with self-referencing foreign key is the most straightforward way to store hierarchical data. In all sections of this paper we use a hierarchy of employees in a company as the running example. The number of levels of the hierarchy is not limited. Therefore, there exists no number n such that all leaves of the hierarchy are no further than n hops from the root. Figure 1 contains data on an example hierarchy recorded in the table `emp`. Figure 2 shows the schema of this table. The standard SQL:1999 query that retrieves all records from the subtree spanned by a particular record is presented on Figure 3.

A. Unrolling

There are database management systems that do not execute recursive queries with MySQL as the most famous example.

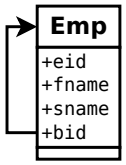

Fig. 2. The schema of the table `Emp`.

```
WITH RECURSIVE rcte (
  SELECT eid, fname, sname, bid,
         0 as level
    FROM Emp  WHERE sname = 'Travolta'
 UNION
  SELECT e.eid, e.fname, e.sname, bid,
         level +1  as level
    FROM Emp e JOIN rcte r
      ON (e.bid = r.eid)
    WHERE r.level<4
)
SELECT e.eid, e.fname, e.sname, bid
  FROM rcte
```

Fig. 3. This query retrieves all subordinates of `Travolta`.

The wide adoption of the LAMP paradigm of web development make us convinced that numerous web enterprises have to write extra code that queries recursive data. Most of such projects have similar data, e.g. nested categories of stock items, posts in discussion forums or revenue sharing chains in multi-level marketing. In order to address such applications, we have created a number of methods to run queries to such data even against database management systems that lack this feature [15]. Since the resulting solutions are non-trivial, we have prepared appropriate extensions to Hibernate. Our intent has been to hide the details from applications programmers and offer them a uniform API regardless of the chosen backend storage. Both methods considered in [15] have been integrated with API as presented on Figure 6. The first method, called *horizontal unrolling*, joins the subject table `maxlevel` times. Figure 4 shows the horizontal unrolling up to the 3$^{\text{rd}}$ level.

```
SELECT *
  FROM Emp l0
    LEFT JOIN Emp l1
      ON (l0.eid = l1.bid)
    LEFT JOIN Emp l2
      ON (l1.eid = l2.bid)
    LEFT JOIN Emp l3
      ON (l2.eid = l3.bid)
  WHERE l0.sname = 'Travolta'
```

Fig. 4. The horizontal unrolling of the query from Figure 3 up to the third level.

The other method, called *vertical unrolling*, uses temporary tables. It sends a number of queries and constructs the answer

from partial results. Both unrolling methods are notably more efficient than the potential naïve method that loops over nodes of the graphs and poses a separate query for each encountered node. Our experiments indicate that the horizontal variant is faster.

An application programmer/designer/architect chooses the required method of unrolling using the annotation `@unrolling`. Its parameter `method` can have two values: `"horizontal"` or `"vertical"`. The second (vertical) variant is the default since this method yields the same form of result as standard recursive queries. The result of horizontally unrolled query is slightly different.

B. Redundant data

If an application frequently queries hierarchical data, the abovementioned unrolling methods will not be efficient. However, in such cases designers can impose using redundant materialized data. As mentioned in Section I a number of such methods has been proposed [16]. Here we consider three of them. The first method called *nested sets* and the second method called *materialized paths* change the definition of base tables. They require adding a new column. The third method called *full paths* leaves the base table intact and puts materialized data into an additional table. In the following subsections we analyze their details.

1) Nested Sets : If the *nested sets* are used, two columns will be added to the base table. These are the columns `left` and `right`. The values of these columns satisfy the following constraints:

- $e.\texttt{left} < e.\texttt{right}$ for every tuple e,
- If a tuple e is in the subtree spanned by a tuple b, then it is true that $e.\texttt{left} > b.\texttt{left}$ and $e.\texttt{right} < b.\texttt{right}$.

Figure 5 shows the values of these two columns for the sample data from Figure 1. Arrows present how the values grow.

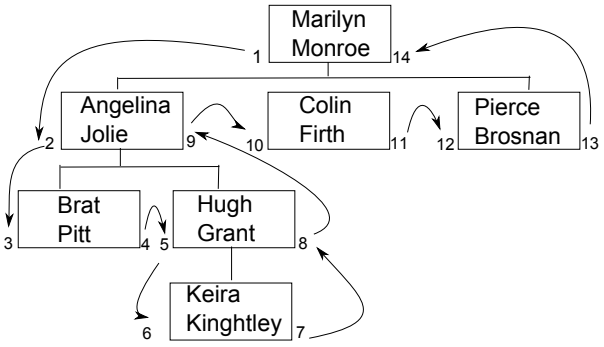

Fig. 5. Values of the redundant columns `left` and `right` in the method *nested set* computed for sample data.

The most significant advantage of this method is the possibility to query for descendants by means of a plan vanilla join. In order to find subordinates of `Travolta` we just execute the following query:

```
SELECT e.eid, e.name
  FROM emp e, emp b
  WHERE b.name = 'Travolta'
    AND e.left BETWEEN b.left AND b.right
    AND e.right BETWEEN b.left AND b.right
```

2) Materialized Paths: The method of *materialized paths* stores the whole path from the node to its root in the additional column `paths` as shown below:

```
 eid | fname |   sname    | bid | paths
-----+-------+------------+-----+------
   6 | Hugh  | Grant      |   3 | [4,3]
   7 | Colin | Firth      |   3 | [3]
   8 | Keira | Knightley  |   6 | [6,4,3]
```

This methods has proven to be noteworthy more universal that *nested sets* as discussed in Section V. Unfortunately, such materialization of paths breaks the first normal form. The following query enumerates all subordinates of `Travolta` when the method *materialized paths* is applied.

```
SELECT *
  FROM emp
 WHERE path_string LIKE (
     SELECT concat(path_string,'%')
       FROM emp
      WHERE sname = 'Travolta'
```

3) Full Paths : The method of *full paths* has been studied in [17]. That paper contains also a comparison of effectiveness of the full paths approach against unrolling methods. The full paths are similar to the *materialized paths*. However, the method of full paths stores redundant data in an extra table. We assume the name of this table to be `fullpaths`. It contains a distinct row for every step in any path towards the root. For `Keira Knightley` and `Colin Firth` the table *fullpaths* will contains the following rows.

```
 eid | bid | pl
-----+-----+----
   7 |   3 | 1
   8 |   6 | 1
   8 |   4 | 2
   8 |   3 | 3
```

The column `pl` (path length) contains the number of steps in the path.

This method is particularly universal. However, if the structure is deep, the size of the table *fullpath* can even be square with respect to the size of the base tables.

If the method of full paths is used, the query for `Travolta` subordinates will have the following form.

```
SELECT e.eid, e.name
  FROM emp e JOIN fullpaths fp USING (eid)
    JOIN emp b ON (fp.bid = b.eid)
  WHERE b.name = 'Travolta'
```

III. ORM CAN HIDE RECURSIVE PECULIARITIES

The layer of object-relational mapping [6], [7] facilitates cleaning the architecture and reducing the complexity of a system. However, an additional overhead between the application logic and the storage layers can hindrance the performance. In our research we assume that it is not the case. In our opinion an additional mapping layer *can* help optimizing the system. We can put there disparate algorithms and redundant data structures that aid improving the communication with the backend storage. The ORM layer also hides most of the peculiarities of such features from application programmers.

A. Hibernate interface for recursive queries

In our research we have presented the integration of recursive queries with object-relational mapping systems [10], [11], [12], [18]. In particular, our API for Hibernate allows defining recursive queries by XML annotations to Java entity classes [12]. Figure 6 shows a sample annotated entity class. For this class, ORM produces the table `Emp` presented in Figure 2.

```
package sample.recursive.mapping;
import org.ncu.hibernate.annotations.*;
@RecursiveQuery (maxLevel = 4)
@Tables (name = "Emp")
@RecursiveCondition (on = "Emp.bid",
                     to = "Emp.eid")
@Filter (seed = "Emp.sname = $Param(sname)")
public class Suboridnates {
    @Column(name = "Emp.eid")
    public String id;
    ...
}
```

Fig. 6. This annotation of an entity class causes generation of recursive facilities.

Consider the following scenario. The class from Figure 6 is registered in Hibernate. If the backend database connected to Hibernate implements recursive queries, the programmer can call the API function `getRecursive(String)`. This function sends the recursive query to the storage layer. If PostgreSQL is the backend, it will process the query from Figure 3.

B. Setting the support for recursive queries

If a programmer wants to use some of the above-mentioned methods to query recursive structures, e.g. unrolling or materialization, he/she just adds the annotation `@unrolling(method = "`*method name*`")`. The name of available methods are: `horizontal unrolling`, `vertical unrolling`, `full paths`, `nested sets`, `materialized paths` and `logarithmic paths`. The method of logarithmic paths is described in Section IV.

If no unrolling is specified and the database does not support recursive queries, the vertical unrolling will be used by default. More details of horizontal and vertical unrolling can be found in [15].

If a method based on materialization is chosen, the ORM layer will build the required redundant data at the first recursive access to the data. Depending on the method chosen, the main table will be altered (for nested sets or materialized paths) or an additional table will be created (for full paths and logarithmic paths). Then, redundant data get populated. Eventually, ORM automatically creates all necessary triggers. Thus, a programmer does nothing but chooses the method and specifies it in the `@unrolling` annotation.

IV. LOGARITHMIC PATHS

Section II-B presents three methods to build redundant materializations that facilitate querying recursive structures efficiently. In this Section we describe another such materialization method, called *logarithmic paths* or shortly *log paths*. This method is a kind of a compromise between full paths and vertical unrolling [15].

The idea of logarithmic paths is to store only those paths whose length is a power o 2. We assume that the data on such paths is stored in the redundant table `logpaths`. For `Keira Knightley` and `Colin Firth` the table *logpaths* will contains the following rows.

```
 eid | bid | pl
-----+-----+----
   7 |   3 | 1
   8 |   6 | 1
   8 |   4 | 2
```

If the data contains n tuples stored in trees of depth m, then the table `logpaths` will contain $O(n \log m)$ tuples. Therefore, we keep only $O(\log m)$ tuples for each arbitrary tuple of the base table, while *full paths* store $O(m)$ redundant tuples for each base tuple. For a user query the method of *log paths* issues $O(\log m)$ database queries for $O(1)$ columns, while the *horizontal unrolling* sends $O(1)$ queries for $O(m)$ columns.

A. Building the table `logpaths`

In order to populate the table `logpaths`, the paths of length 1 are copied from base table:

```
INSERT INTO logpaths
  SELECT eid, bid, 1 AS pl
    FROM emp
```

Next for $n = 1, 2, 4, 8, \ldots$ (powers of 2) the following query is executed as long as it adds new tuples. The population process will certainly finish since at each step strictly longer paths are created. Finite hierarchical data can contain only finite paths. In fact the number of those executions is $O(\log m)$ where m is the maximum depth of the hierarchy.

```
INSERT INTO powpath
  SELECT e.eid, b.bid, 2n AS pl
    FROM powpath e
      JOIN powpath b ON (e.bid = b.eid)
    WHERE e.pl = n and b.pl = n
```

B. Querying

At the query time, we have to reconstruct the information on all paths (as in *full paths*). We use the following auxiliary query:

```
SELECT lp1.eid, lpk.bid,
  lp1.pl + lp2.pl + ... + lpk.pl AS pl
  FROM logpaths lp1
    JOIN logpaths lp2
      ON (lp1.bid = lp2.eid)
    ...
    JOIN logpaths lpk
      ON (lp(k-1).bid = lpk.eid)
  WHERE lp1.pl < lp2.pl
    AND ...
    AND lp(k-1).pl < lpk.pl
```

This query reconstructs data on paths whose length (`p1`) has exactly k ones in its binary representation. Therefore, we have to run this query for $k = 1, 2, ..., \log m$ and merge their results using set union. Obviously, it will generate all paths and no path will be repeated. The resulting union query will be a part of the eventual user query. If it contains selections, the optimizer should push them down the query tree. Thus, with logarithmic paths only a fraction of the potential content of the table `fullpaths` will be actually computed.

C. Using ORM

This method has also been integrated into the Hibernate framework. If the annotation `@unrolling(method = "logarithmic paths")` is present, the table `logpath` will be automatically created and populated at the first recursive query. All necessary triggers are also created automatically.

V. Performace

The methods discussed in this paper has been tested on a computer with AMD Phenom II 3,4GHz, 8GB RAM and 2 Caviar Black 7400rpm 500 GB HDDs. The test has been run against Hibernate with a standard installation of MySQL as the backend database. We used six data sets of various sizes. Three of them contain 100 000 records organized in trees of depths 10, 15 and 20. The other three contain 1000000 records organized in trees with the same depths, i.e. 10, 15 and 20. We have tested seven usage scenarios.

The tables that report the results are organized as follows. Each table is divided into two parts. The first part presents results for data sets of 100 000 records, while the second part corresponds to data sets composed of 1 000 000 records. The first column of each table shows the depths of the trees. The second column presents times of evaluation for the presented methods. The names of two methods, namely *nested sets* and *materialized paths* are abbreviated to *ns* and *mp* respectively.

A. Building redundant materialization

In the first test we examine the time required to build redundant data structures that accelerate perspective recursive queries. We assume that the base table contains appropriate data and the derived table is empty. The results are presented in Table I.

TABLE I
Time necessary to build materialized data

100 000 rec				
	full path	logpath	ns	mp
10	00:00:47,94	00:00:15,90	00:00:29,41	00:00:12,59
15	00:01:26,20	00:00:17,67	00:00:29,26	00:00:13,23
20	00:02:54,21	00:00:21,82	00:00:29,55	00:00:13,54
1 000 000 rec				
	full path	logpath	ns	mp
10	00:22:13,21	00:04:53,27	00:34:59,03	00:05:16,97
15	01:00:24,07	00:05:30,94	00:39:47,73	00:05:10,29
20	02:03:50,40	00:06:24,73	00:39:25,69	00:05:31,39

B. Finding subordinates of root

We assume that we have an object representing a root in the hierarchy. We want to enumerate all nodes in the subtree below this root. The results are presented in Table II.

TABLE II
Time necessary to find subordinates of a root

100 000 rec				
	full path	logpath	ns	mp
10	00:00:01,57	00:00:07,99	00:00:00,51	00:00:00,56

15	00:00:00,01	00:00:00,07	00:00:00,01	00:00:00,01
20	00:00:00,01	00:00:00,08	00:00:00,01	00:00:00,01

TABLE VII
TIME NECESSARY TO MOVE A SUBTREE

100 000 rec				
	full path	logpath	ns	mp
10	00:00:08,53	0:00:26,60	00:00:19,28	00:00:00,61
15	00:00:16,01	00:00:51,14	00:00:08,70	00:00:00,64
20	00:00:52,75	00:01:28,36	00:00:24,15	00:00:01,19
1 000 000 rec				
	full path	logpath	ns	mp
10	00:04:30,89	00:13:37,25	00:00:22,51	00:00:00,47
15	00:07:49,17	00:35:06,68	00:01:20,40	00:00:00,08
20	00:13:38,99	00:57:39,43	00:00:28,07	00:00:00,92

E. Inserting new nodes

The next three tests are devoted to the assessment of the overhead imposed by all four methods when updates of the structure occur. Table V presents efficiency measures for the operation of inserting new rows into an existing base table. In this test we only added leaves to the hierarchy.

TABLE V
TIME NECESSARY TO INSERT NEW NODES TO THE HIERARCHY

100 000 rec				
	full path	logpath	ns	mp
10	00:00:00,14	00:00:00,08	00:00:05,22	00:00:00,06
15	00:00:00,20	00:00:00,09	00:00:04,35	00:00:00,06
20	00:00:00,20	00:00:00,08	00:00:16,54	00:00:00,05
1 000 000 rec				
	full path	logpath	ns	mp
10	00:00:00,15	00:00:00,11	00:07:47,67	00:00:00,05
15	00:00:00,17	00:00:00,12	00:08:27,64	00:00:00,05
20	00:00:00,16	00:00:00,12	00:08:16,85	00:00:00,05

F. Deleting nodes

In this test we examine the time needed to complete the delete operation. As in the previous test, we deleted leaves only. Deleting rows from the structure. The results are presented in Table VI.

TABLE VI
TIME NECESSARY TO DELETE A NODE FROM THE HIERARCHY

100 000 rec				
	full path	logpath	ns	mp
10	00:00:00,05	00:00:00,08	00:00:05,57	00:00:00,06
15	00:00:00,05	00:00:00,08	00:00:06,67	00:00:00,05
20	00:00:00,04	00:00:00,09	00:00:16,92	00:00:00,04
1 000 000 rec				
	full path	logpath	ns	mp
10	00:00:00,04	00:00:00,07	00:09:53,84	00:00:00,05
15	00:00:00,04	00:00:00,08	00:09:37,94	00:00:00,04
20	00:00:00,04	00:00:00,09	00:08:59,66	00:00:00,04

G. Updating nodes

In this test we measure the time needed to move a subtree to some other place. The results are presented in Table VII.

VI. ANALYSIS

In this Section we analyze the results of performance tests presented in Section V. We also formulate recommendations for which usage scenarios each of the analyzed methods is the most suitable. We presented four methods to build redundant data for efficient recursive queries. We divide them into two groups of two methods each. The first group contains methods that store data in additional tables, i.e. *full paths* and *logarithmic paths*. Since they do not require altering the original database schema, it will be easier to introduce them into an existing installation. The size of redundant data for *full paths* is $O(nm)$ where n the size of the data and m is the maximum depth of the hierarchy. In case of *logarithmic paths* this size is only $O(n \log m)$. Thus the method is feasible also in case of deep trees, i.e. when $m = O(n)$.

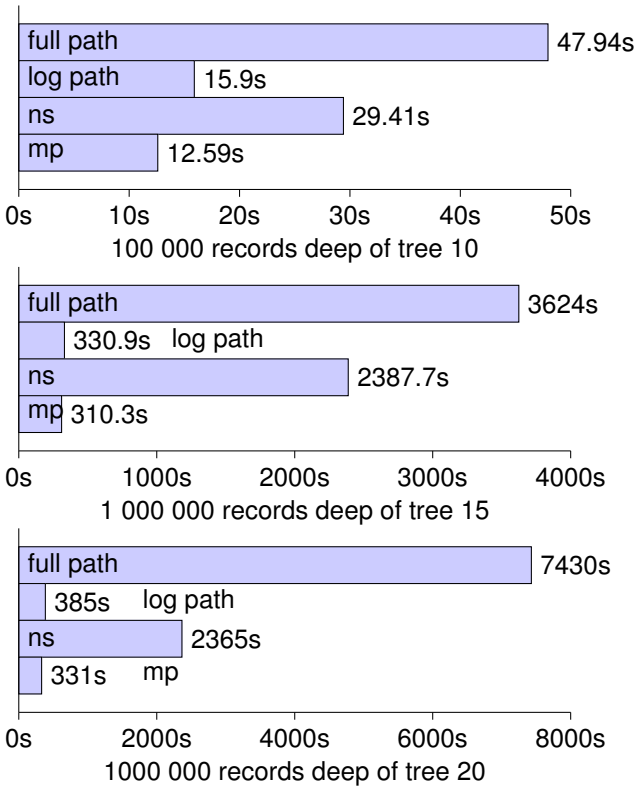

Fig. 7. The comparison of times necessary to build materialized data.

A significant advantage of *logaritmic paths* is the time necessary to construct the redundant data structure. For each analyzed size of data this method has proven to be fast and

comparable only to *materilized paths*. Figure 7 shows this comparison. Unfortunately, the efficiency of queries with this methods is notably lower. It is caused by multiple equijoins that are required to assemble all paths. For depth 20, *logarithmic paths* execute four subqueries combined by the set union. The most complex component of this union is a 4-way self join of the table `logpath`. The tests have shown that if the depth of the hierarchy grows, so does the execution time of queries. Figure 8 presents the comparison of times necessary to run the query that retrieves subtrees.

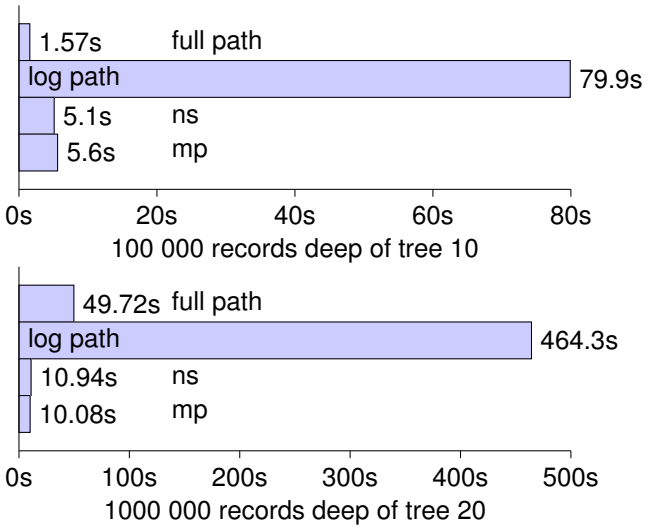

Fig. 8. The comparison of times necessary to retrieve whole subtrees.

On the other hand, *full paths* are useful when the data is collected incrementally as presented on Figure 9. Both creation and synchronization of redundant data is reasonably fast. However, in presence of deletes and updates that thoroughly *change* the structure of the tree, *full paths* are too inert and such operations are exceptionally costly.

The second group of methods modifies the base table by adding extra columns. Such an intervention into the schema may be too severe in existing deployments and probably will never be accepted in such circumstances. This group of methods contains *nested sets* and *materialized paths*. The first of them is optimized for retrieving whole subtrees. It requires careful allocation of identifiers. Furthermore, it is definitely the most expensive for maintenance in case of updates. The operations that modify the structure are two orders of magnitude slower than in case of other methods. On the other hand, *nested sets* are extremely fast for queries that search subtrees.

However, also for such scenarios *materialized paths* are slightly faster. This method is usually more efficient than all other methods. Unfortunately, it is also the only one that uses *semistructured columns*, i.e. non first normal form. If we accept this drawback, we will get the fastest querying method. Its disadvantages show at updates changing the logical structure of the tree.

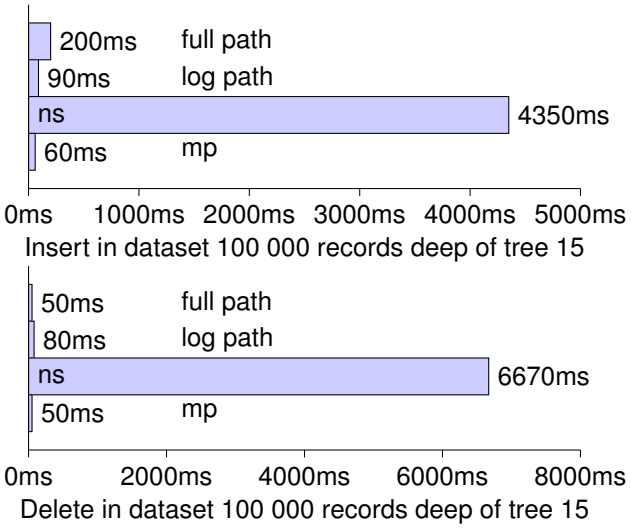

Fig. 9. The comparison of times necessary to insert and delete leaves.

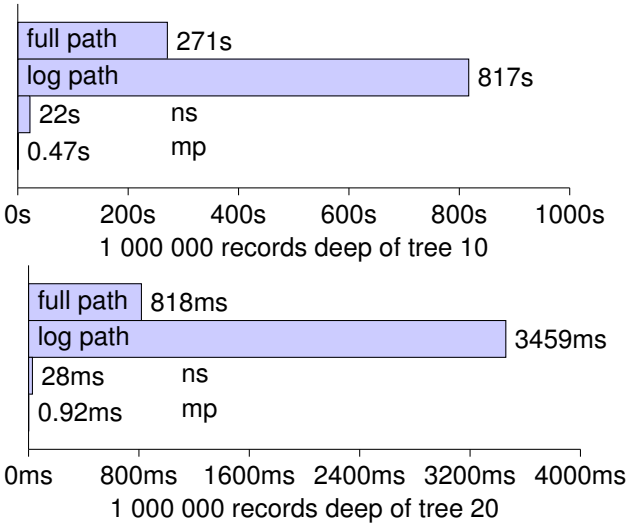

Fig. 10. The comparison of times necessary to move subtrees.

VII. Conclusions

In this paper we discussed four materialized data structures that accelerate recursive queries to hierarchical data. One of them called logarithmic paths is an original contribution of this paper. Logarithmic paths is the place where other methods meet halfway. Its efficiency is worse by a logarithmic factor than other methods that consume square space. However, logarithmic paths consume only linearithmic space.

We reported the results of experimental evaluation of all the four methods. None of them proved to be always worse or better than another tested method. For each of them, there are scenarios where it is the recommended materialization. We summarized our advises when to use each of the methods.

All these methods have been prototypically implemented as part of Hibernate, i.e. the most popular Java object-relational mapping system. This allows (1) hiding all the peculiarities of

these solutions from application programmers and (2) offering architects and tuners an easy choice of the materialization that is the most suitable for the application at hand.

***Abstract*—Most development tools manipulate objects by changing values of their attributes. If the object should change more radically, problems arise. The amount of available information can vary from instance to instance and can be collected incrementally. It can happen that there exists no class suitable for all known attributes and so even movement of the instance to another class can be complicated. We can create exhaustive number of classes to cover all predicted variants, but still some other combinations of data can occur. To solve this situation, appearing often during processing of heterogeneous and mutable data, the model of relaxed objects was invented. It is based on the idea that object classes should be defined loosely in form of conditions – presumptions on data content or availability – and that instances should belong implicitly to all classes that are currently met. Methods associated with such classes assure that each instance is provided by all currently executable methods and its behavior change dynamically with changes of its content. The paper describes the Java-based object interface for this model, its effectivity, and the domain index suitable for efficient data searching.**

I. Introduction

MOST of the object models are designed for situations when we work with groups of objects described by a known set of attributes – with classes. This approach can handle changes of attribute values but can get in troubles when new attributes should be stored and handled. The practice shows that it is sufficient for many cases. The real life is however more complicated and thus the real-life objects can fit to various classes during the time. Sometimes there could be collected some additional data, while other data could be missing. Handling such situations in most class-based object models is very complicated.

Some of the situations could be expected and supported by the application (it could be expected that person can become both parent and driver at once), some could stay hidden (person being a child under 15 and pensioner at once) and could appear during the applications service. An example of an additional attribute could be an e-mail or ICQ for an application being designed sooner than these media got known enough.

The original motivation was the need to implement a historical map that should present given area as it looked like at given time in the past. All data had to be stored temporally together with the period of their validity. The obtaining of historical information from various sources was extremely complicated. A lot of information is lost and thus amount of available/known data differed from object to object and from period to period.

Therefore we wanted an application able storing and processing such data including the originally unexpected ones. Current models and tools were not matching our needs sufficiently. We therefore developed a corresponding object model together with corresponding store ourselves [1].

The *Relaxed object model* was introduced in [2], [3]. It has been developed for handling data of such extensible applications. We have tested it also for prototyping of applications handling complex data and compared it with the currently dominating approach (the use of relational or object-relational database supported by an object-oriented language). We have focused on the development speed, variability of the solution and its resulting efficiency (throughput; it could be interesting in the case when we create single-purpose applications processing large amount of non-trivial data).

II. Background

The relaxed object model presents inner content of objects as an arbitrary set of values assigned to a subset of predefined set of attributes $A = \{a_1, a_2, \ldots, a_n\}$. While the class-based object models define strict set of classes C and assigns each object instance to one of them, the relaxed object model define classes using arbitrary Boolean condition on attribute values. We can thus imagine class *Person* as any object defining values for attributes *Name*, *Surname* and *BirthDate*. Similarly as a *Driver* can be considered any object defining values for attributes *Name*, *Surname*, *BirthDate* and *DriversLicenseNr*, i.e. any *Person* with assigned driver's license. On the other hand, class *Child* can be defined as a *Person* having *BirthDate* greater than current date minus eighteen years. We can see that both *Driver* and *Child* classes are subclasses of *Person* class.

An important difference is the very loose coupling between object instances and classes. The class or classes are assigned to object instances not explicitly by its declaration, but implicitly according to their inner content. If the object gain value of another attribute or current values of the object are changed, the object can be immediately considered belonging to different set of classes.

Methods could be formally expressed as a finite set $F = \{f_1, f_2, \ldots, f_m\}$ of data manipulation functions.

Each method $f_i \in F$ defines a condition $req(f_i)$ of its executability on a given object instance. So the method *RevokeDriversLicense* can require objects having attribute *DriversLicenseNr* set. As the condition on class *Driver* implicates the condition required by a *RevokeDriversLicense* method, this method belongs to the *Driver* class interface.

978-83-60810-53-8/$25.00

Thanks to the concept of Relaxed Object, where the interface $iface(o)$ of given object instance o contains all methods $f_i \in F$ for whose its content fulfills the requirement $req(f_i)$, it is easy to access and use all methods available for a given object at a given moment. The availability can depend not only on physical availability of data, but also on their accessibility with respect to users' rights to individual attributes. Again, the client application can still provide users with the maximum available functionality.

The concept of Relaxed Object promises solving of some problems arising during transformation of real world entities to their abstract object model.

This paper describes basics of first implementation of these concepts that provides programmers writing in Java language with an extension allowing easy access and manipulation with relaxed object stored in the Oracle relational database. The environment selection has been made with respect to its potential enterprise deployment.

Following section discusses related work. Section 3 concerns on main issues of implementing relaxed objects in Java language and presents its results from performance point of view. Section 4 discusses enhancements currently available for the database layer that allows further performance enhancements. The last chapter gives the final conclusion.

III. Related Work

The model presumes data storage by individual columns. The *C-Store* database system [4] deals with this idea. It shows that this approach can be under some conditions quite efficient for data retrieval. To optimize reading operations, *C-Store* keeps data copies organized with respect to particular queries and so slows-down data manipulation. The *Datapile* system [5] targets to be a backup system for heterogeneous operational databases. It stores attribute values including their time validity into a single table. Data can be only imported from or exported to the classical operational databases. The approach does not allow direct data manipulation. A Java interface for relaxed objects [6] was designed to allow direct manipulation with stored relaxed objects, using classical relational database storage and still provide acceptable response time.

Software development method named Design by contract [7] tries to decrease complexity of implemented applications. It is based on the concept of a contract between two modules. Each module guarantees that if all requirements for input parameters are met, the output fulfills declared output conditions. This approach is not much used in the practice today. The problem is that definitions of requirements are not mandatory. Relaxed objects will require definitions of input conditions, as this test checks if the object belongs to supposed class or not and if the method is available. Still the condition check should be optional on production systems for performance reasons. It should be possible to switch the checking off in the code if it is obvious, that the condition is already met. The conditions could be, for example, already checked and the object was not changed afterwards.

As the implementation had to use relational database store, it was necessary to implement object-relational mapping between Java representation of relaxed objects and the database. Most of the known frameworks (for example *Hibernate*[1] for Java), provides more mapping methods or their combinations, as well chosen mapping can substantially increase the application performance and decrease the lag caused by SQL communication. The relaxed objects use quite different approach to data storage, none of common mappings – neither *vertical*, *horizontal* nor *filtered* [8] is applicable. It appeared more efficient to implement a special mapping, optimized for its specific object manipulation. One of the advantages is the possibility to add new attributes at the runtime. As the mapping performance was one of major risks, it was tested in detail.

IV. Relaxed Object Implementation in Java

This chapter describes basic ideas of relaxed object interface in Java. Among others, the solution handles:

- Optimal description of conditions for methods and their parameters.
- Optimal way of checking conditions at runtime.
- Possibility to find a correct implementation of a given method.
- Finding relaxed objects having required characteristics, i.e. fulfilling of a given condition.

A. Relaxed Object Representation

The representation of relaxed objects in the memory has to be chosen first. The focus was held on the speed of in-memory operations and the size of the data representation as we wanted to add as little overhead as possible.

We distinguish primitive data types and object data types in the further text. Primitive data types as int contain data value directly and do not need any space overhead. On the other hand, object data types store data wrapped into objects and reference to them using four byte references.

From the test results shown in the table I is obvious that the creation time depends on the object representation memory size. The object representation sizes are everytime rounded up to 8 Bytes. Class *Object* itself requires 8 Bytes of memory. *Integer* value represented as an Integer instance requires 16 Bytes of memory plus 4 Bytes for each reference. Fortunately, the memory overhead for objects with more attributes is relatively smaller. The results for *String* types have shown to be comparable with int objects (not counting memory for string characters), and so we tested mainly *int* parameters.

The results show average values from five runs, where each run executes the operation one hundred thousand times. The first two rows correspond to the cases where attributes were declared as public and so the manipulation can be done directly, not through getters and setters. A *final* modifier denies further changing of a value once it is already set.

The last three columns compare object creation time without attribute initialization, with attributes set by constructor

[1] http://www.hibernate.org

Table I
IN-MEMORY MANIPULATION WITH JAVA OBJECTS ([6])

Class Content	Size (B)	Get Time (ns)	Set Time (ns)	Creation Time (ns)		
					+Constr.	+Setters
public final int	16	10	n/a	—	25	n/a
public int	16	11	13	—	25	26
Int	16	11	17	18	25	42
2 x int	16	12	16	19	26	44
8 x int	40	20	29	46	51	98
32 x int	136	25	52	—	196	402
32 x int + sync. crit. section	136	89	91	—	189	417
32 x int + sync. method	136	92	95	—	194	428

parameters and with attribute initialization using setters after the object is created. The required initialization time increased with the growing number of parameters.

The last two rows show the time consumption in the case when the attribute access is exclusive and when it forbids parallel processing. The recommended variant that uses synchronized access only for critical section is better than the variant that requires synchronization for the whole method. In both cases the throughput of the initialization phase decreases significantly.

The relaxed objects allow any combination of set attributes what leads to at least $2^{|A|}$ theoretically possible classes. To avoid this, the relaxed object instance representation should allow arbitrary number of attributes and adapt its behavior according to actual inner content. We supposed that from the speed point of view the *HashMap* representation of attribute name – value pairs will be optimal while representation in array will provide more efficient storage. The *HashMap* representation was – surprisingly – 2–5 times slower than array representation for tens of attributes. Moreover the *HashMap* representation takes 80B plus additional 24B for each pair, while arrays require 24B plus 8B for each new pair.

Table II
MANIPULATION WITH RELAXED OBJECT INSTANCES ([6])

Class Content nr. of int	Get Time (ns)	Set Time New (ns)	Set Time Known (ns)	Creation +constr. Time (ns)	Creation +setters Time (ns)
1	30/30	106/106	57/57	30/58	156
2	36/37	107/152	56/60	29/71	296
4	41/54	107/181	59/61	31/89	623
8	53/65	106/322	68/75	30/133	1416
16	80/95	109/650	92/107	32/230	4527
32	104/188	109/650	120/208	30/502	11818
32*Integer	147/190	115/641	162/201	32/677	13060

Table II shows time required by the operations for an array representation. The values were of primitive type int. The last row shows a comparison with the values stored as an object type *Integer*. Most of the results is shown in the format best/worst case. Setting values distinguishes between changing an already existing value and a (slower) setting value for an unknown attribute. Again, the creation of an object instance distinguishes between the creation of the initialized instance and the creation of an empty object instance and the additional setting attributes one by one. The first case corresponds to the situation where attribute values are known in advance while the other models are more probable in the situation when the attributes are set after the instance creation one by one. This approach is up to 30 times slower than the manipulation with classical Java objects.

The overall memory consumption is approximately 2 times larger than in the case of classical object models.

It is possible to suppose that the users will spend significantly more time by reading and processing information than by its modification. Under such condition it was reasonable to implement two different interfaces of the relaxed object instance – *RFObject*[2] and its extension *RMObject*[3]. The first of them represents immutable object instance and provide methods *find*, *get*, *isSet* and *setCallMode*. The second one inherits it and adds additional methods *set*, *setValue*, *unset*, *amend*, *store*, and *delete*.

RFObject instance has all its values set during initialization, which makes checking conditions easier, as they can be checked only once. Methods of this class are thread-safe. The *RMObject* implementation is thread-unsafe and so it was implemented a wrapper that overrides all methods as synchronized. The programmer then can easily choose whether he/she prefers more efficient or safer object manipulation.

Attributes are defined as members of an enumerated type. Their data type is determined by the interface it implements. This way the compiler can check the type consistency. The description of the type is done using annotation. The definition then can look like:

```
// Example 1 - Attribute definition
public enum String implements RString {
  @Info ("State description")
  StateDescription
}
```

Getters and setters take attribute identification as their first parameter. So getters are declared as *get(RBytes): byte[]*, *get(RBoolean): boolean*, *set(RLong,long): void*, *set(RString,String): void*, etc. This allows compiler to check type consistency. Getters return primitive types to decrease memory and time overhead. The *amend(String): void* method loads attributes of object from the database. The *store(): void* method stores object including referenced objects to the database. The *unset(...): void* method marks an instance attribute as deprecated and the subsequent store invocation removes its value from the database.

The most important is the method *find(class<Type>): Type* that allows finding proper implementation of the object according to its inner state and required type. Return value is stored in the object cache. Method *setCallMode* allows programmer to choose if the next method invocation should:

- evaluate the conditions and execute the method, (the default behavior), or

[2]Relaxed Final Object
[3]Relaxed Mutable Object

- execute the method without checking, or
- only checks the executability condition.

B. Sets and Object Lists

As proposed in [2], the sets and lists are represented as collections of references to relaxed objects. Again, the implementation was split to the final *RFSet* and *RFList* interfaces, and their mutable *RMSet* and *RMList* extensions. The *unset* method marks the reference to the object as unused. To remove the referenced object as well, the implementation extends the interface by the method remove. The method *filter* unsets all objects that do not fulfill given condition.

C. Object persistency

Attribute declaration can add other requirements as uniqueness constraint or index enforcement for the attribute. An application can contain a method that goes through all the available classes, creates missing tables for the attributes in the database and registers all the attributes in the catalog. The implementation supports also transient attributes of instances that can hold temporary data during object stay in the memory and that are not stored in the database. To define a transient attribute, *Info* annotation from the example above should be changed to *Transient* annotation.

Transaction support allows setting of isolation level of the transaction or set the transaction as read only. Attributes and/or instances can be explicitly locked in either shared or exclusive mode. An application can request locking objects in the order of the increasing object ID's, which decreases probability of deadlock occurrence.

D. Methods and Class Definitions using Conditions

One of the main goals was to implement suitable way for declaration of conditions for method executability and for their parameters. As a solution the annotations were chosen similarly to attribute declaration. The next interesting problem was the enforcing of a transparent condition checking. The instrumentation of bytecode was chosen as the most feasible implementation. This special Java feature allows us to modify the bytecode of the class in the time of loading it to the memory. The last main problem was the way allowing relaxed object instances calling any method available according to their inner state. The solution through proxies was chosen here. Each method defines its interface. The Java then allows generation of an implementation for a given set of interfaces.

```
// Example 2 - Method definition
public interface Foo {
  Object bar (Object obj) throws BazException;
}
public class FooImpl implements Foo {
  Object bar (Object obj) throws BazException {
    // ...
  }
}

// Example 3 - Proxy Object Implementation
public class DebugProxy implements
  java.lang.reflect.InvocationHandler {
  private Object obj;
  public static object newInstance(Object obj) {
  return java.lang.reflect.Proxy.newProxyInstance (
    obj.getClass().getClassLoader(),
    obj.getclass().getInterfaces(),
    new DebugProxy(obj));
  }
  private DebugProxy(Object obj) { this.obj = obj; }
  public Object
  invoke(Object proxy, Method m, Object[] args)
    throws Throwable
  {
    Object result;
    try {
      system.out.println("before method " +
          m.getName());
      result = m.invoke(obj, args);
    } catch (InvocationTargetException e) {
      throw e.getTargetException();
    } catch (Exception e) {
      throw new RuntimeException(
            "unexpected invocatÝon exception: "
            + e.getMessage());
    } finally {system.out.println("after method "
            + m.getName());
    }
  return result;
  }
}

// Example 4 - Proxy Object Usage
Foo foo =
  (Foo) DebugProxy.newInstance (new FooImpl());
  foo.bar(null);
```

E. Queries

The relaxed object interface in Java tries to hide the database and provides to the developer an object oriented interface. Queries are thus provided through methods taking the conditions and returning either *RFList* or *RMList* implementations according to the necessity to modify results programmatically.

F. System Catalogue

The library keeps information about defined attributes in a class defined as one of relaxed object classes. The *RSetAttributes* attribute represents set of attributes having a defined value in a given instance. Due to the reflexivity of the system catalogue definition, the application can query the catalogue using the same way as other stored data.

```
//Example 5 - System Catalogue Class Definition
public class systemCatalogue {
  public enum String implements RString {
      @Info(value="Name of attribute", unique=true)
    RAttribute,
      @Info("Type of attribute")
    RType,
      @Info("Unit of attribute (e.g. ms,s,CZK,USD)")
    RUnit,
      @Info(
        value="Description of attribute",
        uniqu=true
        )
    RDescription
  }
  public enum Integer implements RInteger {
      @Info(
         value="Index of attribute
                for RSetAttributes",
        unique=true)
    RSetIndex
  }
```

```
  public enum Boolean implements RBoolean {
      @Info(
      "Information if values of attribute
       have to be unique"
      )
    RUnigue
      @Info(
      "Information if index is created
       for attribute"
      )
    RIndex
  }
  public enum Bytes implements RBytes {
      @Info(
     "Bit array of set attributes of relaxed object"
      )
    RSetAttributes
  }
}
```

The main weakness of the provided implementation is the performance of a persistent layer due to splitting of objects to more tables for individual attributes. Searching for k attributes of a given relaxed object requires joining of at least k tables according to equal ID. The search effectiveness in relaxed object storage without support of any specially designed index is shown on figures 1 and 2.

Results show that the time needed for searching grows significantly with the number of stored objects. The querying is complicated also due to the fact, that search can be done according to at most one indexed column and other conditions have to be checked against data stored in other tables and joined by object ID.

To allow effective searching, special type of index had to be designed and implemented. We needed index embedded to some widespread enterprise database management system to support large number of applications and application environments. We choose an Oracle database for its support of extensible indexing through data cartridges[4]. Its first implementation was described in [9]. The index has been significantly evolved and further optimized later.

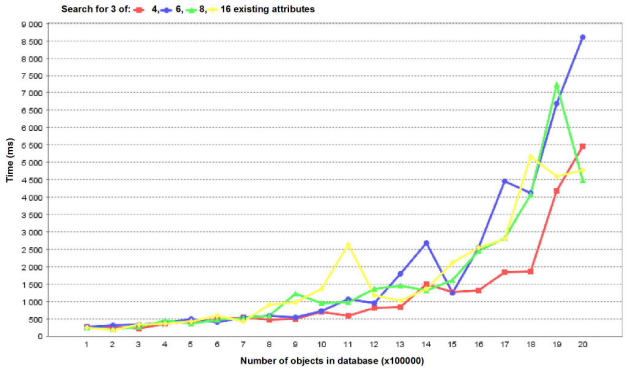

Figure 1. Object search in Relaxed Object Database - 3 attributes

[4]http://download.oracle.com/docs/cd/B19306_01/appdev.102/b14289/toc.htm

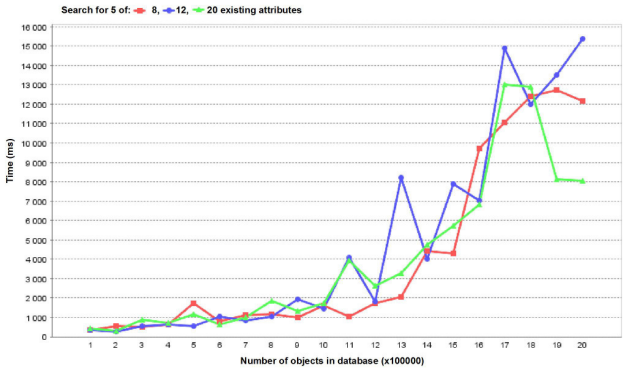

Figure 2. Object search in Relaxed Object Database - 5 Attributes

V. Temporal Relaxed Object Index

Due the restriction, given by predefined domain index interface in Oracle our indexes are created in two phases. First, they are created as *abstract* ones. In this phase the index holds only the metadata, not the data from the indexed attribute set (table set). In this state it is possible to attach new attributes to it, or detach unnecessary ones. At this moment the index is switched to *real* index, it becomes available for query optimization. Real indexes store data in R-tree structure [10] with parameters M and N. The parameters can be set at the creation time. Otherwise the optimal values are set automatically using built-in heuristics. The heuristics tries to find such a largest N that one node can be read by one I/O operation.

Let us begin with an example over Relaxed Object model storing information about people in attributes *Name*, *Surname*, *Degree*, *DrivingLicense*, *NrOfChildren*, and *Income*. The statistical office would like regularly check relation between education degree and the income, while some company would like to find potential customers. For these purposes two different multi-table indexes could be created:

```
-- Abstract index COMPANY creation
EXECUTE INX.CONSTRUCT('COMPANY');

-- Adding attributes
EXECUTE INX.ADD_ATTRIBUTE(
  'COMPANY','DrivingLicense');
EXECUTE INX.ADD_ATTRIBUTE(
  'COMPANY','NrOfChildren');
EXECUTE INX.ADD_ATTRIBUTE(
  'COMPANY','Income');

-- Switch index to real state and index data
EXECUTE INX.MAKE_REAL('COMPANY');

-- Create and populate index for statistics
EXECUTE INX.CONSTRUCT('STATISTICS');
EXECUTE INX.ADD_ATTRIBUTE(
  'STATISTICS', 'Degree');
EXECUTE INX.MAKE_REAL('STATISTICS', 20, 50);

-- Switch index back to abstract one,
-- add new attribute
-- and switch back to real index
EXECUTE INX.MAKE_ABSTRACT('STATISTICS');
EXECUTE INX.ADD_ATTRIBUTE(
  'STATISTICS', 'Income');
```

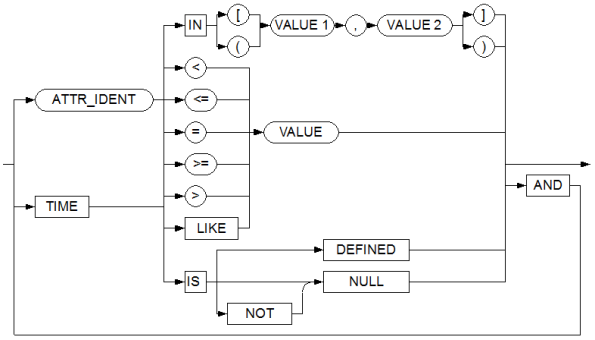

Figure 3. Query language grammar

```
EXECUTE INX.MAKE_REAL('STATISTICS');
```

All R-trees over all sets of columns are held within one domain index instance built on column ID of table $OBJECTS$. The select statements then looks like

```
SELECT * FROM OBJECTS
WHERE MATCH(ID,
  'conjunction of conditions on attribute values'
  ) = 1.
```

The query language used within the string parameter of this operator was defined to be as similar to SQL language as possible. With the exception for standard Boolean operators and comparison operators it allows easy definition of interval queries.

Index search then choose the best R-tree available to search object instances according to known attribute values. This is advantageous as the user need neither know all sets of indexed columns nor decide the specific one to be used.

Queries can either let the datastore choose optimal index, hint appropriate indexes, or force it to explicitly use given R-tree index. The SELECT statement then could look as follows:

```
SELECT *
FROM OBJECTS
WHERE MATCH(ID,
'Income >= 8000 AND NrOfChildren IN[1, 99)
 AND DrivingLicense IS NOT NULL') = 1;

-- Hinting index quality
-- by adding one point to COMPANY
-- and decreasing two points to STATISTIC
SELECT *
FROM OBJECTS
WHERE MATCH(ID,
'/* +COMPANY, --STATISTICS */ Income >= 8000
 AND NrOfChildren IN[1, 999)
 AND DrivingLicense LIKE "%B%"
 AND DEGREE = "MGR."') = 1;

-- Forcing search by index STATISTICS
SELECT *
FROM OBJECTS
WHERE MATCH(ID,
'/* STATISTICS */ Income >= 8000
 AND NrOfChildren IN[1, 999)
 AND DrivingLicense = "B" AND DEGREE = "MGR."') = 1
```

A. Search Language Grammar

The Figure 3 shows the grammar schema. The n-dimensional query is represented by a conjunction of conditions over more attributes – dimensions. Each atomic conjunction consists of the name of attribute or keyword *TIME*, of the comparison operator and of the value (1a). Each dimension can set at most one lower and at most one upper limit (1b). If the boundary for given attribute is not set, the value *MIN_VAL*, respectively *MAX_VAL*, defined internally inside the library for each database type and representing $+\infty$ and $-\infty$ is used.

The equality operator sets both upper and lower limit for given attribute (1c). To simplify interval queries, the *IN* operator was introduced. It defines both limits for the dimension delimited by a comma. Square brackets are used for closed interval boundaries, while the rounded brackets define open boundaries (1d). The value of *VALUE1* has to be less or equal to the value of *VALUE2*. The operator *IS NULL* is used to test equality with *NULL* value as it is usual in the SQL language. The *IS NOT NULL* operator is equivalent to search over closed interval *[MIN_VAL, MAX_VAL]* (1e). The *IS DEFINED* operator is used to find all objects with the value set to any value including the *NULL* value. It is equivalent to "*IS NULL* or *IS NOT NULL*". The *LIKE* operator is allowed only for textual attributes and works accordingly to its SQL equivalent. The following examples show different forms of queries.

```
-- (1a)
'NrOfChildren >= 1 AND NrOfChildren < 999
AND DrivingLicence = "B"'
-- (1b) - error: lower limit set twice
'NrOfChildren >= 1 AND NrOfChildren > 1'
-- (1c) - equiv. to 'DrivingLicence = "B" '
'DrivingLicence >= "B" AND DrivingLicence <= "B" '
-- (1d) - equiv. to 'NrOfChildren IN[1,999)'
'NrOfChildren >= 1 AND NrOfChildren < 999'
-- (1e) - equiv. to 'Degree IN[MIN_VALUE,MAX_VALUE]'
'Degree IS NOT NULL'
```

Syntax of values depends on their data type family – *integer*, *float*, *text* or *datetime*. Details for different database types are shown in Table III.

Strings have to be enclosed in double quotas ". The ordering and comparison is defined by Oracle function *NLSSORT* and is case insensitive. The date and timestamp values are enclosed in double quotas as well. If the length of the literal is shorter than expected, it is completed automatically with respect to the required format. So e.g. the value "2013-05" is by default completed to the timestamp value "2013-05-01 00:00:00.000000000".

B. Heuristics Language Grammar

All hints affecting the heuristics are optional and if present, they must be enclosed in comment brackets /* and */ at the beginning of the query string. The hint grammar is declared on Figure 4. Hint *NONE* explicitly forbids the use of any existing R-tree and data are searched programmatically. If the user wants to use one particular R-tree index, he or she can force its usage by writing its name to the comment. It is possible to write down the list of more R-tree indexes separated by commas. Each index name can be prefixed by a sequence of plus or minus signs. The heuristics then favors, respectively suppresses their usage accordingly to the prefix lengths.

Table III
SUPPORTED DATA TYPES

DB Type	Oracle format	Max	Min_Val	Max_Val
NUMBER(9)	FM999999999	10	-999999999	999999999
NUMBER(12,3)	FM999999999.000	14	-99999999.999	+99999999.999
TIMESTAMP(6)	FXYYYY-MM-DD HH24:MI:SS.FFF	21	0000-01-01 00:00:00.000	9999-12-30 23:59:59.999

VARCHAR2(128)		128	CHR(0)	128xCHR(255)

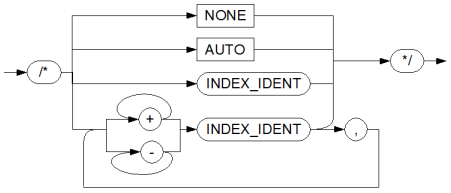

Figure 4. Hint comment grammar

C. The Embedded Heuristics

The optimal R-tree that allows optimal evaluation of given query is chosen by the embedded heuristics. It takes into account two basic factors. First it tries to avoid filter search phase. Second it tries to minimize the number of I/O operations between the R-tree stored in the BLOB and the operational memory. More formally, the heuristics tries to use such a suitable R-tree that provides maximal value of expression (1). Weights H_1 to H_4 are still subject of further research and change.

$$H_1 \frac{N_{Ind}}{N_{Attr}} + H_2 \frac{P_{Ind}}{P_{Tot}} + H_3 \frac{N}{S_{Ch}} + H_4 U_{Pref} \qquad (1)$$

The first expression $H_1(N_{Ind}/N_{Attr})$ tries to identify the biggest subset of indexed attributes. N_{Ind} represents the number of indexed attributes in the query. N_{Attr} stands for the number of attributes in the query. Optimally the number of indexed attributes corresponds with the number of attributes in the query and so $N_{Ind}/N_{Attr} = 1$. The H_1 value is currently set to 3.

The second expression $H_2(P_{Ind}/P_{Tot})$ searches for the index with as much pages read into the cache as possible. P_{Ind} denominates the number of pages already read into the index cache. P_{Tot} then holds the number of all pages that forms the index. Current value of H_2 is set to 2.

The expression $H_3(N/S_{Ch})$ prefers indexes with smaller sizes of attributes, as they can store more rows of indexed data into one index node. N is a parameter of the R-tree, while S_{Ch} stands for system chunk-size. H_3 is set to 1.

The last expression $H_4 U_{Pref}$ takes into account the user preferences. H_4 is currently set to 1. U_{Pref} is defined by the length of plus/minus prefix in the hint. For example, in the case of the hint /* ++COMPANY, -STATISTICS */ the U_{Pref} value is equal to +2 for R-tree *COMPANY* and to -1 for R-tree *STATISTICS*.

Following examples show the influence of hints and further aspects to the R-tree selection:

```
-- index COMPANY will be used (by heuristics)
SELECT * FROM OBJECTS
WHERE MATCH(ID,
'Income >= 8000 AND NrOfChildren IN[1, 9)
  AND DrivingLicense IS NOT NULL') = 1;

-- with LIKE, the STATISTICS will be used;
-- without it, the COMPANY one
SELECT * FROM OBJECTS
WHERE MATCH(ID,
'/* ++COMPANY, -STATISTICS */ Income >= 8000
  AND NrOfChildren IN[1, 9)
  AND DrivingLicense LIKE "%B%"
  AND DEGREE = "MGR."') = 1;
```

D. Combined Search of Data

All searches supported by domain index are primarily done through R-tree indexes. As R-tree indexes are not and cannot be built on all possible subsets of attributes, it is necessary to combine index search with additional comparisons of found object instances with the query.

In this case the search runs in two phases. The first index search phase – *index search* – uses the best available real R-tree index to find out object instance candidates. In the second phase – *filter search* – compares remaining attributes if they match to the user query or not. The obtained result set is then propagated to the application. The filter search evaluation is more time-consuming, but fortunately it is necessary to use it usually for relatively small amount of objects candidates only. If the sufficient R-tree index exists, it is not used at all.

E. Performance Tests

We tested the search speed using real domain indexes with optimal value of N parameter against searches, written in standard SQL both without any index support as well as using a join over *ID* columns supported by standard B-tree indexes on them. Tests run on *Oracle* 11gR2 XE on the PC with the dual-core processor Intel® Pentium® at 2.4 GHz and 4GB RAM DDR3. Third we tried to measure the search with *NONE* hint, so all instances were searched by filter search. Search times achieved over the database are shown in Table IV. Times in seconds spent by domain index search are listed in the column *REAL*. Search times needed by standard SQL search are in column *ORACLE*. The last variant is shown in column *NONE*.

```
-- REAL index STATISTICS
SELECT * FROM OBJECTS
```

```
WHERE MATCH(ID,
'/* STATISTICS */ Income >= 8000 AND DEGREE = "MGR."
AND TIME < "2100"') = 1;

-- ORACLE search
SELECT COUNT(DISTINCT Income.ID)
FROM Income I INNER JOIN DEGREE D
  ON (I.ID = D.ID
      AND ((I.VALID_TO > D.VALID_FROM
            AND I.VALID_FROM < D.VALID_TO)
           OR
           (D.VALID_TO > I.VALID_FROM
            AND D.VALID_FROM < I.VALID_TO)
     ))
WHERE I.VALUE >= TO_NUMBER('8000',
                           TYPES.GET_FORMAT('INT'))
  AND D.VALUE = "MGR."
  AND I.VALID_FROM < TYPES.TO_DATETIME(2100)
  AND D.VALID_FROM < TYPES.TO_DATETIME(2100);

-- NONE R-tree index
SELECT * FROM OBJECTS
WHERE MATCH(ID,
'/* NONE */ Income >= 8000 AND DEGREE = "MGR."
AND TIME < "2100"') = 1;
```

The database was populated with 10, 20, respectively 30 thousands of object instances with two attributes each. The attributes have had 8 to 15 unique values. Queries returned approximately 25% of the database content.

The table shows that the time spent by index creation is relatively large due to tree balancing. Optimal balancing has then positive influence to further index search times.

Table IV
SEARCH TIMES COMPARISON

Objects	Items	Create time (s)	REAL (s)	ORACLE (s)	NONE (s)
10 000	118.582	174.9	0.510	13.730	25.625
20 000	237.695	370.5	1.160	28.020	51.640
30 000	356.974	574.2	1.410	41.950	80.640

The same results are shown graphically on 5. It can be easily seen the major differences in times. Note that the results for Oracle SQL search were obtained in database without additional B-tree indexes on attribute values. Introducing them speeds up the Oracle SQL queries 3 to 4 times in the case of low dimensional queries. The queries on more attributes where the SQL join takes most of the time the speed-up was not so evident. The graph shows also an apparent increase of time between 10 and 20 thousands of object instances. It is caused by returning results in batches what implied more time-consuming calls from the PL/SQL to the C++ code. The tests were run with the batch size of 2000 objects.

VI. CONCLUSION

Using technologies as *Annotations*, *Annotation Processing* and *Java Instrumentation API*, available in Java 6.0 language, the concept of relaxed objects was successfully implemented including polymorphism that was originally not considered. Future planned extensions of Java that suppose storing method names together with parameter names and types in the byte-code in the retrievable way would make condition definitions

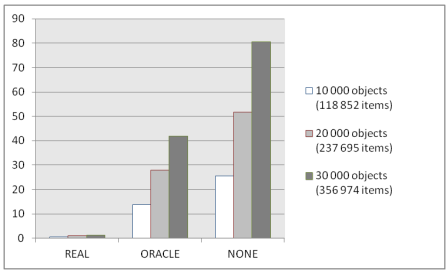

Figure 5. Search Times Comparison in Graphical Form

even simpler. The suitability of the above described implementation was proved by the pilot application – storage for software test management.

Advantage of the model is its ability of maintain heterogeneous data. The checking of method availability on given instance made the application more fault-tolerant. It appears that relaxed objects seem to be a good choice for prototyping applications having complex or heterogeneous data. Current state of implementation of specialized domain index promises even better performance and greater usability of this concept in the near future.

***Abstract*—We discuss some enhancements of approximate SQL extensions available in Infobright's database technology. We explain how these new enhancements can speed up execution of complex correlated subqueries, which are quite popular in advanced database applications. We compare our research to the state-of-the-art solutions in the area of analytic databases. We also show in what sense our technology follows the principles of rough sets and granular computing.**

***Index Terms*—Analytic Databases, Data Granulation, Approximate SQL, Correlated Subqueries.**

I. Introduction

COLUMNAR databases provide a number of benefits with regard to both data storage (e.g.: data compression [1]) and data processing (e.g.: on-demand materialization [2]). Their characteristics are particularly advantageous for exploratory sessions and ad hoc analytics. The principles of columnar stores can be also combined with a pipelined and iterative processing [3], leading toward modern analytic engines able to handle rapidly growing data sets.

Infobright's technology discussed in this article combines the benefits of columnar architectures with utilization of a metadata layer aimed at limiting data accesses while resolving queries [4]. In our solution, the content of each data column is split onto collections of values of some consecutive rows. Each data pack created this way is represented by its statistics. Such statistics are utilized by algorithms identifying data packs sufficient to complete particular stages of a given query execution [5].

The above solution is an example of a more general strategy of scaling complex computations on large data sets. Following the principles of rough sets [6] and granular computing [7], this methodology can be expressed by the four following steps: 1) Decompose data onto granules; 2) Create statistical snapshots for each of granules; 3) Do approximate computations on snapshots; 4) Whenever there is no other choice, access some of granules.

Certainly, such methodology should be compared to other approaches based on decomposing and merging computational tasks (see e.g. [8], [9]). It also requires addressing some details specific for particular applications, such as assuring sufficiently fast data decomposition methods, creating small but sufficiently informative snapshots, redesigning standard computational methods and accessing data granules in a minimized and optimized way.

Once the above challenges are solved, one can achieve a powerful framework where approximate computations assist execution of both standard and novel types of operations over massive data. In particular, in databases, it can be utilized to support both classical SQL statements and their approximate generalizations.

In the case of Infobright's RDBMS products, we distinguish three levels of such approximate assistance: 1) Optimization of data operations, which are components of execution of typical SQL statements [10]; 2) Computation of approximated results of SQL statements that occur in correlated subqueries in order to speed up answering to the main queries [11]; 3) Computation of approximated results visible to end users, which means actually extending standard SQL syntax [12].

In this paper we focus on the last two out of the above-outlined levels. We discuss an enhancement of our previous approximate SQL execution framework, now based on statistical metadata operations combined with accessing a small percentage of heuristically most informative data granules. We also report some performance tests proving that this new implementation can speed up a wide range of practically useful correlated subqueries.

The paper is organized as follows: Section II outlines some examples of understanding approximate SQL. Section III recalls our database technology, that is, Infobright's RDBMS solution. Section IV reports our previous research in the area of approximate SQL. Section V introduces new enhancements into our approximate SQL framework. Section VI recalls basic notions and challenges related to correlated subqueries. Section VII discusses application of enhanced approximate SQL framework to optimization of correlated subquery computation. Section VIII reports some performance tests corresponding to correlated subquery execution. Section IX discusses correlation between data sampling and precision of enhanced approximate query results. Finally, Section X concludes this study.

II. Approximate SQL

In such areas as, e.g., business intelligence or online analytics, there is a discussion whether the answers to SQL

978-83-60810-53-8/$25.00

statements have to be always exact. As an example, in the case of rapidly growing and/or dynamically changing data sets, often with a limited/variable access or limited time/budget resuorces, the outcomes of a standard SQL statement may get practically useless prior to finishing its execution. An analogous dilemma arises for SQL-based versions of some machine learning methods, which work heuristically anyway [13].

There are many aspects of introducing approximate SQL. For instance, one can estimate actual SQL results by executing queries against data samples [14]. One can also rely on data synopses [15]. A database system may build numerous synopses for various subsets of columns and measures. Each query is then translated and calculated using only synopses. The answer obtained in such a way is returned as approximation. Yet another possibility is to generalize SQL operators in order to provide end users with more flexible answers [16]. Such extensions are especially useful when query constraints turn out to be too restrictive to produce any results or columns' data types are too complex for standard conditions and operations.

The two out of the above aspects can be clearly found in Infobright's technology. Our statistical metadata layer can be utilized to heuristically identify subsets of data packs that form sufficiently informative samples. It can be also interpreted as data synopses, which produces query approximations for both internal and external purposes. We go back to these aspects in Section IV, after getting more familiar with the considered database architecture. With regard to the third above-mentioned aspect, which is tending toward more flexible answers by modifying SQL operators, some of our approximate query functionalities can be regarded as SQL syntax extensions. However, one should remember that Infobright's main inspiration for query approximations is to speed up execution and/or decrease a size of standard SQL outcomes by answering with not fully accurate/complete results.

Let us also mention about one more important direction in the area of SQL approximations, specially related to the enhancements proposed in this paper. It is dedicated to controlling a complex query execution over time, by means of converging outcome approximations [17]. Such a convergence can take different forms, e.g.: monitoring partial query results until the calculation is completely finished, with possibility to stop it at any moment in time, or pre-defining some execution time and/or resource constraints that, when reached, will automatically stop further process even if the given query results are still inaccurate. We go back to this topic in Section VI.

III. Infobright's Architecture

In Infobright's RDBMS, rows loaded into a data table are partitioned onto so called row packs, each consisting of, by default, 2^{16} of rows. Each row pack is partitioned onto data packs, each consisting of 2^{16} values of a column. Thus, each data pack corresponds to a single row pack and a single data column. Data packs are compressed and stored on disk. During query execution selected data packs are read from disk, decompressed and analyzed. Decompression stage commonly constitutes query evaluation time or is its significant factor, so one tends to limit number of data packs decompressions. That is why, among others, some subset of most recently used data packs are available decompressed in memory. Prior to compression, various types of statistics are computed for each of data packs. For each data table, there is so called granulated information system with objects corresponding to row packs and attributes – to statistics. If justified we can consider also information systems with objects related to the pairs of row packs from different tables (see e.g. [5]). Granulated information systems constitute so called Infobright's knowledge grid.

There are various strategies of partitioning rows into row packs. In a general area of data processing and mining, we may refer to this task as to data granulation [7]. Appropriate data organization will have, among others, direct impact on informativeness of data synopses and – in consequence – on engine performance. However, we need to realize that in the case of database solutions expected to analyze large amounts of data being loaded in nearly real time such granulation needs to be very fast, possibly guided by some optimized criteria but utilized rather heuristically. While loading (or reloading, e.g., by an `insert from select` operation) data, one may control the number of rows in row packs (that is, the number of rows does not need to be always 2^{16}). To a certain extent, one may also slightly influence the ordering of rows for the purposes of producing better-compressed row packs described by more meaningful statistics, following analogies to data stream clustering [18].

Knowledge grid can be treated as a metadata layer. Besides simple statistics displayed in Fig. 1, it may also contain more advanced structures [19]. However, the size of all such structures needs to be far smaller than the size of data. Since granulated tables residing in knowledge grid are organized in a columnar way, so their columns, called knowledge nodes, can be selectively employed while querying. Another metadata layer stores information about location and status of data packs. It also contains lower-level statistics assisting in data decompression and, if applicable, translating incoming requests in order to resolve them using only partially decompressed data. There is also one more metadata layer responsible for interpretation of the contents of data packs and knowledge nodes. It contains, e.g., value dictionaries for columns with relatively small number of unique values and domain-specific descriptions of values of long alphanumeric columns, which may assist in their better compression [20].

The most fundamental way of using knowledge nodes during query execution refers to classification of data packs into three categories analogous to positive, negative, and boundary regions in the theory of rough sets [6]: Relevant

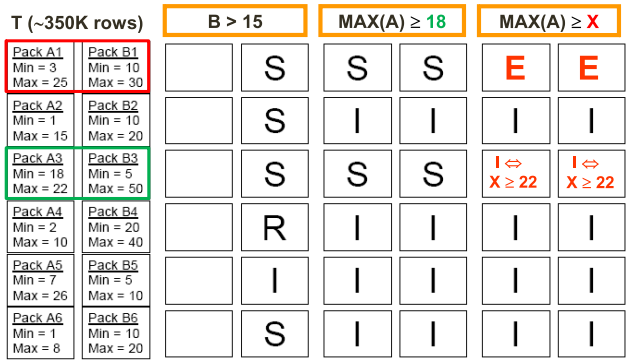

Fig. 1. Illustration for Section III. Simplified min/max knowledge nodes for numeric data columns `a` and `b` in table `T` are presented at the left side. Symbols R, S and I denote relevant, suspect and irrelevant data packs, respectively. E denotes a need of processing at the exact level. I/E means that the decision whether a given pack is irrelevant or requires exact processing will be made adaptively, depending on the outcomes of previous calculations [5].

```
select                  +--------+--------+------+
 min(a), sum(a), b      | min(a) | sum(a) |    b |
 from T                 +--------+--------+------+
 where b > 1            |      2 |      3 |    2 |
 group by b;            |      2 |      2 |    6 |
                        |   null |   null |    5 |
                        |      1 |      3 |    3 |
                        +--------+--------+------+

select roughly          +--------+--------+------+
 min(a), sum(a), b      | min(a) | sum(a) |    b |
 from T                 +--------+--------+------+
 where b > 1            |      1 |      2 |    2 |
 group by b;            |      2 |      3 |    6 |
                        +--------+--------+------+
```

Fig. 2. Example of SQL `select` statement and its rough version. Tables at the right sides display the results of both queries [10].

(R) packs with all elements relevant for further execution; Irrelevant (I) packs with no elements relevant for further execution; Suspect (S) packs that cannot be R/I-classified based on available knowledge nodes.

As an example, consider table `T` with 350,000 rows and columns `a` and `b`. We have six row packs: (A1,B1) for rows 1-65,536, (A2,B2) for rows 65,537-131,072 and so on. Consider knowledge nodes with minimum and maximum values displayed in Fig. 1. Assume there are no nulls and no other types of knowledge nodes available. Consider the following statement: `select max(a) from T where b>15;` [5]. The first execution stage uses min/max knowledge node for column `b` to classify data packs of `b` (and the whole corresponding row packs) onto relevant (B4), irrelevant (B5) and suspect (B1, B2, B3, B6) regions with respect to condition `B>15`. The second stage employs the third row pack to approximate the final result as `MAX(A)` $\geq$ `18`. Thus, only row packs (A1,B1) and (A3,B3) require further investigation. Maximum in A1 is higher than in A3, so, at the third stage, approximation is changed to `MAX(A)` $\geq$ `X`, where X depends on the result of exact processing of the first row pack. If X $\geq$ 22, then there is no need to access the third row pack. Otherwise, we need to proceed with its exact processing to get the precise outcome.

The first realistic implementation of an analogous granulated metadata support for query execution refers to [4], where the idea was to partition data into blocks of consecutively loaded rows, annotate each of such blocks with its min/max values with respect to particular data columns, and use such statistics against `where` clauses in order to eliminate out-of-scope blocks. However, the above example shows that the analysis of fully in-scope row packs is equally useful, as in such cases it is enough to take statistics instead accessing data. Moreover, it is worth re-categorizing data packs as relevant/irrelevant iteratively, which distinguishes us from other approaches.

We refer to the literature for more examples how to utilize knowledge nodes in order to speed up data operations. Let us just mention that in case of multi-column `where` conditions some data packs, within a single row pack, can be identified as relevant/irrelevant while others may remain suspect. Furthermore, statistics and statuses of different data packs can be combined while processing complex (boolean, arithmetic, etc.) expressions treated as dynamically derived data columns [10]. (Actually, results of correlated subqueries investigated in further sections may be interpreted as such complex expressions.) It is also worth noting that knowledge nodes can be computed and efficiently used for intermediate results and structures created during query execution, such as e.g. hash tables storing partial outputs of joins and aggregations [21].

IV. Infobright's Query Approximations

Let us now go back to an outline of approximate SQL approaches that we developed so far. In [5], we introduced informally the notion of rough query, in order to better explain some internal data operations in our database engine. In [22], rough query was formalized for the purposes of correlated subquery optimizations. This topic was continued in [11]. Finally, in [12], we formulated the syntax of rough SQL statements and their results.

The following aspects of rough SQL were studied in [12]: 1) Query execution algorithms; 2) Internal results format; 3) Reporting results to end users. Let us explain those aspects using an example from Section III. Recall that by utilizing min/max knowledge nodes of columns `a` and `b` we could compute that the outcome of `select max(a) from T where b>15;` is at least 18. This is because of row pack (A3,B3), within which there must be at least one row satisfying condition `b>15` and having value not less than 18 on `a`. We obtain approximation in the form of interval $\langle 18, 25\rangle$. This would be actually the answer to query `select roughly max(a) from T where b>15;` within the rough SQL framework introduced in [12].

Every `select` SQL statement returns a set of tuples

labeled with the values of some attributes corresponding to the items after `select`. Approximation of a query answer can be specified as statistics describing attributes of such a tabular outcome. Rough SQL can be assumed to produce a kind of knowledge grid for such attributes. Accordingly, the results of rough queries in [12] were provided as ranges $\langle lower, upper \rangle$ approximating the results of the corresponding standard queries. Here we should notice that, as for now, our approach concerns only numeric columns, however some efforts of analogous representation for alphanumeric columns have been done too.

Consider an example in Fig. 2, where the task is to compute aggregations `min(a)` and `sum(a)` with respect to column `b`. The resulting tuples correspond to the groups induced by `b`. There are three attributes: `min(a)`, `sum(a)` and `b`. Rough version of the same SQL computes ranges for two aggregations and the grouping column. Rough outcome tells us that for each resulting tuple, if its value of `min(a)` is not `null`, then it is for sure between 1 and 2. Similarly, `sum(a)` is in $\langle 2, 3 \rangle$, and `b` is in $\langle 2, 6 \rangle$.

In parallel to our research on rough SQL, in [19] we started to extend Infobright's framework toward a kind of inexact querying. Those studies were further continued in [23]. In this approach, we do not compute query result approximations, neither with full nor partial confidence that they are correct. Instead, we attempt to speed up the query execution process by quickly producing potentially inaccurate results that look in a standard way.

In this case, we follow an expectation that approximate queries yield tuples being almost the same as those resulting from standard queries. We enriched knowledge nodes and the corresponding query processing functions in order to compute degrees of data packs' (ir)relevance. We also investigated inexact knowledge nodes that describe data packs almost correctly, neglecting local outliers in order to provide crisper min/max intervals. Then, basing on some analogies with extensions of rough sets (see e.g. [24]), we loosened the criteria for R/I pack status, i.e., we treated almost not suspect packs as if they were truly (ir)relevant . This way, we created a framework for computing inexact query outputs with a decreased need for data access.

In [23], we also proposed a more probabilistic approach, where so called degrees of (ir)relevance, i.e., dynamically derived coefficients that heuristically estimate how many elements of particular data packs might satisfy query conditions, are employed to randomly select row packs for further processing. In this case, we can work with standard knowledge nodes [5]. However, with some probability proportional to the above degrees, data packs that are potentially almost relevant or irrelevant may be classified as fully relevant or irrelevant, respectively.

The above randomized approach inspired us to develop a number of intelligent sampling techniques. Given the architecture described in Section III, it is important to randomly select a reasonably small subset of row packs and then choose a sample of rows from those row packs only. A challenge is to select row packs providing sufficient representativeness of the final sample. In this case, utilizing knowledge nodes in order to compute degrees of row packs' (ir)relevance with respect to particular query conditions is very helpful. While producing a sample, fully relevant data packs should have the highest chance to get selected while fully irrelevant data packs should not be considered at all. For suspect data packs, their degrees of (ir)relevance should directly influence the probability of taking them into account during sample generation. In further sections, we refer to queries executed over samples generated in this way as to sampled queries.

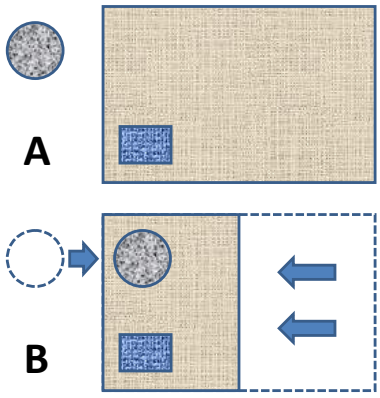

Fig. 3. A: Comparison of a result of a standard `select` statement (symbolized by smaller rectangle) with the results of its sampled (circle) and rough (bigger rectangle) versions; B: Illustration how a sampled result can be modified using knowledge nodes and how rough result may become crisper by accessing some of data packs.

V. Enhanced Rough SQL

Rough SQL reported in [12] provides fast responses, but the spans of approximations are often not informative enough to end users nor internal optimization mechanisms. On the other hand, sampled queries discussed in the end of Section IV provide fast responses (although not as fast as rough queries) that are potentially more informative, but end users have no means to analyze how accurate they are (see Fig. 3A). Certainly, it is crucial to approximate errors occurring for particular data packs and to propagate them through the whole query execution process in order to provide end users with overall estimation. This task gets more complicated along a growing complexity of analytical SQL statements and needs to be considered for all query methods. Thus, a question arises whether it is possible to combine benefits of rough queries and sampled queries within a unified framework.

The above question can be answered in at least two ways (see Fig. 3B). One of possibilities is to enrich sampled queries with an analysis whether their results remain within the bounds produced by rough versions of the same queries. If a given sampled result is not within such bounds, we can quickly move it toward the closest *edge* of rough SQL approximation. Another possibility is to

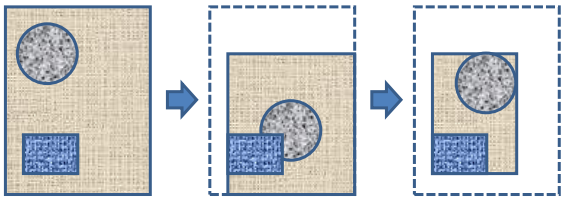

Fig. 4. Illustration how enhanced sampled query results (circles) and enhanced rough query results (bigger rectangles) are expected to behave with respect to a standard query result (smaller rectangle) while accessing more and more data packs.

develop a crisper version of rough SQL that would provide better ranges for both sample-based and fully exact querying, by combining statistical information provided by knowledge nodes with crisp information about opened data packs. Actually, in this case one should expect that rough SQL enriched by additional information about the content of a subset of suspect data packs should provide reasonable ranges for sampled SQL, where a sample is created basing on the same subset of data packs.

From a technical point of view, sampled querying is based on selecting subsets of row packs and then selecting some rows from those row packs. Therefore, it requires decompression of those row packs. Once we have some row packs decompressed, their content can be used to improve rough SQL results in the same time. Realization of this idea is actually very simple: When a data pack is accessed, we can replace its statistics stored in Infobright's knowledge grid with very crisp information about only those of its elements, which are useful at a given stage of query execution (e.g.: which correspond to rows satisfying conditions over other columns in a given `select` statement). This means that knowledge nodes, or rather their copies utilized while executing a given query, can become crisper over time, leading to a crisper final result.

Let us emphasize that from a practical point of view there is no requirement for results of sampled queries to fall within the bounds provided by their rough counterparts. It depends entirely on expectations of end users. For distinction, we will refer to a sampled query mechanism enriched by rough results analysis as to an enhanced sampled querying. Analogously, we refer to a rough query mechanism enriched by information from a subset of suspect data packs as to an enhanced rough querying.

Let us go back for a while to the idea presented in [12], where rough SQL was based entirely on Infobright's knowledge grid. We implemented a number of techniques utilizing knowledge nodes at particular stages of execution of `select` statements. All of them are based on heuristics analogous to the mechanisms of dynamic approximation of standard query outcomes, as shown in Section III. Approximations are often not perfectly precise but can be obtained very fast. However, additional data access may not necessarily lead to a dramatic slowdown of rough SQL execution. For instance, it is worth noting that Infobright caches recently used data packs in memory. Integration of information residing in knowledge nodes with such packs within a framework for enhanced rough SQL may significantly improve precision of results.

Let us also recall that Infobright's query execution should be treated as an iterative process, where knowledge nodes and information acquired from data accessed at a particular stage can be employed for heuristic selection of the very next packs that are likely to mostly contribute to narrowing down the $\langle lower, upper \rangle$ ranges. In general, we can think about several strategies of choosing data packs or row packs to be processed. For instance, to improve enhanced rough SQL results with minimum data accesses, we should choose packs that are expected to maximize information gain for after-select attributes (which may follow exactly the same heuristics as in the example in Section III). On the other hand, in order to increase reliability of sample-based querying, we should rather choose row packs that seem to be statistically representative with respect to the query domain (as discussed in the end of Section IV). Finally, in order to speed up execution without losing quality, we should attempt to combine the above strategies with information about data packs that are currently cached in memory.

Finally, let us note that enhanced rough query result ranges become crisper (or at least not less crisp) when more row packs are taken into account. There is no guarantee that a distance between actual query and approximated query results decreases monotonically. However, while enhanced rough query result ranges become crisper, we intuitively expect to approximate the above distance better and better (see Fig. 4). As mentioned in Section II, there are also some approaches where an end user provides an upper bound for query processing time and acceptable nature of answers (partial or approximate). One can imagine an analogous framework designed for Infobright, wherein a query is executed starting with rough information and then it is gradually refined by decompressing heuristically selected pieces of data. The execution process can be then bounded by means of various parameters, such as time, acceptable errors, or percentage of data accessed. We can also consider a design of Infobright-specific incremental querying, although it would require further extensions of end user interfaces.

VI. Correlated Subqueries

A correlated subquery is a query nested in some other query, called an outer query, which often operates on another table, called an outer table, and which is parameterized by some outer table's values. Correlated subqueries can occur in a number of SQL clauses. For illustrative purposes, consider the following example of the `where` clause of the outer query: `U.x=(select max(T.a) from T where T.b>U.y)`. If `U` and `T` are large, then the execution of the outer query on `T` may be time consuming. However, as pointed out in [22], one can quickly derive rough answers

to particular subqueries and, for each row in `T`, check whether the above condition could be successfully resolved by using such dynamically obtained statistics.

Importance of correlated subqueries is visible in several areas of business intelligence, such as the trend or predictive analysis. Complex nested queries may occur at the reporting stages focused on identifying anomalies and risk indicators. They may be useful also in applications requiring storage of large sets of hierarchical objects in a relational format. In many cases, e.g. for large metadata repositories, a dynamic reconstruction of such objects may be also supported by massive self-join operations or some recursive SQL extensions, if available. However, there are cases where the usage of correlated subqueries seems to be particularly convenient, if they perform fast enough.

Internal rough query algorithms have been utilized in Infobright's RDBMS for a longer time in order to speed up correlated subqueries [11]. Surely, one can adopt here some well-known methods of the correlated subquery optimization [25], such as caching results for last-observed parameters or rewriting nested queries into semi-joins. However, in some cases, the nested part of a query may still need to be processed in its direct form for a huge amount of rows of an external table. Fast production of query approximations may eliminate the need of a standard computation at least for a subset of such rows.

For a subquery in the `where` clause, we launch its rough version with parameters induced by each consecutive row in the outer table. We attempt to use its rough outcome to avoid the exact mode of execution. For the above-mentioned example of the clause `U.x=(select max(T.a) from T where T.b>U.y)`, we can express it in two stages: $(x, \widetilde{s}(y))$ and $(x, s(y))$. The first of them symbolizes, for a given row, the comparison of its value on column x with a rough result of the subquery parameterized by its value on column y. If such a comparison is not sufficient to decide whether that row satisfies the `where` clause, i.e., if the value of `U.x` does not yield fully relevant or fully irrelevant condition when comparing with the result of statement `select roughly max(T.a) from T where T.b>U.y;` then, for that particular row, we need to proceed with the standard subquery execution $s(y)$.

A broader roadmap for rough query-related future optimizations of correlated subqueries was presented in [11]. In all cases presented in that paper, the preciseness of rough query outcomes is crucial for ability to minimize data access and speed up computations.

VII. Optimization of Correlated Subqueries by Enhanced Rough SQL

Efficiency of different forms of approximate or randomized query frameworks can be examined in multiple ways. For example, in [23] we investigated stability and reliability of the results of top-k queries while tuning parameters of random selection of almost suspect data packs. As another example, in [12] we presented some strategies utilizing rough queries to speed up standard SQL calculations. In this paper, we focus on the original idea of using rough SQL to improve performance of correlated subqueries [22]. Our goal is to show that additional employment of enhanced rough SQL mechanisms described in Section VI can lead to further gains in this area. In the nearest future, we plan to extend our tests also onto other aspects of practically most promising enhanced rough SQL applications.

TABLE I
The amount of data packs accessed while querying. The TPCH100 query is a standard benchmark query. The TEST_1 and TEST_2 queries come from Infobright's internal benchmark framework. The SYNAT_1 and SYNAT_2 queries are taken from the SYNAT project [26]. The remaining queries represent Infobright's customers.

SQL statement	rough → exact	rough → enhanced → exact
TPCH100	2869154	185330
TELCO_1	21663	12087
TELCO_2	9579	3
WEBLOGS	51047	28769
TEST_1	40707	40707
TEST_2	40707	3
SYNAT_1	333582	333552
SYNAT_2	252868	251242

At the first glance, one may suspect that accessing data packs slows down producing rough subquery outcomes. However, crisper outcomes let us eliminate more calculations at a higher level. Moreover, we implemented it in such a way that the enhanced rough query execution is triggered only if standard rough query fails. In our previous implementation, we would follow with exact subquery immediately. In the new implementation, we proceed with exact computation only if enhanced rough query fails to give us results that would be precise enough. Therefore, it is not about a trade-off between the amount of accessed packs and precision of results – the way it was implemented assures that we always win by applying this new mechanism. Symbolically, we replace the previous strategy expressed by the pair of stages $(x, \widetilde{s}(y))$ and $(x, s(y))$ by a triple, where $(x, \widetilde{s}(y))$ is followed by $(x, \overline{s}(y))$ and then by $(x, s(y))$, where $\overline{s}(y)$ denotes an enhanced rough execution of inner query s with parameters set up by a value of outer column y. Surely, the other strategies reported in [11] could be extended this way as well.

Mechanism of enhancing is parameterizable. Before running query we can choose how many row packs for single subquery evaluation are permitted to be additionally decompressed. If not specified explicitly, all experiments described in the following section were performed for the only one row pack per subquery evaluation permitted.

VIII. Experimental Results

Table I illustrates one of specific classes of correlated subqueries aimed at selecting and processing extreme cases for some categories. Such nested queries differ from

relatively simpler `group by` statements in a way of considering observations marked as extreme. They are useful for some aspects of time-oriented analysis, extreme behaviour or outliers tracing. Specific tasks corresponding to such queries may look, e.g., as selecting all latest news about each company in the news table

```
select * from news n1 where pub_date
  = ( select max(pub_date) from news n2
      where n1.company_id = n1.company_id )
```

or, for a set of stemmed documents, selecting all stems that are of a maximal TF-IDF value for particular documents (see [26] for comparison)

```
select stem from stemmed_docs x where tf_idf
  = ( select max(tf_idf) from stemmed_docs
      where x.id_doc = id_doc )
```

The results in Table I are displayed by means of data packs that had to be opened. Such measure for considered class of queries, reflects real performance of query evaluation fairy accurately. We will then identify number of decompressed data packs with query performance understood as time spent waiting for the results.

The last column reports the results of our new approach, where the intermediate enhanced rough SQL version of a correlated subquery is computed with only one heuristically selected row pack to be additionally accessed. This shows a huge potential of the proposed method. For some of the considered queries, we were able to provide and test equivalent non-nested `select` statements with additional `group by` or `self-join` operators. Usually, such rewriting significantly improves performance. However, for queries such as TELCO_2 and TEST_2, it was impossible to find an alternative way of execution that would be comparably fast to the strategy based on enhanced rough SQL.

IX. Discussion

Let us now elaborate more on how the data sampling intensity correlates with the precision of enhanced rough query results. First of all, it turns out that queries with correlated subqueries based on MIN/MAX aggregations can particularly gain from enhanced rough SQL as such aggregations are sensitive to information about single observations. Figure 5 illustrates it by presenting enhanced rough queries for selected values of additional decompressions of row packs per query evaluation. Parameter equal to 0 means an ordinary rough SQL (with no extra data accesses). We can see that after accessing nine additional row packs we achieve fully crisp result.

On the contrary, the precision of, e.g., COUNT is expected to be linear with respect to the number of additional accesses [23]. It makes the enhanced rough query sampling strategy for COUNT (as well as SUM and AVG) questionable, although in some cases accessing several data packs may still help in resolving a query condition. Generally, these types of aggregations may be handled better by enhanced sampled queries, although inexactness of their outcomes is not always acceptable by end users.

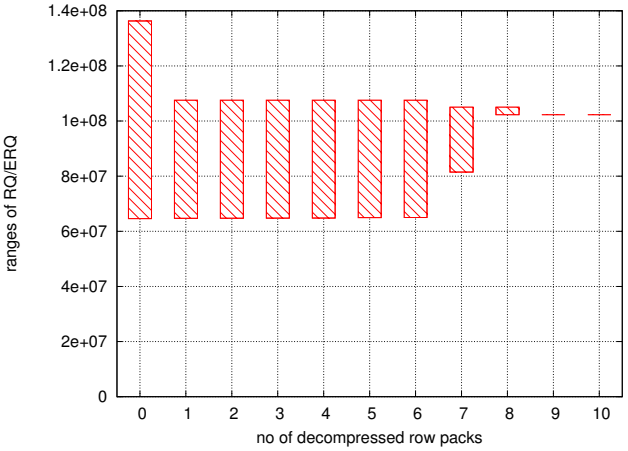

Fig. 5. Exemplary scenario of influence of increasing number of row pack decompressed during enhanced rough query (ERQ) calculation on ranges returned by ERQ performed on customer's data (SELECT ROUGHLY MIN(col) FROM t WHERE cond); 0 stands for original rough query; for 9 row packs we achieve crisp result

It is also worth elaborating on sampling strategies that could decrease a need of additional decompressions by, e.g., achieving crisp results after shorter period of time. For example, one of such strategies for MIN/MAX aggregations is to start decompression from data packs with the most extreme values represented by their knowledge nodes (like in Figure 5). A similar strategy could be followed for COUNT DISTINCT aggregations by referring to data packs with the highest estimated number of distinct values. However, analyzing results from Figure 5 (in particular the little improvement in range estimation between cases with parameter set to 1 and 6) we anticipate the need of enrich sampling strategy development of utilizing information contained e.g. in histograms.

Additional decompressions may be done randomly but a more intelligent procedure is recommended. The presented results also suggest that in case of correlated subquery optimization such mechanism may be complementary to syntactic reformulation of queries (for instance into JOINs). It should be also pointed out that some on-load row reorganization strategies aimed at improving the quality of knowledge nodes may further increase effectiveness of sampling mechanisms [18]. This is because, generally, the increase in the quality of rough information represented by knowledge nodes helps a lot in all aspects of Infobright's querying algorithms.

X. Conclusions

We discussed some enhancements of rough SQL framework developed by Infobright. We reported how such enhancements can speed up execution of correlated subqueries. In our future research, we are going to examine

further cases of practical usage of enhanced rough SQL. We will also attempt to better analyze convergence of query approximations depending on various strategies of sampling blocks of rows during query execution.

Performance Antipatterns of One To Many Association in Hibernate

Patrycja Węgrzynowicz
Institute of Informatics

***Abstract*—Hibernate is the most popular ORM framework for Java. It is a straightforward and easy-to-use implementation of Java Persistence API. However, its simplicity of usage often becomes mischievous to developers and leads to serious performance issues in Hibernate-based applications. This paper presents five performance antipatterns related to the usage of one-to-many associations in Hibernate. These antipatterns focus on the problems of the owning side of collections, the Java types and annotations used in mappings, as well as processing of collections. Each antipattern consists of the description of a problem along with a sample code, negative performance consequences, and the recommended solution. Performance is analyzed in terms of the number and complexity of issued database statement. The code samples illustrate how the antipatterns decrease performance and how to implement the mappings to speed up the execution times.**

I. Introduction

HIBERNATE [1] is a remarkably popular implementation of Java Persistence API, i.e., the official standard of object-relational mapping in Java. However, many developers, especially of enterprise systems, complain on the correctness and the performance of Hibernate-based applications. It turns out that even relatively simple Hibernate applications impose a significant overhead on communication with a database, producing too many and/or inefficient SQL statements.

In this paper, we analyze the subject of the most common mapping, namely one-to-many associations of entities. Because of its wide usage as well as popularity of Hibernate, it seemed that the implementation of this association should have been well optimized. Our research revealed that even simple applications of one-to-many associations can result in (1) unexpected SQL statements being executed, (2) too many SQL statement being executed, and/or (3) too many objects being loaded into memory. Therefore, naïve mapping of one-to-many associations can introduce a significant performance overhead in a Hibernate-based application.

The main contribution of this paper consists of five performance antipatterns (i.e., bad practices with a significant impact on performance) related to the usage of one-to-many associations in Hibernate. Each antipattern consists of the description of a problem, performance consequences, the recommended solution, and a sample code.

II. Related Work

Antipatterns are conceptually similar to design patterns as they describe recurring problems and provide solutions to them. A performance antipattern describes a bad practice that has a significant impact on performance. The articles [2] and [3] provide a good explanation of performance antipatterns along with the definition of 14 performance antipatterns. These papers have formed a good basis for further research on performance antipatterns, mainly in the field of automated detection and fixing of performance problems. The paper [4] introduces a framework for automated detection and assessment of performance antipatterns in component based systems. The authors of [5] focus on detection of performance antipatterns in architectural models. The article [6] explains the method to remove performance antipatterns from software by analyzing UML models. The paper [7] describes modelling and analysis of software performance antipatterns along with their constraints and solvability using different models.

As mentioned above there has been work done in the field of performance antipatterns, defining solid means in terms of their definitions, detection, and fixing. These efforts focus on generic and domain-independent antipatterns, mostly in the application layer. However, they do not touch the data layer. Numerous performance problems have their source in an inefficient way of retrieving or storing large amount of data in a database. Therefore, this area is important to correctly identify the source of performance issues in software. It is especially true nowadays, when the amount of data processed continually increases and the use of automated frameworks for object-relational mapping becomes more and more common.

There is a number of popular ORM libraries, like Hibernate [1], EclipseLink [8], Open JPA [9], and Data Nucleus [10] to name a few. Even though they implement the same specification — Java Persistence API, they differ in mapping policies, generate different schemata and SQL statements that have different performance characteristics. The article [11] analyzes the influence of optimizations on the performance of Hibernate. In another paper [12], the same authors compare the performance of an object-relational mapping tool (Hibernate) vs. an object-oriented database (db4o) using OO7 benchmark. Another comparative study of the performance of object-relational mapping tools for .NET platform can be found

978-83-60810-53-8/$25.00

in [13]. However, these comparative studies focus mainly on queries, which usually are as efficient as SQL queries since they are direct translation to SQL. Some authors (e.g., [14]) identify the need to improve the efficiency of ORM tools by utilizing the features provided by the database engines.

Even though there has been work done on comparing performance of ORM tools, we still lack a systematic approach to identification of their strengths and weaknesses in terms of impedance mismatch [15]. In this paper, we aim at the identification of common performance problems for one-to-many associations in Hibernate. We also define five new antipatterns and provide recommendations how to fix them.

III. Antipattern: Inadequate Collection Type on Owning Side

A. Description

In JPA, *@OneToMany* annotation used on the owning side (i.e., the side used to manage persistency of elements) is one of the most common implementations of a one-to-many association between persistent entities. Such an approach is commonly used in enterprise development mainly due its simplicity and little coding overhead. However, it can introduce a serious performance overhead in Hibernate when combined with an inadequate Java collection type.

Table I presents three types of semantics available in Hibernate, dependent on the combination of a Java collection type and JPA annotations. Each of these semantics has a different performance characteristic. Table II shows the numbers of statements issued while persisting a collection of a given semantics after an addition or removal of a single element.

The bag semantics has the worst performance when it comes to the number of operations since it always re-creates the entire collection. Hibernate issues a delete statement to remove all associations of the old collection from the association table. Then, it issues N inserts to add all associations representing the new collection to the association table. Hibernate does not analyze how many elements have been changed in the collection.

In the list semantics, an addition or removal of a single element from a collection of N elements results in a single insert or delete respectively and M updates. The updates are needed to correct the indices of M elements. In case of addition, Hibernate needs to correct the indices of the elements before the one being added. In case of removal, Hibernate needs to correct the indices of the elements after the one being removed.

The set semantics seems to be the most efficient. For a single operation on a collection, it requires only a single database operation. However, it is worthwhile remembering that the Java set semantics requires a uniqueness check on the elements of a set. It implies that, in case of any additions of new elements to a persistent set, all elements of the set must be loaded into the main memory.

The antipattern relates to the usage of an inefficient collection semantics for a given usage pattern of a collection:

- For usage patterns of collections where in a single transaction the collection is usually left unmodified or only a few elements are added or removed, the usage of the bag semantics (i.e., *java.util.Collection* or *java.util.List* without the index or order annotations) is notably inefficient.
- For usage patterns of collections where in a single transaction most of the elements of the collection are removed, the usage of the set or list semantics (i.e., *java.util.Set* or *java.util.List* with the index or order annotation) is inefficient.

TABLE I
THREE SEMANTICS FOR COLLECTIONS WITH @ONETOMANY ANNOTATION IN HIBERNATE.

Semantics	Java Type	Annotation
Bag semantics	java.util.Collection java.util.List	@OneToMany
List semantics	java.util.List	@OneToMany $\wedge$ (@IndexColumn $\vee$ @OrderColumn)
Set semantics	java.util.Set	@OneToMany

TABLE II
THE NUMBERS OF DML STATEMENTS ISSUED WHILE PERSISTING A COLLECTION OF N ELEMENTS WITH A GIVEN SEMANTICS (DEFAULT TABLE MAPPING WITH AN ASSOCIATION TABLE; NO CASCADE OPTION).

Semantics	One Element Added	One Element Removed
Bag semantic	1 delete, N inserts	1 delete, N inserts
List semantic	1 insert, M updates	1 insert, M updates
Set semantic	1 insert	1 delete

B. Consequences

The performance consequences of the usage of an inadequate collection type on the owning side of a one-to-many association include an increased workload on the database engine because:

- For the bag semantics, Hibernate re-creates an entire collection, performing one delete to clear the collection and as many inserts as there are elements in the collection. For the common usage pattern of collections, where only a few elements are added or removed, such a re-creation results in suboptimal performance due to the operations on data which actually have not been changed. The bigger the collection is, the performance overhead is more significant.
- For the list or set semantics, Hibernate performs single delete or insert per each removal or addition respectively. For the usage pattern of collections, where most elements of a collection are removed, such a strategy results in suboptimal performance due to many deletes instead of one delete to clear the collection in one operation.

C. Solution

The solution to this antipattern is to analyze the usage profile of collections in an application and adjust the type of Java collections accordingly:

- If a collection is constant or is the subject to minimal changes or is relatively small, the recommended collection type is *java.util.Set* with the set semantics.
- If a collection is heavily modified, the recommended collection type is *java.util.Collection* or *java.util.List* with the bag semantics.

D. Sample Code

Listing 1 presents an example of the antipattern related to an inadequate collection type on the owning side. The sample code has two persistent entities (`Forest` and `Tree`), which are connected by an unidirectional association (`Forest` has a collection of `Tree` objects). The classes meet all requirements imposed by JPA and Hibernate on persistent entities (e.g., no-arg constructor). We use a minimal set of additional annotation and configuration parameters, instead relying on default values.

To test the persistency mechanism implemented in Hibernate, we execute two transactions. To ensure the same runtime environment (e.g., clear caches), each transaction is executed with a new `EntityManager` instance. The first transaction creates a `Forest` instance and 10000 `Tree` instances planted in the newly created `Forest`, whereas the second transaction finds the previously created `Forest` instance, creates a new `Tree` instance and plants it in the found `Forest`. It turns out that Hibernate for such a piece of code as in the second transaction re-creates the entire collection (i.e., executes one delete and 10 001 inserts). This behavior of Hibernate is not performance-wise since in our example one insert would be enough to synchronize the state of the object in the main memory with the state of the records in the database. For large collections with only a few changes it imposes a significant performance overhead.

Listing 1. The example of an inadequate collection type on the owning side.

```
@Entity
public class Forest {
    @Id @GeneratedValue
    private Long id;
    @OneToMany
    Collection<Tree> trees =
        new HashSet<Tree>();
    ...
    public void plantTree(Tree tree) {
        trees.add(tree);
    }
}
@Entity
public class Tree {
    @Id @GeneratedValue
    private Long id;
    private String name;
    ...
}
// Transaction 1
// creates and persists a forest...
// ... with 10.000 trees
...
// Transaction 2
Tree tree = new Tree("oak");
em.persist(tree);
Forest forest = em.find(Forest.class, id);
forest.plantTree(tree);
```

IV. Antipattern: OneToMany as Owning Side

A. Description

The antipattern relates to the usage of the collection side (i.e., *@OneToMany*) as the owning side of an association for large collections, especially the ones which expect only a few changes in a single transaction.

According to Section III, for such a use case we should use *java.util.Set* to minimize the performance overhead. However, even usage of *java.util.Set* does not guarantee the optimal performance.

First, due to the Java set semantics the entire collection needs to be loaded into the main memory in order to enforce a uniqueness check in case of addition of elements to the collection. It results in an additional database query (or queries due to batch loading) issued and additional processing dedicated to the transformation of each returned row into an object. These additional queries and processing happen even if the application logic does not access the elements of the collection in question.

Second, there might be an overhead connected with transactions and locking, when the entity containing the collection in question uses optimistic locking with versioning. In such cases, Hibernate locks not only the entity but also the collection, which lowers the capability of an application to serve concurrent requests.

B. Consequences

The performance consequences of the *@OneToMany* as the owning side antipattern are as follows:

- There is an increased workload on the database engine. Hibernate issues an additional database query (or a number of queries in case of batch loading) to retrieve the elements of a collection.
- There is an increased workload on the application server (CPU). Hibernate needs to convert each returned row into an object, even if the application logic does not access those objects.
- The memory footprint is significant, especially for large collections. It can result in slower performance due to insufficient memory available, leading to more frequent garbage collections or even page swaps.

- There may be a decreased throughput. Due to transaction and locking issues, the capability of an application to serve concurrent requests may be significantly lowered.

C. Solution

The solution to this antipattern is to manage a collection from the *@ManyToOne* side instead of *@OneToMany* side, i.e., to make *@ManyToOne* the owning side of the association. In case we are not able to change the owning side of an association, we should at least exclude such a collection from locking by using a Hibernate-specific annotation: *@OptimisticLock(excluded=true)*.

D. Sample Code

Listing 2 presents an example of *@OneToMany* as the owning side antipattern. It mimics Listing 1, introducing only a few changes: (1) the Java type of a collection has been changed to *java.util.Set* and (2) version fields have been added in `Forest` and `Tree` classes. The key piece of code is located in the second transaction, which adds a single `Tree` to the previously created `Forest` with 10 000 trees. It turns out that in the second transaction, the entire forest is loaded into memory. Moreover, we are not able to plant trees in parallel because Hibernate locks the entire `Forest` instance along with all its `Tree` associations.

V. Antipattern: Inadequate Collection Type on Inverse Side

A. Description

This antipattern relates to the usage of *java.util.Set* on the inverse side (also known as the mapped collection) of a bidirectional one-to-many association in Hibernate.

In case of bidirectional associations, it is recommended to synchronize the state of the objects (i.e., the mapped collection and the element entities with *@ManyToOne* pointers) in memory. The common implementation to ensure the consistence of the objects relies on an automated update of the mapped collection by the setter method in an element entity responsible for setting the *@ManyToOne* pointer (see Section V-D).

Therefore, when the type of the mapped collection is *java.util.Set*, it means that the entire collections needs to be loaded into the main memory in response to each addition of new elements, even though the application does not access neither the collection nor its elements. It happens due to the Java set semantics mentioned earlier, which requires a uniqueness check on the elements of a set.

B. Consequences

The performance consequences of the usage of *java.util.Set* on the inverse side of a bidirectional one-to-many association with in-memory state synchronization are as follows:

- There is an increased workload on the database engine. Hibernate issues an additional database query (or a number of queries in case of batch loading) to retrieve the elements of a collection.

Listing 2. The example of @OneToMany as the owning side.

```
@Entity
public class Forest {
    @Id @GeneratedValue
    private Long id;
    @Version
    private Integer version;
    @OneToMany
    Set<Tree> trees = new HashSet<Tree>();
    ...
    public void plantTree(Tree tree) {
        trees.add(tree);
    }
}
@Entity
public class Tree {
    @Id @GeneratedValue
    private Long id;
    @Version
    private Integer version;
    private String name;
    ...
}
// Transaction 1
// creates and persists a forest...
// ... with 10.000 trees
...
// Transaction 2
Tree tree = new Tree("oak");
em.persist(tree);
Forest forest = em.find(Forest.class, id);
forest.plantTree(tree);
```

- There is an increased workload on the application server (CPU). Hibernate needs to convert each returned row into an object, even if the application logic does not access those objects.
- For large collections, there is a significant memory footprint. It can slow down performance of an application due to insufficient memory available, more frequent garbage collections, or even page swaps.

C. Solution

The recommended Java types to be used on the inverse side of a one o many association are *java.util.Collection* or *java.util.List*. These types do not force loading the elements into memory until the elements are accessed by client code.

D. Sample Code

Listing 2 presents an example of *java.util.Set* used on the *@OneToMany* inverse side with in-memory state synchronization. The example continues the previously described `Forest` and `Tree` classes presented in Sections III and IV. Here, `Tree` is the owning side of an association, while `Forest`

Listing 3. The example of an inadequate collection type on the inverse side.

```
@Entity
public class Forest {
    @Id @GeneratedValue
    private Long id;
    @OneToMany (mappedBy = "forest")
    Set<Tree> trees = new HashSet<Tree>();
    ...
    public void plantTree(Tree tree) {
        trees.add(tree);
    }
}
@Entity
public class Tree {
    @Id @GeneratedValue
    private Long id;
    private String name;
    @ManyToOne
    Forest forest;
    ...
    public void setForest(Forest forest) {
        this.forest = forest;
        this.forest.plantTree(this);
    }
}
// Transaction 1
// creates and persists a forest...
// ... with 10.000 trees
...
// Transaction 2
Tree tree = new Tree("oak");
Forest forest = em.find(Forest.class, id);
tree.setForest(forest);
em.persist(tree);
```

is the inverse side. Therefore, to save changes in a database, we need to set a right `Forest` reference in a `Tree` instance. While setting the `Forest` instance in a `Tree`, the collection of `Trees` is automatically updated to include the new tree (the invocation of `plantTree`). Such a pattern is widely used and recommended to ensure up-to-date states of objects. However, it results in a significant performance overhead, when combined with *java.util.Set* on the inverse side. In the second transaction, which only adds a new tree and does not access other trees in the forest, Hibernate has to load the entire collection into the main memory.

VI. Antipattern: Lost Collection Proxy on Owning Side

A. Description

The antipattern relates to the assignment of a new collection object to a persistent field, representing the owning side of a one-to-many association. Thus, a collection proxy returned by Hibernate is lost.

In such a case, Hibernate is not able to track what has been changed in a collection and its policy is to re-create the entire collection regardless of the actual modifications. Therefore, even if the elements of the collection have not been changed, Hibernate issues a delete to remove the associations from the association table and then performs as many inserts as there are elements in the collection.

B. Consequences

The performance consequences of a lost proxy on the owning side are as follows:

- There is an increased workload on the database engine. There are unnecessary database operations performed. Hibernate re-creates an entire collection, performing one delete to clear the collection and as many inserts as there are elements in the collection. Such a re-creation results in suboptimal performance due to the operations on data which actually have not been changed.

C. Solution

The recommended solution to the antipattern is to operate on collection objects returned by Hibernate as in most cases it is a much more efficient approach. However, it might be performance-wise to re-create the entire collection in cases where most elements of the collection have been removed. On the other hand, it is one of the places where Hibernate could apply a smarter policy, especially as it has all required data available.

D. Sample Code

Listing 4 presents an example of a lost (according to Hibernate) collection proxy on the owning side. The example consists of two persistent entities: `Hydra` and `Head`. `Hydra` is a mythical creature that re-grows three heads in place of one head cut off. In order to model this feature, we need to provide strict encapsulation of heads. Therefore, `getHeads` returns an unmodifiable wrapper over the mutable collection of heads. In the first transaction, we create and persist a `Hydra` instance with three `Heads`. In the second transaction, we simply read the previously stored instance. It turns out that for this piece of code Hibernate executes two selects, one delete and three inserts, even though the code is purely read-only. The problem lies in the way Hibernate checks whether or not a property is dirty during the commit of a transaction. In order to check the dirtiness of a collection, Hibernate compares the references on the actual collection and the proxy originally loaded. Unfortunately, in our example Hibernate uses `getHeads` method to access the collection (due to property access mapping). The method returns an unmodifiable wrapper over the original proxy returned by Hibernate. Obviously, it returns a different Java object that the original one loaded by Hibernate. Thus, Hibernate decides that the collection has been changed and re-creates the entire collection.

Listing 5 presents a more straightforward example of a lost collection proxy on the owning side. Again we implement two

Listing 4. The example 1 of a lost collection proxy on the owning side.

```
@Entity
public class Hydra {
  private Long id;
  private List<Head> heads =
    new ArrayList<Head>();
  ...
  @Id @GeneratedValue
  public Long getId() {...}
  protected void setId() {...}
  @OneToMany(cascade=CascadeType.ALL)
  public List<Head> getHeads() {
    return Collections.
          unmodifiableList(heads);
  }
  protected void
      setHeads(List<Head> heads)
  {...}
}

// Transaction 1
// creates and persists the hydra...
// ...with 3 heads
...
// Transaction 2
Hydra found = em.find(Hydra.class, id);
```

Listing 5. The example 2 of a lost collection proxy on the owning side.

```
@Entity
public class Hydra {
  @Id @GeneratedValue
  private Long id;
  @OneToMany(cascade=CascadeType.ALL)
  private List<Head> heads =
    new ArrayList<Head>();
  ...
  public Long getId() {...}
  protected void setId() {...}
  public List<Head> getHeads() {
      return heads;
  }
  public void setHeads(List<Head> heads) {
    this.heads = heads;
  }
}

// Transaction 1
// creates and persists the hydra...
// ...with 3 heads
...
// Transaction 2
Hydra found = em.find(Hydra.class, id);
List<Head> currentHeads =
  new ArrayList<Head>(found.getHeads());
found.setHeads(currentHeads);
```

persistent classes: `Hydra` and `Head`. However, we do not introduce strict encapsulation. Instead we implement simple getters and setters for all fields. In the second transaction, we create a new collection containing the current heads of our `Hydra` instance. In terms of our business model, nothing has changed — the heads are the same heads as originally loaded. However, Hibernate observes a different collection reference and applies the policy of re-creation of the entire collection.

VII. Antipattern: One-By-One Processing of Collection

A. Description

The antipattern refers to a sequential processing of a persistent collection, i.e., a piece of code iterates over the collection and for each element in a collection, it may perform a database operation.

Best practices of database programming highlight the need to operate on the sets of records instead of single records. While SQL provides the means to such a paradigm switch in programming, Java is an object-oriented language without support to relational algebra. Therefore, it is a common approach in the Java world to iterate over persistent collections and process their elements one-by-one. Such an approach often leads to a significant performance overhead, considering the number of database round-trips and the volume of data passed between a database and an application.

B. Consequences

The performance consequences of one-by-one processing of a persistent collection are as follows:

- A high number of database operations is executed. It is proportional to the size of the collection.
- RDBMS engine is used ineffectively.
- Network latency can sum up to a significant performance overhead.

C. Solution

The solution to this antipattern is to utilize the capabilities of a relational database by the usage of bulk statements and aggregate functions. Frequently it requires a different object model.

D. Sample Code

Listing 6 presents an example of a one-by-one processing of a collection. The example continues the previous examples consisting of `Forest` and `Tree`. Here, in the second transaction we want to delete the entire `Forest`. A simple remove causes a constraint violation exception since there are trees associated with the forest to be removed. Therefore, we need to unbind the trees first. Unfortunately, in Hibernate there is no other way to do this than setting the `Forest` reference in each `Tree` instance to `null`. In our example it results in

Listing 6. The example of a one by one processing of a collection.

```
@Entity
public class Forest {
  @Id @GeneratedValue
  private Long id;
  @OneToMany (mappedBy = "forest")
  Set<Tree> trees = new HashSet<Tree>();
  ...
  public void plantTree(Tree tree) {
    trees.add(tree);
  }
}
@Entity
public class Tree {
  @Id @GeneratedValue
  private Long id;
  private String name;
  @ManyToOne
  Forest forest;
  ...
}
// Transaction 1
// creates and persists a forest...
// ... with 10.000 trees
...
// Transaction 2
Tree tree = new Tree("oak");
Forest forest = em.find(Forest.class, id);
for (Tree tree : forest.getTrees()) {
  tree.setForest(null);
}
em.remove(forest);
```

10 000 updates. To fix this inefficiency in Hibernate, we need to change the object model and introduce an explicit class representing the association.

VIII. Conclusion

In this paper, we presented five performance antipatterns related to one-to-many associations in Hibernate. Each antipattern consists of the description of a problem, performance consequences and the recommended solution, as well as a sample code to better illustrate the problem. The identified antipatterns introduce a significant performance overhead in terms of the number of SQL statements executed as well as the number of objects loaded into the main memory. These are two critical factors that have serious impact on the performance of applications. The number of SQL statements executed directly increases the load on the database engine. Usually it also introduces an additional performance overhead due to the network latency which is important in modern multi-tiered applications, where applications and databases are located in different servers/tiers. High memory consumption has indirect impact on the performance as it usually leads to more frequent garbage collection or even page swaps.

The presented antipatterns show that the usage of Hibernate is not as simple as it looks at first glance. Even plain use cases can significantly decrease the performance of an application. The antipatterns explain how to use Hibernate efficiently and what policies should be improved in Hibernate in order to shorten the execution time.

4th Workshop on Advances in Programming Languages

PROGRAMMING languages are programmers' most basic tools. With appropriate programming languages one can drastically reduce the cost of building new applications as well as maintaining existing ones. In the last decades there have been many advances in programming languages technology in traditional programming paradigms such as functional, logic, and object-oriented programming, as well as the development of new paradigms such as aspect-oriented programming. The main driving force was and will be to better express programmers' ideas. Therefore, research in programming languages is an endless activity and the core of computer science. New language features, new programming paradigms, and better compile-time and run-time mechanisms can be foreseen in the future.

The aims of this event is to provide a forum for exchange of ideas and experience in topics concerned with programming languages and systems. Original papers and implementation reports are invited in all areas of programming languages.

Topics

Major topics of interest include but are not limited to the following:

- Automata theory and applications
- Compiling techniques
- Domain-specific languages
- Formal semantics and syntax
- Generative and generic programming
- Grammarware and grammar based systems
- Knowledge engineering languages, integration of knowledge engineering and software engineering
- Languages and tools for trustworthy computing
- Language theory and applications
- Language concepts, design and implementation
- Markup languages (XML)
- Metamodeling and modeling languages
- Model-driven engineering languages and systems
- Practical experiences with programming languages
- Program analysis, optimization and verification
- Program generation and transformation
- Programming paradigms (aspect-oriented, functional, logic, object-oriented, etc.)
- Programming tools and environments
- Proof theory for programs
- Specification languages
- Type systems
- Virtual machines and just-in-time compilation
- Visual programming languages

Magnify – a new tool for software visualization

Cezary Bartoszuk, Grzegorz Timoszuk, Robert Dąbrowski, Krzysztof Stencel
Institute of Informatics
University of Warsaw
Banacha 2, 02-097 Warsaw, Poland

***Abstract*—Modern software systems are inherently complex. Their maintenance is hardly possible without precise up-to-date documentation. It is often tricky to document dependencies among software components by only looking at the raw source code. We address these issues by researching new software analysis and visualization tools.**

In this paper we focus on software visualisation. *Magnify* is our new tool that performs static analysis and visualization of software. It parses the source code, identifies dependencies between code units and records all the collected information in a repository based on a language-independent graph-based data model. Nodes of the graph correspond to program entities of disparate granularity: methods, classes, packages etc. Edges represent dependencies and hierarchical structure. We use colours to reflect the quality, sizes to display the importance of artefacts, density of connections to portray the coupling. This kind of visualization gives bird's-eye view of the source code. It is always up to date, since the tool generates it automatically from the current revision of software. In this paper we discuss the design of the tool and present visualizations of sample open-source Java projects of various sizes.

I. Introduction

THE complexity of software systems and their development processes have rapidly grown in recent years. In numerous companies the high level structure of dependencies between software components is kept only in the heads of developers. This makes the development process fragile, since teams composed of humans are inherently volatile. Therefore, development teams need methods and tools to inspect *current* states of complex systems and their fragments.

In this paper we describe a software visualization tool *Magnify* that caters for these needs. It shows top level views of software entities of disparate granularities: systems, components, modules, classes etc. These views contain graphic presentation of the importance, the quality and the coupling of subcomponents.

Given a source code bundle *Magnify* parses and analyzes it in order to create a graph-based model [1]. This model is then persisted in the architecture warehouse that provides data for software intelligence [2]. One of its methods is visualization. *Magnify* reads the data from the warehouse and produces a graph laid out on a plain. Nodes of the graph are entities (classes, packages etc.) of the provided source code.

The size of a node reflects the importance of the corresponding artefact. In the current version of *Magnify* we use PageRank to assess importance. The colour of a node represents the quality of the corresponding piece of code. In the examples presented in this paper, we use the numbers of lines per class. Any software metrics accompanied with threshold values for green and red can be employed.

Edges represent relationships of two kinds: structural inclusion and dependency.

The paper is organised as follows. In Section II we address the related work. In Section III we recall the theoretical foundations for our research. In Section IV we describe the design of *Magnify* and possible extension points in its architecture. In Section V we present visualizations of sample open-source Java projects of various sizes. Section VI concludes.

II. Motivation

The idea described in this paper has been contributed to by several existing approaches and practices.

A unified approach to software systems and software processes has already been presented in [3]. Software systems were perceived as large, complex and intangible objects developed without a suitably visible, detailed and formal descriptions of how to proceed. It was suggested that software process should be included in software project as parts of programs with explicitly stated descriptions; software architect should communicate with developers, customers and other managers through software process programs indicating steps that are to be taken in order to achieve product development or evolution goals.

Multiple graph-based models have been proposed to reflect architectural facets, e.g. to represent architectural decisions and changes [4], to discover implicit knowledge from architecture change logs [5] or support architecture analysis and tracing [6]. Graph-based models have also become helpful in UML model transformations, especially in model driven development (MDD) [7].

Visualization of software architecture has been a research goal for years. The tools like Bauhaus [8], Source Viewer 3D [9], Gevol [10], JIVE [11], evolution radar [12], code_smarm [13] and StarGate [14] are interesting attempts in visualization.

However none of them simultaneously supports aggregation (e.g. package views), drill-down, picturing the code quality and dependencies. Moreover, all of them are significantly more complex when compared to our proposal. In our opinion noteworthy better effects can be achieved with simpler facilities. Movies and the third dimension are not necessary to quickly assess the quality, robustness and resilience of an architecture.

978-83-60810-53-8/$25.00

III. Theoretical foundations

A. Model

We recall the theoretical model [1] for unified representation of architectural knowledge. Definition of the model is based on directed labelled multigraph. According to the model, the *software architecture graph* is an ordered triple $(\mathcal{V}, \mathcal{L}, \mathcal{E})$ where $\mathcal{V}$ is the set of vertices that reflect all artefacts created during a software project, $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{L} \times \mathcal{V}$ is the set of directed edges that represent dependencies (relations) among those artefacts, and $\mathcal{L}$ is the set of labels which qualify the artefacts and their dependencies.

Example 1. Each artefact can be described by a set of labels. A method can be described by labels showing that it is a part of project source code (*code*); written in Java (*java*); its revision is 456 (*r:456*); it is *abstract* and *public*. Edges are directed and may have multiple labels as well, e.g.: a package *contains* a class; a method *calls* another method.

The transformations and metrics recalled below give the foundation for the layer of *software intelligence* tools [2].

B. Transformations

Our graph model is general and scalable, fits both small and huge projects [15], and has been tested in practice [16].

The tests proved that in case of a large project its graph model is too complex to be human-tractable as a whole. This has confirmed that transformations and views of the graph model are a must.

Example 2. For a given software graph $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathcal{L})$ and a subset of its labels $\mathcal{L}' \subseteq \mathcal{L}$, its *filter* is a transformation $\mathcal{G}|_{\mathcal{L}'} = (\mathcal{V}', \mathcal{E}', \mathcal{L}')$ where $\mathcal{V}'$ and $\mathcal{E}'$ have a label in $\mathcal{L}'$.

C. Metrics

For complex projects their quantitative evaluation is a must. The graph-based approach is in line with best practices for metrics [17], [18], allows for easy translation of existing metrics into graph terms [19], ensures they can be efficiently calculated using graph algorithms. It also allows designing new metrics that combine both software system and software process artefacts [20].

Example 3. For a given software graph $\mathcal{G} = (\mathcal{V}, \mathcal{L}, \mathcal{E})$, its *metric* is a transformation $m : \mathcal{G} \mapsto \mathcal{R}$ where $\mathcal{R}$ denotes real numbers and m can be effectively calculated by a graph algorithm on G.

IV. Magnify

We implemented *Magnify* as a server system, based on a graph database, with web front-end written in Scala. *Magnify* functionality allows loading source code bundles, analyzing them and displaying the resulting graphs of software components. Figure 1 shows a sample of *Magnify*'s GUI.

The analytical backend is composed of three main modules: the parser, the graph storage and the analysis engine.

The parser is the only part of *Magnify* that must be programming language specific. Its responsibility is to transform

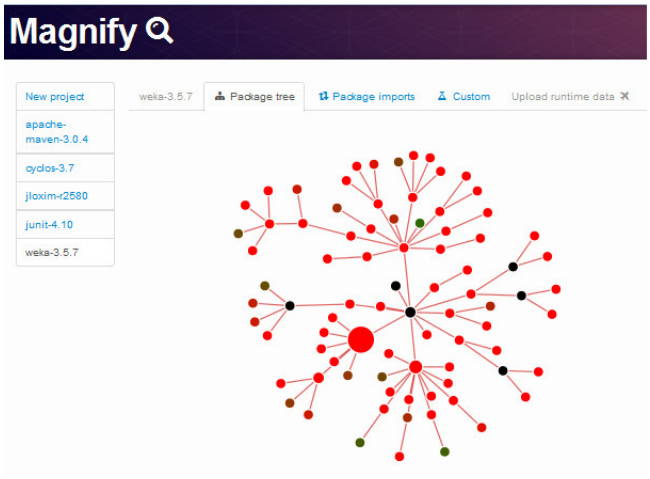

Fig. 1. *Magnify* functionality - main view

contents of a source code bundle into an abstract software graph. This graph is then persisted. Currently the implementation contains a Java 5 parser based on the `javaparser` library. The graph storage is based on Tinkerpop Blueprints specification. When the source code is converted and stored in the abstract language-agnostic form, the analysis engine will run. The implementation computes PageRank of every node in the graph and code quality metrics for classes. These metrics are then escalated to the package level. Figure 2 shows the referential deployment diagram of *Magnify*.

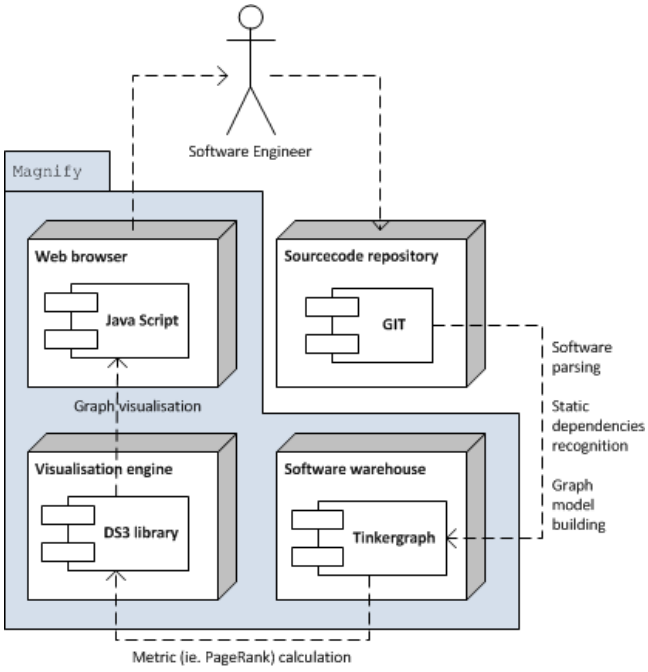

Fig. 2. General architecture of *Magnify*

The architecture of *Magnify* is flexible enough to replace any of its components and add new constituents. As noted

above, we can replace the repository with any graph database that conforms to Blueprints API. New data providers can be added, like parsers for more programming languages, runtime profilers, analyzers of version control systems, and analyzers of web data (e.g. forum discussions).

V. Evaluation

In this Section we show sample visualizations produced by *Magnify*. We have chosen five open-source projects that significantly vary in size and quality. All of them have a noteworthy number of users. They are well adopted by the software development community.

These are Cyclos, Play, Spring and Karaf. For each system we present its top-level visualization created by *Magnify*. Then, we analyze the resulting images and enumerate conclusions that can be drawn from them.

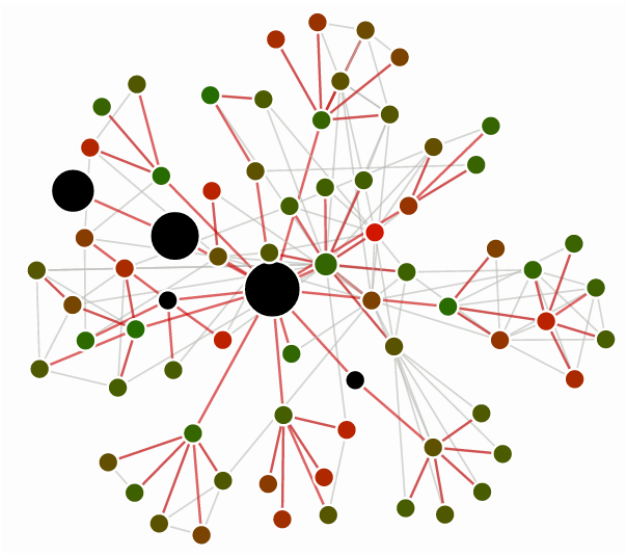

Fig. 3. The visualization of Spring context 3.2.2 produced by *Magnify*

A. Spring context 3.2.2

Spring is one of the most popular enterprise application frameworks in the Java community. It provides an infrastructure for dependency injection, cache, transactions, data base access and many more. Figure 3 shows the visualization of Spring produced by *Magnify*.

The structure of dependencies implies that Spring is well designed. The graph is notably sparse. The only packages detected as important are empty vendor packages. All the packages that do contain classes are of the same importance. This indicates a well balanced software. Figure 3 contains no brightly red packages. This means that on average the classes are small in most of packages. Thus, the overall quality is satisfactory.

B. Cyclos 3.7

Cyclos is a complete on-line payment system. Figure 4 presents visualization of this system produced by the *Magnify* tool.

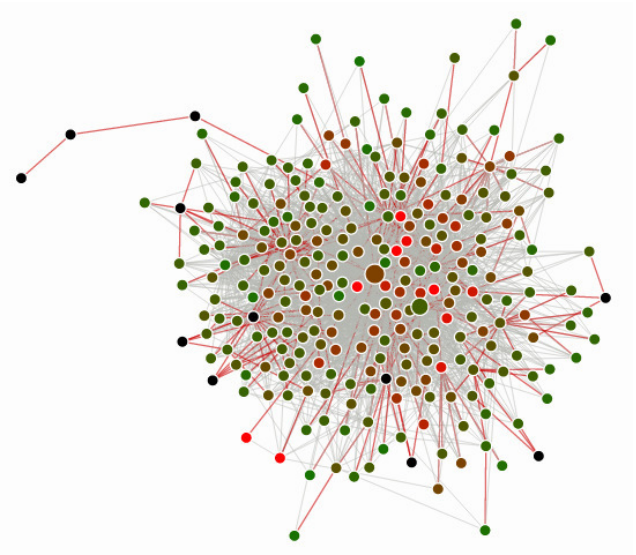

Fig. 4. The visualization of Cyclos 3.7 produced by *Magnify*

Unfortunately, this time the dependency graph is exceptionally dense. The software engineering experience indicates that the development and maintenance of software systems with so tight coupling is difficult, costly and error-prone. On the other hand, Figure 4 shows few packages in which classes are big on average. That means that overall complexity of the classes themselves is acceptable.

Cyclos is a profound example of a system that should be split into orchestrated group of communicating systems. This kind of refactoring will significantly improve the quality of this software. It will also reduce the cost of further development and maintenance.

C. Play 1.2.5

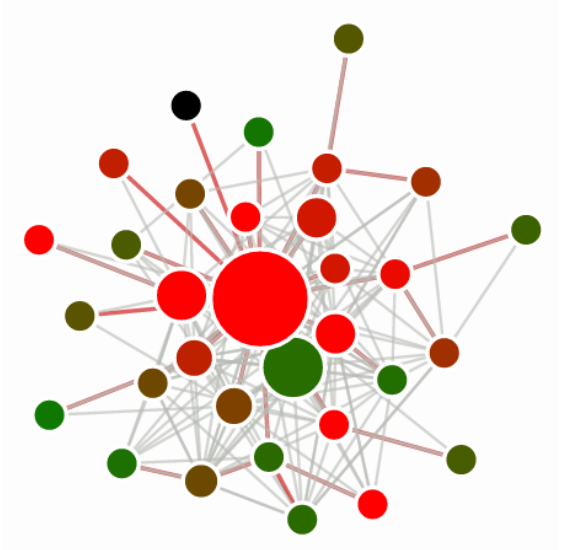

Fig. 5. The visualization of Play 1.2.5 produced by *Magnify*

Play is a popular Scala and Java web framework. Figure 5 shows the visualization of Play using *Magnify*.

It presents a small project with decent amount of dependencies. The flat package structure is typical for dynamic languages. The biggest node corresponds to the project root package `play`. Brightly red packages reveal potentially high complexity of their classes.

D. Apache Karaf 3.0.0 RC1

Apache Karaf is a small OSGi container to deploy various components and applications. Even though it is split into many packages, the number of dependencies is small. Many subtrees of the package hierarchy have only a single dependency on the rest of the system. Thus, Karaf is well packaged.

Figure 6 shows that overall code quality in Karaf is good. There are only a few packages where the average class size is alarming.

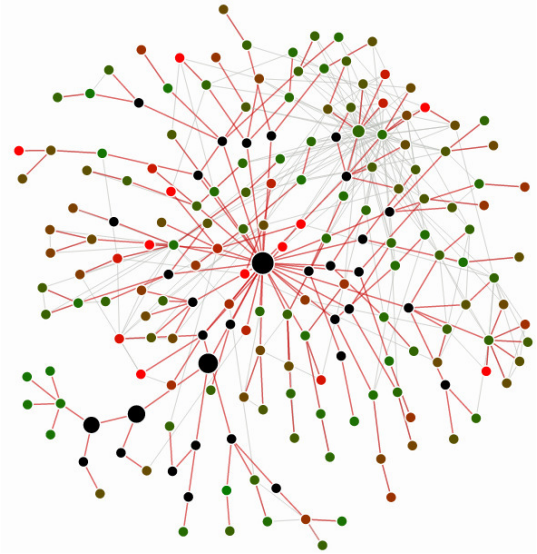

Fig. 6. The visualization of Karaf 3.0.0-RC1 produced by *Magnify*

VI. Conclusion

We follow the research on anayslis and visualisation of software and software process, and promote an approach that avoids separation between software and software process artefacts. We demonstrate that the implementation of such approach is feasible. We implement software intelligence on top of a software warehouse based on our theoretical graph-based model. We execute experiments on open-source Java programs using those tools.

In this paper we presented *Magnify* - a tool that performs static analysis and visualization of software systems. It focuses on relationships between components rather than on their internal structure.

Magnify is a general tool that can adapt other quality metrics and importance estimates. Flexibility of its design allows replacing any of its components and adding new parts. In order to support the analyses for another programming language, we have to add only an appropriate parser. All other facilities (the repository and analytic algorithms) need not be changed.

Promising ideas worth implementing in the near future include: (1) improving the vertex clustering algorithm for module repackaging, (2) gathering the information across revisions and (3) adding metadata stating how packages are split into modules and how these modules depend on each other. This kind of metadata would constitute a specification that can be matched against the source code.

***Abstract*—The conjunction operator can be augmented with temporal constraints to define an arbitrary pattern of events in event stream processing (ESP). However, using temporal constraints to specify patterns can be complex. This research has defined an operator hierarchy, where the top of the hierarchy defines the conjunction operator and the leaves of the hierarchy define more specific semantics associated with a sequence of events. The use of the specialized operators simplifies pattern expression and make the sequence semantics clear. Furthermore, in an experimental study, patterns using operators from the hierarchy outperform patterns expressed using the conjunction operator with temporal constraints in run time performance, further validating the usefulness of the operator hierarchy.**

***Keywords*-event operators; sequence; event processing language; operator semantics;**

I. Introduction

REAL world applications have become increasingly event-driven in nature, focusing on the occurrence or non-occurrence of several activities or their combinations to respond to a situation of interest using event processing systems such as [1], [2]. The situations of interest are encoded as complex event patterns using a specific ESP language, where complex event patterns are specified using event operators and other events. These complex event patterns are matched by the event processing system to detect complex events.

Encodings of event patterns should be able to define a situation in a unique manner. However, existing work [3], [4], [1], [2] defines patterns in an ambiguous way. For example, suppose in a health care application, situations of importance are detected if i) a high temperature is detected after nausea is detected and ii) a high temperature event is followed by a low temperature. Both *i* and *ii* can be defined as sequential occurrences of two events. In these situations, there are several possibilities that can be true of the patterns. For instance, in situation *i*, the nausea event occurs while there is a high temperature. However, in case of *ii*, a high temperature cannot occur at the same time as a low temperature. This example shows that the sequence pattern may have different interpretations. One of the possible solutions to this problem is to use the conjunction operator with relevant temporal constraints to restrict the detection of the event patterns. When an interval-based event is considered, this approach can specify all the possible patterns [5]. However, it is desirable to specify the intended semantics in an explicit way such as by using special operators. For example, rather than expressing a sequential pattern, E_1 followed by E_2 as $AND(E_1, E_2)$ **WHERE** $E_1.t_e < E_2.t_e$, where t_e represents an ending time of event occurrence, it would be intuitive to express the condition as $SEQ(E_1, E_2)$, where the **SEQ** operator explicitly defines the intended meaning.

To address the issues of specification complexity and ambiguous operator interpretation, this research defines an operator hierarchy based upon the conjunction and the sequence operators. The top of the hierarchy defines the conjunction operator. Moving down the hierarchy introduces specialized operators to express more specific situations. Though any pattern defined using the operators from the hierarchy can be expressed as a combination of the conjunction operator and appropriate temporal constraints, the use of specialized operators in defining event patterns makes the pattern specification an easier and more expressive task.

To verify the usefulness of the operators in the operator hierarchy, the operators have been implemented with reference to the conjunction operator implementation and are found to run better than their alternative versions using the conjunction operator with temporal constraints. Moreover, the work in this paper makes the following contributions:

1) Design of operators to incorporate different meanings for the sequence and the conjunction operators.
2) Design of an operator hierarchy defining the relationships pertaining to time intervals using Allen's relations [6].
3) Experimental evaluation of operators from the operator hierarchy to describe usefulness of the newly defined operator hierarchy.

II. Related Work

Past work on event processing, such as Snoop [3], Ode [7], and SAMOS [8] have collectively defined a powerful set of event operators to specify complex event patterns. However, operators such as the sequence and the repetition operators are not consistently defined in these languages. SEL [9] analyzes these event languages and identifies problems with the semantics of the negation, sequence, and repetition operators. The recent languages ([1], [2]) have adopted operators similar to past work on event processing, but have not considered the semantic inconsistency among the definition of event operators as discussed in [9]. Non-overlapping sequence defined in [10]

978-83-60810-53-8/$25.00

is considered to be an immediate sequence (i.e., an event A is immediately followed by B with no event in between), while sequence in [4] considers an arbitrary sequence (i.e., without restrictions on intervening events). These inconsistent definitions of the sequence operator as an overlapping and a non-overlapping sequence is relevant when an event is associated with an interval. The work in [5] defines a generic operator with a temporal constraint list to define all of the possible relations among intervals to remove inconsistency in the definition of event operators. However, the expression of event patterns becomes more complex.

III. Event Specification and Basic Concepts

For any two time intervals $i_1 = [t_1, t_2]$ and $i_2 = [t_3, t_4]$, there are thirteen possible relations defined as Allen's interval relations [6]. When an event e has event time $i = [t_s, t_e]$, e is said to have occurred over the interval i, where the event e started occurring at time point t_s and ended at time point t_e.

TABLE I: Situation Monitoring Event Definition

SON()	Stove is brought to ON state.
SOFF()	Stove is brought to OFF state.
LO()	A lid of a kettle is opened.
LC()	A lid of a kettle is closed.
KP()	A kettle is put on the surface.
IPOUR()	An item is put in the kettle.
T(v)	Regular event to provide temperature inside the kettle with the given value.
IP(items)	**TIMES**(IPOUR(), 3) **WITHIN** 2 MINUTES
KL()	**SEQ**(LO(), IP(items), LC()) **WHERE** IP.items.has({"water","milk","tea leaves"})
TP()	**AND**(SON(), KL(), KP(), T(v)) **WHERE** TEMP.v $\geq$ 100

Let us define a scenario to detect an activity defining the situation that the "tea has been prepared". Table I defines several events that are either observed or produced from the external environment (external events), or are a complex combination of other events (internal events). In Table I, the *T(v)* event is an external event that is generated by a thermometer. Other external events are *SON()*, *SOFF()*, *LO()*, *LC()*, *KP()*, and *IPOUR()*. An internal event is a composition of several external or other internal events. The *IP(items)* event, the *KL()*, and the *TP()* defined in Table I are internal events. The *IP(items)* event occurs when the *IPOUR()* event is detected three times within a 2 minutes window. The *KL()* event occurs with the sequential occurrence of the *LO()*, *IP(items)*, *LC()*, where *items* from the *IP(items)* event has water, milk and tea leaves in it. The *TP()* is represented as a pattern defining the occurrences of four events *SON()*, *KL()*, *KP()*, *T(v)*, where the temperature value is $\geq 100°\mathrm{C}$.

Discussion in later sections will consider events from the situation monitoring application (Table I) and the occurrences of events shown in Figure 1.

IV. Issues and Semantics of Conjunction and Sequence Operators

This section analyzes the semantics of event operators to identify the issues that must be addressed to define the

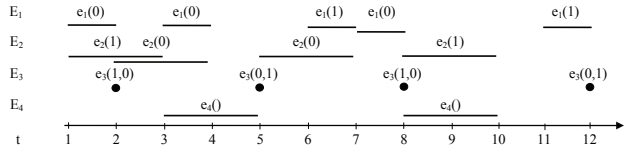

Fig. 1: Example Event Streams

semantics of operators in a clear and consistent way. Work such as that of [3], [4], [1] describes various powerful event constructs that can be categorized into conjunction, disjunction, repetition, negation, and sequence operators. Among different event operators, this work focuses on the semantics of the conjunction and sequence operators with interval-based temporal representation.

Conjunction of events E and F, denoted as *AND*(E, F), occurs when both E and F occur without temporal ordering restrictions. Detection of *AND*(E, F) starts when either E (or F) occurs and ends when F (or E) occurs. In case of interval-based semantics, all thirteen possible relations between interval are valid.

Example: The *TP()* event from Table I is a conjunction of five events *SON()*, *KL()*, *KP()*, *T(v)*, and *SOFF()*. Since the constituent events are combined using the **AND** operator, the *TP()* event occurs when all of the constituent events occur.

The complex event defined by a sequence operator has an implicit temporal constraint on events. A sequence of two events E and F, *SEQ*(E, F), detects the occurrence of an event E followed by the occurrence of the event F. Detection of *SEQ*(E, F) starts with the detection of an event E and ends with the detection of an event F. Such a requirement of event order by a sequence operator imposes temporal restrictions on event occurrences. When events are considered to be point-based, then *SEQ*(E, F) is detected if and only if $E.t < F.t$, where t is the time of event occurrence. If events are interval-based, then *SEQ*(E, F) is detected if and only if $E.[t_1, t_2] < E.[t_3, t_4]$, where $t_1 \leq t_2$ and $t_3 \leq t_4$. With these temporal conditions on event detection, we have two possible conditions: i) $t_2 < t_3$ and ii) $t_2 < t_4$. Though condition ii is included within condition i, the condition i gives the definition of a non-overlapping sequence operator, whereas the condition ii gives the definition of an overlapping sequence operator. In this section, the condition ii is used to define the sequence operation unless otherwise mentioned.

Example: The KL() event is a sequence of *LO()*, *IP(items)*, and *LC()*. The KL() event occurs when all of the constituent events occur with the constraint $LO.[t_s, t_e] < IP.[t_s, t_e] < LC.[t_s, t_e]$.

Using the definition of sequence, *SEQ*(E, F) says, E must occur before F. As discussed in this subsection, there are two possibilities for the sequence operator defining overlapping and non-overlapping sequences. Past work on event processing considers either an overlapping version of a sequence operator or a non-overlapping version. When an overlapping version of a sequence operator is used, then the sequence operator can be used to detect non-overlapping events, but it requires an

explicit temporal condition to specify that the non-overlapping sequence is intended. However, if a non-overlapping sequence is used, it cannot be used to specify an overlapping sequence. One of the solutions to this problem could be the use of the temporal filter on overlapping sequence. However, an application can demand specification of sequences of both kinds and, to make event specification more explicit, a separate operator for non-overlapping sequence may be suitable.

Examples: If only a non-overlapping version is defined, the sequence of events, such as *SEQ(SON(),SOFF())* is intuitively explicit as the stove on event precedes the stove off event. Let us encode the pattern specifying the situation that describes the condition where a kettle loading (*KL()*) process is followed by the detection of an item put (*KP()*) event. In this case, *KL()* can start before the *KP()* event and ends after the *KP()* event. This condition defines the sequence given as *SEQ*(*KP()*, *KL()*), which has the meaning of an overlapping sequence that cannot be encoded using the non-overlapping version.

V. Operator Design

This section addresses the semantic issues discussed in Section IV to design a set of event operators in a way such that each operator has a clear and consistent definition, and the operators are expressible in terms of its intended meaning. While discussing semantics of operators, only the binary operators are considered. One can extend the semantics of binary operators to their n-ary version using the binary semantics. Also, for readability, events are represented using its name only, instead of its schema.

A. Allen's Relations, Sequence, and Conjunction

Allen's 13 relations [6] define all of the possible relations between two intervals when both end points of intervals are fixed. When we have open end point relations, then the disjunction of Allen's relations to capture the desired relation can be complex. Also, the disjunction of Allen's relations or a hierarchical representation of composite relations [11] cannot express pair-wise relations among events due to non-transitivity of some operators such as overlaps [5]. Regardless of difficulty in specifying complex interval patterns, however, Allen's operators are concise constructs for capturing common interval relations. The use of these relations to express event patterns also defines the meaning of the pattern in an expressive manner. For example, the pattern defining the situation that an event E overlaps with an event F, $OVERLAPS(E, F)$ is easier to understand than *AND*(E, F) **WHERE** $E.t_s < F.t_s$ **and** $F.t_s < E.t_e$ **and** $E.t_e < F.t_e$. On the other hand, a pattern expressing the situation such as an event E ends before an event F is easier to understand as *AND*(E, F) **WHERE** $E.t_e < F.t_e$ than the encoding *OR*(*BEFORE*(E, F), $OVERLAPS(E, F)$, $MEETS(E, F)$, $STARTS(E, F)$, $DURING(E, F)$). The paragraphs that follow discuss the use of event operators and the use of temporal constraints in a suitable way to balance between understandability of expression using specific operators and the complexity of specifying the patterns.

Consider the sequence operator (**SEQ**) discussed in Section IV. To be consistent, consider that the semantics of the **SEQ** operator includes overlapping or non-overlapping occurrences of events ordered by end points. Then such a definition will include both interpretations of **SEQ** events from Section IV and this definition of **SEQ** corresponds to the definition of an overlapping sequence from Section IV. When an event pattern seeks only the overlapping sequence or only the non-overlapping sequence, then either a sequence operator with a required temporal restriction can be used to define the restricted sequence, or different operators defined for each condition can be used to specify a restricted sequence. For example, *SEQ*(E, F) **WHERE** $E.t_e < F.t_s$ is the same as Allen's *before* operator. The idea of using temporal constraints with operators or the definition of an equivalent operator defines the hierarchy of sequence operators with respect to Allen's operators. Figure 3 shows the hierarchy of a sequence operator with respect to two different forms of sequence operations along with the relation to Allen's operators. The hierarchy shown in Figure 3 depicts that the sequence operation combines *before*, *meets*, *overlaps*, *starts*, and *during* relations from Allen's relations. Section V-B further analyzes and discusses the sequence hierarchy to define operators.

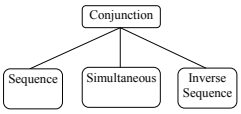

Fig. 2: Conjunction Hierarchy

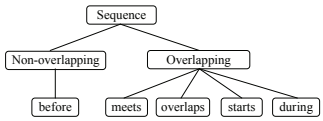

Fig. 3: Sequence Hierarchy

Conjunction (**AND**) is one of the well understood operations in event processing. The use of the conjunction operator does not define temporal restrictions on event occurrences, so the use of temporal constraints with **AND** can define every possible combination of interval relations. This idea of using temporal constraints with the conjunction operator is similar to the work done in [5], where an operator for an interval sequence *iseq*[1] is defined with the temporal constraints to define arbitrary relations on intervals. The sequence operator can be considered as a temporally restricted conjunction operator such that *SEQ*(E, F) = *AND*(E, F) **WHERE** $E.t_e < F.t_e$. Using the relations between the sequence operator and the conjunction operator, the hierarchy shown in Figure 2 can be defined. The conjunction hierarchy shown in Figure 2 defines restrictions of conjunctive combinations of events as sequential combinations, simultaneous combinations, or the inverse of sequential combinations. Section V-B further discusses the conjunction hierarchy to describe the event operators discussed in this work.

B. Operator Hierarchy

Allen's thirteen relations provide a powerful way to express relationships among interval-based events. However, there are

[1]The paper [5] defines it as ISEQ. As this work also defines an operator called **ISEQ** to denote inverse **SEQ**, we use *iseq* to denote an interval sequence operator.

2^{13}-1 (8191) total relations when Allen's relations are combined using disjunctions. When all 8191 relations are treated as operators, then the complexity of pattern specification reduces, although, the large number of event operators to specify an event pattern is undesirable from a language point of view. Further, it is not practical to define all of the operators. To cope with this situation, this section describes an operator hierarchy that defines a small set of event operators as shown in Figure 4.

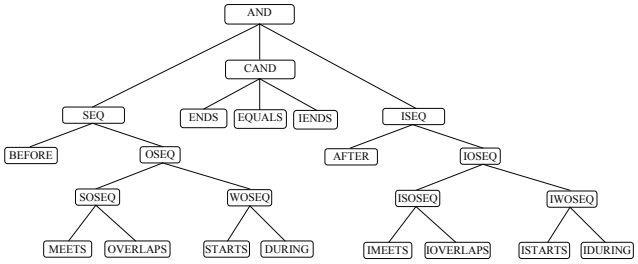

Fig. 4: Operator Hierarchy Defining Conjunction and Sequence

1) Conjunction Operators: Consider the hierarchy shown in Figure 2. The figure shows the trichotomy between two intervals i_1 and i_2 that defines sequence to describe $i_1 < i_2$, simultaneous to describe $i_1 = i_2$, and the inverse sequence to describe $i_1 > i_2$. This trichotomy between intervals considers two events as simultaneous if they end at the same time period. So, the actual relation here is described by a trichotomy between end time-points of two intervals expressed as natural numbers. In other words, if t_{e1} is the end time of the interval i_1 and t_{e2} is the end time of the interval i_2, then $i_1 < i_2$ if and only if $t_{e1} < t_{e2}$, $i_1 = i_2$ if and only if $t_{e1} = t_{e2}$, and $i_1 > i_2$ if and only if $t_{e1} > t_{e2}$. With this idea, the **AND** operator is divided into three different operators **SEQ**, **CAND**, and **ISEQ** as shown in Figure 4. Conceptually, the **AND** operator defines the relation that includes all of Allen's relations, since conjunction has no temporal constraint. The **CAND** operator is meant for concurrent conjunction and, as there are three interval relations specifying the same end time, Figure 4 defines three of Allen's operators, *ends*, *equals*, and *ended by* as **ENDS**, **EQUALS**, and **IENDS**, respectively, as specializations of a concurrent conjunction. Two other operators **SEQ** and **ISEQ** are the inverse of each other and this work does not discuss **ISEQ** in detail as its concepts can be derived from the **SEQ** operator. The hierarchy shown in Figure 4 defines the equivalent event patterns shown in Table II.

Example: In Figure 1, up to time $t = 12$, we can observe that $\mathit{CAND}(E_2, E_4)$ is detected as $\mathit{CAND}^{[8,10]}(E_2, E_4)$. Also notice that the **CAND** pattern is equivalent to the equivalence 3 in Table II, where $\mathit{AND}(E_2, E_4)$ is detected as $\mathit{AND}^{[1,5]}(E_2, E_4)$, $\mathit{AND}^{[2,5]}(E_2, E_4)$, $\mathit{AND}^{[1,10]}(E_2, E_4)$, $\mathit{AND}^{[2,10]}(E_2, E_4)$, $\mathit{AND}^{[5,10]}(E_2, E_4)$, $\mathit{AND}^{[3,7]}(E_2, E_4)$, $\mathit{AND}^{[3,10]}(E_2, E_4)$, and $\mathit{AND}^{[8,10]}(E_2, E_4)$. Similarly other equivalences can be verified.

TABLE II: Equivalent Event Patterns

1)	$\mathit{AND}(E, F)$	$\equiv$	$\mathit{OR}(\mathit{SEQ}(E, F), \mathit{CAND}(E, F), \mathit{ISEQ}(E, F))$
2)	$\mathit{SEQ}(E, F)$	$\equiv$	$\mathit{AND}(E, F)$ **WHERE** $E.t_e < F.t_e$
3)	$\mathit{CAND}(E, F)$	$\equiv$	$\mathit{AND}(E, F)$ **WHERE** $E.t_e = F.t_e$
4)	$\mathit{CAND}(E, F)$	$\equiv$	$\mathit{OR}(\mathit{ENDS}(E, F), \mathit{EQUALS}(E, F), \mathit{IENDS}(E, F))$
5)	$\mathit{ISEQ}(E, F)$	$\equiv$	$\mathit{AND}(E, F)$ **WHERE** $E.t_e > F.t_e$
6)	$\mathit{ENDS}(E, F)$	$\equiv$	$\mathit{CAND}(E, F)$ **WHERE** $E.t_s < F.t_s$
7)	$\mathit{EQUALS}(E, F)$	$\equiv$	$\mathit{CAND}(E, F)$ **WHERE** $E.t_s = F.t_s$
8)	$\mathit{IENDS}(E, F)$	$\equiv$	$\mathit{CAND}(E, F)$ **WHERE** $E.t_s > F.t_s$

2) Sequence Operators: In Figure 3, there are five Allen's relations that are clustered within the hierarchy of the sequence operator with respect to the definition discussed in the previous sections. The other five Allen's relations correspond to the inverse of sequence that can be described similarly as the sequence hierarchy is described. The remaining three Allen relations correspond to concurrent conjunction as discussed in Subsection V-B1. Figure 4 depicts that the five Allen's relations *before*, *meets*, *overlaps*, *starts*, and *during* are categorized into two different groups defining a sequence that does not overlap ($\mathit{BEFORE}(E, F)$ implied by Allen's *before* relations and an overlapping sequence ($\mathit{OSEQ}(E, F)$) implied by the other four relations. The overlapping sequence can be further sub-divided into two groups based upon the relationships between the starting time points of the intervals. For the first division, the sequence of E and F has $E.t_s < F.t_s$ and for the second division $E.t_s \geq F.t_s$. The former sub-division is given the name, strong overlapping sequence ($\mathit{SOSEQ}(E, F)$) where both the start time points and the end time points satisfy the $<$ relation. The later sub-division is understood as a weak overlapping sequence ($\mathit{WOSEQ}(E, F)$), where a start time is strictly not following the $<$ relation. Using the hierarchy shown in Figure 4, the equivalent event patterns for sequence operators can be similarly defined as in Table II, which are omitted due to space constraints. *Example:* In Figure 1, up to time $t = 12$, we can observe that $\mathit{SOSEQ}(E_1, E_2)$ is defined as $\mathit{SOSEQ}^{[1,4]}(E_1, E_2)$ and $\mathit{SOSEQ}^{[7,10]}(E_1, E_2)$ and $\mathit{WOSEQ}(E_1, E_2)$ is defined as $\mathit{WOSEQ}^{[1,3]}(E_1, E_2)$. With this, $\mathit{OSEQ}(E_1, E_2)$ is detected as one of the **SOSEQ** or the **WOSEQ** pattern is detected that verifies the equivalence: $\mathit{OSEQ}(E_1, E_2) \equiv \mathit{SOSEQ}(E_1, E_2)$ *OR* $\mathit{WOSEQ}(E_1, E_2)$.

VI. Experiments and Results

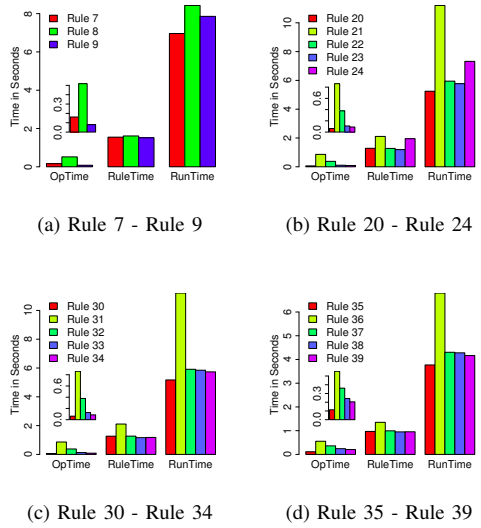
A. Experimental Setup

The experiments were conducted with 12 different pattern groups having equivalent patterns corresponding to each operator from the hierarchy with the implementation of the **AND** operator and the operators from subtrees rooted at **SEQ** and **CAND** in Figure 4. Table III shows examples of two pattern groups, where the first group has three equivalent patterns defined for the **ENDS** operator (Rule 7 - Rule 9) and the second group has five equivalent patterns defined for the **OVERLAPS** operator (Rule 35 - Rule 39). For space reasons, discussion of all the groups with equivalent patterns are omitted from this paper.

TABLE III: Examples of Equivalent Pattern Groups

No.	Pattern
7	$ENDS(E_4(), E_2())$
8	$AND(E_4(), E_2())$ **WHERE** $E_4.t_e = E_2.t_e \wedge E_4.t_s > E_2.t_s$
9	$CAND(E_4(), E_2())$ **WHERE** $E_4.t_s > E_2.t_s$
35	$OVERLAPS(E_5(), E_2())$;
36	$AND(E_5(), E_2())$ **WHERE** $E_5.t_s < E_2.t_s \wedge E_2.t_s < E_5.t_e \wedge E_5.t_e < E_2.t_e$
37	$SEQ(E_5(), E_2())$ **WHERE** $E_5.t_s < E_2.t_s \wedge E_2.t_s < E_5.t_e$
38	$OSEQ(E_5(), E_2())$ **WHERE** $E_5.t_s < E_2.t_s \wedge E_2.t_s < E_5.t_e$
38	$SOSEQ(E_5(), E_2())$ **WHERE** $E_2.t_s < E_5.t_e$

Each pattern was run 10 times for an episode of 3000 time units. For each run, the total time taken by all operators (OpTime), the total time taken by the rule processor for processing a rule after an event to be processed has been identified by event processor (RuleTime), and the total time taken by the event processor (RunTime) were recorded.



(a) Rule 7 - Rule 9 (b) Rule 20 - Rule 24

(c) Rule 30 - Rule 34 (d) Rule 35 - Rule 39

Fig. 5: Experimental Results of Run-Time Performance of Operators

B. Experimental Results

Figure 5 shows the comparisons of run-time for four different pattern groups. In each sub-figure, the first group of bars shows the OpTime, the second group of bars shows the RuleTime, and the third group of bars depicts the RunTime. Notice that each graph in Figure 5 has a graph in an inset to show the magnified form of the OPTime. In all of the graphs and all of the bar groups, the first bar shows the running time for the pattern using the operators designed in this work. Similarly, the second is associated with the equivalent pattern using the **AND** operator with temporal constraints. Other bars represent equivalent patterns, as discussed in Section V, using the parent operator with the temporal constraints, or the use of disjunction of the immediate children operators (See Figure 4).

From the experiments with run-time performance, the following results about the event operators can be observed:

a) 1: The RunTime for patterns defined using the operators from the operator hierarchy is minimum compared to all other alternatives at the higher levels of the hierarchy due to the filtering of incoming events prior to processing them (except for the **ENDS** operator), while an alternative scheme does the post-processing of incoming events.

b) 2: The RuleTime is better than other alternatives for the patterns using the operator set defined in this work, except for some patterns with the graphs shown in Figure 5.

a The graph in the sub-figure 5a shows that the pattern using the **ENDS** operator (Rule 7) takes more time to process the rule than the pattern defined using the **CAND** operator (third bar - sub-figure 5a – Rule 9). This is the direct consequence of processing the event buffer required for the **ENDS** operator and filtering the events after the buffer management. Whereas, Rule 9 detection does not maintain a buffer and events are filtered prior to the detection process.

b The RuleTime for the pattern using the **SOSEQ** operator (sub-figure 5b, first bar – Rule 20) is greater than the pattern using the **OSEQ** operator with temporal constraints (fourth bar – Rule 23). Though Rule 20 spends less time in processing event operators, Rule 20 uses expensive operations such as pattern duplication to manage partial patterns. This makes the RuleTime for Rule 20 greater than Rule 23. In a similar manner, the RuleTime for the patterns using the **MEETS** operator, represented by the first bar (Rule 30) in the sub-figure 5c is higher than the pattern using the **OSEQ** operator (fourth bar – Rule 33) with temporal constraints and the pattern using the **SOSEQ** operator (fifth bar - Rule 34) with temporal constraints. Also, Rule 35 using the **OVERLAPS** operator (first bar – sub-figure 5d) has a RuleTime greater than Rule 38 (fourth bar) using the **OSEQ** operator with temporal constraints and Rule 39 (fifth bar) using the **SOSEQ** operator with constraints.

c) 3: The OpTime is better for the patterns using the operators discussed in this work than other alternative representations for all the groups except for pattern using the **ENDS** operator (Figure 5a- Rule 7). For reasons discussed above, in case of the **ENDS** operator's buffer management and post processing filtering of events, Rule 9 runs faster than Rule 7.

d) 4: Processing with use of the new set of operators always runs faster than the use of the **AND** operator with temporal constraints for all cases of run-time comparisons.

e) 5: When a complex pattern is defined by the temporal constraints among different groups, then it is appropriate to define them using the closest upper level operator with temporal constraints or the disjunction of different operators. This result is seen from the run time comparisons of patterns shown in the graphs represented by the third and beyond bars.

As a conclusion, with the analysis of the run time results discussed above, the set of operators from the operator hierarchy are performing better than using other alternative approaches

that use parent operators from the hierarchy with additional temporal constraints or the disjunction of the children operators from the operator hierarchy in terms of total running time.

VII. Conclusions

The work in this paper has identified ambiguities in the definition of event operators in current event processing languages. The conjunction operator and its relationship with the sequence operator is used to define several possible sequential operations using the idea of Allen's interval relations and a relation hierarchy. The definition of the operator hierarchy defines how an event operator should be selected to achieve the required semantics, making the event specification semantically clear. All the operators discussed in this paper were evaluated by comparing the run-time performance. The experimental results showed that the new set of operators performs better than other alternative approaches on run-time.

There are several possible future research directions. The repetition operator is one of the powerful constructs in event pattern specification. Current event processing systems, however, define the repetition operator in an incomplete way. For example, if one specifies five occurrences of an event E, is it that we are expecting sequential repetition over the time (semantics of **SEQ**) or that the repetition does not have any temporal constraints (semantics of **AND**)? Other issues related to the definition of event operators, such as event time computation and event detection have not been addressed in this work and are left as future work.

***Abstract*—Our research is focused on the simplification of parallel programming for distributed memory systems. Our overall goal is to build a unifying framework for creating, debugging, profiling and verifying parallel applications. The key aspect is a visual model inspired by Colored Petri Nets. In this paper, we will present how to use the visual model for debugging and profiling as well. The presented ideas are integrated into our open source tool Kaira.**

I. Introduction

PARALLEL computers with distributed memory have recently become more and more available. A lot of people can participate in developing software for them, but there are well-known difficulties of parallel programming. Therefore for many non-experts in the area of parallel computing (even if they are experienced sequential programmers), it can be difficult to make their programs run in parallel on a cluster computer. The industrial standard for programming applications in the area of distributed memory systems is *Message Passing Interface* (MPI)[1]. It represents a quite low-level interface. There are tools like *Unified Parallel C*[2] that simplify creating parallel applications, but the complexity of their development lies also in other supportive activities. Therefore, even an experienced sequential programmer can spend a lot of time learning a new set of tools for debugging, profiling, etc.

The overall goal of our research is to reduce complexity in parallel programming. We want to build a unified prototyping framework for creating, debugging, profiling and formally verifying parallel applications, where a user can implement and experiment with his/her ideas in a short time, create a real running program and verify its performance and scalability. The central role in our approach is a visual programming language (based on Petri nets) that we use for modeling developed applications. In this paper, we present how to use the same model for debugging and profiling. The presented ideas are implemented in Kaira[3], a tool that we are developing.

II. Tool Kaira

This section serves as an overview for our tool Kaira; for more details see [1], [2]. Our goal is to simplify the development of MPI parallel applications and create an environment where all activities are unified under one concept.

The key aspect of our tool is the usage of a visual model. In the first place, we have chosen the visual model to obtain an easy and clear way how to describe and expose parallel behavior of applications. The other reason is that a distributed state of the application can be shown through such visual model. The representation of an inner-state of distributed applications by a proper visual model can be more convenient than traditional ways like stack-traces of processes and memory watches. With this feature, we can provide visual simulations where the user can observe a behavior of developed applications. It can be used for incomplete applications from an early stage of the development. In a common way of developing MPI programs, it often takes a long time to get the developed application into a state where its behavior can be observed. In context of this paper, the visual model is also useful for debugging and a performance analysis as will be demonstrated later.

On the other hand, we do *not* want to create applications completely through the visual programming. Sequential parts of the developed application are written in the standard programming language (C++) and combined with the visual model that catches *parallel aspects* and *communication*. We want to avoid huge unclear visual diagrams; therefore, we visually represent only what is considered as "hard" in parallel programming. Ordinary sequential codes are written in a textual language. Moreover, this design allows for easy integration of existing C++ codes and libraries.

It is important to mention that our tool is *not* an automatic parallelization tool. Kaira does not discover parallelisms in applications. The user has to explicitly define them, but they are defined in a high-level way and the tool derives implementation details.

Semantics of our visual language is based on Coloured Petri nets (CPNs)[3]. Petri nets is a formalism for the description of parallel processes. They also provide well-established terminology, a natural visual representation for visual editing

978-83-60810-53-8/$25.00

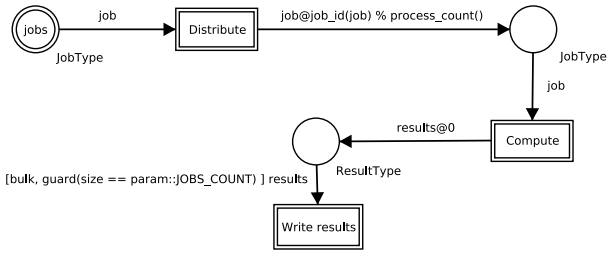

Fig. 1. The example model

of models and their simulations. Modeling tool *CPN Tools*[4] was also the great inspiration for us (especially how to visualize the model).

To demonstrate how our model works, let us consider the model in Figure 1. It presents a problem where some jobs are distributed across computing nodes and results are sent back to process 0. When all the results arrive, they are written into a file. Circles (*places* in terminology of Petri nets) represent memory spaces. Boxes (*transitions*) represent actions. Arcs run from places to transition (*input arcs*) or from transition to places (*output arcs*). The places contain values (*tokens*). Input arcs specify what tokens a transition needs to be *enabled*. An enabled transition can be executed. When a transition is executed, it takes tokens from places according to input arcs. After finishing the computation of the transition, new tokens are placed into places according to output arcs. In CPNs places store tokens as multisets, in our approach we use queues.

A double border around of a transition means that there is a C++ function inside and it is executed whenever the transition is fired. A double border of a place indicates an associated C++ function creating the place's initial content. Arcs' inscriptions use C++ enriched by several simple constructions. A computation described by this model runs on every process. Tokens can be transferred between processes by expressions after "@" symbol on output arcs.

As a more advance example, we use the heat flow problem on a cylinder. We will use a version of this problem where the body is discretized by a grid depicted in Figure 2. The implementation of this problem in Kaira is depicted in Figure 3. The transition *Compute* executes single iteration of the algorithm. It takes a process' part of the grid and two rows, one from neighbor above and one from below. It updates the grid and sends top and bottom rows to neighbors. When the limit of iterations is reached then the results are sent to process 0 where they are written. The init area (depicted as the blue rectangle) is used to set up initial values of places not only on process 0 but over specified processes (all processes in our case). The measurements of this program and a comparison to the sequential version are part of Section V.

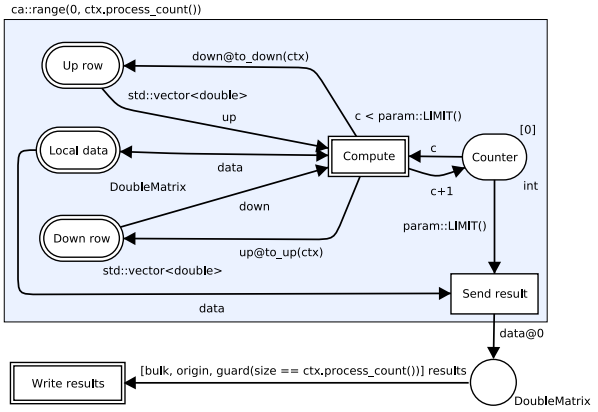

Fig. 3. The implementation of the heat flow problem in Kaira

III. Simulations and records of generated applications

In this section, we will introduce two crucial features: *simulations* and *tracing* of generated applications. Both can be used for debugging and the latter for profiling. Later we will describe two other features and we will also discuss the drawbacks of our approach.

A. Simulations

Besides generating standalone parallel applications from the model, the user can also run the developed application in the simulator. The main task of the simulator is to expose an inner state and it allows for controlling a run of the generated application. The inner state is shown in the form of labels over the original model (see Figure 4). The three types of information are depicted:

- Tokens in place (The state of memory)
- Running transitions (The state of execution)

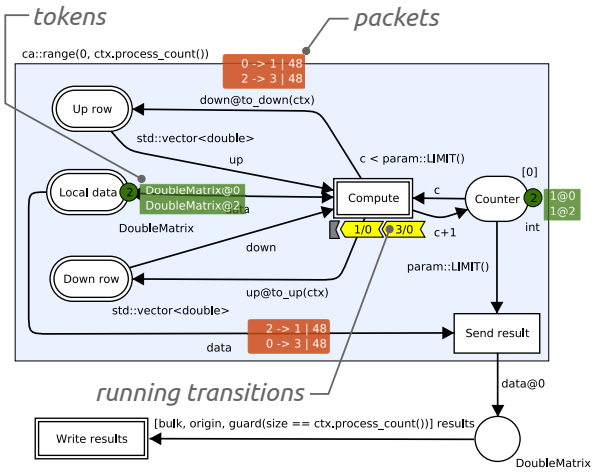

Fig. 4. The model in the simulator

- Packets transported between nodes (The state of the communication environment)

It completely describes a distributed state of the application. The user can control the behavior of the application by the three basic actions:

- Start an enabled transition
- Finish a running transition.
- Receive a packet from a network.

By executing these three types of actions, the application can be brought to any reachable state. The model naturally hides irrelevant states during sequential computations and only aspects important to parallel execution are visible and controllable.

This approach also gives us the possibility to observe the behavior of the application in a very early state of the development without any additional debugging infrastructure. For example, we can see which data are sent to another process even if there is no implementation of the receiving part.

The user has complete well-formed control of the application in the simulator; therefore, the application can be put into an interesting state (and the user can observe the consequences) even if the application rarely reaches such state.

B. Tracing

An application developed in Kaira can be generated in the tracing mode, where activities of a run of the application are recorded into a *tracelog*. When the application finishes its run, the tracelog can be loaded back into Kaira and used for the *visual replay* or for statistical summaries. Generally, issues with such post-mortem analysis can be categorized into these basic groups: *selection what to measure*, *instrumentation* and *presentation of results*. Such tracelogs can be useful both for profiling and debugging.

In the case of debugging, we usually want to collect detailed information of the run for the reconstruction of the cause of the problem. In the case of profiling, we want to discover performance issues and therefore need to measure a run with time characteristics as close as possible to real runs of the application. But the measurement itself creates an overhead that devalues the gathered information about performance. Therefore, in both cases, it is important to specify what to store in the tracelog. In common profilers, specifications of measurements are usually implemented as a list of functions that we want to measure/filter out. But it can be a non-trivial task to assemble such a list, especially in the case when we use some third-party libraries with an unclear purpose to the user. It often needs some experience to recognize what can be safely thrown away.

In Kaira, the user specifies what is measured in terms of places and transitions. It is done just by placing labels in a model (Figure 6). The tracing of transitions enables the recording of information about their execution. The tracing of places enables the recording of information about tokens that go through them. The user can easily control what to measure and it is obvious what information will be gained or lost after switching on or off each setting. Moreover, our approach also allows for simply enriching the model by more detailed tracing. Places and transitions can trace additional data. It is implemented as connecting functions to places and transitions.

The usage of this feature is demonstrated in the experiment in Section V. The experiments also demonstrate tracelog sizes so even if we trace all transitions and names of all tokens in places (that is useful for debugging), sizes of tracelogs are usually manageable. The recording of high-level information from the perspective of our visual model is far from recording every function call in the program.

The second task is the *instrumentation*, i.e. putting the measuring code inside the application. In our case, Kaira can automatically place the measuring codes during the process of generation of the parallel application. Parallel and communication parts are generated from the model, therefore we know where are interesting places where to put measuring codes. By this approach, we can obtain a traced version of an application that does not depend on the complier or computer architecture. In contrast to a standard profiler or debugger for generic applications, we do not have to deal with a machine code or manual instrumentation.

As we already said, the results are presented to the user in the form of a visual replay or as statistical summaries. In replay, the data stored in tracelog are shown in the same way as in the simulator, thus as the original model with tokens in places, running transitions and packets on the way (Figure 5). The user can jump to any state in the recorded application. Our tool also provides statistical summaries and standard charts like a normal profiler, and additionally, information is presented using the terms of the model. For example, the utilization of transitions (Figure 10), the numbers of tokens in places, etc.

C. Combination of simulation and recording

The useful feature for debugging parallel applications is a technique usually called *deterministic replay* [4]. Existing

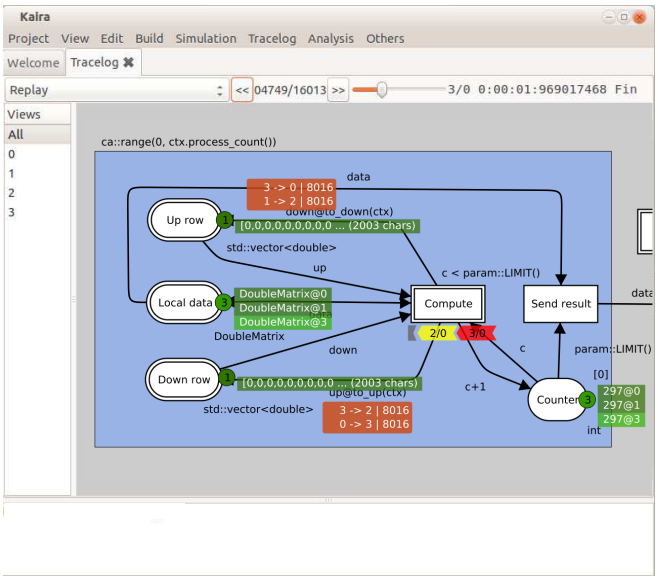

Fig. 5. The screenshot of a replay.

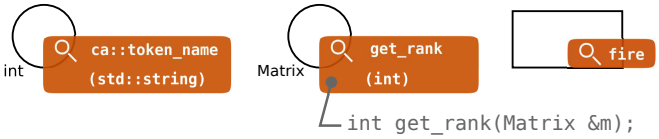

Fig. 6. Tracing labels, from left: Tracing names of tokens that arrive into the place; tracing values obtained by applying a function to each token arriving to this place; tracing transition firing.

tools use the *data-replay*, the *order-replay* or some combination of both approaches. In the data-replay approach, every communication message is recorded and a single process can be rerun with the same communication as was recorded. The advantage is that it is feasible even for instances with many processes. The disadvantage is huge tracelogs and it can be hard to discover errors that need an overall context. In the order-replay approach, we store the ordering of incoming messages. We get smaller tracelogs, but we must simulate all processes during the replay.

In Kaira we have implemented the order-replay approach in the form of *control sequences*. This feature naturally connects the infrastructure of our simulator with tracing abilities. A control sequence is a list containing actions. Each action is one of three basic types from Section III (starting and finishing transitions and receiving packets). Actions contain information about the process and the thread where the activity is executed, the transition's name (in the case of transition firing) and the source process of the message (in the case of receiving packets). When we store this information we are able to repeat the run of the application.

Sequences are generated in the simulator or they are extracted from tracelogs. The simulator can replay sequences and get the application into the desired state. Because the control sequence and the model are loosely connected, the

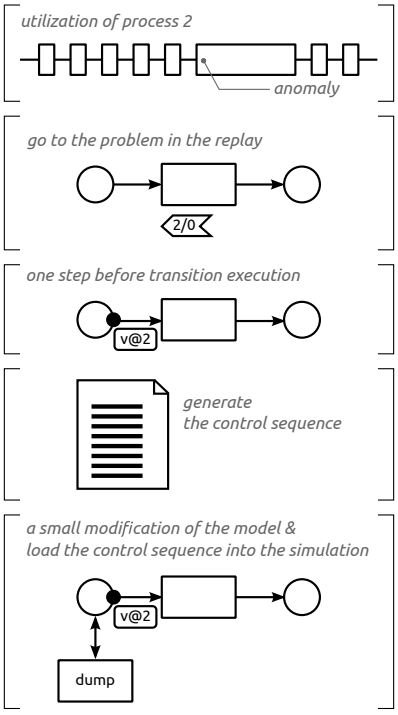

Fig. 7. The use case of control sequences

sequence remains relevant even if we make some changes into the model. The usefulness can be exposed by the following scenario: The user finds a problem by a visual replay or by summaries obtained from a tracelog. Then a sequence that brings the application exactly one step before the problem can be exported from the tracelog. Then the model can be enriched by more precise debugging outputs. For example, it can be a `printf` added into a transition's code or an extra debugging transition. Now we can get the application into the state before the problem by replaying the sequence in the simulator. In this situation, we have the possibility to obtain more information about the problem because of the modified version of the application. This scenario is captured in Figure 7.

D. Other features

Our model allows implementing two additional features that can be used for debugging or the performance analysis. Because we control how parallel aspects are generated, we can always generate the sequential application from the model. Such generated application works like the original one but it is performed exactly by one thread independently on how many processes are specified. This feature does not need any change in the model. It enables easy profiling and debugging of sequential parts of developed programs by the tools designed for sequential applications without problems caused by threads or MPI.

The other feature is the possibility to connect into a running application. We can start a generated application in a mode where the application listens on a TCP port. The application normally runs but when we connect to this port, the run is

paused and the inner state of the application is displayed in the simulator. The application can be also controlled in the same way. When the connection is closed, the application continues computing. This way we can easily debug situations when the application hangs up or we can just observe how far the computation is. But in the current implementation there are some limitations. This feature works only for applications generated with the thread backend (i.e. it does not work for MPI applications) and after the connection to the application, the control is passed to the user after finishing all current running transitions.

E. Drawbacks

Here, we want to discuss the drawbacks of our approach. The most obvious issue is that our approach does not give us any tool to debug or profile codes in places and transitions. We can say what data were on the input of the transition, what was the output. We can get the application into a state before or after execution of the transition or profile the transition as a whole. But we cannot observe, debug or profile the inner state of transition executions. This can be a serious problem and may force the user to use other tools in some situations. On the other hand the codes in transitions are sequential codes without any communication so they can be easily profiled or debugged separately. It can be further simplified by the fact that we can always generate the sequential version of the program.

Other issue is connected with our current implementation. We have focused on minimizing the performance impact of the debugging and profiling infrastructure on generated applications. On the other hand, our tool itself was not subject of optimizations, and therefore, processing a huge tracelog or a long control sequence can be time consuming and demanding on memory. Therefore, our infrastructure is not yet suitable for debugging or profiling long running applications. Some numbers to this topic are provided in Section V.

IV. Related Works

In this section, we want to compare Kaira with selected tools for profiling and debugging. For the comparison with other types of tools we refer to [2].

Different approaches have been proposed for debugging MPI applications. More about debugging in MPI environment can be found in [5], [6].

First, a MPI application runs on each computing node like a normal program; therefore, we can use standard tools like *GDB*[5] (for debugging) or *Callgrind*[6] (for profiling). This approach is sufficient to find some types of bugs or performance issues, but the major disadvantage is completely separated instances of the supportive tool for each process. It is not easy to control more debugger instances simultaneously or merge several profiler's outputs.

There are specialized debuggers and profilers to overcome this issue. For debugging there are tools: *Distributed Debugging Tool*[7] or *TotalView* [8]. They provide the same functionality like ordinary debuggers (stack traces, breakpoints, memory watches), but they allow to debug a distributed application as a single piece. Besides these tools, there are also non-interactive tools like *MPI Parallel Environment*[9]. It provides additional features over MPI, like displaying traces of MPI calls or real-time animations of communication. These tools are universal in the sense that they can debug any application. In our approach, we can only debug applications created in Kaira. On the other hand, we are able to provide the debugging infrastructure on a higher level of abstraction than source codes.

To deal with hundreds of processors, there are also automatic debugging tools. These tools usually use the static analysis of source codes to discover misuse of MPI calls (*MPI-Check*) or the analysis based on the state space exploration (*ISP* [7]).

As it was mentioned in previous sections, a potentially powerful technique for debugging of MPI applications is the deterministic replay. An example of a tool implementing this approach is MPIWiz [4].

In the case of profilers for parallel applications, one of the most successful freely available tools is *Scalasca* [8]. The big advantage is the ability to work in an environment of thousands of processors. Scalasca implements the direct instrumentation approach, it provides data summarizations at a runtime or traces for postmortem analyses. In the tracing mode, Scalasca records performance related events. Summarized performance profiles are based on functions call paths. In both cases, resulting reports can be interactively explored in the graphical browser.

The similar tool to Scalasca is *TAU* (Tuning and Analysis Utilities) [9]. It is capable of gathering performance information through instrumentation of functions, methods, basic blocks, and statements. From this perspective, both Scalasca and TAU adopt similar strategies. The main difference is in the low level measuring systems.

There are also different tools that focus mainly on the visualization of traced data like Vampir [10] and Paraver [11]. These tools are able to import tracelogs produced by others and the user is able to browse traced data. Usually, a set of filters can be specified to remove unnecessary details.

V. Experiments

This section contains two example programs. Their purpose is to demonstrate features mentioned in Section III. All programs were executed on a machine with 8 processors AMD Opteron/2500 (32 cores in total) and compiled with Intel Compiler at the optimization level `-O2`.

A. Basic measurements

As the first example, we show results for the heat flow problem introduced at the end of Section II. In this example, we

[5]http://www.gnu.org/software/gdb/
[6]http://valgrind.org/docs/manual/cl-manual.html

[9]http://www.mcs.anl.gov/research/projects/perfvis/software/MPE/

show a comparison between the hand-made solution profiled by Scalasca and the version created and profiled in Kaira. Both implementations are distributed together with Kaira.

The implementations share the same computation code. It is about 380 LOC (lines of code without comments). The solution in Kaira contains 25 LOC in transitions and places and 10 LOC for binding the external types. The hand-made solution contains 100 LOC, which are not shared with the solution in Kaira. The following experiments were executed on the instance of the size 6400×32000 and 300 iterations.

All places and transitions are traced except for places *Up row* and *Down row*. The standard function writing token name for the type `std::vector<double>` stores all values from the vector into the tracelog. (6400 doubles for places *Up row* and *Down row*). In our example, we do not need such information, so we can change this writing function to store a smaller amount of data or we can just switch off the tracing (as we have done here). In the case of the hand-made solution profiled by Scalasca, 5 patterns in the filter file was used (23 functions were filtered out). These numbers are small, because of simplicity of the example. For illustration, the code generated by Kaira contains more internal functions and when it is profiled in Scalasca, we had to use 14 patterns in the filter file and 382 functions were filtered out. Without the filter file, Scalasca produces extremely huge logs (in the order of gigabytes) and it deforms runs of the application, because traced data are very often flushed on the disk.

Table I shows the comparison between the solutions generated by Kaira and the handmade solution. In both cases, the measurements were done without writing the resulting matrix into the file. Our problem scales well up to 16 processors, then it reaches limits of used computer.

In case of Scalasca we have instrumented all source files. This instrumentation adds some overhead. It can be improved by additional separation of computation code and communication, but it cannot be always possible. For example when we use an external library.

Figure 8 shows that solution produced by Kaira is comparable to handmade solution and our tracing introduces only a small overhead. For this small number of processors, the measured times are better than the handmade solution profiled by Scalasca. Scalasca is designed for thousands of processors; therefore it is not well suited for this experiment. But our goal was to show that Kaira tracing is comparable (in the scale of tens of processes) with existing mature parallel profilers and Scalasca is a well-established tool in this area.

Figure 9 shows the grow of tracelog sizes. Kaira tracelogs are bigger but still comparable. In Kaira case, they contain information for a replay, not only profile data.

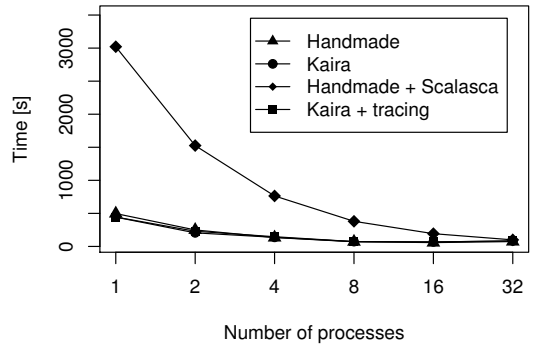

Fig. 8. The comparison of running times between the hand-made solution and the solution generated by Kaira for the heat flow example (based on Table I).

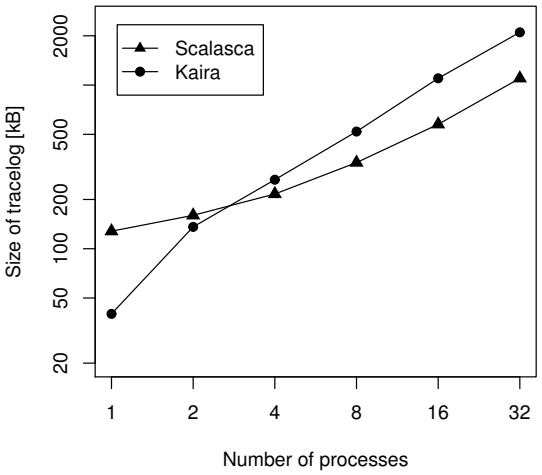

Fig. 9. The comparison of tracelog sizes between the handmade solution traced by Scalasca and Kaira's solution traced by Kaira (based on Table I).

B. Advanced measurement

In this section we will demonstrate how a tracelog can be enriched by custom data and how tool R[10] can be combined with Kaira to obtain various statistics. R is one of the most popular statistical tools. Kaira can export collected data from a tracelog in a form of a table that can be loaded into R. Each row of this table corresponds to the three basic events (explained in Section III) and their subevents (token add, token removed, packet sent). In Kaira's distribution, there is a simple script for R that provides basic operations over such table. It is often easy to extract useful information about the performance from data in this form.

As the example, we have chosen the *Ant Colony Optimization* (ACO) algorithm that is used to solve *Traveling Salesman Problem* (TSP). There are many ways to parallelize this algorithm; the presented solution is described in more detail in the paper [12]. The visual model for the solution is depicted in Figure 11. We will show how to get specific data from the application's run and present them with the help of R.

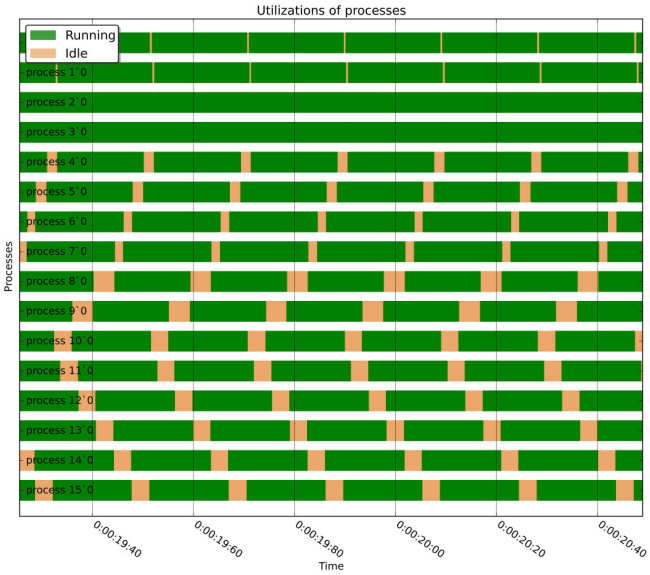

Fig. 10. The example of zoomed chart of process utilizations in the heat flow example with 16 processes.

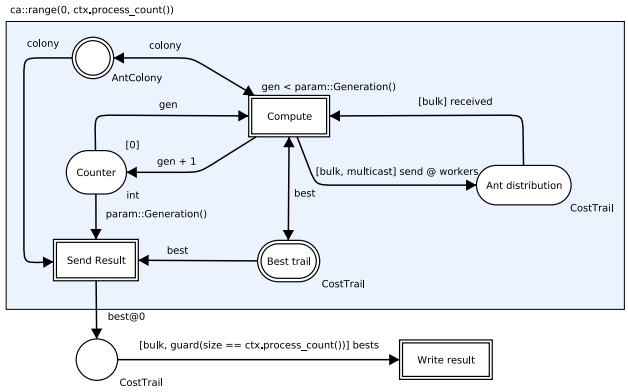

Fig. 11. The implementation of Ant Colony Optimization.

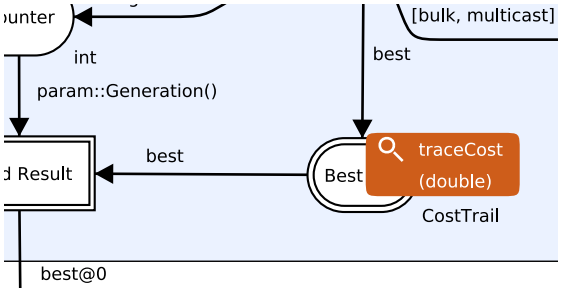

Fig. 12. Connecting a tracing function to the place *Best trail*.

For our experiment, we used the file *eil51.tsp* from TSPLIB[11].

In the used version of the ACO algorithm, ants are separated into colonies and the evolution of each colony is computed in parallel (each colony is assigned to a single MPI process). A colony is stored in the place in the top-left corner. The transition *Compute* takes a colony and computes the next generation of ants. In each iteration, every process saves the best solution to the place *Best trail*. It is distributed to other processes through the place *Ant distribution*. When the last generation is computed, *Send results* takes the best solution and it sends them to process 0, where the overall best solution is chosen.

To verify that the solution works properly, it is useful to inspect the fitness value (i.e. the quality of the solution) in time. We use the ability to connect a tracing function with a place. In our case, we connect a simple function returning a fitness value of an ant to place *Best trail* (Figure 12). When a token arrives to this place, its value is stored in the tracelog (in the scope of an event that creates this token). After exporting the tracelog table into *R*, we obtain the charts in Figures 13 and 14.

[11]It is available at http://comopt.ifi.uni-heidelberg.de/software/TSPLIB95/

When the best solution for each colony is sent to others, the convergence is the same for all processes (Figure 13), as we may expect. To check this assumption, we can disable communication, by removing the edge with the expression `[bulk, multicast] send@workers`. The fitness values for this case are shown in Figure 14.

VI. CONCLUSION

In previous papers, we have been focused on the development of MPI applications by usage of the visual model and visual programming. Our visual language is based on well-known formalism – Coloured Petri Nets. In this paper, we have presented how the same visual model and in fact the same approach was used for debugging and performance analyses. The presented ideas are implemented in our tool Kaira.

We introduced a simulator that allows the live introspection into developed programs. This simulator uses the original visual model. Thus the developer is able to inspect the de-

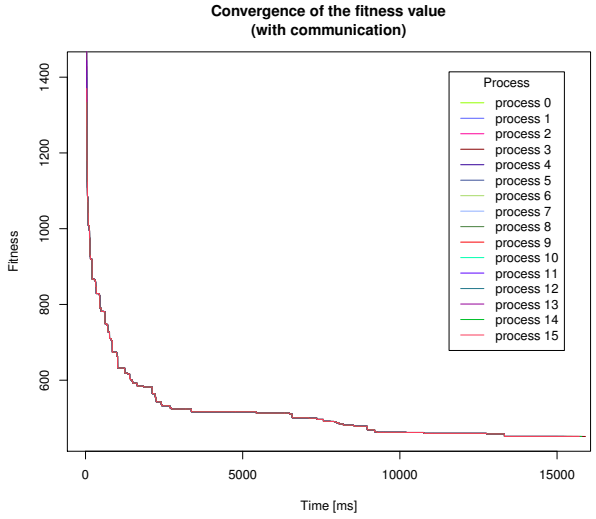

Fig. 13. Minimization of fitness values in time; colonies exchange the best solution.

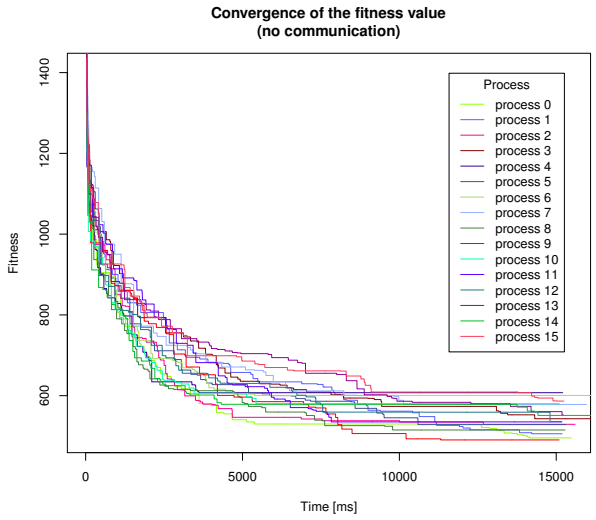

Fig. 14. Minimization of fitness values in time; without communication.

veloped application's behavior using the same visual model that he developed and that he understands. Using control sequences, we are able to capture a simulation and later it can be reproduced even on a modified visual model. They serve as basic infrastructure and they allowed us to implement deterministic replay and we want to implement more advanced features like a massive parallel replay.

Also for profiling we use a similar approach and we use the original model. We use it not only to present the obtained data (application's replay) but also to simplify the measurement specifications. This is crucial for profiling, because when we measure everything, the obtained data are usually useless and setup measurement filters in a standard tool can be hard.

We also demonstrate that presented features can be implemented with a performance that is comparable with existing mature tools. Practical experiments show that a performance of the handmade solution is comparable with the solution generated by Kaira. Measured times differences were up to 20%. The overhead introduced by tracings in Kaira is up to 3%. Our tracelogs are bigger than Scalasca's tracelogs, but their growths is similar.

We consider these features to be a successful step towards providing the unifying framework for prototyping and development of MPI applications. We are also working on more advanced features: performance prediction and verification. These parts are interconnected by our model and results from one analysis can be used in the rest of Kaira infrastructure. It can serve as another argument why to use Kaira.

***Abstract*—Grammar-dependent software development and grammarware engineering have recently received considerable attention. As a significant cornerstone of grammarware engineering, grammar refactoring is, nevertheless, still weakly understood and practiced. In this paper, we address this issue by introducing pLERO, formal specification language for preserving knowledge of grammar engineers, complementing mARTINICA, the universal approach for automated refactoring of context-free grammars. With respect to other approaches, advantage of mARTINICA lies in refactoring on the basis of user-defined refactoring task, rather than of a fixed objective of the refactoring process. To understand the unified refactoring process, this paper also provides a brief insight into grammar refactoring operators, providing universal refactoring transformations for specific context-free grammars. To preserve knowledge considering refactoring process, we propose formalism based on patterns, seen as well-proven way of knowledge preservation in variety of domains, such as software architectures.**

I. Introduction

AUTOMATED grammar refactoring is the field where two or more equivalent context-free grammars may have different forms. Although two equivalent grammars generate the same language, they do not necessarily share other specific properties measurable by grammar metrics [1]. The form in which a context-free grammar is written may have a strong impact on many aspects of its future application. For instance, it may affect general performance of a parser [2], or it may influence, and in many cases limit, the choice of parser generator [2].

Since there is a close relation between the form in which a grammar is expressed and the purpose for which it is designed, different grammars become domain-specific formalizations if generating the same language. Thus, the ability to transform a grammar to another (equivalent), indeed, becomes the power to shift between domains of possible applications. Even if making each grammar more universal in its application scope, the practical benefits may be easily thwart by the difficulties. The problem is, refactoring is often a non-trivial task and if done manually, it is prone to errors, especially with large grammars. This is an issue, as in general there is no formal way to prove two context-free grammars generate the same language.

We addressed this issue in [3] by proposing mARTINICA, metrics Automated Refactoring Task-driven INcremental syntactIC Algorithm. Its main idea is to apply a sequence of simple transformation operators to a chosen context-free grammar to produce an equivalent grammar with the desired properties. Each refactoring operator transforms arbitrary context-free grammar to an equivalent context-free grammar which may have different form than the original. Properties the grammar should possess are defined by so called objective function. That is, the purpose of mARTINICA is to find a sequence of refactoring operator instances transforming particular context-free grammar to an equivalent with a form satisfying user-defined requirements. Current state of the algorithm development requires grammar production rules to be expressed in the BNF notation as it in general, unlike EBNF, expresses elementary properties, e.g. left/right recursion or iteration.

With respect to diversity of possible requirements on the qualitative properties, refactoring operators provide relatively universal grammar transformations. Although the relative universality of refactoring operators contributes to versatility of the algorithm, it also may lead to high computational complexity and, in specific cases, to inability to fulfill the refactoring task. Within the current research, we propose a solution of these issues based on patterns which, in this context, we consider to be a problem-specific refactoring operators.

In general, we consider a pattern to be a problem-solution pair in given context [4] [5]. Alexander argues each pattern can be understood as an element of reality, and of language [4]. As an element of reality, pattern reflects a relation between specific context, certain system of forces recurring in given context, and certain spatial configuration leading to balance in a given system of forces [4]. As an element of language, pattern reflects an instruction showing how certain spatial configuration can be repeatedly used to balance certain system of forces wherever specific context makes it relevant [4].

As such, patterns are tools for documenting existing, well proven design knowledge, supporting construction of systems with predictable properties and quality attributes [5]. Thence, the role of patterns in the field of grammar refactoring is:

1) To preserve knowledge of language engineers about when and how to refactor context-free grammars, and
2) To support process of grammar refactoring by providing this knowledge.

To incorporate patterns in automated grammar refactoring, we have coined a new term: *grammar refactoring patterns*. Each grammar refactoring pattern describes a way in which a context-free grammar can be transformed preserving generated language, and a specific situation of this to be possible. Description of the situation, in which transformation provided by

978-83-60810-53-8/$25.00

a pattern can be applied, defines refactoring problem addressed by the pattern, while grammar transformation defines solution of the refactoring problem.

II. Motivation

Grammarware engineering as an up-and-rising discipline aims at solving grammar development issues, promising an overall rise in grammar quality, and development productivity [6]. Grammar refactoring may occur in many fields, e.g. grammar recovery, evolution and customization [6]. In fact, it is one of five core processes of grammar evolution, alongside the extension, restriction, error correction, and recovery [7]. However, unlike a well-proven practice of program refactoring, grammar refactoring is little understood and practised [6].

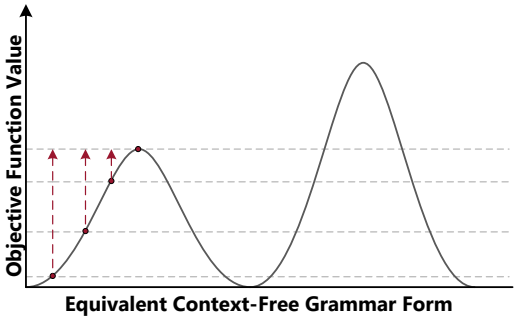

Fig. 1. Previous research approach

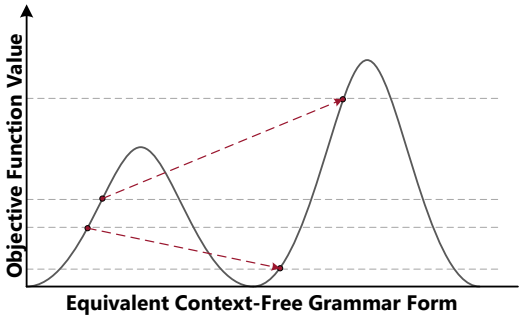

Fig. 2. Current research approach

Fig. 1 and 2 both reflect the objective function value at particular grammar forms. Horizontal axis, indeed, denotes a hypothetic area (not a dimension) of all the equivalent context-free grammar forms, and vertical axis denotes the objective function values of this grammar.

The points marked in the graphs represent forms of a context-free grammar. All the points originate from a single point, corresponding to the initial grammar form and its objective function value.

Our previous approach involved an improvement of the objective function through the application of refactoring operators [3]. Its potential to improve is expressed by the up arrows in Fig. 1. The issue lied in local extrema: If populations reached them, further slide over the function became uncertain.

The algorithm of mARTINICA solved this issue by enabling the populations to regress, but merely in a certain number of steps [8], which is one of the few possible heuristics. Two potential ways of the algorithm are to enable a progress to a certain value or a certain number of steps. However, neither of them is ideal and cannot work universally. Further, the issue lied in a negative impact on the computational complexity as well.

Consequently, the current approach considers *refactoring patterns*. If applied to a grammar, at the corresponding objective function it is possible to skip the local extremus (Fig. 2), what is their primary feature. Certainly, various patterns concern various objective functions. That is, this solution is not universal, however, it is ideal for domain-specific tasks, such as left recursion removal.

Since this approach is not heuristic and it always works, it is considered to be progressive according to the previous one.

Generally, the main idea behind our research lies in grammar modifications according to their objective functions, which is supplemented by the current research dedicated to creation of a tool for grammar modifications according to properties of refactoring operators.

III. Related Work

Unfortunately, it was possible to find very little reported research in the field of automated grammar refactoring. The small amount of the published work is mostly concerned with refactoring context-free grammars achieving some fixed domain-specific objective.

Kraft, Duffy and Malloy developed a semi-automated grammar refactoring approach to replace iterative production rules with left-recursive rules [9]. They present a three-step procedure consisting of grammar metrics computation, metrics analysis to identify candidate nonterminals, and transformation of the candidate nonterminals. The first and third step are fully automated, while the process of identifying nonterminals, to be transformed by replacing iteration with left recursion, is done manually. Since grammar metrics are calculated automatically, this approach is called metrics-guided refactoring. However, the resulting values must be interpreted by human, using them as a basis for making the decisions necessary for resuming the refactoring procedure. The work also provides an exemplary illustration of the grammar refactoring benefits, since left-recursive grammars are more useful for some aspects of the grammar application [10], and are also more useful to human users [11] than iterative grammars.

In the field of compiler design, the procedure of left-recursion removal is a well-known practice. Louden reports an algorithm for automated removal of direct and indirect left recursion [12]. This approach is further extended by Lohmann, Riedewald and Stoy [11], presenting a technique for removing left-recursion in attribute grammars and semantic preservation while executing this procedure.

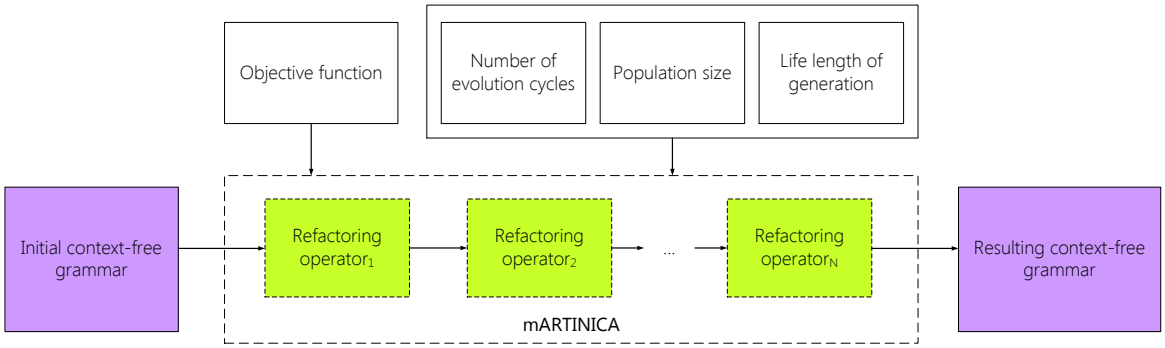

Fig. 3. Black-box view of mARTINICA

Lämmel presented suite of fifteen grammar transformation operators, four considering grammar construction, five considering grammar destruction and six considering grammar refactoring [13]. These operators are in large degree tailored for solving issues of two specific problem domains e.g. grammar adaptation and grammar recovery. Paper [13] also introduced the idea of incremental grammar refactoring through the sequence of simple transformations deriving from application of refactoring operators, however no specific automated refactoring approach, such as mARTINICA [3] was introduced.

Lämmel and Zaytsev introduced suite of four refactoring operators, specifically aimed for tackling refactoring tasks occurring in the process of grammar extraction from multiple diverse sources of information [14].

IV. Background

This section discusses refactoring operators as a basis for understanding grammar refactoring patterns and the core idea of the approach. This section also briefly introduces a method of describing a context-free grammar properties through the formalism of an objective function, used as a specification of the refactoring objective.

A. Refactoring Operators

Formally, grammar refactoring operator is a function taking a context-free grammar $G = (N, T, R, S)$ and using it as a basis for creating new grammar $G' = (N', T', R', S')$ equivalent to G. At this stage of development, the experiments were performed on the basis of eight operators: Unfold, Fold, Remove, Pack, Extend, Reduce, Split and Nop. The first three have been adopted from Lämmel's paper on grammar adaptation [13], while the others are proposed by us [8].

Grammar refactoring patterns are proposed as an addition to the base of refactoring operators. However, in this context, the key difference between refactoring operators and patterns is that the growth in the number of patterns (in the base of operators) does not have significant negative impact on the algorithm complexity, and the opposite is often true. This is caused by their domain-specific orientation and quite narrow scope of refactoring tasks to which individual patterns are applicable.

B. Objective Function

We adopt a modified understanding and notation of objective functions from mathematical optimization. An objective function describes properties of a context-free grammar to be achieved by refactoring. However, it does not describe the way in which the this should be performed, and the condition in which desired context-free grammar properties are achieved.

In our view, the objective function consists of two parts: *objective* and *state function*. Our refactoring algorithm works with only two kinds of objectives, which are minimization and maximization of a state function. We define a state function as an arithmetic expression whose only variables are the grammar metrics [1] calculable for any context-free grammar. As such, a state function is a tool for qualitative comparison of two or more equivalent context-free grammars.

Exemplary objective function prescribing minimization objective under state function consisted of count of nonterminals (var) and count of production rules ($prod$) is (1).

$$f(G) = minimize\ 2 * var + prod \tag{1}$$

C. mARTINICA: Refactoring Algorithm

The main idea behind mARTINICA (Fig. 3) lies in applying a sequence of grammar refactoring operators to a context-free grammar, to produce an equivalent grammar with a lower value of the objective function if the objective is minimization, or a higher if the objective is maximization. On the other hand, pLERO allows specifying one operator of such a sequence.

Since mARTINICA is an evolutionary algorithm, it also requires other input parameters, in addition to the *initial grammar* and the *objective function*, in order to be executed. It requires three other input parameters: *number of evolution cycles*, *population size* and *length of a generation life*. The first two are typical for algorithms of a similar type, while the third parameter is our own.

As shown in Fig. 4, presenting a white-box view, the algorithm starts with creation of an initial population of grammars. Each population member is then created in the basis of the initial grammar, transformed by semi-random sequence of refactoring precesses. After the initial phase, the algorithm iterates for count of evolution cycles through:

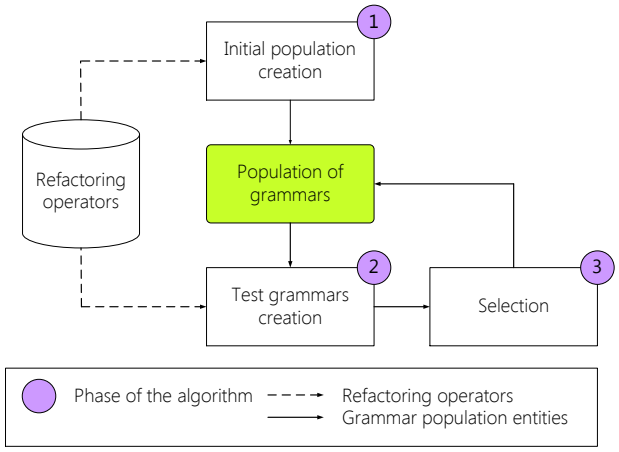

Fig. 4. White-box view of mARTINICA

1) *Test grammars creation* in which candidate population members are created. For each grammar in each generation three test grammars are created:
   a) Self-test grammar that attempts to redouble transformation that led to improvement in value of objective function in past generations of this population member.
   b) Foreign-test grammar that attempts to incorporate transformation that led to progress in value of objective function in past generations of some other population member.
   c) Random-test grammar that attempts to transform grammar towards optimization of value of objective function on the basis of random sequence of refactoring operators.
2) *Selection* in which population members are substituted by candidates with best value of objective function.

The resulting grammar reflects a population member of the last generation with the best value of the objective function.

Detailed description concerning proposal and implementation of mARTINICA algorithm along with some experimental results can be found in [3] [8].

V. Grammar Refactoring Patterns

In our view, each grammar refactoring pattern provides an equivalent transformation to context-free grammars. In this sense, the concept of grammar refactoring patterns is closely related to the concept of refactoring operators. However, there are several key differences between grammar refactoring patterns and refactoring operators.

First of all, refactoring operators provide problem-independent transformations, while grammar refactoring patterns provide problem-specific transformations. This means refactoring operators provide general transformations, with usage not bound by any specific class of refactoring tasks, while grammar refactoring patterns provide domain-specific transformations, intended for tackling the issues of particular class of refactoring problems.

Secondly, each of the refactoring operators can be applied to an arbitrary context-free grammar, including the situation of particular grammar form not allowing occurance of a specific transformation. In this case, the original grammar form is returned as a result of the transformation. On the other hand, each grammar refactoring pattern prescribes some specific preconditions a context-free grammar must fulfill in order to be transformable by a particular refactoring pattern.

In our approach, each pattern is represented as a specification consisting of a set of transformation rules, while transformation rule provides transformation on some subset of grammar's production rules that exhibit specific structural properties. In this notion of refactoring patterns, each instance of refactoring operator is actually a refactoring pattern which lacks explicit specification of required structural properties of grammar's production rules, and each refactoring pattern is in fact non-parametric refactoring operator.

VI. Core

For the purposes of patterns expression, we propose pLERO, pattern Language of Extended Refactoring Operators.

pLERO is currently being developed in two distinct dialects e.g. imperative [15] and functional. Refactoring patterns written in imperative dialect of pLERO are more process-centric, meaning that they are intended for specification of particular steps of a refactoring process, while refactoring patterns written in functional dialect are more result-centric and facilitate understanding of a grammar's structural changes. In this paper, we present the functional dialect of pLERO, while detailed description of the imperative dialect of pLERO can be found in [15].

A. pLERO

Through pLERO it is possible to define patterns for grammar refactoring or other transformations, applicable to grammars expressed in BNF. That is, pLERO is a language for defining parameterless operators of a problem class.

Pattern description consists of a set of transformation rules, while each rule comprises predicate describing the shape of a grammar's production rules, and transformation defining how production rules matched against predicate should be changed.

Predicate and transformation are expressed in similar fashion by formalism of meta-production rules. Each meta-production rule defines structure of some subset of a grammar's production rules. Predicate is specified by exactly one meta-production rule matched against grammar's production rules, while transformation is described by set of meta-production rules defining shape of production rules to be included in grammar during refactoring process.

Each meta-production rule can be divided in two parts, namely, left side of meta-production rule and right side of meta-production rule. Left side of meta-production rule specifies nonterminal on the left side of a grammar's production rule, while right side of meta-production rule specifies sequence of symbols that can be found on the right side of a grammar's production rules. Left side of meta-production rule

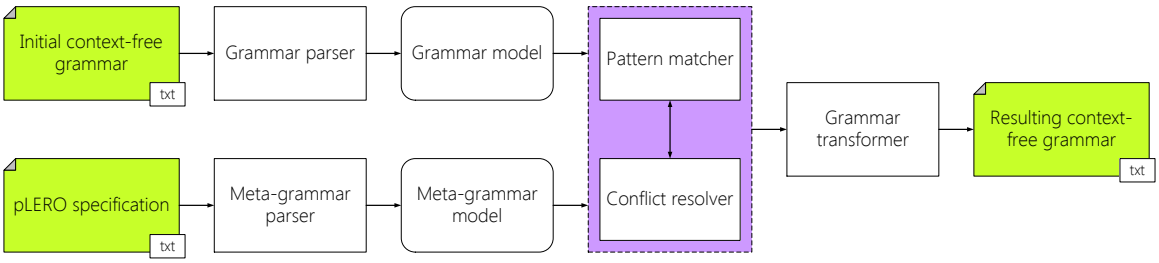

Fig. 5. Architecture of pattern application system

is some pattern variable, while right side of meta-production rule is concatenation of pattern variables.

Pattern variable specifies homogenous sequence of symbols in a grammar's production rules, consisting of variable prefix and name. Variable prefix describes possible matched symbols and their number, while variable name is identifier of this sequence. The prefix can be "t" for terminals, "n" for nonterminals, and "s" for both terminals and nonterminals. The letter specifying the symbol type can be followed by the asterisk "*" denoting the variable can match a sequence of symbols instead of a single symbol. For instance, the most generic variable type has prefix "s*" that can match any sequence of symbols. Variable prefix and name are separated by dot ".". After the dot, the variable name follows, e.g. "s*.symbols".

Pattern variable on the left side of meta-production rule may only have prefix "n" not followed by asterisk, denoting exactly one nonterminal. Each pattern variable on the right side of meta-production rule can have arbitrary valid prefix.

Each specification of refactoring pattern in pLERO must comply with the same template (Fig. 6) which allows specification of global pattern variables denoting same symbol sequences in all transformation rules of a pattern during entire refactoring process.

```
pattern [pattern_name] {
   variables:
        [prefix1].[variable_name1],
        [prefix2].[variable_name2],
           ...
        [prefixn].[variable_namen];
   new symbols:
        [prefixI].[variable_nameI],
        [prefixII].[variable_nameII],
           ...
        [prefixN].[variable_nameN];
   [transformation_rule1];
   [transformation_rule2];
      ...
   [transformation_rulem];
}
```

Fig. 6. Template of a pattern notation

The template also enables to specify new nonterminal symbols, which need to be generated for the use in production of new production rules. Notion of individual transformation rules must also follow specific template shown in Fig. 7.

```
predicate -> transformation
```

Fig. 7. Transformation rule decomposition

While variables may consist of all the possible prefixes, new variables may not; more specifically they cannot consist of partially deterministic constructs such as "*" or "s", and in current version of pLERO only "n" is allowed. Reason for this is that these constructs do not specify unambiguous concatenation of symbols and though it is not possible to generate definite sequence of symbols on their basis. Moreover new variables may be used only in meta-production rules contained within transformation part of transformation rule, and their use in predicate is prohibited. Reason for this is that new variables correspond with sequences of symbols that occur only in refactored grammar, and not in the original grammar.

1) Pattern Matching:

In order to apply transformation provided by refactoring pattern on some context-free grammar it is first necessary to match this grammar against this pattern. Process of pattern matching has two purposes:

- Determining if a grammar is transformable by a pattern
- Determining which pattern variable represents which sequence of symbols within production rules of a grammar

To each assignment of specific sequence of symbols to particular pattern variable we refer as to variable binding and to each variable representing definite sequence of symbols we refer as to bound variable.

Variables are bound during the matching of the rule and used in the replacement construction process. Global variables keep their value after they are bound during the first successful match. Other variables (to which we refer as to local variables) are bound only during the application of a rule and cleaned before the next matching.

The matching of a predicate against a grammar production is successful if all the pattern variables can be bound to a

part of the production and no unmatched symbols are left. Variables can match only some type of symbols, based on their prefix. Simple variables must match exactly one symbol of a specified type, while sequence variables can match any number of symbols (including zero).

For instance, the predicate "`n.1 ::= n.2 s*.1 t.1`" would match production "`A ::= B 'c' 'd' 'e'`", resulting in bindings "`n.1`" = "`A`", "`n.2`" = "`B`", "`s*.`" = "`'c' 'd'`", "`t.1`" = "`'e'`", and also "`B ::= D 'f'`", "`n.1`" = "`B`", "`n.2`" = "`D`", "`s*.`" is empty, "`t.1`" = "`'f'`". Since it does not start with a nonterminal, it would not match "`C ::= 'd' 'e' 'f'`".

If the pattern "`n.1 ::= s*.1 n.2 s*.2`" is matched against the production "`A ::= B C D`", the resulting binding would be "`n.1`" = "`A`", "`s*.1`" is empty, "`n.2`" = "`B`", and "`s*.2`" = "`C D`".

Variable prefix specifies only structure of some sequence of symbols, and it does not define particular symbols of a specific grammar. On the other hand, variable name is an identifier of a specific variable binding established during a particular pattern matching process. For instance, the predicate "`n.1 ::= n.1 n.2`" would match production "`A ::= A B`", however it would not match production "`A ::= B C`" since in this case variable `n.1` would be bound to two different nonterminals (`B` and `C`).

The matching of sequences is non-greedy. This means that short sequences are performed first during the matching. The process continues while the entire production is matched.

However, there are some cases in which conflicts in matching of predicate against production can arise, e.g. conflict always occurs if predicate contains two consecutive sequences of arbitrary symbols ("`s*.A s*.B`"). In this case, we have adopted first-match found resolution strategy.

2) Pattern Application:

Each transformation rule of refactoring pattern describes structure of some production rules and specifies new production rules that should replace this production rule. Predicate is a concatenation of pattern variables, which can match a sequence of production rule symbols and then represent these symbols in the transformation.

If a variable of the same type and name is present in a transformation rule, it will represent the same sequence of symbols in all its occurrences. In the transformation, meta-production rules have to consist only of the variables occurring on the predicate side of the transformation rule or in global variables. After the predicate matches any grammar production, its variables are bound to parts of the production and the replacement productions are constructed on the basis of transformation patterns.

If applied to a grammar, all transformation rules of a pattern are traversed in the order of their specification. Predicate is then matched against all the unprocessed productions of the original grammar. If the match is successful, replacement production is constructed and the production is replaced in the grammar.

Order of specification of transformation rules within a pattern is important, for it serves as conflict resolution mechanism in case when there are multiple predicates that can be matched against one production rule.

On the other hand, multiple production rules can be matched against one predicate, but only if all global variables of a predicate are bound to a same sequence of symbols in each production, and in that case replacement productions are constructed for each such rule.

B. Implementation

To be able to perform experiments and to demonstrate the correctness of the approach, automated pattern application system (Fig. 5) has been implemented, in which pLERO plays a central role.

The system takes the initial grammar and the pLERO pattern specification from the two different text files, and after the refactoring it creates new text file containing the resulting grammar.

The first text file is parsed by grammar parser which creates its representation in the form of grammar model, while the second is parsed by meta-grammar parser which creates meta-grammar model.

The core of the system is divided in two coexisting entities:

1) *Pattern matcher* – The purpose is matching of grammar model against meta-grammar model
2) *Grammar transformer* – The purpose is construction of replacement productions and generating of refactored grammar.

To resolve various conflicts occurring during the process of pattern matching, various resolution strategies are implemented in a separate module to which we refer to as a *conflict resolver*.

VII. Experimental Results

As an example, see Fig. 8 and 9 containing fragment of Algol 60 grammar [16] and pattern for immediate left-recursion removal (not direct). Then, Fig. 10 and 11 reflect equivalent grammar fragments produced after two sequential pattern applications.

After the first application of the pattern immediate left-recursion concerning nonterminal "`term`" was removed.

After the second application of the pattern immediate left-recursion concerning nonterminal "`factor`" was removed.

VIII. Conclusion

The most significant contribution, that we expect based on the results presented in this paper, is the contribution to automated grammar evolution. As such, our refactoring approach presents an appropriate basis for creation of new theory concerning automated task-driven grammar refactoring, while the provided experimental results as well as the other experiments [3] [8] explicitly demonstrate correctness and effectiveness of this approach.

However, achievement of this goal also requires deeper understanding and intensified research in refactoring operators,

```
term ::= factor
term ::= term multiplying_operator factor
multiplying_operator ::= 'x'
multiplying_operator ::= '/'
multiplying_operator ::= '÷'
factor ::= primary
factor ::= factor '↑' primary
primary ::= unsigned_number
primary ::= variable
primary ::= function_designator
primary ::= '('arithmetic_expression')'
```

Fig. 8. Fragment of Algol 60 grammar [16]

```
pattern LeftRecursionRemoval {
   variables: n.A;
   new symbols: n.A1;
   n.A ::= n.A s*.x ->
           n.A1 ::= , n.A1 ::= s*.x n.A1;
   n.A ::= s*.x ->
           n.A ::= s*.x n.A1;
}
```

Fig. 9. Example of a pattern for immediate left-recursion removal

```
term ::= factor N4
N4' ::=
N4' ::= multiplying_operator factor N4
multiplying_operator ::= 'x'
multiplying_operator ::= '/'
multiplying_operator ::= '÷'
factor ::= primary
factor ::= factor ↑ primary
primary ::= unsigned_number
primary ::= variable
primary ::= function_designator
primary ::= '('arithmetic_expression')'
```

Fig. 10. Resulting grammar after first application of refactoring pattern

as well as quality-based grammar metrics. Crucial part of this research are refactoring patterns, since they operate with knowledge derived from experience of language engineers, and thus they present an appropriate tool for converging of state-of-art and state-of-practice in the field of grammar refactoring.

In the future, we would like to focus on achieving greater abstraction power of the pLERO language, so it would formalize other knowledge considering refactoring problems and context of their occurrence, such as consequences of pattern's application on grammar's quality attributes. We would also like to adopt our approach to EBNF notation, which is structurally richer and would cause pattern matching to be more deterministic.

```
term ::= factor N4
N4 ::=
N4 ::= multiplying_operator factor N4
multiplying_operator ::= 'x'
multiplying_operator ::= '/'
multiplying_operator ::= '÷'
factor ::= primary N20
N20 ::=
N20 ::= '↑' primary N20
primary ::= unsigned_number
primary ::= variable
primary ::= function_designator
primary ::= '('arithmetic_expression')'
```

Fig. 11. Resulting grammar after second application of refactoring pattern

However, our vision goes even further, since mARTINICA and pLERO currently cover only one aspect of grammar adaptation, e.g. grammar refactoring, while the ultimate goal is to create universal approach covering other processes concerning grammarware engineering, e.g. grammar construction and destruction.

In case of interest, it is possible to download automated pattern application system from:

Incremental JIT Compiler for Implicitly Parallel Functional Language

Petr Krajča

petr.krajca@upol.cz

***Abstract*—We present a novel method for automatic parallelization of functional programs which combines interpretation and just-in-time compilation. We propose an execution model for a Lisp-based programming language which involves a runtime environment which is able to identify portions of code worth running in parallel and is able to spawn new threads of execution. Furthermore, in order to achieve better performance, runtime environment dynamically identifies expressions worth compiling and compiles them into a native code.**

I. Introduction

With advent of multi-core processor we are experiencing growing demand for programs which are able to utilize multiple processor cores to increase their efficiency. This trend is likely to continue as the hardware manufacturers have switched their focus from increasing performance by scaling clock speed to developing processors that are able to process multiple tasks simultaneously. Traditionally, programmer has to explicitly define which parts of a program will run in parallel and eventually has to use special means, e.g., locks, semaphores, critical sections, to synchronize parallel branches of execution in order to ensure correct outputs of the program. Currently, this approach to parallel programming is the prevailing one, on the other hand, it is also a very demanding approach from the programmer's point of view.

Another approach, we call it *implicit parallelism*, is to provide a language which is used the same way as any sequential language but its execution can be implicitly parallelized by a compiler or an interpreter of the language. Basically, compiler or runtime environment identifies portions of code which can be run in parallel and takes care of their proper synchronization, and thus, program returns always the same results, no matter which parts of the program were executed simultaneously. If this is achieved, the programmer can completely forget about the issues with parallel execution which is the desirable effect. Nowadays, implicit parallelism is relatively rare and has limited use.

In [14] we outline an evaluation model of the Lisp-based language called Schemik. The execution model of the language is based on a pushdown automaton which allows to describe operational semantics of the language in terms of transitions of the automaton. This model allows for further extensions. The most important extension detects expressions which are worth evaluating in a separate thread of execution and spawns new threads computing values of expressions in parallel. The model has shown its practical merits. (1) Implementation of the model shows that programs can be implicitly parallelized. (2) Using the automaton it can be proved that program returns always the same results no matter which parts of the program run in parallel. (3) One can incorporate software transactional memory to isolate side-effects performed in each thread of execution, hence efficiently parallelize even programs with side effects as discussed in [15]. On the other hand, the model itself is proposed for an interpreted language and this brings significant overhead. This paper presents a new extension for the evaluation model proposed in [14] which incorporates methods of just-in-time (JIT) compilation and preserves all mentioned features of the execution model, especially the ability to run programs in parallel without the need to use dedicated language constructs.

The paper is organized as follows. First, we provide a brief description of the language and of the formal model of the execution, including the methods which are used to automatically parallelize programs. Afterwards, we describe new extension which adds support for JIT compilation. The paper is concluded with a section focusing on implementation details and experimental evaluation.

II. Interpreter

A. Evaluation Model: An Overview

In this section, we briefly describe a sequential evaluator which is essential for understanding our approach to parallel computation. We assume that readers are acquainted with some dialect of Lisp or Scheme, and therefore, in the following text we tacitly use the usual terminology which can be found in [4], [9], [12].

Our stack-based evaluator is a deterministic pushdown automaton with two stacks—*execution stack* (denoted E) containing *stack operations* controlling the evaluation, and *result stack* (denoted R) containing Schemik objects playing the roles of operands and intermediate results of operations.

The input (first expression to be evaluated) is encoded on the execution stack and the output (result of evaluation) is pushed on the result stack at the end of the computation. The content of both stacks is what completely describes the current state of the evaluator. Therefore, a setting of the stacks shall be called

978-83-60810-53-8/$25.00

a *configuration* of the evaluator. The result stack contains first-class objects of Schemik in their internal representation which are basically the same objects as in Scheme [12] (i.e., numbers, symbols, functions, special operators, etc). The execution stack can be seen as a stack for pending operations. Unlike the result stack, it contains stack operations which are not Schemik objects. The stack operations are represented by tuples of the form $\langle$operation-name, $arg, \mathcal{E}$, flag$\rangle$ where operation-name is a name for a step of evaluation (e.g., EVAL, FEVAL, FUNCALL, IF, INSPECT, etc.); *arg* is an object representing argument for stack operation; $\mathcal{E}$ is an environment (i.e., a table describing bindings of lexical variables) associated to the stack operation; flag is an indicator of the tail-recursion optimization [12]. For brevity, attributes *arg*, $\mathcal{E}$, and flag can be omitted from descriptions of a stack operations if they are not used in that particular operation.

During the computation, the automaton changes its configuration. A change from one configuration to another will be called a *transition*. Each transition is determined by stack operation which resides on the top of the execution stack. The computation halts if the execution stack is empty and the object on the top of the result stack is a *result* of the computation. Each transition of the automaton may be depicted by two pairs of stacks—configuration *before* and *after* the transition—and it may be written as follows:

E: *stack with operations before transition* ⟧
R: *stack with results before transition* ⟧
E: *stack with operations after transition* ⟧
R: *stack with results after transition* ⟧

The first pair of stacks represents the configuration *before* the transition. The second pair of stacks, drawn below the first one, represents the configuration *after* the transition. Bottom of all stacks is on the right and is denoted by symbol ⟧.

The *start configuration* of the automaton contains a single stack operation $\langle$EVAL, $expr, \mathcal{E}_t$, N$\rangle$ on the execution stack and an empty result stack, meaning that symbolic expression $expr$ will be evaluated in the top-level environment $\mathcal{E}_t$ (environment containing initial bindings of lexical variables), N says that *expr* does not appear in a tail position, see [12].

The operation $\langle$EVAL, $object, \mathcal{E}$, f$\rangle$ initiates evaluation of $object$ (e.g., a symbolic expression) in environment $\mathcal{E}$. If this operation is on the top of the execution stack, an appropriate transition is made depending on the type of *object*. Three situations may occur: (i) *object* is a self-evaluating object (i.e., neither a symbol nor a non-empty list), in which case *object* is pushed on the result stack; (ii) *object* is a symbol (name of a lexical variable), its value in environment $\mathcal{E}$ is pushed on the result stack; (iii) *object* is a list $(head\ arg_1 \cdots arg_n)$ then the top of the execution stack is replaced as follows:

E: $\langle$EVAL, $(head\ arg_1 \cdots arg_n), \mathcal{E}$, f$\rangle \cdots$ ⟧
R: $\cdots$ ⟧
E: $\langle$EVAL, $head, \mathcal{E}$, N$\rangle$,$\langle$INSPECT, $(arg_1 \cdots arg_n), \mathcal{E}$, f$\rangle \cdots$ ⟧
R: $\cdots$ ⟧

The previous transition has prepared the $head$ of the original list for evaluation. The role of INSPECT is to distinguish between different evaluation rules based on the value of the *head*, i.e. the first element in the list. The *head* may evaluate to a function, a special operator, or a macro. For instance, if INSPECT is on the top of the execution stack and the top of the result stack contains a *function*, INSPECT will prepare application of the function, i.e., it will prepare all arguments for evaluation and then it prepares a function call using FUNCALL:

E: $\langle$INSPECT, $(arg_1 \cdots arg_n), \mathcal{E}$, f$\rangle \cdots$ ⟧
R: $function \cdots$ ⟧
E: $\langle$EVAL, $arg_1, \mathcal{E}$, N$\rangle, \ldots, \langle$EVAL, $arg_n, \mathcal{E}$, N$\rangle$,
$\langle$FUNCALL, $n, \mathcal{E}$, f$\rangle \cdots$ ⟧
R: $function \cdots$ ⟧

The application of functions is performed by FUNCALL which is used in the form $\langle$FUNCALL, $n, \mathcal{E}$, f$\rangle$, where n is the number of arguments. Arguments and the function itself are stored on the result stack. In general, $\langle$FUNCALL, $n, \mathcal{E}$, f$\rangle$ takes $n+1$ objects from the result stack where first n objects represent arguments and the last object taken is the desired function. If the function is a primitive function (i.e., a built-in function), the arguments are passed to the function and the result is pushed on the result stack. If the function is a user-defined function, a body of the function is evaluated in a local environment where formal parameters of the function are bound to arguments obtained from the stack. Therefore, if the body of the function is B, the corresponding transition is the following:

E: $\langle$FUNCALL, $n, \mathcal{E}$, f$\rangle \cdots$ ⟧
R: arg_1, $arg_2, \ldots,$ arg_n, *user-defined fn. with body* $B \cdots$ ⟧
E: $\langle$EVAL, $B, \mathcal{E}'$, T$\rangle \cdots$ ⟧
R: $\cdots$ ⟧

Note that $\mathcal{E}'$ denotes the local environment. According to the value of the flag f, $\mathcal{E}'$ is a fresh new environment (if f equals N) or a reused old environment (if f equals T), which corresponds to a proper tail call, see [12]. For each of the operators, INSPECT has a separate rule of evaluation. For instance, for the special operator `if` the INSPECT operation enforces that only one branch of execution is performed as follows.

Typically, the operator `if` is used in the form: `(if` *cond then-branch else-branch*`)`. If *cond* evaluates to anything but `#f`, the special form returns the value of *then-branch*; otherwise the value of *else-branch* is returned or `#void` is returned in case *else-branch* is not present. Since the result is given by the value of *cond*, INSPECT places the two branches on the result stack, evaluates condition with the operation EVAL, and a new stack operation IF is used to select branch for further evaluation according to the value of *cond*:

E: $\langle$INSPECT, $(cond$ *then-branch else-branch*$), \mathcal{E}$, flag$\rangle \cdots$ ⟧
R: *special operator* `if` $\cdots$ ⟧
E: $\langle$EVAL, $cond, \mathcal{E}$, N$\rangle$,$\langle$IF, $\mathcal{E}$, flag$\rangle \cdots$ ⟧
R: *then-branch*, *else-branch* $\cdots$ ⟧

Now it remains to clarify the newly introduced stack operation IF. The stack operation pops three values from the result stack—an object O representing the value of the *cond*, *then-branch*, and *else-branch*. If O is not equal to `#f`, *then-branch* is pushed back to the execution stack for evaluation:

E: $\langle \mathsf{IF}, \mathcal{E}, \mathsf{flag} \rangle \cdots]\!]$
R: `#f`, *then-branch*, *else-branch* $\cdots]\!]$
E: $\langle \mathsf{EVAL}, \textit{else-branch}, \mathcal{E}, \mathsf{flag} \rangle \cdots]\!]$
R: $\cdots]\!]$

Otherwise, *else-branch* is pushed back to the execution stack for evaluation.

B. Parallel Evaluation Model

In this section, we introduce the implicit parallel evaluation model which is an extension of the evaluation model proposed in the previous section. We outline only the parallel evaluator of a purely functional subset of the language, i.e., subset of Schemik without assignment operations and mutators of pairs (`set!`, `set-car!`, `set-cdr!`), I/O functions (`display`, etc.), and continuations (`call/cc`). Description of the language in its full extent can be found in [16].

Our parallel evaluator of purely functional subset of the language is based on the idea that each operation EVAL may be processed in an independent evaluator as far as the resulting value is dependent only on given arguments and environment. We introduce a new stack operation FEVAL (abbreviation for "fork eval") representing evaluation in an *independent evaluator*, i.e., a thread. Basically, all the independent evaluators form a tree structure with a single (main) evaluator at the top of the hierarchy. Each evaluator has its own independent pair of stacks and environments are shared among all evaluators. We can share environments without any inconsistency issues because we are considering programs without side effects only. This means, once an environment is established, it does not change bindings of symbols (lexical variables).

C. Stack Operation FEVAL

Operation FEVAL is similar to EVAL; it prepares an expression for evaluation in an independent evaluator, i.e., using a new pair of stacks. Operation FEVAL is specific in that it is not a result of any transition caused by another operation. The appearance of FEVAL on any execution stack is caused by external entity called *scheduler* which converts a suitable EVAL operation on an execution stacks to the FEVAL operation and creates a new evaluator containing the original EVAL on top of its execution stack. This way a parallel branch of the evaluation is created. The transition created by scheduler may be depicted as follows:

EV_1: E: $\cdots \langle \mathsf{EVAL}, \textit{object}, \mathcal{E}, \mathsf{f} \rangle \cdots]\!]$
R: $\cdots]\!]$
$\vdots$
EV_1: E: $\cdots \langle \mathsf{FEVAL}, \langle EV_2, \textit{object} \rangle, \mathcal{E}, \mathsf{f} \rangle \cdots]\!]$
R: $\cdots]\!]$
EV_2: E: $\langle \mathsf{EVAL}, \textit{object}, \mathcal{E}, \mathsf{N} \rangle]\!]$
R: $]\!]$

An invocation of FEVAL represents merging of two branches of the evaluation. If $\langle \mathsf{FEVAL}, \langle EV_i, \textit{object} \rangle, \mathcal{E}, \mathsf{f} \rangle$ appears on the top of the execution stack, the evaluation in the referred evaluator EV_i is stopped and its stacks are appended to the corresponding stacks of the current evaluator processing the FEVAL operation.

This behavior of FEVAL is correct because the referenced evaluator EV_i has performed right the same transitions that should be otherwise performed by the evaluator containing the FEVAL operation. We can consider the creation of this operation as a request for parallel evaluation to other evaluator and processing of FEVAL operation as a request for obtaining (partial) results from the referenced evaluator.

D. Scheduling Strategies

An important issue in implicit parallel evaluation is how to decide which expression is worth evaluating in a parallel branch. In theory, an arbitrary expression may be parallelized but it is desirable to focus on particular expressions that require larger amounts of transitions.

The decision on which expression will be evaluated in a parallel branch is done by the *scheduler*, associated to each evaluator, regularly seeking through the execution stack for operations EVAL that may be converted into the FEVAL operations. A stack operation $\langle \mathsf{EVAL}, \textit{object}, \mathcal{E}, \mathsf{f} \rangle$ is considered as a good candidate for parallel evaluation if $\textit{object}$ is a list or a list fulfilling further criteria. For instance, $\textit{object}$ should be a list containing other list, or a list with a user-defined function as its first element.

In particular, we use strategy assigning limited number of independent evaluators to candidate expressions which has its origin in the organization of the execution stack. This strategy assumes that more complex expressions are at the bottom of the stack and their evaluation will need more transitions, and thus, their evaluation in a parallel branch will be more beneficial. Therefore, scheduler walks through the execution stack from the bottom and looks for candidate expressions.

III. Just-in-Time Compilation

The ability of the execution model to automatically parallelize programs comes from the fact that one can easily determine the structure of the program execution by inspection of the automaton. Particularly, by inspection of the *execution stack*. However, if the program, or its portion, is compiled, we are losing the ability to analyze the program structure since scheduler is unable to identify expression for parallelization. In order to combine JIT compilation with the ability to parallelize programs, we propose an extension which compiles into a native code only expressions which are insignificant from the point of parallelization, and thus, compiler does not interfere with the mechanism for automatic parallelization. Such typical insignificant expression is an atom (symbol or self-evaluating object) or function call where arguments are atomic expressions. Apparently, their evaluation is very fast and their evaluation in parallel branches would lead to fine-grained parallelism and to a related overhead caused by

scheduling and spawning too many threads of execution. These expressions which are insignificant from the point of view of parallelization and which are, on the other hand, worth compiling shall be called *compilable*. Formally, an expression E is *compilable* if it satisfies one of the following conditions:

(1) Expression E is either atom (i.e., symbol, number, string, etc.),
(2) or E is an expression of a form $(E_1\ E_2\ \ldots E_n)$ where E_1 is a primitive function or a special operator and $E_2, \ldots, E_n$ are all compilable expressions.

Remark 3.1: Notice that the definition of compilable expression is recursive. Later, we use this fact to incrementally compile complex expression using the less complex ones.

Remark 3.2: It might be impossible to decide whether expression is compilable or not, strictly speaking, generally, it is an undecidable problem. Therefore, in a case when we are unable to determine if an expression is compilable, we assume that the expression is not compilable at all. When determining compilability of a non-atomic expression, it is crucial to determine the type of the first expression. For this purpose we use the following approximation. If the first expression E_1 is a symbol defined only in the top-level environment (w.r.t. the environment in which E_1 is evaluated) and if a primitive function or a special operator is bounded to this symbol, we assume that E_1 evaluates to a primitive function or a special operator. Note that this condition can be checked in a constant time and covers among others common function calls where symbol is used to directly represent a primitive function. For instance, `(+ a 1)` is an example of such expression.

A. Compilation: An Overview

The compilation process consists of several independent steps.

Before the program execution starts, all lists in the source code consisting solely of atoms are marked with a flag indicating that the given expression is a good candidate for compilation. For this purpose all source code expressions are equipped with a data structure similar to property-lists known from Common Lisp [9] which contains flags and further information produced by compiler, e.g., native code. Notice that this flag does not mean that expression is compilable, rather it is an indicator that compiler should try to compile this expression.

Every time the operation EVAL is on the top of the execution stack, its argument (evaluated expression) is checked if it has associated native code generated by the compiler, if so, the given code is executed and returned value is pushed on the result stack as if the evaluation was performed in a usual way. Otherwise, if the given expression is marked as a good candidate for a compilation, it is inserted into a queue of expressions waiting for compilation. In any case, if the expression has not attached any native code, it is evaluated in a standard way as described in Section II.

All expressions waiting for compilation in a queue are processed one by one by a compiler. For each expression, compiler checks whether is compilable, and if not, flag representing that an expression is a good candidate for compilation is removed. Otherwise, expression is compiled and the results of the compilation process (native code and intermediate representation of the code) are attached to the expression. Furthermore, expression containing this expression is marked as a good candidate for compilation.

Remark 3.3: Marking a parent expression as a candidate expression for compilation is a necessary step allowing us to incrementally compile complex expressions. For example, initially entire expression `(+ a (+ b 1))` is not marked as a good candidate for compilation since the second argument is not an atom and one can not decide if `(+ b 1)` is compilable. However, subexpression `(+ b 1)` is marked as a good candidate. If this subexpression is compiled, an entire expression `(+ a (+ b 1))` becomes also a good candidate and may be compiled into a native code. This corresponds with the recursive definition of *compilable* expression.

The key part of the compilation process is a transformation of a given expression into a native code, this transformation and related implementation aspects are discussed in the next section.

B. Compilation: Code Generation

The main task of the compiler is to take an expression and transform it into a native code which under the same conditions evaluates to same value as it would be evaluated usually. For instance, having an expression `(+ a 1)` we need to generate function with a prototype like this:

```
value *plus_a_1(environment *)
```

which gets value of `a` in a given environment and returns its value increased by one.

The process of expression compilation we propose can be divided into three steps. At first, expression is compiled into a high-level intermediate representation (HIR), this representation by its nature is very close to three-address code used by many compilers. In the next step optimization techniques are applied. Afterwards, HIR is transformed into a native code. Optionally, this step may consist of additional transformation. For instance, we transform HIR into a corresponding low-level intermediate representation (LIR) which is used to perform low-level optimizations, and after that, the native code is generated.

The high-level intermediate representation we propose consists of operations having up to three arguments. These arguments may be constants (regular Schemik objects), registers playing the role of (temporary) variables, or lists of operations of HIR playing the role of code blocks. We assume that registers are enumerable and shall be denoted R_i where i is an integer. List of essential operations used by HIR along with their semantics is presented in Table I.

The recursive way we define compilable expressions has been reflected in a way we compile expressions into a HIR. Entire process of transformation of the expression to HIR is described by the recursive procedure COMPILEHIR procedure

TABLE I
LIST OF OPERATIONS USED IN HIGH-LEVEL INTERMEDIATE REPRESENTATION

operation	meaning
`set` R_i, *source*	assigns value of *source* to the register R_i; *source* may be either a constant or register
`eval-symbol` R_i, S	evaluates symbol S w.r.t. current environment and stores the result into the register R_i
`prepare` *count*	an auxiliary operation introducing each function call, its purpose is to declare number of arguments
`putarg` i, *source*	passes value of *source* as the i-th argument of the function; *source* may be either a constant or register
`funcall` R_i, *fun*	calls function *fun* and stores the returned value into the register R_i
`add` R_i, R_j, *value*	adds R_j and *value*, which may be a constant or register, and stores the result into R_i; note that there are also operations for subtraction, multiplication, comparisons, etc.
`car` R_i, R_j	extracts the *car*-part of a dotted pair stored in the register R_j and stores the result into the register R_i
`cdr` R_i, R_j	analogous operation to `car` extracting the *cdr*-part of a dotted pair
`if` R_i, BRANCH$_1$, BRANCH$_2$	if value in the register R_i is other then `#f`, code in BRANCH-1 is performed, otherwise, BRANCH-2 is executed; note that BRANCH-1, BRANCH-2 represents an entire list of operations in HIR, i.e., correspond to code blocks
`rslt-push` R_i	pushes value in the register R_i on top of the result stack
`exct-push` *expression*	pushes value of *expression* on the execution stack; *expression* may be either a constant or register

which is presented in Algorithm 1. This procedure has two arguments—the given expression E and register number $base$. This number identifies the first register that can be used to compute the value of the expression E. The crucial feature of this procedure is that COMPILEHIR does not generate code directly, but returns a procedure which generates the final HIR for the expression. This procedure has one argument i and allows to shift used registers by offset i. In other words, COMPILEHIR does not generate final code, but rather a template of the code. This behavior is illustrated in Figure 1 (top) containing the result of COMPILEHIR procedure for expression `(foo a 1)` and argument $base$ equal to 10. As one can see this "template" is very close to three address code and the main difference is that registers does not have fixed numbers and may be shifted by offset i. Nonetheless, without loss of generality we may apply optimization techniques proposed for three-address code, e.g., constant and copy propagation, or dead-code elimination.

We now turn our attention to the HIR(i) procedure which is a result of the COMPILEHIR(E, $base$) procedure, as described in Algorithm 1. We assume that the generated code satisfies

Algorithm 1 Procedure COMPILEHIR(E, $base$)

```
1:  return procedure HIR(i) such that:
2:  if E is a constant (e.g., number) then
3:      emit operation set R_{base+i}, E
4:  if E is a symbol then
5:      emit operation eval-symbol R_{base+i}, E
6:  if E has attached HIR code then
7:      invoke HIR(base + i)
8:  if E is an expression (fun E_2 E_3 ... E_n) where fun
    is a primitive function then
9:      for all E_j where j ∈ {2, ..., n} do
10:         invoke COMPILEHIR(E_j, base + i + j − 1)
11:     if operation exct-push was emitted then
12:         abort compilation
13:     if fun is primitive function + then
14:         invoke COMPILEADDITION(base + i, n)
15:     else if fun is primitive function car then
16:         emit operation car R_{base+i}, R_{base+i+1}
17:     else
18:         invoke COMPILEFUNCALL(base + i, n, fun)
19: if E is expression (if E_cond E_1 E_2) and E_cond is
    compilable then
20:     invoke COMPILEIF(base + i, E_cond, E_1, E_2)
21: if E is quotation (quote val) then
22:     emit operation set R_{base+i}, val
23: otherwise abort compilation
```

the following conditions:

(i) The result of the computation is stored in the register R_{base+i} or generated code modifies content of the evaluator's stacks directly and in that case no value is returned.
(ii) No register with an index lesser than $base + i$ will be used to compute the result.

If the expression is an atom (see Algorithm 1, lines 2–5), procedure HIR generates operation which gets the value of the atom and stores the result into the register R_{base+i}. In case we encounter an expression which has attached code in HIR, see lines 6–7, we use the fact that intermediate code is already available and we use it to compute value of the expression. Notice that HIR is in fact a procedure and is invoked with an argument $base+i$. This ensures that once generated HIR code may use different set of registers which does not interfere with the registers already used. Furthermore, from the assumption (i) follows that the result, if returned, will be in the register R_{base+i}.

Code generation for non-atomic expressions consists of multiple sub-actions, see lines 8–22. Initially, the value of the first element is determined, i.e., the called function is determined. Subsequently, code that computes values of all arguments is generated, assuming that all arguments are evaluated in the left-to-right order and arguments are stored in registers $R_{base+i+1}$, $R_{base+i+2}$, …, $R_{base+i+n}$. To generate code evaluating arguments, we recursively invoke the COM-

Procedure HIR(i):
emit operations:
`eval-symbol` R_{11+i}, a
`set` R_{12+i}, 1
`prepare` 2
`putarg` 1, R_{11+i}
`putarg` 2, R_{12+i}
`funcall` R_{10+i}, *foo*

Procedure HIR(i):
emit operations:
`eval-symbol` R_{11+i}, a
`if` R_{11+i}, {
`set` R_{11+i}, 0
`rslt-push` R_{11+i}
}, {
`exct-push (foo b)`
}

Fig. 1. HIR of `(foo a 1)` (top) and HIR of `(if a 0 (foo b))` (bottom)

PILEHIR procedure at lines 9–10. Due to the assumption (ii), it is guaranteed that the registers used to compute arguments will not overlap in an undesirable way. This means, values of already computed arguments which are stored in the registers will not be overwritten during the computation of remaining arguments. Note that if any argument is compiled expression which does not return a value and rather directly manipulates with stacks, it is a sign that we can not obtain a value of this argument and entire expression is not compilable and compilation process has to be aborted, see lines 11–12. Situation when the generated code directly tempers with the execution stack is discussed later.

If the called function is a primitive function and if the compiler has mean to compile this function into a native code, appropriate code is generated. This is the case of frequently used functions, for instance, function for addition, subtraction, `car`, `cdr`, etc. Procedure presented in Algorithm 1 shows how this rule applies for addition and function `car`, see lines 13–16 and related Algorithm 2. Otherwise, code for generic function call is generated, see line 18 in Algorithm 1 and Algorithm 3.

Remark 3.4: In case of frequently called functions (e.g., addition) it may be efficient to generate code directly instead of performing generic function call, since calling a function in native code has overhead related to argument passing.

Compilation of special operators requires different approach. In this paper we discuss only two operators—`if` and `quote` since our experiments have shown, these operators affect the program performance the most. Compilation of the `(quote val)` expression is straightforward, it suffices to assign value of `val` to the register R_{base+i}. In case of the `if` operator is situation much more complex.

Let us consider the following two snippets of source code `(if (> a 0) 1 (+ a 1))` and `(if (> a 0) 1 (foo a))` and let us assume that `(> a 0)`, `(+ a 1)` are compilable expressions and

Algorithm 2 Procedure COMPILEADDITION(i, n)

1: **emit** operations:
`set` R_i, 0
`add` R_i, R_i, R_{i+1}
...
`add` R_i, R_i, R_{i+n}

`(foo a)` is not compilable. In the first case we have an expression which can be safely compiled because all subexpressions are compilable. In the second case we have limited information on `(foo a)` and we have to assume that this expression may perform any sequence of operations, and thus, is significant from the parallelization point of view. In conclusion, we may assume that only `(> a 0)` is compilable. Unfortunately, the second type of conditions appears in real-world programs more often than the first one, hence we have to take this fact into account.

The compilation process of conditional expression is presented in the COMPILEIF procedure (described in Algorithm 4) which is invoked from COMPILEHIR. While compiling conditional expression, we always assume that the condition is compilable expression and its HIR is available, see lines 1–4 in Algorithm 4. For expressions representing branches two situations may occur. (1) Both branches are compilable and HIR is available, (2) or at least one expression is not compilable or HIR is not available for this expression. In the first case, we generate a code which computes value of the condition and if the value is true or false, it computes value of the first or the second branch, respectively, and stores the result into a given register, see lines 5–10 and 15 in Algorithm 4. Notice that this case corresponds to the first snippet of the code discussed in the previous paragraph. In the second case, which corresponds to the second code snippet from the previous paragraph, we are unable to determine the value of the expression entirely and at some point we have to pass control back to the evaluator. Basically, generated code has to compute value of the condition and accordingly perform one branch of the execution. Code generated for each branch depends on the nature of the expression in a given branch. If HIR of the expression is available, this code is returned along with the operation `rslt-push` which pushes result on the *result stack* and passes execution back to the evaluator, see lines 11–14 in Algorithm 4. Otherwise, operation `exct-push` is performed, this operation pushes given expression on the execution stack, in other words, it evaluates expression by means of the evaluator. An illustrative example of compiled conditional expression `(if a 0 (foo b))`, which is generated by the COMPILEIF procedure, is presented in Figure 1 (bottom).

C. Native Code Generation

Using the COMPILEHIR procedure we have obtained high-level intermediate representation of the expression. This representation by its nature allows multiple optimizations, especially, those based on data-flow analysis. Since the HIR is very

Algorithm 3 Procedure COMPILEFUNCALL(i, n, *fun*)

emit operations:
`prepare` n
`putarg` 1, R_{i+1}
`putarg` 2, R_{i+2}
...
`putarg` n, R_{i+n}
`funcall` R_i, *fun*

Algorithm 4 Procedure COMPILEIF(i, E_{cond}, E_1, E_2)

if E_{cond} has attached HIR code without the `exct-push` operation **then**
    invoke HIR(i)
else
    abort compilation
for all E_j where $j \in \{1, 2\}$ **do**
    // create code block BRANCH$_j$ *such that:*
    if E_j has attached HIR code **then**
        BRANCH$_j$ $\leftarrow$ HIR(i)
    else
        BRANCH$_j$ $\leftarrow$ operation `exct-push` E_j
if E_1 has attached HIR code **and** BRANCH$_2$ contains `exct-push` **then**
    append to BRANCH$_1$ operation `rslt-push` R_1.
if E_2 has attached HIR code **and** BRANCH$_1$ contains `exct-push` **then**
    append to BRANCH$_2$ operation `rslt-push` R_2
emit operation `if` R_i, BRANCH$_1$, BRANCH$_2$

close to three-address code, we may directly apply optimization techniques. Namely we use copy propagation, constant propagation, constant folding, and dead code elimination. All these techniques significantly simplify the resulting code. These techniques are well-known and thoroughly studied, for instance, in [18] or [2], therefore we omit discussion on this topic and refer readers to these books.

Apparently, each operation of the HIR may be transformed into an assembly language. Usually, it requires less than ten instructions of assembly language to express these operations, because operations of HIR are in fact very simple. However, in order to increase portability of the compiler, our implementation converts HIR into a low-level intermediate representation (LIR) which is afterwards compiled to a native code, by a library. Our implementation is based on the MyJIT library [1], therefore our low-level intermediate representation is equivalent to the instruction set of this library. This library generates machine code for numeric operations, conditional and unconditional jumps, function calls, memory access operations, and takes care of register allocation. Since the LIR is tightly coupled with implementation aspects of the interpreter/compiler, we do not describe transformation from the HIR to the LIR and code generation in this paper. Nonetheless, it could be possible to use any other similar library to generate native code, for instance, LLVM.

Major part of our JIT compiler is written in Schemik itself, i.e., the JIT compiler is self-hosted and its code is a part of the standard library and all intermediate representations are objects (lists) in Schemik language as well. This way we benefit from the expressiveness of the Schemik language, especially, from the ability to conveniently transform one list of values to another. Every time the evaluator encounters compilable expression, it invokes the `jit:compile` function which is an ordinary function written in Schemik taking care of the transformation of an expression into the HIR and, subsequently, into a native code. For this purpose, Schemik has bindings to the MyJIT library. Function `jit:compile` returns representation of the expression in the HIR and a native code and an evaluator assigns these results to a given expression. The `jit:compile` function is always evaluated in a separate thread, however, it is evaluated with a regular evaluator as discussed in Sections II and III, hence benefits from the parallel evaluation of expressions and even from the JIT compilation of expressions. Since the compilation of the user supplied source code is mixed together with the compilation of the compiler itself, it usually takes some minimal amount of time for compiler to take effect, because compiler tends to compile itself first. However, if compiled version of an expression is not available, regular evaluation process is used, hence compilation has minimal impact on the execution time, if compared with the regular evaluator.

IV. EXPERIMENTS

In order to evaluate impact of the JIT compiler we performed set of experiments on a computer equipped with two Intel Xeons E5642 (eight CPU-cores in total) using standard benchmarks. Results of these experiments are presented in Table II containing times needed to compute given task for various configurations of the interpreter. First two columns represent results for an interpreter/compiler running only with one thread. The next two columns represent results when interpreter/compiler was allowed to use up to eight threads to compute results. The last column shows the results for the Guile Scheme (1.8.8). Experiments shows typical performance improvement by factor 2 or 3 depending on the type of benchmark and data size. It also shows that the results are fully comparable with Guile.

Important feature of parallel systems is their scalability. Our experiments show that the compiler slightly decreases scalability, see Figure 2. However, this is mostly only an effect of the Amdahl's law. Nevertheless, this shortcoming is adequately compensated since the compiler significantly improves performance, as it is apparent from Table II.

V. RELATED WORKS

Basically, two approaches to impose implicit parallelism into programming languages can be distinguished. The first is static code analysis which hard-wires parallel execution into a program during the compilation. This technique proved to be useful and has become part of the commercial compilers.

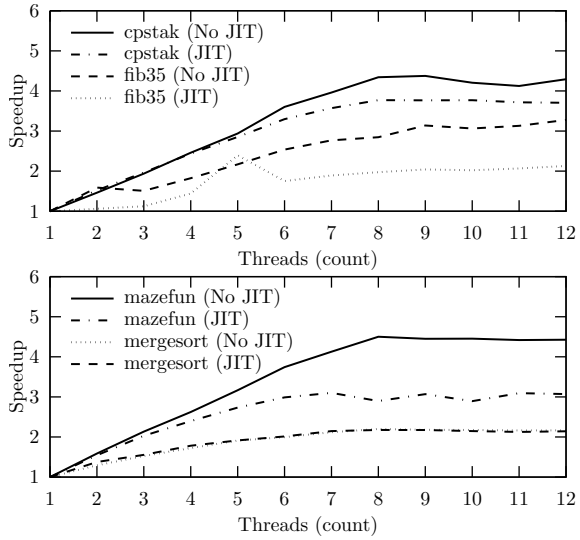

Fig. 2. Scalability of standard benchmarks

However, static code analysis usually focus only on loop parallelization, see [5], [13], what limits its use.

The second approach utilizes run-time analysis and dynamic parallelization. From this category most influential programming languages are Fortress [3] and Concurrent Haskell [19], [6]. However their execution model is tied to specifics of given languages and therefore it is hardly possible to transfer their model into other languages, e.g., into Scheme. Idea to parallelize Lisp-programs is not novel and many approaches to parallel execution of programs in Lisp [17] and Scheme [8], [10] appeared. Nevertheless, majority of this approaches were focusing on explicit parallelism, survey of these approaches can be found in [11]. Relatively, new approach to automatic parallelization of Scheme programs is proposed in [7] which is an interpretation model based on a speculative execution model. To the best our knowledge there is no other execution model like ours which combines run-time analysis and dynamic parallelization along with compilation.

VI. CONCLUSIONS

We have proposed an extension of the execution model for an implicitly parallel programing language. Our extension introduces means of JIT compilation into the execution model which was originally intended for interpreted programming language. Our experiments show that JIT compiler can efficiently decrease execution time of programs while preserving all features of the underlying model language, especially the ability to automatically parallelize programs. In future we intend to focus on further optimizations which are able to decrease program execution time even more, e.g., function inlining or specialization.

***Abstract*—Machine-code decompilation is a reverse-engineering discipline focused on reverse compilation. It performs an application recovery from binary executable files back into the high level language (HLL) representation. One of its critical tasks is to produce an accurate and well-readable code. However, this is a challenging task since the executable code may be produced by one of the modern compilers that use advanced optimizations. One type of such an optimization is usage of so-called instruction idioms. These idioms are used to produce faster or even smaller executable files. On the other hand, decompilation of instruction idioms without any advanced analysis produces almost unreadable HLL code that may confuse the user of a decompiler. In this paper, we present a method of instruction-idioms detection and reconstruction back into a readable form with the same meaning. This approach is adapted in an existing retargetable decompiler developed within the Lissom project. The implementation has been tested on several modern compilers and target architectures. According to our experimental results, the proposed solution is highly accurate on the RISC (Reduced Instruction Set Computer) processor families, but it should be further improved on the CISC (Complex Instruction Set Computer) architectures.**

***Keywords*—compiler optimizations, reverse engineering, decompiler, Lissom, instruction idioms, bit twiddling hacks**

I. Introduction

REVERSE engineering is a process analyzing existing objects to discover knowledge about their functionality. Within the computer and information security, reverse engineering is often used for analysis of binary executable files. This is useful for vulnerability detection, malware analysis, compiler verification, code migration, etc. In present, this analysis is commonly done by using low-level tools such as disassemblers and dumpers.

Machine-code decompilers (i.e. reverse compilers) are more effective but not so wide-spread. Their task is to recover HLL representation (e.g. C source code) from executable files. In contrast to compilation, the process of decompilation is much more difficult because the decompiler must deal with incomplete information on its input (e.g. information used by the compiler but not stored within the executable file). Furthermore, the input machine code is often heavily optimized by one of the modern compilers (e.g. GCC, LLVM, MSVC); this makes decompilation even more challenging.

This work was supported by the BUT grant FEKT/FIT-J-13-2000 Validation of Executable Code for Industrial Automation Devices using Decompilation and BUT FIT grant FIT-S-11-2.

Code de-optimization is one of the necessary transformations used within decompilers. Its task is to properly detect the used optimization and to recover the original HLL code representation from the hard-to-read machine code. One example of this optimization type is the usage of *instruction idioms* [1]. An instruction idiom is a sequence of machine-code instructions representing a small HLL construction (e.g. arithmetic expression, assignment statement) that is highly-optimized for its execution speed and/or small size.

The instructions in such sequences are assembled together by using Boolean algebra, arbitrary-precision arithmetic, floating-point algebra, bitwise operations, etc. Therefore, the meaning of such sequence is usually hard to understand at the first sight. A notoriously known example is the usage of an exclusive or to clear the register content (i.e. `xor reg, reg`) instead of an instruction assigning zero to this register (i.e. `mov reg, 0`).

The goal of this paper is to present an approach how to deal with instruction-idioms detection and their reconstruction during decompilation. This approach has been successfully adapted within an existing decompiler developed within the Lissom project [2, 3]. Moreover, this decompiler is developed to be retargetable (i.e. independent on a particular target platform, operating system, file format, or a used compiler); therefore, the proposed analysis has to be retargetable too.

This paper is organized as follows. In Section II, we give an introduction to instruction idioms and their usage within compiler optimizations. Then, we briefly describe the retargetable decompiler developed within the Lissom project in Section III. Afterwards, we present our own approach in Section IV. The most common instruction idioms employed in the modern compilers are presented and illustrated in the same section. Section V discusses the related work of instruction idioms reconstruction. Experimental results are given in Section VI. Section VII closes the paper by discussing future research.

II. Instruction Idioms used in Compilers

In present, the modern compilers use dozens of optimization methods for generating fast and small executable files. Different optimizations are used based on the optimization level selected by the user. For example, the GNU GCC compiler supports these optimization levels[1]:

- `O0` – without optimizations;

[1] See http://gcc.gnu.org/onlinedocs/gcc/Optimize-Options.html for details.

978-83-60810-53-8/$25.00

- `O1` – basic level of speed optimizations;
- `O2` – the common level of optimizations (the ones contained in `O1` together with basic function inlining, peephole optimizations, etc.);
- `O3` – the most aggressive level of optimizations;
- `Os` – optimize for size rather than speed.

In the nowadays compilers, the emission of instruction idioms cannot be explicitly turned on by some switch or command line option. Instead, these compilers use selected sets of idioms within different optimization levels. Each set may have different purpose, but multiple sets may share the same (universal) idioms. The main reasons why to use instruction idioms are:

- The most straightforward reason is to exchange slower instructions with the faster ones. These optimizations are commonly used even on the lower optimization levels.
- The floating-point unit (FPU) might be missing, but a programmer still wants to use floating-point numbers and arithmetic. Compilers solve this task via floating-point emulation routines (also known as *software floating point* or *soft-float* in short). Such routines are generated instead of hardware floating-point instructions and they perform the same operation by using available (integer) instructions.
- Compilers often support an optimization-for-size option. This optimization is useful when the target machine is an embedded system with a limited memory size. An executable produced by a compiler should be as small as possible. In this case, the compiler substitutes a sequence of instructions encoded in more bits with a sequence of instructions encoded in less bits in general. This can save some space in instruction cache too.

Another type of optimization classification is to distinguish them based on the target architecture. Some of them depend on a particular target architecture. If a compiler uses platform-specific information about the generated instructions, these instructions can be classified as platform-specific. Otherwise, they are classified as platform-independent.

As an example of platform-independent idiom, we can mention the `div` instruction representing a fixed-point division. The fixed-point division (signed or unsigned) is one of the most expensive instruction in general. Optimizing the division leads to a platform-independent optimization.

On the other hand, clearing the content of the register by using the `xor` instruction (mentioned in the introduction) is a highly platform-specific optimization. Different platforms can use different approaches to clear the register content. As an example, consider the zero register on MIPS (`$zero` or `$0`), which always contains the value of 0. Using this register as a source of zero bits looks like a faster solution than using a `xor` instruction.

Furthermore, different compilers use different instruction idioms to fit their optimization strategies. For example, GNU GCC uses an interesting optimization when making signed comparison of a variable. When a number is represented on 32-bits and bit number 31 is representing the sign, logically shifting the variable right by 31 bits causes to set the zeroth bit equal to the original sign bit. The C programming language classifies 1 as *true* and 0 as a *false*, which is the expected result of the given less-than-zero comparison. This idiom is shown in Fig. 1. The Fig. 1a represents a part of a source code with this construction. The result of its compilation with optimizations enabled is depicted in Fig. 1b. We illustrate the generated code on the C level rather than machine-code level for better readability.

The compiler used the before-mentioned instructions idiom—replacing the comparison by the shift operation. The not-standardized `lshr()` function is used in the output listed in Fig. 1b. The C standard does not specify whether operator ">>" means logical or arithmetical right shift. Compilers deal with it in an implementation-defined manner. Usually, if the left-hand-side number used in the shift operation is signed, arithmetical right shift is used. Analogically, logical right shift is used for unsigned numbers.

III. Lissom Project Retargetable Decompiler

In this section, we briefly describe the concept of an automatically generated retargetable decompiler developed within the Lissom project [2]. This decompiler aims to be independent on any particular target architecture, operating system, object file format, or originally used compiler. The concept of the decompiler is depicted in Fig. 2. Its detailed description can be found in [3]. Currently, the decompiler supports decompilation of MIPS, ARM, and Intel x86 executable files stored in different file formats.

The input binary executable file is preprocessed at first. The preprocessing part tries to detect the used file format, compiler, and (optional) packer, see [4] for details. Afterwards, it unpacks and converts the examined platform-dependent application into an internal uniform Common-Object-File-Format (COFF)-based representation. Currently, we support conversions from UNIX ELF, Windows Portable Executable (WinPE), Apple Mach-O, Symbian E32, and Android DEX file formats. The conversion is done via our plugin-based converter described in [5, 6]. Afterwards, such COFF-file is processed in the decompilation core that consists of three basic parts—a *front-end*, a *middle-end*, and a *back-end*. The last two of them are built on top of the LLVM Compiler Infrastructure [7]. LLVM Intermediate Representation (LLVM IR) [8] is used as an internal code representation of the decompiled applications in all particular decompilation phases.

```
int main(void)
{
  int a, b;

  /* ... */

  b = a < 0;

  /* ... */
}
```

(a) Input.

```
int main(void)
{
  int a, b;

  /* ... */

  b = lshr(a, 31);

  /*... */
}
```

(b) Output (for better readability in C).

Fig. 1: Example of an instruction idiom (C code).

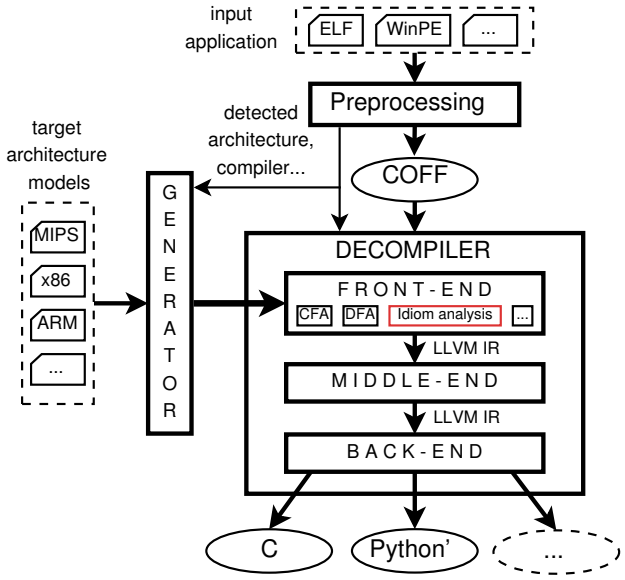

Fig. 2: The concept of the Lissom project retargetable decompiler.

After that, the unified COFF files are processed by the front-end part.Within this part, we use the ISAC architecture description language [9] for an automatic generation of the *instruction decoder*. The decoder translates the machine-code instructions into sequences of LLVM IR instructions. The resulting LLVM IR sequence characterizes behaviour of the original instruction independently on the target platform. This intermediate program representation is further analysed and transformed in the static-analysis phase of the front-end. This part is responsible for eliminating statically linked code, detecting the used ABI, recovery of functions, etc. [3]. When debugging information (e.g. DWARF, Microsoft PDB) or symbols are present in the input application, we may utilize them to get more accurate results, see [10].

The output of the front-end part (i.e. LLVM IR code representing input application) is sizable. The main reason is because it reflects a complete behavior of each machine-code instruction, which may not be necessary. For example, each side-effect of an instruction (e.g. setting a register flag based on instruction operands) is represented via the LLVM IR code, but results of these side-effects may not be used anywhere. Therefore, the front-end output is further processed within the middle-end phase, which is built on the top of the LLVM `opt` tool. This phase is responsible for reduction and optimization of this code by using many built-in optimizations available in LLVM as well as our own passes (e.g. optimizations of loops, constant propagation, control-flow graph simplifications).

Finally, the back-end part converts the optimized intermediate representation into the target high-level language (HLL). Currently, we support C and a Python-like language. The latter is very similar to Python, except a few differences—whenever there is no support in Python for a specific construction, we use C-like constructs. During the back-end conversion, high-level control-flow constructs, such as loops and conditional statements, are identified, reconstructed, and further optimized. Finally, it is emitted in the form of the target HLL.

The decompiler is also able to produce the call graph of the decompiled application, control-flow graphs for all functions, and an assembly representation of the application.

```
%a = load i32* @regs0
%b = xor i32 %a, %a
store i32 %b, i32* @regs0
```

(a) Optimized form of an instruction idiom in LLVM IR.

```
store i32 0, i32* @regs0
```

(b) De-optimized form of an instruction idiom in LLVM IR.

IV. Idiom Analysis and Reconstruction in the Retargetable Decompiler

The aim of the decompiler presented in the previous section is to allow retargetable decompilation independently on the particular target platform or the used compiler. Therefore, the methods of instruction idiom detection and reconstruction have to be retargetable too. For this reason, we implement these methods within the front-end phase because it uses the unified code representation in the LLVM IR format.

Detection of instruction idioms is based on a detection algorithm operating on the LLVM IR code. LLVM IR is a set of low-level instructions similar to assembly instructions. Moreover, LLVM IR is platform-independent and strongly typed, which meets our requirements. Therefore, machine instructions from different architectures can be easily mapped to sequences of LLVM IR instructions. This brings an ability to implement platform-independent instruction-idiom analysis.

The detection algorithm is similar to a peephole technique used in optimizing compilers [11]. It operates on a basic-block level, where each basic block contains a continuous sequence of instructions described via LLVM IR operations. A particular idiom is detected only if a basic block contains predefined LLVM IR instructions stored in a proper order and they must contain expected operand values (e.g. constant, register number). While examining instructions in an idiom sequence, we may found unrelated instructions (e.g. inserted by a code-motion compiler optimization). The detection algorithm may skip these instructions and continue the search on the following ones, but only if they do not modify the operands of already detected instructions. Otherwise, the search continues behind the current instruction from the beginning. Whenever an instruction idiom is detected, it is substituted by its more readable de-optimized version, once again in the LLVM IR form. The skipped instructions are left untouched on their original positions.

It should be noted that this algorithm does not search for a particular idiom over multiple basic blocks in present. The detection enhancement via usage of a control-flow analysis represents a future research. However, according to our experimental tests, the nowadays common compilers rarely scatter instructions related to idioms over multiple basic blocks. Therefore, the impact of this enhancement may be low.

An example demonstrating this substitution on the LLVM IR level is shown in Fig. 3. Fig. 3a represents the already mentioned `xor` bit-clear instruction idiom. To use register

TABLE I: Shortened list of instruction idioms found in compilers.

Instruction idiom	GNU GCC	Visual Studio C++	Intel C/C++ Compiler	Open Watcom	Borland C Compiler
Less than zero test	✓	×	✓	×	×
Greater equal zero test	✓	×	×	×	×
Bit clear by using `xor`	✓	✓	✓	✓	✓
Bit shift multiplication	✓	✓	✓	✓	✓
Bit shift division	✓	✓	✓	✓	✓
Division by `-2`	✓	×	×	×	×
Expression `-x - 1`	✓	✓	×	×	×
Modulo power of two	✓	✓	✓	×	×
Negation of a float	✓	×	×	×	×
Assign `-1` by using `and`	×	✓	✓	×	×
Multiplication by an invariant	✓	✓	✓	✓	×
Signed modulo by an invariant	✓	×	✓	×	×
Unsigned modulo by an invariant	✓	✓	✓	×	×
Signed division by an invariant	✓	✓	✓	×	×
Unsigned division by an invariant	✓	✓	✓	×	×
Substitution by `copysignf()`	✓	×	×	×	×
Substitution by `fabsf()`	✓	×	×	×	×

content, a register value has to be loaded into a typed variable `%a`. Using the `xor` instruction, all bits are zeroed and the result (in variable `%b`) can be stored back into the same register. To transform this idiom into its de-optimized form, a proper zero assignment has to be done. This de-optimized LLVM IR code is shown in Fig. 3b. In this case, the typed variable `%b` holds zero, which can be directly stored in the register.

In Table I, we can see a shortened list of instruction idioms used in common compilers. This list was retrieved by studying the source codes responsible for code generation (this applies to open-source compilers—GNU GCC 4.7.1 and Open Watcom 1.9) and via reverse engineering of executable files generated by these compilers (this method was used for other compilers—Microsoft Visual Studio C++ Compiler 16 and 17, Borland C++ 5.5.1, and Intel C/C++ Compiler XE13). Some of these instruction idioms are widespread among modern compilers. We have also found out that actively developed compilers, such as GNU GCC, Visual Studio C++, and Intel C/C++ Compiler, are using these optimizations heavily. For example, they generate the `idiv` instruction (fixed signed division) only in rare cases on the Intel x86 architecture; they generate optimized division by using magic number multiplication instead. The decompiler currently supports all of these idioms, among others.

A decompilation of an executable file is a time consuming process. The decompilation time highly depends on the executable size. A good approach how to optimize instruction-idioms analysis is to use any available information to save decompilation time. This is especially important when we support many instruction idioms. Some of them are specific for a particular compiler and therefore, they can be omitted from the detection phase whenever another compiler is detected. On the other hand, detection of the used compiler (as described in [4]) may be inaccurate in some cases and the algorithm will not detect any used compiler. In that case, the idiom analysis tries to detect all the supported idioms. Another optimization approach is to detect only the platform-specific idioms based on the target architecture and omit idioms for other architectures.

Transformation of instruction idioms by using LLVM IR is a quite straightforward task and it is entirely platform independent. On the other hand, the detection of an instruction idiom is more challenging. For example, the expected operand values (e.g. values used for magic number multiplication) may not be stored as clearly as in a original HLL source code. For example, the original HLL constant may not be stored directly as a number (i.e. immediate value), but it may be computed through several machine-code instructions. These instructions fold the original value at run-time based on different resources (e.g. register value, memory content). For example, the MIPS instruction set does not allow direct load of 32-bit immediate value and it has to be done using more instructions (e.g. `lui` and `ori`). Therefore, the operand value is not stored directly within one instruction but it is assembled by an instruction sequence. This is quite complicated because the idiom-detection phase (as well as the rest of the decompiler) is done statically and run-time information is unavailable. To deal with this problem, we utilize a static-code interpreter, originally used for function reconstruction—see [3] for a detailed description of the static-code interpreter.

Using an interpreter to statically compute a value stored in a register is quite common task in instruction-idiom analysis. An example is shown in Fig. 4. An interpreter has to be run to statically compute a number stored in register `@regs3` by using the backtracking of previously used operations and their operands. The obtained result is in this case `680390859`. This number is used in optimized division by number `101` performed by the magic-number multiplication on ARM and the GNU GCC compiler. Another similar issue is accessing the data segment to load constants; the interpreter can solve this issue as well.

The last implementation issue is not related to idiom detection or transformation, but to the processing within the middle-end phase of the decompiler. This phase is responsible for optimization of the LLVM IR code generated by the front-end phase. We exploit the LLVM `opt` and its optimizations for this purpose. For example, it serves to reduce the code size, which has a positive impact on the decompilation results (as

```
%a = add i32 679477248, 0
store i32 %a, i32* @regs3

%b = load i32* @regs3
%b_1 = add i32 913408, 0
%b_2 = add i32 %b_1, %b
store i32 %b_2, i32* @regs3

%c = load i32* @regs3
%c_1 = add i32 203, 0
%c_2 = add i32 %c_1, %c
store i32 %c_2, i32* @regs3

; @regs3 contains value 680390859
; = 203 + 913408 + 679477248
```

Fig. 4: An example of a constant computation in LLVM IR.

has been discussed in Section III). Besides our decompilation project, `opt` is normally used as an optimization part of the LLVM compiler toolchain. However, LLVM is a modern compiler toolchain and it also uses instruction idioms for code optimizations. Therefore, the `opt` tool has tendencies to bring back idioms instead of the de-optimized code. Therefore, we had to disable these optimization passes used in `opt`.

In Fig. 5, we demonstrate reconstruction of another idiom. In this figure, we can compare decompilation results with and without the instruction-idiom analysis. Fig. 5a illustrates a simple C program containing the division idiom. Decompilation result obtained without instruction-idiom analysis is depicted in Fig. 5c. It contains three shift operations and one multiplication by a magic value. Without the knowledge of fundamentals of this idiom, it is almost impossible to understand the resulting code. On the other hand, the decompilation result with instruction-idiom analysis enabled is well readable and a user can focus on a program sense, not on deciphering optimizations done by a compiler, see Fig. 5b.

```
int main(void)
{
  int a;

  /* ... */

  a = a / 10;

  /* ... */
}
```

(a) Input.

```
int main(void)
{
  int a;

  /* ... */

  a = a / 10;

  /* ... */
}
```

(b) Output with idiom analysis enabled.

```
int main(void)
{
  int a;

  /* ... */

  a = (lshr(a * 1717986919, 32) >> 2) -
      (a >> 31);

  /* ... */
}
```

(c) Output with idiom analysis disabled.

Fig. 5: C code example of decompilation with and without the idiom analysis.

```
#include <stdio.h>
int main(void)
{
  int a;

  /* ... */

  printf("1. Multiply: %d\n", a * 4);
  printf("2. Divide: %d\n", a / 8);
  printf("3. >= 0 idiom: %d\n", a >= 0);
  printf("4. Magic sign-div: %d\n", a / 10);
  printf("5. XOR by -1: %d\n", -a - 1);
  return a;
}
```

Fig. 6: C source code used for decompilers' testing.

V. Related Work

The fundamentals of instruction idioms and their usage within compiler optimizations are well documented, see [1, 12–16]. From these publications, we can gain insights into the principles behind instruction idioms as well as how and when to use them to obtain a more effective machine code.

Contrariwise, the detection and reconstruction of instruction idioms from a machine code is mostly an untouched area of machine-code decompilation. This topic is only briefly mentioned in [17–19]. Nevertheless, some of the existing (non-retargetable) decompilers support this feature. In order to observe the state of the art, we look closely on their approaches.

We used a test containing five idioms from a larger list listed in Table I. These idioms are the most common ones (e.g. multiplication via left shift) and the support of idiom reconstruction within a tested decompiler should be easily discovered via these idioms. A source code of this test is listed in Fig. 6. Each expression of the `printf` function represents one instruction idiom, whose meaning is described in Section IV. This source code was compiled for different target platforms (i.e. processor architecture, operating system, and file format) based on their support in each decompiler. Finally, each decompiler was tested by using this executable file and we analysed the decompiled results afterwards.

Boomerang is the only existing open-source machine-code decompiler [20]. However, it is no longer developed. According to our tests, it was able to reconstruct only the first instruction idiom.

REC Studio (also known as REC Decompiler) is freeware, but not an open-source decompiler. It has been actively developed for more than 25 years [21]. None of the instruction idioms was successfully reconstructed. We only noticed that REC Studio can reconstruct the register cleaning idiom (via the `xor` instruction) described in Section I.

SmartDec decompiler is another closed-source decompiler specialising on decompilation of C++ code, see [22] for details.

However, SmartDec was unable to reconstruct any instruction idiom from the machine-code.

Hex-Rays decompiler [23] achieved the best results—three successfully reconstructed idioms from five (it succeeded in the 1st, 2nd, and 4th test). Therefore, we have chosen this decompiler for a deeper comparison with our own solution as described in Section VI.

There are two other interesting projects. The *dcc* decompiler was the first of its kind, but it is unusable for modern real-world decompilation because it is no longer developed [17, 24]. On the other hand, the *Decompile-it.com* project looks promising, but the public beta version [25] is probably still in an early version of development and it cannot handle any of these instruction idioms.

In conclusion, we cannot compare our idiom-detection algorithm with approaches used in other tools because of two reasons. (1) They are either not distributed as open-source. (2) The open-source solutions do not support idiom recovery at all or they support only a very limited number of idioms. On the other hand, we can compare our results with the Hex-Rays Decompiler.

VI. Experimental Results

This section contains an evaluation of the proposed method of instruction-idiom analysis and reconstruction. The decompiled results are compared with the nowadays decompilation "standard"—the Hex-Rays Decompiler [23] that is a plugin to the IDA disassembler [26]. We used the latest versions of these tools, i.e. Hex-Rays Decompiler v1.8.0.130306 and IDA disassembler v6.4.130306. The Hex-Rays Decompiler is not an automatically generated retargetable decompiler, such as our solution, and it supports the Intel x86 and ARM target architectures. Our solution also supports the MIPS architecture at the moment.

All the three mentioned architectures are described as instruction-accurate models in the ISAC language in order to automatically generate our retargetable decompiler. MIPS is a 32-bit processor architecture, which belongs to the RISC processor family. The processor description is based on the MIPS32 Release 2 specification [27]. ARM is also a 32-bit RISC architecture. The ISAC model is based on the ARMv7-A specification with the ARM instruction set [28]. The last architecture used for the comparison is Intel x86 (also known as IA-32) that belongs in the CISC processor family. The model is based on the 32-bit processor core specified in [29] without extensions (e.g. x86-64).

We created 21 test applications in the C language. Each test is focused on a detection and reconstruction of a different instruction idiom. The Minimalist PSPSDK compiler (version 4.3.5) [30] was used for compiling MIPS binaries into the ELF file format, the GNU ARM toolchain (version 4.1.1) [31] for ARM-ELF binaries, and the GNU compiler GCC version 4.7.2 [32] for x86-ELF executables (the 32-bit mode was forced by the `-m32` option).

As can be observed, we used the ELF file format in each test case; however, the same results can be achieved by using the WinPE file format [33, 34]. All three compilers are based on GNU GCC. The reason for its selection is the fact that it allows retargetable compilation to all three target architectures and it also supports most of the idioms specified in Sections II and IV.

Different optimization levels were used in each particular test case. Because of different optimization strategies used in compilers, not every combination of source code, compiler, and its optimization level leads to the production of an instruction idiom within the generated executable file. Therefore, we count only the tests that contain instruction idioms. Furthermore, it is tricky to create a minimal test containing an instruction idiom without its removal by compiler during compilation.

An example of this problem is depicted by using a C code with multiplication idiom in Fig. 7a. The result of this code can be computed during compilation; therefore, the compiler emits directly the result without the code representing its computation (see the example in Fig. 7b). Therefore, we use functions from the standard C library for initialization of variables used in idioms. For example, this can be done by using statements `a = rand();` or `scanf("%d", &a);`. Example of an enhanced test is depicted in Fig. 7c. Such code cannot be eliminated during compilation and the instruction idiom is successfully generated in the executable file, see Fig. 7d.

The testing was performed on Intel Core i5 (3.3 GHz), 16 GB RAM running a Linux-based 64-bit operating system. The GCC compiler (v4.7.2) with optimizations enabled (`O2`) was used for creation of the decompiler.

Finally, we enabled the emission of debugging information in the DWARF standard [35] by using the `g` option because both decompilers exploit this information to produce a more accurate code, see [10] for details. The debugging information help to eliminate inaccuracy of decompilation (e.g. entry-point detection, function reconstruction) that may influence testing. However, the debugging information does not contain information about usage of idioms and therefore, its usage does not affect the idiom-detection accuracy.

All test cases are listed in Table II. The first column represents description of a particular idiom used within the test. The maximal number of points for each test on each architecture is

```c
int main(void)
{
  int a = 1;
  a = a * 8;
  return a;
}
```

(a) Test C code.

```c
int main(void)
{
  return 8;
}
```

(b) Compiler optimized code without instruction idiom.

```c
#include <stdlib.h>
int main(void)
{
  int a = rand();
  a = a * 8;
  return a;
}
```

(c) Enhanced test C code.

```c
#include <stdlib.h>
int main(void)
{
  int a = rand();
  a = a << 3;
  return a;
}
```

(d) Compiler optimized code with an instruction idiom.

Fig. 7: Problem of idiom removal by compiler.

TABLE II: Experimental results—number of successfully detected and reconstructed instruction idioms. Note: several tests differ only in the used numeric constant; however, different instruction idioms are emitted based on this value.

Tested instruction idiom	MIPS			ARM					Intel x86				
		Lissom			Lissom		Hex-Rays			Lissom		Hex-Rays	
	tests	✓	(%)	tests	✓	(%)	✓	(%)	tests	✓	(%)	✓	(%)
`intA = intB < 0`	5	5	100.0	5	5	100.0	0	0.0	5	0	0.0	0	0.0
`intA = intB >= 0`	5	5	100.0	5	5	100.0	0	0.0	5	5	100.0	0	0.0
`intA = 0`	0	-	-	0	-	-	-	-	1	1	100.0	1	100.0

five (i.e. one point for each optimization level – `O0`, `O1`, `O2`, `O3`, `Os`). Some idioms are not used by compilers based on the optimization level or target architecture; therefore, the number of total points can be lower than five. For example the MIPS and ARM architectures lack a floating-point unit (FPU) and the essential FPU operations are emulated via *soft-float* idioms. On the other hand, the Intel x86 architecture implements these operations via the x87 floating-point instruction extension; therefore, the instruction idioms are not used in this case.

The decompilation results are depicted in Fig. 8. We can observe four facts based on the results. (1) The Hex-Rays decompiler does not support the MIPS architecture; therefore, we are unable to compare our results on this architecture. (2) Results of the Hex-Rays decompiler on ARM and Intel x86 are very similar (approximately 60%). Its authors covered the most common idioms for both architectures (multiplication via bit shift, division by using magic-number multiplication, etc.). However, the non-traditional idioms are covered only partially or not at all (e.g. integer comparison to zero, floating-point idioms). (3) Our solution achieved almost perfect results on MIPS and ARM; only one test for each architecture failed.

(4) The concept of idiom detection within the front-end phase reaches its limits on the Intel x86 architecture, where the accuracy drops to 20%. The difference between the same tests for ARM (or MIPS) and x86 lies in the complexity of the instruction-semantics description. In general, RISC instructions have only a few side effects (modification of registers, flags, or memory) and their behavioural description in LLVM IR is compact. Therefore, detection of instruction idioms on such smaller pieces of code is quite easy. Contrariwise, almost every CISC instruction has several side-effects and its description in LLVM IR is much more longer. In such long code sequences of LLVM IR, we are unable to detect idioms with higher accuracy. The solution of this problem represents a future research and it is described in Section VII.

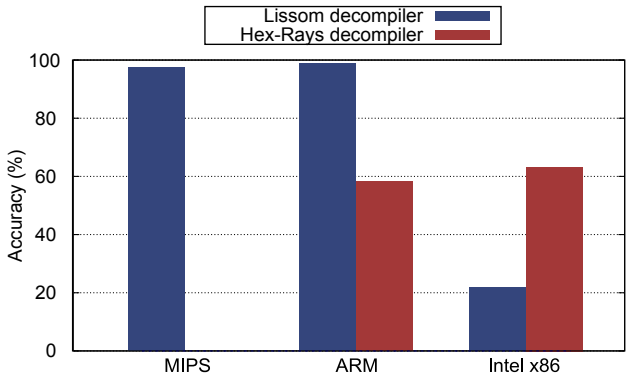

Fig. 8: Results of idiom analysis and reconstruction architecture.

VII. Conclusion

In this paper, we have focused on the problem of instruction idiom detection and reconstruction during the decompilation process of an existing retargetable decompiler. We proposed a new concept of this analysis that has been successfully tested on the MIPS, ARM, and x86 architectures within the Lissom project [2] retargetable decompiler.

In conclusion of the experimental results, our solution is capable to detect and reconstruct instruction idioms for the common RISC architectures with a very good accuracy (i.e. more than 97%), which is better than existing non-retargetable decompilers (some of them lacks this analysis as we demonstrated in Section V). However, the accuracy drops down significantly with the increasing instruction-set complexity. This issue has to be solved in the future research.

The major problem is the code complexity of CISC instructions during the early phases of decompilation (i.e. the front-end phase). On this level, it is problematic to properly detect the idiom without an increase of the false-positive ratio (that

is kept to be zero). However, it should be possible to perform this analysis after the optimization phase (i.e. the middle-end phase) that is based on the LLVM `opt` tool. This optimization phase will simplify the analysed code and it should be possible to detect idioms more easily. Moreover, changing order of this phase is supposed to have a minimal effect on the other phases.

The second propose of the future research lies in further testing of the retargetable idiom detection and reconstruction by using executables created by different compilers and for different target architectures. There is always a room for improvement by adding new instruction idioms into our database of supported idioms.

Finally, usage of control-flow analysis for instruction-idiom detection may be useful when dealing with more aggressive optimizations.

Declarative Specification of References in DSLs

***Abstract*—The occurrence of identifiers and references in computer languages is a common issue. The same applies for domain specific languages, whose popularity is increasing and there is a need for aid in their design process. This paper analyses the problem of identifiers and references in computer languages. Current methods use an imperative approach for supporting references in languages; therefore a language designer is required to manually write reference resolving. The method proposed in this paper perceives references and identifiers as language patterns, which can be specified in a declarative manner with much less knowledge about the problem of resolving references in computer languages.**

I. Introduction

REFERENCES in languages are common. We use simple identifiers in our everyday life to identify objects, activities, abstract designs, etc. Even every one of us has an identifier, which we call "name". If we want to reference to somebody else, we use the name of that person. The problem arises when somebody uses short name *John* and there is more than one person with that short name known to him. How do we know, which *John* is he or she referring to? In that case we have to know more information and understand the mutual scope of names between the communicating parties to be able to properly identify the correct person.

The situation is not different in the area of computer languages. Majority of computer languages use references in a form of variable names, function names or any other named structures. How can we decide if the identifier used in our code refers to this particular structure, if we have more than one structure declared with the same name? In the theory of computer languages, the process of searching for these identifiers is called *reference resolving*. The basic solution of reference resolving is routine: A language designer creates a table of identifiers for storing every identifier declared in the code. Then he/she defines a lookup method for searching in the table for a suitable identifier based on the given textual reference in the code. Every language needs to solve the lookup process with its own function even when such a function is well-known and similar in most languages. Defining the lookup function is a common and routine task, but the implementation is poorly automatized.

In the last few years we can notice the increase in the language-oriented development [1]. Developers create special small or medium sized languages, called *domain specific languages (DSLs)* for many different areas. The development of DSLs is difficult [2] and identifiers and references are common in DSLs, which doesn't make it easier without proper support. The problem of a reference resolving is particularly acute in the area of external DSLs, as they need to function autonomically without any existing general purpose language (GPL). In this paper we aim to simplify the specification of DSLs with references by proposing declarative manner of specifying language constructs as identifiers and references.

II. Declaring References in Languages

Every GPL uses some sort of references. Even the oldest ones use some a form of named variables and they need a method to resolve the variable identifiers on their places of usage. It is possible to identify two types of statements concerning variables:

- *declaration* - a place where a name (and, optionally, a type) is assigned to a variable
- *usage* - a place where we use or change the value contained in a named variable by referring to its name

The declaration of one variable can occur only once in a language sentence scope but usage of the variable can occur on multiple places. A typical example of a declaration is:

```
float a;
```

It is a declaration of a variable `a` restricted to contain a decimal value. A typical example of usage is an assignment or reading of a value:

```
a = 10; //assignment
factor(a); //reading of a value
```

Supporting tools for processing and executing sentences from a language can be created in two different ways. A language designer can design a language and manually implement all the tools needed for language processing. The second option is to write a language specification using any of the existing compiler generators and then generate the processing tools. Use of a compiler generators is preferable because it provides better automation and is frequently used in the area of specification of DSLs.

Compiler generator tools help with specifying lexical units, syntax, semantic actions [3] and sometimes they even explicitly define language concepts by means of abstract syntax. There are many compiler generator tools, we can mention the most common known Yacc [4], or even more sophisticated ones such as ANTLR [5], Beaver [6], LISA [7], [8], JastAdd [9] or Xtext framework [10], [11]. If we look on the problem of resolving textual references to places of its declaration, usually it can be addressed within the semantic

978-83-60810-53-8/$25.00

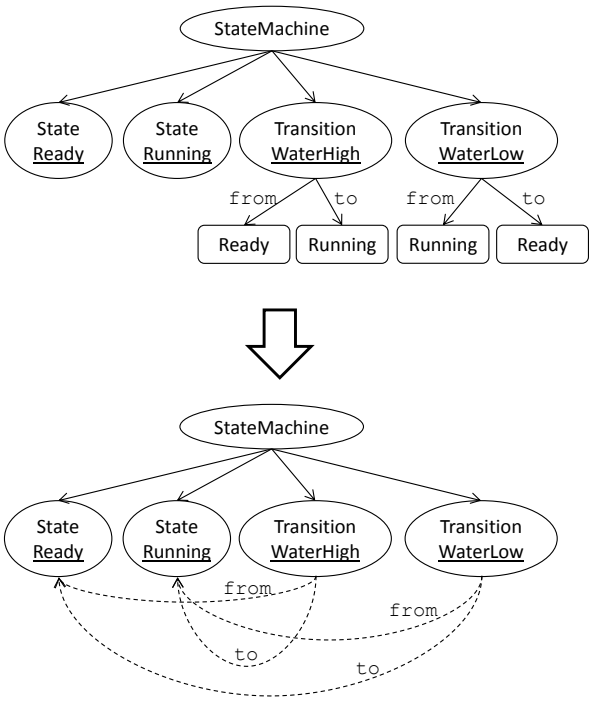

Fig. 1. Transformation from the abstract syntax tree to the abstract syntax graph

actions of the designed language. Some of the current compiler generators use attribute grammars in order to simplify the specification of semantic actions, for example in LISA. JastAdd uses an expanded version of attribute grammars [12] described by Hedin [13], [14] as reference attributed grammars (RAGs). RAGs aim to simplify attribute grammars for references by allowing attributes to be of reference type to other nodes in the syntax tree. RAGs only expand theoretical type model of attribute types and the actual process of discovering nodes in the tree needs to be manually implemented in the semantic actions of an attribute grammar. Xtext framework offers different approach with simple definition of referenced node types, scoping needs to be programmed with provided API.

We would like to show the usual process of declaring and resolving references on an example of a simple language of state machines. For the purposes of better comparison with the existing research we will use the example of the state machine language used in the JastAdd tutorial paper [15].

Listing 1. EBNF context-free grammar for a state machine language [15]

```
<statemachine> ::= <declaration>*
<declaration>  ::= <state> | <transition>
<state>        ::= "state" ID ";"
<transition>   ::= "trans" ID":" ID"->" ID ";"
ID = [a-zA-Z][a-zA-Z0-9]*
```

In the listing 1 is specified the grammar of the state machine language, which consists of *declarations*. A declaration can be a *state* or a *transition*. A non-terminal for a *state* contains only the state name represented by the named token *ID*. A *transition* contains the name (*ID*) of the transition, the name of the starting *state* and the name of the ending *state* of the transition. The abstract syntax of the state machine language is displayed in the listing 2. For every non-terminal there is one concept in the abstract syntax and instead of using just textual terminals for references (as it is common during the language desing phase) we used declarations of actual references.

Listing 2. Abstract syntax for the state machine language

```
concept StateMachine
  AS: declarations: list of Declaration

concept Declaration

concept State : Declaration
  AS: name: string

concept Transition : Declaration
  AS: name: string, from: State, to: State
```

In the abstract syntax and the grammar, it is possible to identify the point where there is a need for reference resolving during the language processing. Every *transition* has a textual name reference to the existing *state* concept. A sentence in the state machine language can be represented by a simple example of identifiers and references (see listing 3).

Listing 3. State machine language example sentence

```
state Ready;
state Running;
trans WaterHigh: Ready -> Running;
trans WaterLow: Running -> Ready;
```

Each *state* has a name, which acts as an identifier as well as each *transition* has a name serving as an identifier, but in this example we actually need only the state identifier because there will be no reference to the transition names. In the listing 3 we can see two states: *Ready* and *Running* and there are two transitions, each using the already defined state names as starting and ending states. During the language processing, the names represented as strings have to be connected to the actual state declarations. The process of interconnecting the referenced language concepts in any computer language can be perceived as a transformation from abstract syntax tree (AST) to abstract syntax graph (ASG). AST is a tree structure of language concepts created directly after parsing of the language textual form. Tree structure of textual forms of languages does not allow creation of direct references to existing declaration.Therefore we need textual placeholder for identifier to make references possible in later phase of language processing. ASG is a structure transformed from AST, which allows references from any node to any other node, so it means that a graph structure is created by extending the tree structure. The AST and ASG of our state machine code are displayed in fig. 1.

The transformation from AST to ASG in current compiler generators is accomplished manually within semantic actions. An example of semantic actions defined via attributed grammar written in JastAdd for a simple name analysis of the state machine language is shown in listing 4. Attributes are specified

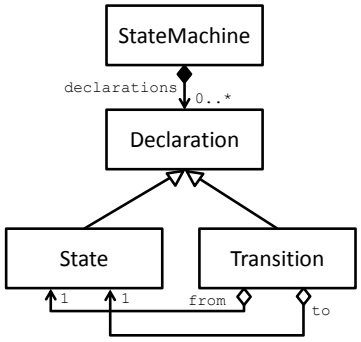

Fig. 2. Model of the state machine language

for *from Transition* named *source* and for *to Transition* named *target*. The *lookup* attribute is used for searching for a specific named *State* in the already specified list of *States*. Understanding of the provided example requires more knowledge about the specification notation used in JastAdd [15], but it shows the common amount of code needed to solve references in a language sentence and this problem is repeating in most of existing languages.

Listing 4. Code for name analysis for the state machine language specification in JastAdd [15]

```
aspect NameAnalysis {
 syn State Transition.source() =
       lookup(getSourceLabel());
 syn State Transition.target() =
       lookup(getTargetLabel());
 inh State Declaration
               .lookup(String label);

 eq StateMachine.getDeclaration(int i)
       .lookup(String label) {
   for (Declaration d :
              getDeclarationList()) {
     State match = d.localLookup(label);
     if (match != null) return match;
   }
   return null;
 }
 syn State Declaration
    .localLookup(String label) = null;
 eq State.localLookup(String label) =
   (label.equals(getLabel()))?this:null;
}
```

III. Language specification with annotated classes

There are different methods of specifying languages. The most common is in form of *grammars*. In our approach we use our own tool for language specification, which allows to model languages as classes in object-oriented programming paradigm [16]. This way the reuse of UML modeling tools for modeling languages [17] is possible.

In order to use our approach, the model of the state machine language has to be described by classes as described in Fig. 2. Each class in the model represents exactly one language concept. The connections between the language concepts are represented by the relationships in the model (inheritance, composition). Each UML composition relationship describes a required connection between the concepts, while the aggregation relationship means a connection created with identifiers. Generalization is used to represent alternation for the parent concept.

Modeling a language in a *graphical form* is great for general overview, but as we enrich a model with additional information such as concrete syntax and semantics, it becomes hard to understand. Execution of a plain model without any specified actions or supporting tool is usually not possible. In order to solve these problems and for practical purposes we define the language concepts in a textual form of classes of object oriented languages. The first class could be created for the root concept (*StateMachine*) of the state machine language.

Listing 5. StateMachine concept specification

```
class StateMachine {
  List<Declaration> declarations;

  StateMachine(List<Declaration> decls) {
    this.declarations = decls;
  }
}
```

Each class diagram is a representation of the abstract syntax with the recognized language concepts and their connections, as it is possible to notice in Fig. 2. Abstract syntax of *StateMachine* in listing 5 is represented by the definition of the class fields, in this case we have only one field named *declarations* for storing the list of *Declaration* concepts. Concrete syntax is represented by the class constructor. In this case there is only one concrete syntax representation (hence one constructor) which consists only of the list of *Declaration* concepts. It is a simple example for defining language constructs in a form recognizable to any programmer with a knowledge of object-oriented programming. In later examples we will discuss additional forms of concrete syntax specification. More details about this representation can be found in [16].

The next specification is a declaration of an abstract language concept *Declaration*, which in grammar form serves as a non-terminal for choosing between *State* and *Transition* non-terminals. It is possible to achieve the same effect in our language specification using inheritance and abstract classes. Therefore, the *Declaration* concept can be specified as a simple empty abstract class or an interface. We have chosen to use abstract class as this representation is closer to our model situation.

Listing 6. Declaration concept specification

```
abstract class Declaration {}
```

A. Declaring identifiers

The presence of identifiers and references is so common in computer languages, that we can consider it a language pattern. This pattern was already used in languages, but we have identified and distilled it as one of the building blocks of languages and therefore it can be extracted and later used

in any language in form of declaration. Our example of the state machine language uses a special form of unique named identifiers for the *State* concepts. And this is where our method comes forward and provides the capability to simply annotate a field which should be used as a special identifier for encapsulating the language concept. In our example we have the *State* language concept with the *label* property, which serves as an identifier of the *State* instance (see listing 7). In order to declare the *label* property to be used as identifier, we only need to annotate the property with the *@Identifier* annotation. The optional options available for the *@Identifier* annotation will be discussed later in this paper.

Listing 7. State concept specification

```
class State extends Declaration {
  @Identifier
  String label;

  @Before("state")
  @After(";")
  State(@Token("ID") String id) {
    this.label = id;
  }
}
```

We have used also other annotations, which are not new in our language specification. The *@Before* and *@After* annotations serve for defining terminal symbols in textual concrete syntax of *State*. The *@Token* annotation has a similar purpose, it can be used to concretize the lexical symbol used for checking and extracting data. If we compare this concrete syntax specification with the grammar defined for the state machine language in listing 1, it is simple to find connections between both specifications. The token *ID* is already defined in a special language configuration file in our tool and it serves for accepting names.

B. Declaring references

For the identifiers to have a logical meaning in the language, it is needed to reference to them from another place in the language sentence. The places used for referencing to existing identifiers are marked with the *@References* annotation. In our example we marked the constructor parameters *sourceLabel* and *targetLabel* as referencing names to the *State* concept. We need to define the concrete syntax according to the grammar from listing 1, therefore we are using the *@Before*, *@After* and *@Token* annotations as well.

Listing 8. Transition concept specification

```
class Transition extends Declaration {
  String label;
  State source;
  State target;

  @Before("trans")
  @After(";")
  Transition(
    @Token("ID")
    String label,

    @Before(":")
    @Token("ID")
    @References(State.class, field = "source")
    String sourceLabel,

    @Before("->")
    @Token("ID")
    @References(State.class, field = "target")
    String targetLabel
  ) {
    this.label = label;
  }
}
```

The usage of the *@References* annotation has an impact on some programming techniques. We are using *@References* to annotate constructor parameters and this way we are assigning special behavior to those parameters. Our language specification implementation allows us not to store the value of the annotated constructor parameter in any traditional programming way, actually this value is automatically stored for us during the language processing phase. Therefore, in the listing 8 it is possible to leave the constructor body with only one statement for storing the *label* of the transition. The requirement for the usage of the *@References* annotation is that it should be used on a *String* parameter and it is required to specify the referencing class (in the *value* parameter of the annotation), in our example it is the *State* class. The next parameter of *@References* is *field*, which allows us to define the name of the referenced class field (sometimes called property) used to store the specified language concept (object of the specified class). Both parameters are used later to filter all identifiers according to their corresponding language concepts, and they are used for injecting [18] appropriate object into the class field using reflection [19]. In our example of the *Transition* concept the objects of the *State* class are injected into the *source* and *target* fields, which are also checked for type consistency.

IV. Scope of References

References in computer languages are seldom created within one universal scope of availability. Even if there is a universal scope, called global scope, languages are not using only this one scope. Every variable in the language can be declared in a different scope and the rules for discovering a proper defined variable can be very difficult to define. An example of different scopes for the *count* variable is shown in listing 9. The *count* variable is declared in the global scope and at the same time it is also declared in the local scope of the *foo* function (D2), therefore the output of *foo* is `0` as we are using the variable declared closer to the place of its usage. The output of *goo* is `10` as the *count* variable name is referencing to the global variable declaration (D1) because there is no other closer variable declaration with this name.

Listing 9. Simple scope example with the *count* variable

```
int count = 10; // D1

void foo() {
  int count = 0; // D2
  print count;
}
```

```
void goo() {
  print count;
}
```

Support for using identifiers and references in scopes is very different in most compiler generator tools. Most of the tools are delegating this work to the designer by means of custom implementation (Yacc [4], Flex [20], JavaCC [21], Beaver [6]), they offer attribute grammars to help with the issue as it is done in JastAdd [9] and Lisa [7] or Xtext framework provides API for implementing scopes [11]. Still the language designer needs to know how to implement the scoping of references for his/her new language. ANTLR [22] provides a special support for defining scopes of variables for non-terminals and it allows easier access in order to find the declared variable in the tree of scoped variables, but still the user is required to specify proper variables and implement the use of scopes in the lookup functions. Therefore we can summarize, that all popular compiler generator tools require the user to write a custom solution for almost every issue concerning the reference resolving of identifiers within any scope.

In our method we support automatic reference resolution with scoping rules. Result of parsing language sentence is provided in a form of AST. References with scopes are allowed by selecting valid nodes in the required scope. In order to select nodes in AST it is useful to use a tree quering method. Our current solution uses the XPath querying language [23] as it is specially designed for efficient filtering of XML nodes [24] and use simple syntax. AST is usually not represented in XML, but XML is also a tree structure, therefore, the transformation from AST to XML is straighforward.

Each language is different and each reference in the language can be defined in a different scope. In order to characterize scoping, we have divided references to three levels of scoping:

- Global scope
- Simple local scope
- Complex scope

A. Global scope

The state machine language used in the previous sections uses references without scope or we can say that it uses global scope. Every *State* language concept is uniquely named within the full scope of a language sentence. Therefore it is a language within the first level of scoping and there is no need to declare it with any additional parameters. Previous listings (5, 6, 7 and 8) of class specifications of the state machine language are sufficient for our compiler generator with automatic resolution of references.

B. Simple local scope

Declaration of a referenceable language concept in the scope of parent concept is an example of a simple local scope level. Any scoping with a simple XPath query is considered to be a simple local, scope level. We can illustrate the problem on an example of a language for description of departments with cars and employees. Every car has a name, a fuel type and a year of acquisition. Every employee has a name and he/she can have a name of a car, which can be used by him/her. Employees can have a permission to drive the car owned by the same department, but it is not possible to use cars from different departments. Name of the car in the employee specification line is actually a reference to a declared car name in the department. Textual representation of this language is displayed in listing 10.

Listing 10. Department language with cars and employees

```
department: Accounting
  car: Audi A4; diesel; 2008
  car: Ford Focus; gas; 2012
  empl: John Smith {Audi A4}
  empl: Emma Fisher {Ford Focus}
  empl: Jim Parker

department: Technical services
  car: VW Golf; diesel; 2010
  car: Ford Focus; gas; 2005
  empl: Steve Cosby {Ford Focus}
```

Specification of the *Employee* language concept in our class form is displayed in listing 11. Scoping in references is allowed with the *path* parameter in the *@References* annotation. The value of the *path* parameter is an XPath query for accessing all relevant *Car* concepts. In our example we have used the XPath `parent::Department/Car`, which means that we are expecting to traverse the AST from the actual *Employee* node to the parent node named *Department* and then to find all child nodes named *Car*. This way, we have specified scoping for referencing to the *Car* concept within the same *Department* concept. The method of finding the *Car* node with a proper identifier is included in our method and it is not necessary to specify it in the XPath query, the user only needs to define the path for all relevant language concepts.

Listing 11. Specification of the *Employee* concept in the department language

```
class Employee {
  String name;
  Car car;

  @Before("empl:")
  Employee(
    String name,
    @Before("{")
    @After("}")
    @References(value=Car.class,
        path="parent::Department/Car")
    String car
  ) {
      this.name = name;
  }

  @Before("empl:")
  Employee(String name) {
    this.name = name;
  }
}
```

In the context of our approach, the *simple local scope* can be perceived as any local scope, which can easily be defined with an XPath query inside the *@References* parameter *path*. The complexity of a possible query is depending on the user's knowledge of XPath. Although, we are not restricted only to XPath, it is possible to use any other language for traversing the tree structures, however it needs to be included in our language tool.

C. Complex scope

In our research we aim for tool support of DSLs, which are usually not as complex as general purpose languages and therefore do not need to use complex scopes. Although, sometimes it is useful to have complex scope rules. In this section we will discuss the power of XPath expressions in our language design method and we provide an overview for advanced scoping.

A usual behavior of reference resolving using an XPath expression in the *path* parameter of the *@References* annotation consists of adding an XPath predicate with a test of the name of an identifier to the end of the original expression. For example an expression for finding a *Car* with the name `Audi A4` from listing 11 is converted to the following XPath expression.

```
parent::Department/Car[_id="Audi A4"]
```

In some XPath queries it is useful to specify a place for filtering nodes before getting all nodes. In order to write an XPath expression for searching for appropriate variable `count` declaration from listing 9 we can use an XPath expression

```
(ancestor::*[Variable/_id="count"])[last()]/
    Variable[_id="count"]
```

In order to parameterize this XPath expression we can use `##cmp##` as a placeholder for `_id = "NAME"`, therefore our extended XPath expression can be written as follows:

```
(ancestor::*[Variable/##cmp##])[last()]/
    Variable[##cmp##]
```

This XPath expression first chooses the appropriate ancestor with expected named variable declaration.

There is always a possibility to completely forget our declarative way of solving references and to implement it on our own. Our language method allows it without any problems, but the user would lose a great advantage. Still there can be some very specific scoping rules, which cannot be properly described with XPath and in this case we recommend using the traditional manual implementation of referencing to identifiers. The user has to be aware that he needs to manage his own storage of identifiers as well as the method for connecting places of identifier usage to the language concepts with the declared identifiers. Manual solution is possible and sometimes needed, although we are sure it is not necessary in most DSLs and our identifiers and references patterns are sufficient in such scenarios.

V. Process of Reference Resolving

Our method for reference resolving consists of three main steps:

- Unique identifier
- Reference searching and injecting
- Creation of undefined identifiers

A. Unique identifier

The first step in our reference resolving method is to check for uniqueness of identifiers. Every identifier for one language concept needs to be unique in its own scale. If identifiers are not unique it would cause a problem in reference resolving process, as one reference needs to reference only one language concept. This part of our method is providing functionality, which is not commonly used in other tools and where the user needs to implement it on his own using a table of identifiers or any other similar method. The default behavior of the *@Identifier* annotation without parameters is that the concept name is unique in the global scale of a language sentence and for language concept. Standard setting for uniqueness of identifiers used for specifying the *state* concept in the state machine language (see listing 7) is using the *@Identifier* annotation without parameters, therefore during language processing it is tested if every *state* has a unique name.

In order to specify other scale of identifier uniqueness, we are using XPath expressions as it was described in the section IV-B. It is possible to define a query for nodes of AST in which there is only one occurrence of an identifier of the specified type. This way we can define automatic checking for uniqueness of identifiers of *car* in *department* in our department language example (listing 10).

Listing 12. Specification of the *Car* concept in the department language

```
class Car {
 @Identifier(unique="parent::Department")
  String name;
  String fuelType;
  int year;

 @Before("car:")
  Car(
   @Token("NAME")
    String name,

   @Before(";")
   @Token("NAME")
    String fuelType,

   @Before(";")
   @Token("YEAR")
    int year) {
      this.name = name;
      this.fuelType = fuelType;
      this.year = year;
  }
}
```

Listing 12 specifies the language concept *car*, but our main focus is on the *@Identifier* annotation with the *unique* parameter. With this parameter we have specified that every *car*

has a unique name only in the scope of its parent *department* language concept. Therefore it is possible to have cars with the same name in different departments and the parsing process will finish without any error. Otherwise, in the case of not specifying the *unique* parameter, the uniqueness of *car* name would be tested in the global scale, producing an error even if different departments would have a car with the same name.

Scoping of references defined in the section IV-B and scoping of identifier uniqueness is based on similar XPath expressions. It is recommended to scope uniqueness of an identifier when we are using scopes for referencing. Identifier XPath scopes are usually simpler then XPath expressions for finding proper identifiers in *@References*. As an example, consider uniqueness scope of identifier in a function for listing 9, which can be defined as a simple XPath for variable identifier: `parent::Function` and if we compare it with XPath expression for finding proper variable reference shown in the section IV-C, it is obvious that the XPath expression for uniqueness scope is much simpler to write and understand.

B. Reference searching and injecting

The second and the most important part of our method is actual resolving of textual references. Details about textual reference resolving were already described in this paper in section III and scoping details in section IV. In our method we are using declarative specification of references with the *@References* annotation, which marks the textual parameters containing names of referencing language concepts defined in the fields marked with the *@Identifier* annotation. Referencing can be constrained with the scope rules defined by XPath. Our method discoveres referenced language concepts and inject them into fields specified in the *field* (for specifying the field name of class) and *value* (used to define the referencing type) parameters of the *@References* annotation.

Reference resolving can be carried out in two ways:

- after parsing an entire input sentence (explicit)
- during the parsing process (implicit)

The explicit approach is about an explicit execution of reference resolvining at the end of the parsing process. After execution we get an exact information about any inconsistencies in identifiers and references. Any error can be detected right after explicit execution call and propagated to the user. On the other hand it needs this one explicit execution of reference resolving and it makes this solution less modular.

The implicit approach is about resolving references and identifiers after each language concept creation (usually during the parsing process). For each parsed language concept it is trying to resolve the unresolved references and to match them with identifiers. The advantage of such solution is elimination of explicit execution of reference resolving, on the other hand it is hard to check for inconsistencies as it cannot tell if the registration of the new language concepts has finished or not. It is possible only to check for the actual state of reference resolution and to get information about the non-resolved references. At the end of the process of language parsing we should not have any non-resolved references. It is optional to check for non-resolved references, when we are using the implicit approach to resolution of references.

Both presented approaches to reference resolution have advantages and disadvantages and it is possible to use either of them. A language designer should decide which approach would be preferable to his new language. The implicit approach does not need any action for resolution of the references, but cannot guarantee that all references have been resolved properly without any optional check. The explicit approach is better in performance as the resolution of references is done only once and it can propagate the error in case of unresolved references, but it is required to execute this method explicitly and therefore there is a direct dependency between the parsing process and the reference resolution process.

C. Creation of undefined identifiers

The third part of our method is focused on the solution of one specific problem concerning references and identifiers within languages. In languages it is possible to have a reference to an identifier without the previous declaration of the identifier. It is a common occurrence in untyped or dynamically typed languages to use a variable without previous declaration (see listing 13). It is safe to claim, that a declaration of an identifier is required only if the declaration contains additional information about the language concept except the identifier name.

Listing 13. Example of a language without variable declaration

```
x = 10; // it is possible to use this

var x;  // instead of this
x = 10;
```

The previous example represents a GPL sentence fragment, but the same situation can be found when designing a DSL language. If we would look on the sentence written in the state machine language in listing 3 it is clear that the declaration of *state* does not contain any additional information except the name of a *state*. Taking that information into account, we can write the same state machine without any state declaration as it is shown in the following listing 14.

Listing 14. State machine language example without state declaration

```
trans WaterHigh: Ready -> Running;
trans WaterLow: Running -> Ready;
```

The *Ready* and *Running* states are declared in the place of their usage and the later usage is used as a reference to the existing state. This feature allows simplification of language sentences for common language users, as DSLs usually require syntax, which is more practical than technical.

Our method supports the automatic creation of language concepts in the place of their reference in case of non-existent variable declaration in the language sentence. It can be specified by the *create* parameter in the *@References* annotation (example in listing 15). This parameter is set to *false* by default, therefore a non-existent referenced concept is not created. Setting the *create* parameter to *true* allows the automatic creation of language concepts. The only requirement

is the existence of a constructor with a string parameter and the usage of global scope for referencing as well as identifier uniqueness.

Listing 15. References annotation with create parameter

```
@References(State.class,
            field = "source", create = true)
```

Automatic creation of undefined identifiers is the last phase of our method for resolving identifiers and references. It runs after the phase of resolving references and only if there is at least one *create* parameter with value *true*. After each creation of a new language concept it is required to resolve references as AST has been modified.

VI. Conclusion

Current language tools support creation of languages with one or more methods, but they fail in the area of an exact declaration of references and identifiers in the created languages. A language designer has to implement checking of identifier uniqueness and lookup methods for finding proper referenced identifiers manually, as it is common with other tools such as Beaver, JavaCC, JastAdd, ANTLR or at least programatically select language concepts from the scope using API in Xtext framework.

In this paper we have presented the method for declarative specification of computer languages with identifiers and references. We have discovered and described language patterns for identifiers and references. These language patterns have different possible parameters to adjust their impact. It is possible to define the scope of uniqueness of an identifier. We have described different levels of scopes for referencing other language concepts and we have explained different levels of scoping on illustrative examples. The scoping levels we discovered are global scope, simple local scope and complex scope. Complex scope is used mostly for advanced scoping of variable names in programming languages. During our research, we have analyzed various languages and discovered the pattern for identifiers without explicit declaration of identifier before the usage. In order to cope with such form of languages we provide an option to automatically create language concept on the first occurrence of identifier and to use it as a reference on every other occurrence.

Every mentioned pattern and option has been integrated in our method for working with references and identifiers in computer languages, with a special orientation to DSLs. Our method allows declarative definition of identifiers and references instead of more common imperative solutions of other methods. A summary of our method is a declarative transformation of AST to ASG. The method has been implemented in our YAJCo[1] tool, which can be found on the central Maven repository. All languages mentioned in this paper has been successfully tested in YAJCo and they serve as a proof of concept for the proposed method.

***Abstract*—Generic programming plays an essential role in C++ software through the use of templates. However, both the creation and use of template libraries is hindered by the fact that the language does not allow programmers to specify constraints on generic types. To date, no proposal to update the language to provide concepts has survived the committee process. Until that time comes, as a form of early support, this paper introduces SimpleConcepts, an extension to C++11 that provides support for concepts, sets of constraints on generic types. SimpleConcepts features are parsed according to an island grammar and source-to-source translation is used to lower concepts to pure C++11 code.**

***Keywords*—Generic Programming, C++ Templates, C++ Concepts**

I. Introduction

GENERIC programming is made possible in C++ through the use of templates [1]. Templates are language constructs that operate with generic types and that are instantiated as needed during compile-time [2]. Templates are ubiquitous in many C++ libraries and systems, most notably the Standard Template Library (STL), which provides generic implementations of commonly used containers and related algorithms. Essential to the STL are concepts, which are sets of constraints on types [3]. A type is called a model of a concept if that type satisfies all of its requirements, and templates can impose these concepts on their arguments; this is done to ensure type safety. For example, to be able to sort a list, its elements must support the == and < operators, and these requirements are expressed by the concepts EqualityComparable and LessThanComparable. If the concepts associated with a template class or function are not satisfied, then the instantiation of that template code will fail, and a compile-time error will result. It is important to note that concepts are not features of the C++ language, but are rather the products of what Gregor et al. refer to as a "grab-bag of template tricks" [4]. The first issue with concepts as they are currently known is that they do not lend themselves to informative error messages. Violations cannot be reported without exposing the programmer to the details of the implementation. This means that compile-time errors can lead to dense barrages of esoteric error messages that give the programmer little insight into what went wrong. The second issue is that the complex nature of template metaprogramming makes it difficult to map concepts as described in the documentation to the specifics of their implementation. For those who create and maintain generic libraries, this means that it can be extremely difficult to detect bugs and other issues in their code. The root problem is that the C++ language lacks a construct to perform a vital function, and this forces the developers of generic libraries to resort to bricolage, cobbling together a functional equivalent from whatever materials they have at hand. This satisfies the immediate needs of the developers. However, in that concepts do not formally exist, they cannot be formally reasoned about or analyzed. For users, this is what leads to incomprehensible error messages when they misuse templates. For developers, this means that writing and maintaining template code becomes unnecessarily burdensome. The main contribution of this work is the introduction of SimpleConcepts, a lightweight extension to the C++ language to facilitate that development, maintenance, and usage of generic libraries. SimpleConcepts introduces several useful abstractions that perform the same role as concepts via metaprogramming while being easier to write, read, and formally analyze. This paper is organized as follows. In §II, we characterize the previous work that has been done to help modernize concepts in C++. In §III, we describe the problem domain by investigating how concepts work in generic libraries such as the STL, and in §IV we introduce SimpleConcepts, give justifications for our approach, and show how the functionalities provided by concepts via metaprogramming map to the new model. In §V, we provide formalisms for the syntax and semantics of SimpleConcepts. In §VI, we compare our approach to previous and contemporary alternatives. Finally, in §VII and §VIII we provide discussion, conclusions, and plans for future work.

II. Background

The first comprehensive attempt to provide high level language support for concepts was the development of Tecton, a domain-specific language (DSL) for generic programming that was conceived by Stepanov, Kapur, and Musser in the late 1970s [5]. The work that was done on that language fed into the development of the STL by A. Stepanov [6]. After the Hewlett-Packard implementation of the STL was made publically available in 1994, the language evolved into one that specialized in concept specification, as seen in Musser's technical report in 1998 [7]; Tecton sought to provide a language-independent means of describing constraints on generic types. While it did not see widespread adoption, it did provide a formal framework through which concepts could be understood, laying the foundation for further developments. 1998 also marked the birth of the Boost libraries for C++ [8], and two years later the collection was extended to include the Boost Concept Check Library (BCCL), an effort spearheaded by

978-83-60810-53-8/$25.00

Siek [9]. The BCCL is meant to provide clean and accessible mechanisms for programmers to use concepts in generic code, an improvement upon concepts as known in the STL. In the last decade, the goal of researchers shifted away from providing support for concepts in C++ by means of DSLs and library support and towards the incorporation of concepts into the C++ language as an extension. A detailed review of this period has been provided by Voufo and Lumsdaine [10]. The most successful of these movements was ConceptC++, a project which culminated in a proposal to the C++ standardization committee that was not accepted in 2009 for want of simplification and more testing [11] [12]. It is from ConceptC++ and the work done in the intervening period that SimpleConcepts draws much of its inspiration.

III. Domain Analysis

Here we shall provide a description of concepts as they are known in the C++ Standard Template Library. As previously described, the term concept refers to a set of constraints or requirements on types. For instance, the concept EqualityComparable defines what it means for a type T to be comparable for equality. In C++, this means that the expressions `a == b` and `a != b` be valid for any two values `a` and `b` of type `T`. In the STL, concepts are implemented as assertions with the help of macros and made use of through statements such as

```
__STL_REQUIRES(X,_EqualityComparable);
```

which checks to see whether the type of a template parameter X models the concept EqualityComparable. Aside from requiring that a type support certain operations, concepts can also require that certain functions be supported or class members exist. For example, the concept Container requires that its models implement a size() method. Additionally, concepts may require certain associated types be defined (e.g. a size_type for the value returned by a call to a Container's size() method). Lastly, the documentation for a concept may also state that certain invariants must be satisfied (e.g. identity or transitivity), but these are assumed to be the case, and no actual verification occurs. Concepts can be defined as a refinement of any number of previously existing concepts. A refined concept adopts the requirements defined by the concepts that it is refining. For instance, the concept ForwardContainer is a refinement of the concepts Container, EqualityComparable, and LessThanComparable (if its elements model LessThanComparable). That is, a ForwardContainer is a Container that also requires that its elements be comparable to one another.

In order to produce an extension to the C++ language that captures what these concepts do, we have to provide a formalism that allows us to understand concepts independently of their realizations. It would be a mistake to begin with a deconstruction of the syntax and semantics of STL concepts, because we are less interested in what they are; rather, we seek to describe what they are meant to be. We ought to begin with seeing the task of identifying and expressing concepts as a problem domain that happens to intersect with the task of generic programming. This domain is not complete or self-contained as we cannot speak of constraints on types without dealing with the particulars of some type system. However, concepts, as entities in their own right, can be reasoned about. Following the work of van Deursen and Klint [13], we shall

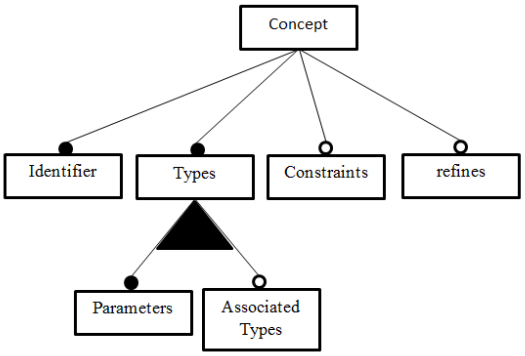

Fig. 1. FDL Diagram for Concepts

give a formal description of STL concepts using the Feature Description Language (FDL). From attempting to derive a formal description of concepts from our informal description, we can discern several truths. First, concepts cannot be anonymous. They must exist prior to and independently of the circumstances in which they are used, and therefore must be named. Second, concepts must have one or more generic type parameters. Concepts connect constraints to types, and a concept that does not do this is an invalid concept. Third, concepts are allowed to have no constraints, that is, they can be empty. A concept with no constraints is trivially satisfied; all types are models of an empty concept. This may seem puzzling at first, but consider that a concept that introduces no new constraints can still be useful if that concept is a refinement of two or more concepts, because it implicitly expresses the union of those concepts. Fourth, a concept may refine one or more other concepts. To refine a concept is to implicitly add its constraints to the concept. Lastly, comparing the informal description of STL concepts and the diagram shown in Fig. 1, one may note that invariants are not listed as a feature of concepts, and this is deliberate. Invariants are the consequences of satisfying both the syntactic and semantic requirements of a concept. To state that invariants are a feature of concepts means that there exists some has-a relationship between the two, when in fact this is not the case. For example, the STL documentation states that the reflexivity of the == operator is an invariant of the concept EqualityComparable, that is, `x == x` for all `x` of type `T` that is a model EqualityComparable. From a mathematical perspective, the invariant naturally follows if we assume the conventional definition of equality. However, in that C++ is a language that allows for operator overloading, knowing that a type supports the `==` and `!=` operators does not tell us whether those operators behave in some prescribed way. From this, we can conclude that there must be a limit to the enforceability of concepts with regards to their semantics. At the very least, finding the means to do so goes beyond the scope of this paper.

IV. Concepts

In SimpleConcepts, concepts are first-class representations of constraints on type parameters of templates. The concepts of SimpleConcepts obviate the need to use template metaprogramming to specify what a template requires of its type

```
concept EqualityComparable<typename T> {
        bool T::operator==(T rhs);
        bool T::operator!=(T rhs);
}
```

Fig. 2. SimpleConcepts concept definition

```
template<typename R> requires EqualityComparable<R>
bool foo(R x, R y) { /* ... */ };
```

Fig. 3. Requires clause

parameters. We designed SimpleConcepts with the following goals in mind:

1) To provide the same functionality as STL concepts while allowing programmers to write concept code that preserves readability and allows the compiler to produce meaningful error messages.
2) To make our extension to the C++ language as lightweight and undemanding as possible, providing more expressive power yet preserving the efficiency of template programming.

A concept definition consists of a declaration and a body containing concept member specifications. Fig. IV depicts the definition of the concept EqualityComparable.

A concept definition establishes what it means for a type T to be comparable for equality. Once a concept has been defined, it can be used in template code by means of a "requires" clause as is shown in Fig. IV. The requires clause places a restriction on the type R to being one which supports the == and != operators. Attempting to use the function foo with any x and y of a type that does not support these operators will lead to a compile-time error, informing the programmer that the EqualityComparable concept was not satisfied.

V. Implementation

As was stated previously, a major consideration in the design of SimpleConcepts was to produce an undemanding extension, one that did not require significant overhaul or that could break existing code. Our approach can be summarized as follows. First, the source code is parsed according to an island grammar that allows us to identify SimpleConcepts features [14]. These constructs are then translated to existing C++11 features, and the resulting source code is passed to an ordinary compiler. There are several advantages to this approach. First, this approach allows us to handle both the syntactic and semantic analysis of concepts without need to modify an existing compiler. Second, using an island grammar allows us to analyze the syntax of concepts in a context-free fashion. Lastly, by means of translational semantics, we are able to express the meaning of concepts in terms of language features whose semantics are already well-known. The remainder of this section addresses the details of this compilation model.

A. Abstract Syntax of SimpleConcepts

SimpleConcepts extends the C++ language to provide two new language constructs: concepts and constrained templates. A concept specifies a set of member function declarations and

```
concept Flammable<typename T>{
        double T::burn();
}
template<typename V> requires Flammable<V>
void makeCampfire(V v){
        double heat = v.burn();
        /*...*/
}
```

Fig. 4. Example of SimpleConcepts in action

```
template<typename T>
struct Flammable {
        Flammable_Requirements<T> rq0;
}

template<typename V>
void makeCampfire(V v){
        while(false) { Flammable<V>(); }
        /*...*/
        double heat = v.burn();
        /*...*/
}
```

Fig. 5. The first layer of the translation

associated types, and a list of other concepts that are refined by it. A constrained template is one that has a concept requirement clause, dictating what restrictions are placed on the template's parameters. Table I gives the abstract syntax and the syntactic domains for SimpleConcepts.

B. Concrete Syntax of SimpleConcepts

An island grammar is a context-free grammar which describes some subset of the features of a language and uses catch-all productions to ignore all else; the name of this technique is derived from the view that the features we are interested in capturing with the grammar are "islands" amidst a vast sea of other language features. In this case, we are only interested in parsing concept definitions and their uses so that we can perform the necessary translations, and therefore a grammar that allows us to identify salient features while skipping the rest is ideal. Table II gives an EBNF grammar for SimpleConcepts.

C. Summary of Translation Model

Our approach is based on the work done by Valentin and Magne [15], which describes a means of converting ConceptC++ code to pure C++03 code by translating the concepts of ConceptC++ into sets of class templates. Here we shall use a toy problem as a vehicle to explore the translation scheme. Consider the code fragment in Fig. V-C.

A type T models the concept Flammable if it has a member function called burn that takes no arguments and returns a double. In other words, Flammables burn, and burning produces an amount of heat expressed as a double. Below the concept definition we see an example of a function template that uses the concept Flammable. We shall describe, step by step, the translation process. The translation from concept code results in what can be seen as three distinct layers of template code. Fig. V-C shows the first layer of the translation.

The struct Flammable has, as a member, another struct representing the requirements associated with the concept

TABLE I. ABSTRACT SYNTAX AND SYNTACTIC DOMAINS OF SIMPLECONCEPTS

Type Variables	$\alpha \in TyVar$
Concept Names	$s \in CName$
Member Names	$f, a_t \in MemName$
Concept	$C \in \mathbb{C} := conceptC_{id}\ \{B\}; \| \ conceptC_{id}\ requires R\ \{B\}$
Concept Identifier	$C_{id} := s < P >$
Concept Parameters	P := $\alpha P \| \alpha$
Refinement Clause	R := $C_{id} R \| C_{id}$
Concept Body	B := $MB \| \epsilon$
Concept Member	M := $f\ func; \| typename\ a_t$
Constrained Template	$T \in \mathbb{T}_c := template\ < params >\ requires\ R\ template - body$

Here $\mathbb{C}$ refers to the set of all concepts, and $\mathbb{T}_c$ refers to the set of all constrained templates.

TABLE II. CONCRETE SYNTAX OF SIMPLECONCEPTS

<concept-id> := <concept-name> "<" <concept-parameter list> ">"
<concept-name> := **<identifier>**
<concept-definition> := "concept" <concept-id> <requires-clause>? <concept-body> ";"?
<concept-body> := "{" <concept-member-specification>? "}"
<concept-member-specification> := <concept-member-specifier> <concept-member-specification>?
<concept-member-specifier>:= <associated-function> | <associated-type>
<associated-function> := **<function-definition>**
<associated-type> := **<typename-specifier>**
<requires-clause> := "requires" <requirement-list> | "requires" "(" | <requirement-list> ")"
<requirement-list> := <requirement> "&&" <requirement-list> | <requirement>
<requirement> := <concept-id>
<declaration> := <concept-definition>
<template-declaration> := "template" "<" **<template-parameter-list>** ">" <requires-clause>?
<concept-parameter list> := **<template-parameter-list>**

Non-terminals that refer to pre-existing C++11 features are in bold for clarity.

```
CREATE_MEMBER_FUNC_SIG_CHECK(burn,double (T::*)(void));
template<typename T>
struct Flammable_Requirements {
        static_assert(has_member_func_burn<T>::value,
            "The member function 'burn' is not available"
            " or does not match signature.")
};
```

Fig. 6. The second layer of the translation

Flammable. The requirements are separated from the concept itself in order to support refinement; a concept that refines another concept "inherits" the requirements from its ancestor, and the ancestor's requirements struct is listed there as well. Attempting to instantiate the Flammable template will require the instantiation of the template Flammable_Requirements. If that instantiation fails, the code will fail to compile. To implement constraints on template functions, we cause trigger the instantiation of Flammable in the template function as seen in the template function code. The call to the constructor of Flammable is placed in an unreachable block of code to guarantee that no run-time overhead will result. Now we examine the second layer of the translation: expressing the requirements enumerated by a concept. A Requirements struct contains a set of static assertions that express the requirements that must be fulfilled by a type or set of types in order to model a concept. These assertions are checked when the compiler attempts to instantiate the Flammable_Requirements template. The code that we generate for the definition of Flammable_Requirements is provided in Fig. V-C.

The macro CREATE_MEMBER_FUNC_SIG_CHECK provides template code necessary to check the existence of a member function that matches both the name and the signature specified by the concept. The instantiation of has_member_func_burn will always succeed, but its member 'value' will be true if and only if T has a burn method that matches the signature specified in the concept definition. This, in turn, determines whether the corresponding static assertion succeeds or fails. The code generated by the pre-processor is shown in Fig. V-C.

This then is the third and innermost layer of the translation. Our mechanism verifies the existence of the member function burn in a way that gives a true or false value which is used in the static assertion. This allows us to report meaningful error messages.

D. Semantics of SimpleConcepts

We shall describe the translational semantics of SimpleConcepts. In that concepts and constrained templates are ultimately converted to template code, the semantics of concepts are a subset of the semantics of templates. With that in mind, we adapt the work done by Siek and Taha [16] to provide formalisms to describe the semantics of C++ templates. By providing a mapping from the abstract syntax of SimpleConcepts to that of C++ template code, we can then make the jump to the semantics. We represent our translation function as a set of functions that map SimpleConcepts code to C++11 code. The first subset of these translation functions, defined in Fig. V-D, describes the translation of concepts and their members (note that $\mathbb{T}$ refers to the set of all C++11 templates).

```
template<typename T, T>
struct match_signature : std::true_type {};
template<typename T, typename = std::true_type>
struct has_member_func_burn : std::false_type {};
template<typename T>
struct has_member_func_burn<T, std::integral_constant < bool , match_signature<fSig, &T::fName>::value >> : std::true_type {}
```

Fig. 7. The innermost layer of the translation.

$$
\begin{aligned}
F_C(C \in \mathbb{C}) = \{ & C_{id} \{ \{ requirements_{C_{id}} \langle P \rangle \} \\
& \cup \{ requirements_r \langle P_r \rangle \forall r \in R \} \in \mathbb{T}, requirements_{C_{id}} \langle P \rangle \{ F_{m1}(B) \} \in \mathbb{T}), F_{m2}(B) \} \\
F_{m1}(B) = \{ & static\_assert(has\_member\_func\_fname \langle P \rangle :: value, errormsg) \forall f \in R \} \cup \{ typedef a_t \forall a_t \in R \} \\
F_{m2}(B) = \{ & CREATE\_MEMBER\_FUNC\_SIG\_CHECK(fname, fsignature) \forall f \in B \}
\end{aligned}
$$

Fig. 8. A formal description of the translation function

```
// function member checking template macros here,
// one for each associated function f ∈ B
template<P>
struct ConceptName_Requirements {
  // A list of static assertions, one for each associated function f ∈ B,
  // and a list of typedefs, one for each associated type definition a_t ∈ B
};
template<P>
struct ConceptName {
        ConceptName_Requirements<P> rq_c;
        id_0_Requirements<P_0> rq_0;
        // . . . for every concept refined by this concept . . .
        id_n_Requirements<P_n> rq_n;
};
```

Fig. 9. Summary of the output of the translation function

In terms of the concrete syntax, this translation amounts to the code fragment depicted in Fig. V-D.

The second subset of the translation functions transform constrained function and class templates into C++11 legal templates. These can be summarized as follows: for a constrained function template, our translation moves the concept requirements into the body of the function as calls to constructors; for a constrained class template, the concept structs are made members of the class. The result of this translation scheme is that instantiations of constrained class templates amount to a chain of instantiations that perform the necessary checks to confirm that the types involved are models of the concepts required. Concept instantiations lead to requirement template instantiations, and those in turn lead to member function checking template instantiations. With that, the only way to make use of a constrained template class or function is to supply it with valid types, or compile-time errors will result. As for the concepts themselves, whose capabilities are limited to checking the existence of function members, we know that our translation does exactly that and nothing more.

VI. Related work

As has been stated in previously, the absence of concepts in C++ is not a new problem; each attempt at a solution has built upon the groundwork laid by predecessors. In this section, we shall attempt to compare and contrast past and current approaches with SimpleConcepts.

A. Concepts Lite

At this time, there exists another proposal to provide support for C++ concepts by Sutton and Stroustrup known as Concepts Lite [17] [18]. In this section, we shall attempt to compare and contrast that approach with SimpleConcepts.

Sutton and Stroustrup, the creators of Concepts Lite, have summarized their vision as "concepts = constraints + axioms" [19]. Concepts are abstract predicates that represent sets of requirements on generic types. These requirements can either be constraints or axioms. Constraints are syntactic requirements on the properties of generic types, which are checked at compile-time, and axioms are semantic requirements, analogous to the invariants of the STL documentation. As of the latest proposal, Concepts Lite supports constraints, but does not yet support axioms or concepts. With the understanding that the specifics of this proposal may be changed in the near future, we note the key differences between the two approaches.

First, while both SimpleConcepts and Concepts Lite share a similar notion of constraints, they differ greatly in terms of their implementation. In Concepts Lite, a constraint predicate is defined as a function template that contains a constant expression, referred to as a "use pattern". A type or set of types satisfies a constraint if the template can be legally instantiated, which is to say that the constant expression is valid. For example, a type `T` is Addable provided that for expression `a + b` is valid for any `a` and `b` of type `T`. In the syntax of Concepts Lite, this constraint might be expressed as follows:

```
   template <typename T>
constexpr bool Addable() { return
__is_valid_expr{bool={declval<T>() +
declval<T>()} }
```

This approach differs from that of SimpleConcepts in three ways. First, Concepts Lite decouples concepts and constraints, which allows us to define Addable as a stand-alone constraint; in SimpleConcepts, which keeps constraints and concepts coupled, Addable would be expressed as a concept with a single constraint member. Second, Concepts Lite requires extensions to the compiler to support new intrinsics such as `__is_valid_expr`; SimpleConcepts uses a preprocessor to

lower concepts to existing C++11. Third and most importantly, whereas Concepts Lite uses constant expressions to define constraints, SimpleConcepts relies on function signatures.

Next, in contrast to Concepts Lite, this paper rejects the inclusion of axioms in its definition of concepts as going outside of the role that concepts are intended to fulfill, which is to provide compile-time support for templates. According to its authors, axioms are not statically evaluable, which implies that the question of whether a generic type truly models a concept, both syntactically and semantically, cannot be decided at compile-time. While we recognize the fundamental relationship between the two kinds of requirements, and we appreciate the simplicity and beauty of an approach that unifies them, we do not see a pressing need to incorporate axioms.

B. ConceptsC++

SimpleConcepts draws inspiration from the ConceptsC++ proposal, and in a certain sense can be seen as an evolution of it. In ConceptsC++, as in SimpleConcepts, concepts are sets of requirements, which can be expressed as signatures and associated types, and these concepts can be refined from other concepts, and they can be imposed upon generic types through the use of requirement clauses. Key to ConceptsC++ is its emphasis on retroactive modeling, that is, the ability to extend types to model concepts without modifying those types. This is accomplished through the use of concept maps, which detail how a type satisfies the requirements of a concept; concept maps can contain implementations of the functions required by the concept, either providing new functionalities or overriding exisiting ones. In contrast, SimpleConcepts does not support retroactive modelling, and does not support concept maps. There are also several other differences between the two approaches, which we shall list here:

- ConceptsC++ allows for non-member associated functions. The implementations of these functions can either be defined via a concept map or a default implementation can be provided in the concept itself. SimpleConcepts, meanwhile, requires that all associated functions be member functions.
- ConceptsC++ distinguishes between refinement clauses, and associated requirements, both of which allow a concept to "inherit" requirements from other concepts. In SimpleConcepts, no such distinction is made; a concept can have a requires clause that lists all of the other concepts that it draws requirements from.
- ConceptsC++ supports axioms. As was explained in the previous subsection, SimpleConcepts does not support this language feature.

VII. Discussion

Our approach is not without limitations. Most notably, when translating refined concepts or constrained templates, it is assumed that the concepts that are being refined or used already exist, but this is not guaranteed to be the case. Referencing a non-existent concept will lead to a compile-time error, but that error is reported in terms of the translated code rather than the original source code, which could be problematic.

VIII. Conclusion and Future Work

It has been shown that C++ lacks language support to specify constraints on generic types, and that this lack is the underlying cause of many difficulties for both the users and developers of generic libraries. To that end, we introduced SimpleConcepts, an extension to the C++ language to provide such support. Our approach uses source-to-source transformations to provide an extension that is intended to be compatible with pre-existing C++11 compilers, while providing simple but powerful abstractions to aid in the design and use of C++ template libraries.

Moving forward, if the completed Concepts Lite is incorporated into the next iteration of the C++ language, then we shall turn our attention towards providing a formal analysis of such C++ concepts. In the short term, we hope to release a compiler front-end to provide experimental support for SimpleConcepts.

***Abstract*—The quality of the source code structure is a matter of the point of view, one programmer might consider one structure the best, the other not. A concrete structure can help in certain situations with the program understanding. Therefore we propose using dynamic structuring that allows assigning multiple structures to one source code to aid program comprehension. Concern-oriented source code projections facilitate this dynamic structuring expressed by custom metadata and provide multiple views of the source code that reflect logical structures provided by the dynamic structuring. This way in a specific situation a programmer can get a structure (by a view) that meets his/her current needs the best.**

I. Introduction

PROGRAM comprehension is a process of retrieving information and knowledge about a software system by studying its source code. Software system maintenance and evolution consumes up to 80 percent of system's lifetime [8]. Program comprehension tries to reduce this time. However, a more radical solutions, like for example literate programming [7] or elucidative programming [9], were not adapted in the industry, probably because they were too distant from the industrial practice.

We recognized that good design and source code structure are properties of *the point of view*. We believe that one static structure that is prevalent nowadays is not sufficient. Concern-oriented source code projections (or shortly code projections) contribute to the field of program comprehension by providing means to simultaneously express and use multiple structures of the source code.

II. Motivation

OOP uses classes and techniques such as dynamic binding to increase modularity, but on the other hand it also tears the source code structure to smaller parts (to submit it to single responsibility principle). AOP goes even further; it tears the structure even more according to concerns. It may help with modularity, but since the code as a whole (and thus the sequence of instructions) is scattered in more files, it is harder to follow the program logic. Considering which approach is better depends on the qualities taken into account – it is a matter of the point of view.

The same way it is difficult to find the best design, the best structure in a given paradigm. The quality of a design is a matter of point of view too. Let us consider a simple explanatory example from the AOP. An OOP method from listing 1 does some work and afterwards logs the process to the standard output.

Listing 1. Simple `doSomething()` method that is logged to standard output

```
public void doSomething() {
    ...
    // logging to standard output
    System.out.println
       ("Something was done!");
}
```

The AOP divides the source code into concerns that are implemented by aspects. Here a programmer Jack will identify a concern of logging in the system and will create a new aspect that will implement the logging concern. However, a programmer Jill will identify a concern of printing to standard output (for example to ensure that she will be able to easily switch from standard output to some other interface). So she would want to put the same line of code to the standard output aspect. So in this example Jack is interested in the logging concerns, while Jill in printing to standard output concern. However, these two concerns do not have to cover the same source code. Printing to standard output does not necessarily be logging. In this scenario Jack would say that creating logging aspect is better structuring that creating printing to standard output aspect, while Jill would say exactly the opposite.

Currently the source code has to have exactly one design, one structure. The concerns cannot overlap. The classes cannot either. Multiple design decisions can have good reasoning, but none of them tackles all the problems – e.g., sometimes the OO structuring is more useful, other times AOP structuring is advantageous. Usually it depends on whether the target of interest is a feature (OOP) or a concern (AOP).

The problem is based on the observation that the "best" structuring of the source code depends on the point of view. There are three main factors that influence the current best structuring:

- *Person* – each person has his/her own experience and opinion. Therefore each person has his/her own point of view.
- *Time* – even one person changes his/her opinion in time and in consequence his/her point of view. Usually the early structuring of the program evolves over the time to the required one even when there is only one programmer that authors it.

978-83-60810-53-8/$25.00

- *Character of the problem/solution* – of course the structuring also closely depends on the character of the problem or the solution. Not only the people involved in the software development do evolve in time, but also the character of the problem.

III. Concern-oriented Source Code Projections

In our work we recognize that the problem of multiple points of view is a consequence of *static structuring* of the source code. The problem of current approaches such as the AOP or OOP is that they allow the structure to meet some concrete needs, but does not support easy adaptation to new needs. Metaphorically speaking, using AOP instead of OOP is analogical to tearing down a house and building it again rotated in 90 degrees just to provide a view from side. Wouldn't it be more effective if the house would stay untouched and instead a programmer would walk around the corner? The same way as in the analogy, we don't want to change the building process, we just want to provide a programmer with a view that he/she wants.

A. Static vs. Dynamic Structuring

The problem is current technologies support merely one structure of the source code. This structure has to fully describe the system and does not allow any duplication of code. If current structure of the source code is not viable for current needs, the programmer has just bad luck. He/she has to work with the current structure, or refactor it and hope that the original structure won't be needed later. Or after refactoring the code[1] he/she has to hope that there will not be a need of the original aspect.

To deal with these problems we propose to use *dynamic structuring*. By dynamic source code structuring in this context we mean a case when a source code of one system has multiple different structures at the same time. In a particular situation the programmer would be able to choose the structure that currently the most relevant. This concept of dynamic structuring changes the role of refactoring. Instead of refactoring in sense of dropping the old structure and building a new one, with dynamic structuring a programmer is able to arbitrarily add a new structure to the source code or remove an existing one.

The usual representation of the structure is the source code itself. This will not suffice in case of dynamic structuring. It would be too difficult and cumbersome to write multiple versions of system source code and to keep them consistent through the time. Instead of this "physical" structures' representation dynamic structuring should use logical representation. Source code itself would be written (and stored) only once using some *base structure*. Adding new structures should be done by adding metainformation about their new relationships and properties.

[1]That is not an easy task even with current tool support for code refactoring. Tools support automation of merely trivial tasks such as changing a name of a variable, etc. However here we talk about structure on higher abstraction level, like the choice of using inheritance instead of composition.

The idea of dynamic structuring that allows having multiple different source code structures at the same time is the core of the concern-oriented source code projections method. We consider this idea the main contribution of our work.

B. Views

Code projections are based on dynamic structuring of program's source code. These structures have to be properly presented to programmer; otherwise they would be useless for program comprehension. Code projections map a set of base source code structures to a set of *views*. A view is an abstract structure of source code that is presentable to programmer. A view does not have to fully describe the system and multiple views can overlap (one code fragment can be a part of multiple views). The *Identity* projection defines a view that is identical to base source code structure; therefore it has to fully describe the system.

A single view consists of source code fragments that are somehow related. We will call these fragments view members. Relations between view members may be explicitly expressed in the view – a view can be graphical.

A code projection is specified by a sentence in a program query language[2]. Practically any PQL can be used; however, it has to support querying custom metadata too.

A programmer creates a *projection query* that specifies which concerns are relevant to his/her current situation. Projection queries can be shared and stored for later reuse, or modified if their current user is not satisfied with their current state. The concept of the code projections is outlined in figure 1.

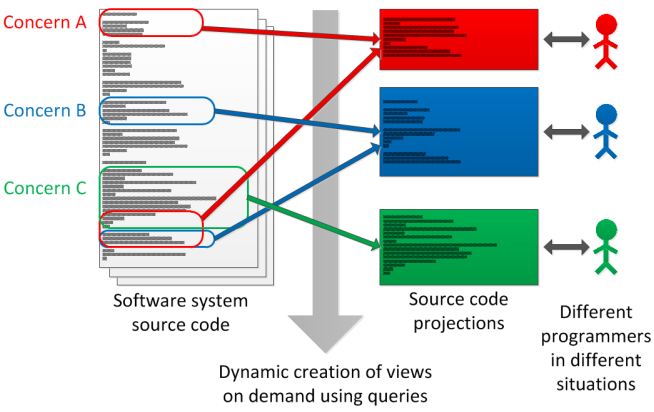

Fig. 1. The concept of the concern-oriented source projections

Our hypothesis in this work is that *current tools don't support flexible creating of views for viable price by using custom metadata*.

C. The Role of the Metadata

We will use term *software system metadata* (from now on only metadata) for the total sum (the set) of what one

[2]There are already programming query languages (PQL) in the world, this is not a new idea. However, PQLs are usually used to do source code checking (e.g., [4]). Our method uses PQL to provide a code projection.

can say about any program element, in a machine or human understandable representation.

Current IDEs provide programmers with code projections that operate on *intrinsic* metadata[3]. Navigator view uses the class intrinsic metadata to present the class members. Navigating to implementation through Ctrl and left mouse click uses the program element identifier. IDEs can use inheritance hierarchy to show implementations of interfaces or classes. Find Usages view uses also program element identifier to bind the implementation to its usages and provides a very useful projection of the source code.

In an example with Jack and Jill (listing 1) Jill would get desired result merely using intrinsic metadata. She can just query for any `System.out.println` call.

However, a situation would change if the logging was encapsulated in a `Logger` class (listing 2) that would provide a `PrintStream` that should be used for logging.

Listing 2. Logger implementation

```
public class Logger {
   private static PrintStream stream
      = System.out;

   public static getStream() {
      return stream;
   }
}
```

Listing 3 shows a modified `doSomething()` method with obscured printing to standard output. In this case it would be much more difficult to create a query that could find all the lines printing to standard output.

Listing 3. Obscured usage of standard output for logging

```
public void doSomething() {
   ...
   // logging to standard output
   Logger.getStream().println
      ("Something was done!");
}
```

Therefore we propose the utilization of the *custom* metadata to provide more information about program elements and to use that as a basis for different source code projections. Custom metadata are a tool that can be used to enrich the source code with metainformation about the semantic or design intents of the program elements at a higher abstraction level than the GPL is itself. In this way projections can use this metadata to present code to a programmer at a higher abstraction level too. A projection maps *concern-enriched* source code to a view. For listing 3 one could use for example simple marker annotations `@Log` and `@WritesToStandardOutput`.

D. The Role of the IDE

To provide code projections there has to be a tool that would be able to create a view while managing the source code in its base structure. In case of code projections we see as a best option utilization of the *Integrated Development Environment* (IDE) thanks to its approach to handle language in its infrastructure (considering IDE is an integrated set of language tools).

IDE infrastructure usually works with three language representations shown in figure 2, Notation, Model and View level. We want to utilize the editor to dynamically modify a view of the language.

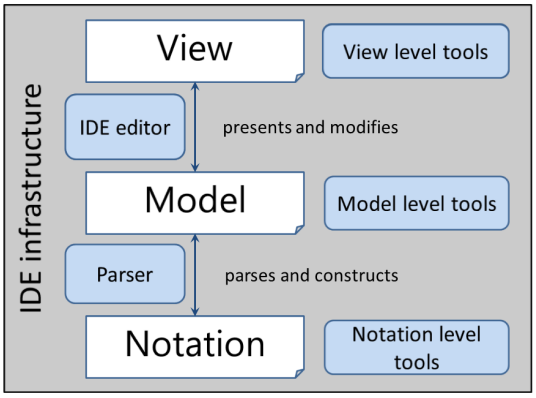

Fig. 2. Language representations in IDE infrastructure

If we will return to the analogy from the introduction to section III, concern-oriented source code projections provide a cheaper alternative to tearing down a house and building it in another angle. Instead of this invasive and inflexible solution code projections propose to change the view of an architect (analogy of programmer). Instead of moving the building merely the architect is moved to see what he/she needs to see.

IV. Related Work

We have applied a similar approach to *reduce the syntactic noise in internal domain-specific languages* in our previous work [6]. We were able to remove some undesired syntactic constructs (such as import section, class declaration, etc.) from the internal DSL based on Java language.

In modern IDEs there are many *standard projections* like the Navigator, TODOs, and others that we mentioned in section III-C. All these use projections to provide different views on the source code to provide a better orientation in the code.

Similar approach is used by Desmond et al. [1] in so called *Fluid source code views*. They allow viewing method bodies in place of their calls, thus reducing the need of browsing the source files. It is kind of similar to Go To Declaration projection of current IDEs, however using fluid source code views the body is shown directly in place of call using a tooltip.

Intentional source code views [5] are sets of related program elements that share some intention. In this sense they are

[3]Intrinsic metadata are standard metadata that define a program element. For example, for a class it is its name, its superclass, its interfaces, its methods and its attributes.

very similar to concern-oriented code projections. In Intentional views the intentions of the source code are specified using logic metaprogramming. Although they are close to our approach by providing means of defining architectural and conceptual information about source code, they differ in few rather important aspects. Intentional views require knowledge of logic metaprogramming. It is hard to expect every programmer to be a logic programmer. In our code projections we want to utilize common programmer's natural environment – code projections are to be made integral part of a modern IDE. Intentional views use code conventions that tend to be fragile (see [3]). And our projections can be used to edit the code, while Intentional views are read-only.

Source code annotations are used in [2], where Eisenberg et al. propose *simple edit-time metaobject protocol* that uses annotations as extensibility point of language. The editor is composed of multiple figures that have knowledge of what and how can be edited in them. These figures are configured by annotations.

V. Conclusion and Future Work

In this paper we argue that only one static structuring is not sufficient for software system source code. The quality of the source code structure is a matter of view, one programmer might consider one structure the best, the other not. A concrete structure can however play a significant role in program comprehension, since the point of view of looking at a code depends on the goal the programmer needs to achieve.

We presented the idea of so called dynamic structuring that allows assigning multiple structures to one source code. Our idea builds upon using logical structures that are expressed by metadata. When a new structuring is needed, it can be simply added to source code instead of overriding the existing one. Code projections utilize the view level of the language representation in the IDE infrastructure to reduce the price of their implementation and to still provide a modern professional IDE.

The *code projections* and *dynamic structuring* are the main contributions of the paper. Their purpose is to aid program comprehension. They can play significant role in documenting the source code, system maintenance and evolution.

Although we believe that dynamic structuring along with code projections may be a significant contribution to software engineering, we are aware of some problems with it. These problems we see as a space for our future work.

Dynamic structuring allows multiple, possibly uncountable, structures of the one source code. As we already argued, a good structure is a matter of the point of view. Therefore they may be just as many "good" structures as there are people working on the system. The *Babel effect*[4] is a consequence of the freedom in specifying the structure. Everybody has his/her own opinion and then it is hard to communicate. If two people are looking at two different views, it may be hard if not impossible to unambiguously talk about a specific source code fragment.

The second problem is the *price* of creating a projection. The source code annotations, or in general concern metadata only hardly can be created automatically. The source code has to be annotated explicitly either by it author or another programmer that recognize a need for a new structure. In this case a programmer has to consider the price annotating the source code to provide the space for code projections and the chance that the annotations will be reused later. If there is no real chance that the projection will be used, there is no good reason to create it. This is mainly a problem of development phase of software lifecycle, since the design decisions are made and the intended semantic properties are clearest in this phase.

[4]Named after famous story about building the Tower of Babel from the Bible.

***Abstract*—In this short paper, we advocate the importance of problem solving for teaching "Introduction to Programming", instead of merely teaching the syntax and semantics of a programming language. We focus on the role of the programming language used for an introductory course. For this purpose we propose CAL, a C-like algorithmic language, which is essentially a well-defined and behaved subset of C with a small number of modest, "educational" extensions. We present the design rationale for CAL, its main features, syntax and illustrative examples.**

I. Introduction

IN THIS short paper, we present our experiences with teaching programming through *problem solving* in the School of Electrical and Computer Engineering of the National Technical University of Athens. We focus on the role of the programming language for this purpose and describe the approach that we have taken. Let us begin with two observations:

1) In some students' minds, algorithmic programming is strangely enough an intellectual process that is not connected to everyday problem solving.
2) Students often have no sense of what is good and what is bad in programming, even after taking a number of courses on the design of algorithms and complexity.

We believe that these are both due to the way we teach students how to program. Starting from secondary school, students often begin by learning a Pascal-like programming language. They learn to use variables, assignments, control-flow statements, arrays. They do not learn, however, because we do not teach them early enough, *what these should be used for!* Young children realize early that they need to solve problems; they are hungry and they want their parents to feed them, they want to play with that shiny car in the toy shop's window, etc. Later on, they learn to speak and use the *language* to communicate their needs. Children learn to speak after they know what they want to say! Why do we teach programming languages to students before they know what to use them for?

The main goal of our proposal is a quick introduction to programming for absolute beginners. Such an introduction would be useful for teenagers in high-school, who may not continue to be programming specialists but who want to support their literacy in mathematics by hands-on attractive algorithmically solvable problems. It would also be useful to first-year university students who have (somehow) escaped a proper exposure to programming in high school (and this is the majority of our students). Thus, this goal translates to:

- a quick educational introduction to self-evident programming concepts and tools, without cryptic, hardware-dependent and special purpose structures; but also
- fluency in a programming language which can be easily extended and/or modified to a language that is currently useful in practice, without a total rethinking of the basic algorithmic techniques.

Our historic prototype for a self-evident educational programming language is of course Pascal [10], whereas programming languages that are currently useful in practice are of course C [7], [5], C++ [9] and Java [2].

II. The Role of the Language

Since the 1950s, scores of different programming languages have been designed and implemented and many more are yet to come. Those with a relative experience in the field will agree that there is no such thing as "the best programming language" and this is what we need to explain to our students early on. Some languages are better than others *for some specific purpose* and indeed: (a) some specific languages are almost exclusively used for some specific purposes, and (b) for some specific purposes people use almost exclusively some specific languages.

For example, C [7], [5] is a very good language for systems programming. It is a low-level language, offering programmers the opportunity to directly interact with the hardware, but not the best language for numerical and scientific computing today. We believe that C is an inappropriate language for teaching "Introduction to Programming". Some of its characteristics are so low-level that tend to focus on the hardware, instead of on the algorithms. When you start learning how to program, you don't need twelve different types for integer numbers (including characters and Boolean values) and three more for real (floating-point) numbers. You don't need a `for` statement so powerful that you can use it to implement a binary search algorithm in just one line. You don't need to struggle to understand the meaning of `x = x++;` (most people, including some who teach C, think that it does something although opinions vary when it comes to what exactly this is; the truth is that this statement is illegal, or causes "undefined behaviour"

978-83-60810-53-8/$25.00

as the ANSI C standard puts it, because the value of variable `x` changes twice between two successive sequence points).

Pascal [10], [6] is arguably one of the best programming languages for teaching purposes. It is a concise, general purpose language which supports a systematic, structured and algorithmic approach to problem solving. Programs in Pascal are usually easy to read and understand with a clear structure that favours stepwise refinement. The language helps programmers to avoid programming mistakes and to be able to verify the correctness of their programs. On the other hand, Pascal is very little used today by software practitioners.

Java and other object-oriented languages are also poor candidates for teaching "Introduction to Programming". If the focus is on problem solving and algorithmic thinking, such languages add an unbearable level of noise. Using Java, the only logical approach is to teach programming in a purely object-oriented fashion and this necessarily takes the focus away from problem solving, although OOP might be a good choice for a second (e.g., data structures) course.

There is a trend towards Python, in the last few years. Python is a relatively good candidate; its syntax is concise and enforces proper indentation, it supports imperative and object-oriented programming equally well, and it is widely used in the software industry. The drawbacks for Python are: (a) it is dynamically typed and requires very few declarations; this is bad if you want the students to detect programming errors early and to learn to program in a disciplined way; (b) it is so high-level that students do not develop an intuition about how data are represented and how operations are implemented; this is bad if you want the students to understand the connection between the programming language and the underlying hardware; and (c) its data structures are so high-level that algorithmic complexity issues are obscured by the way data structures are implemented; e.g., in Python there are no arrays, but there are lists and dictionaries; however, in a data structure course, all three would need to be covered and with three different implementations, requiring $O(1)$, $O(n)$ and $O(n \log n)$ time for accessing an element, respectively.

The second drawback (b) is also true for functional languages, like Scheme, ML or Haskell, which are also very good from an educational point of view and are indeed used for teaching "Introduction to Programming" in several Computer Science departments [8], [3], [1], [4].

All this said, we decided to design a new educational programming language for an introductory course in which emphasis is on problem solving. However, this educational language will naturally evolve before the students' eyes to a full-scale programming language, useful later on. In the next sections we describe CAL, a *C-like algorithmic language*, starting from the design choices that we had to make, proceeding with the syntax, the main characteristics of the language and concluding with a few examples.[1]

[1]An implementation of CAL, based on GCC and using macros, is available from https://github.com/softlab-ntua/pazcal.

III. The Design of CAL

Disregarding some drawbacks, C is an adequate choice for teaching "Introduction to Programming", with emphasis on problem solving and algorithmic thinking. Its core is a quite simple algorithmic language, easy to explain and use. Moreover, it is a useful language to know, heavily used in practice, either directly or indirectly, through a line of descendants that share a large part of its syntax and semantics (C++, Java, C#, etc.). A list of drawbacks:

- Its syntax and semantics is often cryptic and obfuscated; e.g., allowing side-effects anywhere inside expressions.
- The use of "declarators" (as in `int*(f[3])(int);`) is counter-intuitive and hard to explain.
- Non trivial library functions (e.g., `printf` and `scanf`) are required for beginners to write programs that input and output data. The corresponding header files must be `#include`d. Pointers are required for `scanf`.
- Before the simplest program is written, students must see `int main()` and `return 0;` unless of course we want to teach them to be sloppy from the first lecture...
- The type system allows programmers to deliberately misuse data and to neglect declaring function prototypes. Both are bad from an educational point of view.

We therefore base CAL on an appropriate "educational subset" of C, which we extend with a number of macros, library functions and one extra feature (call by reference) to suit the needs of our introductory course. The result is a language reminiscent of Pascal but with C notation. All extensions are written with *uppercase letters* (e.g., **WRITE**), so that students immediately know if something that they have learnt exists in C or is one of our educational extensions. The main characteristics of CAL, whose complete syntax is defined in figure 1, are the following:

- A program is organized as a set of modules, each consisting of constant and type definitions, variable definitions, routine declarations, routine definitions and (optionally) the body of the main program, which must only be present in one module. The visibility of module definitions is controlled with **PRIVATE** and **extern**.
- There are *functions* and *procedures*, defined with **FUNC** and **PROC** respectively; the misleading type **void** is not used. The main program begins with the special keyword **PROGRAM**.
- The type system is simplified. There are types for Boolean values (**bool**, as in C99, with constants **true** and **false**), integers (**int**), characters (**char**) and real numbers (**REAL**). There are also enumerations, structures and unions, but these must be defined and given a name before they can be used. Arrays and pointers complete the picture of types. However, the syntax for declarators is very simplified in comparison with C; type synonyms (**typedef**) can be used for defining, e.g., double pointers, arrays or pointers, pointers to arrays, etc.
- Operators **NOT**, **AND**, **OR** and **MOD** are synonyms of C's (not so intuitive) standard operators `!`, `&&`, `||` and `%`.

⟨module⟩ ::= (⟨const_def⟩ | ⟨type_def⟩)* (⟨declaration⟩)* (⟨definition⟩)* [⟨program⟩]
⟨declaration⟩ ::= ["**PRIVATE**" | "**extern**"] (⟨var_def⟩ | ⟨routine_decl⟩)

⟨call⟩ ::= ⟨id⟩ "**(**" [⟨expr⟩ ("**,**" ⟨expr⟩)*] "**)**"

Fig. 1. A context-free grammar defining the syntax of CAL in EBNF. Operator precedence and associativity are the same as in C.

- Assignment (simple or composite) is a statement. (Alas, for compatibility purposes we have to give up the assignment operator `:=` and accept the commonly used `=`, which we would prefer not to confuse with the equality operator known from mathematics.) There is just one type of increment and decrement operators (postfix, e.g., `x++`), used again as statements. Therefore, expression evaluation cannot contain direct side-effects. Also, we omit bitwise operators and conditional expressions (`?:`).

- We omit the **`for`** statement, which is too general for our purposes, and replace it with a **`FOR`** statement following the style of Pascal, mentioning the control variable and a (precomputed) range of values that the control variable will take. Using **`FOR`**, the maximum number of iterations is always finite and known before the loop starts executing; **`break`** and **`continue`** can be used to exit the loop and proceed with the next iteration.

- The **`switch`** statement is sanitized; **`case`** labels cannot appear everywhere. Furthermore, clauses are required to end either with a **`break`**, or with the new keyword **`NEXT`** in order to explicitly proceed to the next clause.

- Four kinds of **`WRITE`** statements are used for the output of data, allowing any number of arguments of any type, with a number of formatting options that are useful for an introductory course. Library functions `READ_INT`, `READ_REAL` and `getchar` are used to input data.

- The use of pointers has also been sanitized. The connection between pointers and arrays is still present, but it only allows the use of a pointer as an array; no pointer arithmetic is allowed and there is no "address of" operator (`&`). Pointers are used for dynamic memory allocation; **`NEW`** and **`DELETE`** help students for this purpose (in the spirit of C++, instead of `malloc` and `free` in C).

- Call by reference is allowed, using the same notation that

C++ uses for references.

IV. Introduction to Programming using CAL

Our course is based on the simplicity philosophy of the great teachers of the 1960s: Dijkstra, Hoare, and Wirth. We only give some highlights for lack of space.

- As early as in the second week, students are able to write simple programs that input, process and output data.

```
PROGRAM area_of_circle ()
{ WRITE("Give the radius: ");
  REAL r = READ_REAL();
  REAL a = 3.1415926 * r * r;
  WRITELN("The area is: ", a);
}
```

- Control flow and combinatorial calculations.

```
PROGRAM primes ()
{ int p;
  WRITELN(2);
  FOR (p, 3 TO 1000 STEP 2)
  { int t = 3;
    while (p MOD t != 0) t += 2;
    if (p == t) WRITELN(p);
  }
}
```

- Structured programming: modules, functions and procedures, parameter passing, stepwise refinement.
- Recursion. Euclid's algorithm for the greatest common divisor is one of the examples that we use:

```
FUNC int gcd (int i, int j)
{ if (i==0 OR j==0) return i+j;
  else if (i > j)   return gcd(i MOD j, j);
       else         return gcd(i, j MOD i);
}
```

- Call by reference: e.g., in `swap`, useful for sorting.

```
PROC swap (int &x, int &y)
{ int t = x; x = y; y = t; }
```

- Arrays: merge sort and quick sort, which are also examples of recursion.

```
PROC merge (int a[], int fst, int mid, int lst);

PROC mergesort (int a[], int first, int last)
{ if (first >= last) return;
  int mid = (first + last) / 2;
  mergesort(a, first, mid);
  mergesort(a, mid+1, last);
  merge(a, first, mid, last);
}
```

- Dynamic data structures, such as linked lists and trees, e.g., in-situ reversal of a simply linked list.

```
struct node { int data; struct node *next; };
typedef struct node *list;

PROC reverse (list &l)
{ list q = NULL;
  while (l != NULL)
  { list p = l;
    l = p->next; p->next = q; q = p;
  }
  l = q;
}
```

When grading, we reward the design of efficient algorithms for solving problems such as the following:

MAXSUM: Read a sequence of n integer numbers (positive, zero, or negative) and output the largest value of the sum of (arbitrarily many) consecutive numbers in the sequence.

We expect students who correctly solve this problem to come up with one of three general types of solutions, or variations thereof. The first, is the obvious $O(n^3)$ algorithm: for all possible starts (`i`) and ends (`j`) of subsequences, calculate the sum and find the largest. The second is the slightly less obvious $O(n^2)$ algorithm that, for every given start (`i`) avoids recomputing the sum of a subsequence from scratch but reuses the sums of smaller subsequences. Finally, the third is a linear algorithm — $O(n)$ time and requiring $O(1)$ memory — which works in a greedy fashion.

```
PROGRAM maxsum_On ()
{ int n = READ_INT();
  int i, sofar = 0, best = 0;
  FOR (i, 0 TO n-1)
  { int x = READ_INT();
    sofar += x;
    if (sofar < 0)          sofar = 0;
    else if (sofar > best) best = sofar;
  }
  WRITELN(best);
}
```

V. Concluding Remarks

We have presented CAL, a C-like algorithmic language that we advocate for teaching "Introduction to Programming" focusing on problem solving. We discussed the design of CAL, which is essentially a controlled subset of C with some appropriate extensions. We would like to see CAL, or appropriate subsets of it, as a vehicle to teach computer programming to high-school students, making a bridge between mathematics and computer science in secondary education.

***Abstract*—In this paper we further investigate nQML, a functional quantum programming language that follows the "quantum data and control" paradigm. We define a semantics for nQML, which translates programs to quantum circuits in the category FQC of finite quantum computations, following the approach of Altenkirch and Grattage's QML. This semantics, which coincides with the denotational semantics for nQML over density matrices and unitary transformations, serves as a compiler from nQML programs to quantum circuits. We also provide an implementation of this compiler, written in Haskell, as well as an interpreter for quantum circuits.**

I. Introduction

QUANTUM computing processes data that is stored in the form of quantum bits (qubits) and, for doing so, it employs quantum mechanical phenomena such as the superposition and entanglement of quantum states. Roughly speaking, a qubit may contain the digit "0", the digit "1", or any superposition of these two. Although research towards the manufacturing of quantum computers has not yet led to mature results, *quantum circuits* seem to be today a commonly accepted model for quantum hardware. Such circuits consist of appropriate formations of quantum gates, acting upon qubits in the same way that classical logic gates act upon bits in ordinary computers.

Most quantum programming languages that have been proposed so far are based on the principle "quantum data, classical control", that is, on the idea that the execution of a quantum program follows a specific control-flow, exactly as the execution of a program in a classical computer. Such languages allow programmers to use quantum data, in addition to classical, and through their manipulation to implement quantum algorithms. On a different track, we see languages following the "quantum data and control" paradigm. Such languages use quantum control flow; in other words, they allow the execution flow of a program to be in a superposition of various different states in exactly the same way as the quantum data that the program manipulates.

nQML [15], [14] is a high-level functional language based on the concept of "quantum data and control." It was defined by Lampis *et al.*, inspired by Altenkirch and Grattage's QML [1], [8], [9], and its main design goal was to give programmers sufficient expressive power to implement quantum algorithms easily, while preventing them from breaking the rules of quantum computation. nQML includes constructs which allow any unitary transformation to be expressed as a program in nQML quite naturally, more or less using the same notation that is used by the designers of quantum algorithms. It also permits quantum measurements to be carried out at any point during the execution of a program.

As explained in the paper defining nQML [14], the relative ease of use of the language comes at the cost of putting aside a number of important practical issues, such as the existence of imperfect quantum hardware, the need for quantum error correction and the fact that every quantum program will eventually have to be implemented as a quantum circuit using only a finite set of quantum gates and, therefore, some of the unitary transformations that nQML allows will have to be approximated. Similar problems were a source of concern for the founders of the classical programming model many decades ago. Fortunately they have been resolved and their solutions have been abstracted in such a way that people who use modern high-level programming languages need not know anything about them. The same can and must be done for quantum programming languages and, therefore, such issues should be tackled not by the designer and users of a quantum programming language, but by the architect of a quantum computer, the designer of its operating system and, to a lesser extent, the designer of the compiler.

In order to demonstrate the feasibility of using nQML as a quantum programming language and to draw attention to the assumptions that are necessary and to the problems that remain to be resolved, in this paper we define a compiler for nQML, targeting quantum circuits in the category FQC of finite quantum computations [1], [8]. We also provide an

978-83-60810-53-8/$25.00

implementation of the compiler in Haskell, as well as an interpreter for quantum circuits in FQC. The combination of these two can be used for the execution of quantum programs and for a direct comparison with the original definition of the language, using denotational semantics over density matrices and unitary transformations [14].

The rest of the paper is structured as follows. In section II we give the syntax of the language nQML and explain its constructs. Section III contains a description of the quantum circuits that we will use as the target language for our nQML compiler, which is in turn defined in section IV. Section V contains a number of examples in nQML, corresponding to well known quantum algorithms, and the quantum circuits in which they are compiled. We conclude with an exposition of related work, followed by some remarks and directions for future work.

Due to space limitations, in this paper we do not have the luxury to explain how quantum programming works. It is assumed that the reader is familiar with the basics of quantum computation and quantum circuits. There are several introductory books [3], [12], [24], [16], as well as publicly available manuscripts and course material on this field.

II. The language nQML

The syntax of nQML is given by the following grammar. It is assumed that x is a variable identifier and λ is a complex constant. The grammar defines two syntactic classes. Quantum expressions are denoted by e; they represent quantum programs and their syntax is similar to that of QML. Classical expressions are denoted by c; they are only needed in the quantum transformation construct $|e\rangle \to x, x'.\, c$ and they can represent two types of information: a structure of classical bits or a complex number.

$$
\begin{array}{rcl}
e & ::= & x \mid \{\,(\lambda)\,\mathbf{qfalse} + (\lambda')\,\mathbf{qtrue}\,\} \\
& \mid & \mathbf{let}\ x = e_1\ \mathbf{in}\ e_2 \\
& \mid & (e_1, e_2) \mid \mathbf{let}\ (x_1, x_2) = e_1\ \mathbf{in}\ e_2 \\
& \mid & \mathbf{if}\ e\ \mathbf{then}\ e_1\ \mathbf{else}\ e_2 \mid \mathbf{ifm}\ e\ \mathbf{then}\ e_1\ \mathbf{else}\ e_2 \\
& \mid & |e\rangle \to x, x'.\, c \\
c & ::= & x \mid \mathbf{false} \mid \mathbf{true} \mid \lambda \mid \mathbf{let}\ x = c_1\ \mathbf{in}\ c_2 \\
& \mid & (c_1, c_2) \mid \mathbf{let}\ (x_1, x_2) = c_1\ \mathbf{in}\ c_2 \\
& \mid & \mathbf{if}\ c\ \mathbf{then}\ c_1\ \mathbf{else}\ c_2 \mid c_1 = c_2 \mid c_1 < c_2 \\
& \mid & \mathbf{int}\, c \mid c_1 + c_2 \mid c_1 - c_2 \mid c_1 * c_2 \mid c_1/c_2 \mid c_1^{c_2}
\end{array}
$$

Variables in nQML are viewed as references to quantum information that is stored in a global quantum state. There are two types of quantum information: qubits and products. A new qubit is allocated in the quantum state when the superposition operator $\{\,(\lambda)\,\mathbf{qfalse} + (\lambda')\,\mathbf{qtrue}\,\}$ is used, in the same way that new objects are allocated on the heap when a data constructor is used in a functional programming language. Products are introduced and eliminated with the constructs (e_1, e_2) and $\mathbf{let}\ (x_1, x_2) = e_1\ \mathbf{in}\ e_2$. nQML also features three control constructs:

- $\mathbf{ifm}\ e\ \mathbf{then}\ e_1\ \mathbf{else}\ e_2$: It conducts a measurement on e, which must be of type qubit. Depending on the result, it executes one of its branches. It is similar to a classical random branching, based on a toss of a biased coin with probabilities depending on the state of the qubit being measured.
- $\mathbf{if}\ e\ \mathbf{then}\ e_1\ \mathbf{else}\ e_2$: It allows the programmer to perform quantum branching. If e, which must be of type qubit, is in a classical state, then the effect is what we would expect from **ifm**. But if e is in a quantum superposition, the program proceeds in a quantum superposition of both branches, most likely creating entanglement among the qubits of the quantum state.
- $|e\rangle \to x, x'.\, c$: A generic means of expressing any unitary transformation, which has to be relied upon when a transformation can not be easily broken down to a series of controlled operations, expressible with **if**. Its advantage is that, rather than forcing programmers to precompute and provide the whole unitary matrix of the transformation, whose size is exponential in the number of qubits that it affects, it allows them to express that matrix as a complex function of the input and output state of the transformed qubits. This leads to a succinct and clear expression of many useful quantum algorithms, such as the Deutsch-Jozsa or Grover's algorithm that are described in Section V.
  In quantum pseudocode notation, all unitary transformations can be expressed in the form:
  $$|i\rangle \to \sum_{j=0}^{2^n-1} f(i,j)\,|j\rangle$$
  where $f(i,j)$ is a function of the input state i of the quantum register and its output state j. The construct $|e\rangle \to x, x'.\, c$ allows the programmers to use precisely this natural notation: the classical variables x and x' denote the register's input and output state and the classical expression c denotes the function's body.
  From this notation, if the function f is known, the unitary matrix can be easily constructed by taking $S_{j,i} = f(i,j)$. Of course, not all functions f result in unitary matrices and the type system of nQML cannot efficiently decide whether the resulting transformation is indeed unitary. The type system of Altenkirch and Grattage's QML is able to do that, at the expense of making the size of the program exponential and complicating the typing with orthogonality constraints.

nQML admits a simple type system and denotational semantics [14]. By simple, we mean that both use structures and techniques that are typical in the study of classical programming languages of similar size and complexity.

The main novelty of nQML's type system is that the type of a quantum expression conveys information which reveals the exact qubits of the quantum state in which the expression's value resides. Qubit aliasing is allowed in such a way that the "no cloning" and "no dropping" principles are not violated. Programmers have the look-and-feel of a classical programming language, without linearity restrictions. The type system can be extended to support polymorphic higher-order

functions, where polymorphism is over the exact qubits of the quantum state that are used for representing data [14].

Quantum types, in the type system of nQML, are defined by the grammar

$$\tau \ ::= \ \mathbf{qbit}[n] \ | \ \tau_1 \otimes \tau_2$$

where n is the exact qubit of the state that is used, e.g., an expression has type $\mathbf{qbit}[5]$ if its value is stored in the 5th qubit of the state. This information is used to make sure that the same qubit cannot be used twice in a transformation.

There are two typing relations: $\Gamma; n \ \vdash^{\circ} \ e \ : \ \tau; m$ is for type checking pure quantum expressions (i.e. without measurements); on the other hand, $\Gamma; n \ \vdash \ e \ : \ \tau; m$ is for type checking arbitrary quantum expressions, We refer to both by $\Gamma; n \ \vdash^{\alpha} \ e \ : \ \tau; m$, allowing the superscript $^{\alpha}$ to be either $^{\circ}$ or empty. As the types of nQML convey information regarding the position of qubits in the quantum state, the typing relation is forced to process and propagate such information. In $\Gamma; n \vdash^{\alpha} e : \tau; m$, the natural number n appearing on the left side of the relation stands for the number of qubits of the original quantum state, before e starts evaluating. The natural number m appearing on the right side of the relation stands for the number of new qubits that are allocated during the evaluation of e. The typing rules are defined in [14].

The denotational semantics of nQML is based on the use of density matrices to describe quantum states. The meaning of a well-typed nQML program is a function from density matrices to density matrices and describes the program's effect on an arbitrary quantum input state. Pure well-typed programs, i.e., programs which conduct no measurements, are also assigned a meaning in the form of a unitary matrix which describes the transformation they perform on the quantum state. The execution of an nQML program can be seen as a sequence of steps which affect the quantum state by allocating new qubits, by applying unitary transformations to existing qubits or by measuring existing qubits.

III. Quantum circuits

Quantum circuits are one possible model of quantum computation. We extend the Haskell data type proposed by Altenkirch and Grattage [6], [8] by adding one more constructor for arbitrary unitary matrices (`Unit`), which will be the target of nQML's $|e\rangle \to x, x'.\, c$ construct.

```
data Circ = Rot (C,C) (C,C)
          | Wire [Int]
          | Par Circ Circ
          | Seq Circ Circ
          | Cond Circ Circ
          | Unit (Matrix C)
```

The set of quantum circuits operating on a state of n qubits are defined inductively using these constructors:

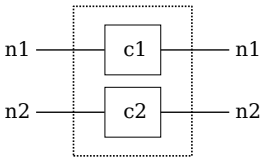
- Rotation `Rot` $(\lambda_0, \lambda_1)\,(\kappa_0, \kappa_1)$: introduces a new unitary transformation on one qubit ($n = 1$), defined by the following matrix, where $\lambda_0^* \kappa_0 + \lambda_1 \kappa_1^* = 0$.

$$\begin{pmatrix} \lambda_0 & \lambda_1 \\ \kappa_0 & \kappa_1 \end{pmatrix}$$

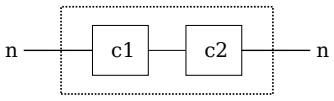
- Wire reordering `Wire` p: reorders the qubits in the state. The parameter p must be a permutation of the sequence $[0\,..\,n-1]$. If the i-th element of this permutation is j, this means that the wire at the i-th position in the input state becomes the j-th wire of the output state. The identity permutation corresponds to the identity unitary matrix which leaves the state unchanged. When drawing quantum circuits, we will not use quantum gates to implement wire reordering; we will just draw crossing wires, e.g., as follows:

  In all circuits, the numbers next to the wires denote multiplicity, i.e., the number of qubits in the state. If $n_1 = n_2 = n_3 = n_4 = 1$, the reordering shown above would be encoded in Haskell by `Wire [1,3,0,2]`.

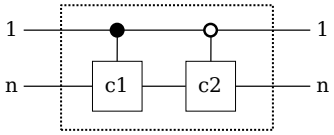
- Parallel composition `Par` $c_1\, c_2$: combines c_1 and c_2 in parallel, adding the number of qubits in their states.



- Sequential composition `Seq` $c_1\, c_2$: combines c_1 and c_2 in sequence, The two circuits must have a state of n qubits, where n is also the number of qubits in their composition.



- Conditional `Cond` $c_1\, c_2$: creates a conditional circuit that is controlled by an extra qubit. The two circuits must have a state of n qubits, whereas the number of qubits in the conditional circuit is $n + 1$.

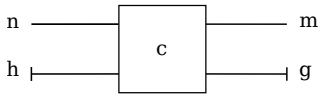


- Arbitrary unitary matrix `Unit` C: creates a circuit with a state of n qubits corresponding to the unitary matrix C. Such a circuit must in general be approximated by an appropriate composition of elementary quantum gates.

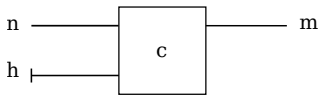
Reversible finite quantum circuits form the category $\mathsf{FQC}^{\approx}$, whose objects are states of n qubits and morphisms are unitary

transformations. Following Altenkirch and Grattage [6], [8], we define two larger categories, FQC and FQC$^\circ$.

Circuits in FQC are not necessarily reversible: they can also contain measurements and/or qubit initializations (which also amount to measurements). To model circuits in FQC, we separate a number of qubits of the input state, which we call *heap*, and a number of qubits of the output state, which we call *garbage*. Qubits in the heap are considered to be initialized to $|0\rangle$. Qubits in the garbage are measured and discarded. When drawing circuits, we denote the heap and garbage by terminating lines. It must be $n + h = m + g$.



Also, the category FQC$^\circ$ is a subset of FQC where circuits are allowed to have a heap, but not garbage. Such circuits are pure, in the sense that they do not contain measurements, and can be modelled by unitary transformations between pure quantum states. It must be $n + h = m$.

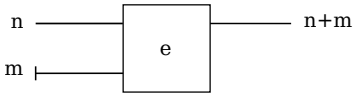


Obviously, FQC$^\approx$ $\subset$ FQC$^\circ$ $\subset$ FQC.

IV. A COMPILER FOR NQML

Following the compilation approach used by Altenkirch and Grattage [6], [8] we use the typing relation for compiling (pure and impure) quantum expressions. However, in contrast to the approach used for QML, the process is not guided by the linear type system, deciding how to split the wires of the input state. Instead, purity information and the numbers n and m from nQML's typing information are used.

If e is a pure quantum expression such that $\Gamma; n \vdash^\circ e : \tau; m$, then e is compiled to a circuit in FQC$^\circ$ which has an input state of n wires plus m wires of heap and an output state of $n + m$ wires (without garbage). We draw this as follows:



On the other hand, if e is an impure quantum expression such that $\Gamma; n \vdash e : \tau; m$, then e is compiled to a circuit in FQC which has an input state of n wires plus $h \geq m$ wires of heap and an output state of $n + m$ wires plus g wires of garbage. It must be $h = m + g$. We draw this as follows:

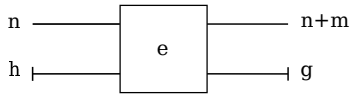


Fig. 1 shows how nQML constructs are compiled to circuits. The compilation process is based on the typing of expressions.

- **Superposition.** A new qubit is added to the state corresponding to $\{ (\lambda)\,\mathbf{qfalse} + (\lambda')\,\mathbf{qtrue} \}$. The remaining n qubits of the state are unaltered, whereas the new qubit is initialized with the transformation matrix:

$$\begin{pmatrix} \lambda & \lambda' \\ \lambda' & -\lambda \end{pmatrix}$$

- **Let construct and products.** Although the typing rules for these three constructs (simple let, product formation and product elimination) are different when it comes to the types of the participating expressions, they are all the same w.r.t. the number of qubits in the state and they produce the same quantum circuit, which is essentially the sequential composition of two expressions.

- **Quantum conditional.** In the typing of $\mathbf{if}\ e\ \mathbf{then}\ e_1\ \mathbf{else}\ e_2$, the condition is the k-th qubit of the state and the pure expressions e_1 and e_2 are not allowed to refer to the k-th qubit (as the environment $\Gamma|_k$ suggests in the figure). The circuit corresponding to condition e is generated first and the k-th qubit of the output state is isolated. This qubit controls the conditional circuit of e_1 and e_2. Notice that it is not strictly true that this conditional circuit is composed of e_1 and e_2. First of all, we have to translate away the (unused) k-th qubit, by inductively transforming the circuits corresponding to e_1 and e_2. Then, we have to extend the input state of the smallest of the two circuits, so that both expect an input state of $n + m - 1 + \max(m_1, m_2)$ qubits.

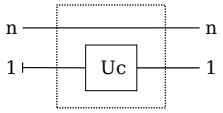
- **Measurement.** The difference between the quantum conditional and the measurement is that (a) impure expressions are allowed in branches, (b) the branches can use the qubit of the condition, and (c) the qubit of the condition is measured at the end of the circuit. In order to be used by the two branches and (at the same time) be measured at the end, the qubit of the condition must be duplicated (creating a quantum entanglement). This is achieved by using one extra qubit and the controlled CNOT gate. The two expressions may, of course, use the measured value of this qubit. Notice that this is the only circuit which explicitly creates garbage, by measuring the qubit of the condition. Also, this is one of the two circuits that explicitly use qubits from the heap (the other one is generated by superposition).

- **Unitary transformation.** In $|e\rangle \to x, x'.\, c$, it is assumed that $c(x, x')$ defines an arbitrary unitary transformation on states of $n + m$ qubits, and this transformation is applied to the result of expression e.

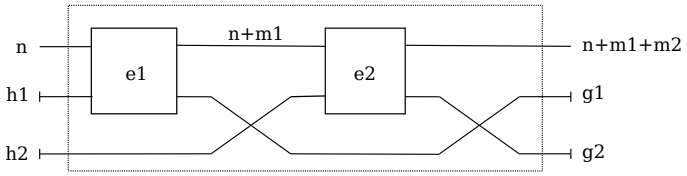
The implementation of our compiler applies several simple optimizations to the generated quantum circuits.[1] In general,

[1]The implementation of nQML can be found at http://www.softlab.ntua.gr/~nickie/Research/nqml/. It consists of approximately 3,200 lines of Haskell code. Parts of it have been written by Michael Lampis.

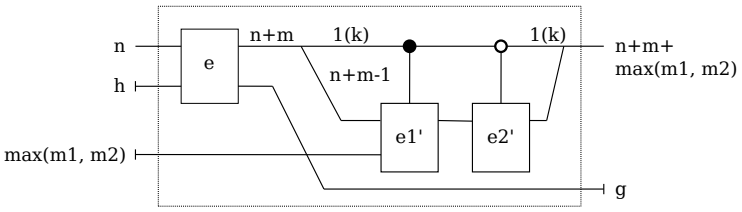
Superposition:
$\Gamma; n \vdash^{\circ} \{ (\lambda)\, \mathbf{qfalse} + (\lambda')\, \mathbf{qtrue} \} : \mathbf{qbit}[n]; 1$



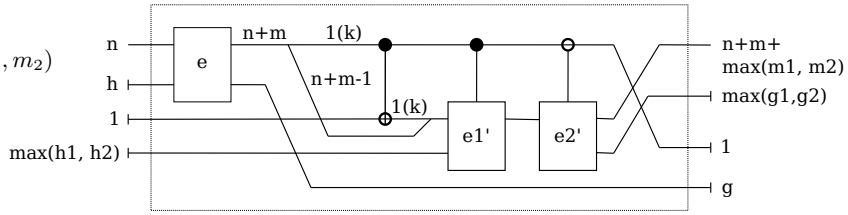
Let and products:
$\Gamma; n \vdash^{\alpha} \mathbf{let}\ x = e_1\ \mathbf{in}\ e_2 : \tau; m_1 + m_2$
$\Gamma; n \vdash^{\alpha} (e_1, e_2) : \tau; m_1 + m_2$
$\Gamma; n \vdash^{\alpha} \mathbf{let}\ (x_1, x_2) = e_1\ \mathbf{in}\ e_2 : \tau; m_1 + m_2$
where:
$\Gamma_1; n \vdash^{\alpha} e_1 : \tau_1; m_1$
$\Gamma_2; n + m_1 \vdash^{\alpha} e_2 : \tau_2; m_2$



Quantum conditional:
$\Gamma; n \vdash^{\alpha} \mathbf{if}\ e\ \mathbf{then}\ e_1\ \mathbf{else}\ e_2 : \tau; m + \max(m_1, m_2)$
where:
$\Gamma; n \vdash^{\alpha} e : \mathbf{qbit}[k]; m$
$\Gamma|_k; n + m \vdash^{\circ} e_1 : \tau; m_1$
$\Gamma|_k; n + m \vdash^{\circ} e_2 : \tau; m_2$



Measurement:
$\Gamma; n \vdash \mathbf{ifm}\ e\ \mathbf{then}\ e_1\ \mathbf{else}\ e_2 : \tau; m + \max(m_1, m_2)$
where:
$\Gamma; n \vdash e : \mathbf{qbit}[k]; m$
$\Gamma; n + m \vdash e_1 : \tau; m_1$
$\Gamma; n + m \vdash e_2 : \tau; m_2$



Unitary transformation:
$\Gamma; n \vdash^{\alpha} |e\rangle \to x, x'.\, c : \tau; m$
where:
$\Gamma; n \vdash^{\alpha} e : \tau; m$
$c(x, x')$ defines a unitary transformation on $n+m$ qubits

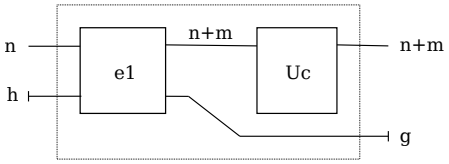


Fig. 1. Compiling nQML expressions to quantum circuits: A typing-directed approach.

the implementation is written in Haskell; it targets the polymorphic language described in [14] and consists of:

- a parser,
- a type checker,
- a first interpreter, based on the denotational semantics of nQML, using density matrices and unitary transformations,
- the compiler from nQML to quantum circuits, defined in this paper, and
- a second interpreter, based on the simulation of quantum circuits generated by our compiler.

The implementation checks that the outputs of the two interpreters coincide, thus testing the correctness of our compiler.

V. Examples

In this section, we outline the use of nQML and its compiler with two relatively simple but historically important examples: Deutsch's algorithm for testing whether a function on one bit is balanced or constant [4], and Grover's algorithm for searching an unsorted database [11].

We begin by providing a couple of auxiliary functions, **not** and **had**, that will be useful in both examples. They correspond to the NOT gate and the Hadamard gate. Their definitions can be given by simple unitary transformations.

```
def not q = |q> -> x, x'.
  if x' = x then 0 else 1;

def had q = |q> -> x, x'.
  (if x then (if x' then -1 else 1) else 1)
    / sqrt(2);
```

The syntax of function definitions in nQML follows the proposed extension with polymorphic functions [14]. Such functions could be treated as macros by the compiler.

We will also abbreviate tuples of more than two elements by writing (x, y, z) instead of $(x, (y, z))$. Furthermore, we will

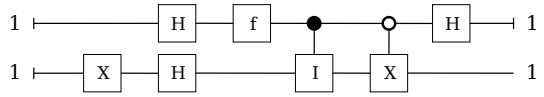

Fig. 2. The circuit produced for Deutsch's algorithm, where f is the parameter: the function that we want to determine if it's constant or balanced.

use **qtrue** as syntactic sugar for $\{\,(0)\,\mathbf{qfalse} + (1)\,\mathbf{qtrue}\,\}$ and **qfalse** as syntactic sugar for $\{\,(1)\,\mathbf{qfalse} + (0)\,\mathbf{qtrue}\,\}$.

A. Deutsch's Algorithm

Deutsch's algorithm (later generalized by Deutsch and Jozsa) was one of the first quantum algorithms to be studied. Supposing that we have a function $f(x) : \{0,1\} \to \{0,1\}$, we want to determine whether this function is *constant*, i.e., $f(0) = f(1)$, or *balanced*, i.e., $f(0) \neq f(1)$, by just computing it once.

There is obviously no classical solution to this problem. The quantum solution employs the trick of computing the function once, with a superposition of the two inputs, then appropriately measuring the result. (The interested reader is refered to the introductory literature in quantum computations for analyses of the algorithm and proofs of correctness.) In nQML, it can be written as follows. The measurement of **had** i gives 1 if function f is balanced and 0 if it is constant.

```
def Deutsch f =
  let (i, j) = (had qfalse, had qtrue) in
  let r = if f i then j else not j in
  ifm had i then qtrue else qfalse;
```

The circuit that our compiler produces for this program (just measuring the result and excluding the new qubits for the branches of **ifm**), is shown in Fig. 2.

B. Grover's Algorithm

As a second example, let us see an implementation of Grover's fast database search. Consider an unsorted database with $N = 2^n$ entries and the problem of finding the index of a particular database entry that satisfies some criterion. To simplify things, let us assume that c denotes the index that we are searching for. We first need to implement the query operator, which is a transformation corresponding to a matrix which has 0 everywhere, 1 along the primary diagonal and -1 at the element with coordinates (c, c).

```
def query q = |q> -> x, x'.
  if x = x' then
    if int x = c then -1 else 1
  else
    0;
```

We now define the diffusion operator, a transformation corresponding to the matrix $2P - I$, where P a matrix with 2^{-n} everywhere.

```
def diffusion q = |q> -> x, x'.
  if x = x' then 2 / 2^n - 1 else 2 / 2^n;
```

The algorithm proceeds by repeated iterations of queries and diffusions. Let us now consider the most simple application of Grover's algorithm: searching in a space of size $N = 4$ (with $n = 2$ qubits). In this special case, one iteration is enough to produce the correct result with certainty:

```
def grover2 =
  let qs = (had qfalse, had qfalse) in
  diffusion (query qs);
```

In the general case, $O(\sqrt{N})$ iterations of the two operators are required to obtain the result with a high probability. Consider $N = 16$ (with $n = 4$ qubits). Three iterations suffice:

```
def grover4 =
  let qs = (had qfalse, had qfalse,
            had qfalse, had qfalse) in
  let step1 = diffusion (query qs) in
  let step2 = diffusion (query qs) in
  let step3 = diffusion (query qs) in
  qs
```

The circuit that our compiler produces for grover4 is shown in Fig. 3. The result is implicitly measured.

VI. Related work

The design of quantum algorithms, such as Shor's algorithm for the factorization of integer numbers in polynomial time [21] and Grover's algorithm for searching an unordered list of n elements in $O(\sqrt{n})$ time [11], has shown that the quantum model of computation is strictly more powerful than the classical model; although both can compute the same set of functions, some functions can be computed in the quantum model strictly faster than in the classical one. Quantum algorithms are usually studied at a low level, either expressed directly in the form of quantum circuits or using appropriate mathematical models. The fact that reasoning about quantum circuits is no easier than reasoning about their classical counterparts has given rise to quantum programming languages, that is, languages that allow programmers to implement quantum algorithms and make use of the added power of the quantum computational model, while respecting its special restrictions.

Knill's conventions for quantum pseudocode [13] was the first proposed formal language for the description of quantum algorithms, tightly connected with the Quantum Random Access Machine. Since then, several quantum programming languages have been proposed; the reader is referred to an excellent (although slightly outdated) survey of the emerging field [5]. Ömer's QCL is an imperative language with quantum primitives and automatic quantum scratch space management [17]. Moreover, van Tonder has proposed a λ-calculus for higher-order quantum programs without measurements [22]. Both languages, however, do not compile to quantum circuits and, in the case of van Tonder's λ-calculus, it is not clear how this can be done. Sanders and Zuliani have defined qGCL, an extension of Dijkstra's guarded command language [18], and they have shown how to compile qGCL to a form of assembly language for a quantum computer [25].

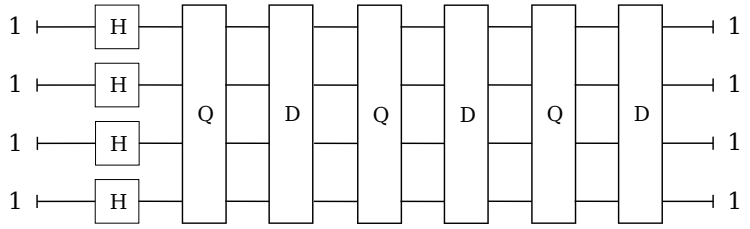

Fig. 3. The circuit produced for Grover's algorithm, where $N = 16$ ($n = 4$). The transformations Q and D correspond to the query and diffusion operators, which are applied iteratively.

Selinger's QPL is a language following the paradigm "quantum data, classical control" [20]. It is functional in nature, although from a programmer's point of view it looks more imperative than functional. QPL allows the programmer to access both classical and quantum memory and includes high-level features such as loops and recursion. Program control is strictly classical and quantum branching can only be implemented indirectly with appropriate unitary transformations. The denotational semantics of QPL is given in the form of superoperators on density matrices. A higher-order extension of QPL in the form of a quantum lambda calculus has also been proposed by Selinger and Valiron [19]. In the same paradigm, Green *et al.* have recently defined Quipper [10], a functional, higher-order quantum programming language designed to be used for implementing large-scale quantum algorithms. They have shown how programs can be compiled to quantum circuits consisting of a large number of gates.

On the other hand, Altenkirch and Grattage's QML is a functional language that follows the paradigm "quantum data and control" [1], [7], [8]. QML comes with a linear type system prohibiting implicit weakening, which would lead to implicit measurements and quantum collapse. The authors describe a way to compile QML programs to quantum circuits in the category FQC of finite quantum computations [6], [9]. Variables in QML correspond to wires in the produced quantum circuit and thus have to be shared implicitly when they are used in several places in a program so as not to break the "no cloning" rule. The sharing of wires is monitored by a linear type system. Altenkirch and Green have recently presented a monadic purely functional interface to quantum programming (the QIO monad) and they provide an implementation in the form of a quantum DSL in Haskell [2]. Again, there is an almost direct translation from QIO to quantum circuits. A similar embedding in Haskell, in the form of arrows, is proposed by Vizzoto *et al.* [23].

VII. Concluding remarks

We have defined a compiler for quantum programs written in the language nQML that follows the paradigm "quantum data and control". The compiler targets quantum circuits in the category FQC of finite quantum computations, defined by Altenkirch and Grattage. We have implemented our compiler as part of nQML's implementation, which is publicly available.

The real challenge in quantum programming, and a definite direction for future work, is the integration of features that are at a higher-level than quantum gates and unitary transformations, for example, reversible binary arithmetic, quantum data structures, etc. The proper integration of such features in quantum programming languages is a hard problem in terms of language design and usability, especially if one wants to keep compatibility with the way in which quantum algorithms are expressed (mostly by non-programmers) today.

Grammar-Driven Development of JSON Processing Applications

Antonio Sarasa-Cabezuelo, José-Luis Sierra
Fac. Informática. Universidad Complutense de Madrid. 28040 Madrid (Spain)

***Abstract*—This paper describes how to use conventional parser generation tools for the development of JSON processing applications. According to the resulting grammar-driven development approach, JSON processing applications are architected as syntax-directed translators. Thus, the core part of these components can be described in terms of translation schemata and can be automatically generated by using suitable parser generators. It makes it possible to specify critical parts of the application (those interfacing with JSON documents) by using high-level, grammar-oriented descriptions, as well as to promote the separation of JSON processing concerns from other application-specific aspects. In consequence, the production and maintenance of JSON processing applications is facilitated (especially for applications involving JSON documents with intricate nested structures, as well as for applications in which JSON formats are exposed to frequent changes and evolutions in their surface structures). This paper illustrates the approach with JSON-P as the generic JSON processing framework, with ANTLR as the parser generation tool, and with a case study concerning the development of a player for simple man-machine dialogs shaped in terms of JSON documents.**

I. Introduction

JSON (JavaScript Object Notation) [15][34] is a data exchange format based on a subset of the JavaScript programming language that in recent years has achieved enormous relevance in industry. Indeed, many times JSON results in a more natural mechanism for representing data structures than other alternative formats (e.g., XML [25], which is more suitable for representing hierarchical data). In fact, JSON makes it possible to use collections of name-value pairs and ordered sequences of values, which mirrors the typical data included in mainstream programming languages structures (records, objects or hash tables for collections of name-value pairs, and arrays or lists for ordered sequences of values). This JSON feature makes it natural to map JSON documents to data structures in a target programming language. Still, since JSON is based on text encoding, it is independent from particular programming languages and binary formats; indeed, it can be inspected and, with some effort, interpreted by humans, which facilitates development, debugging and system interconnection tasks. Finally, JSON has also found an important application area as a storage format in non-relational database systems [12][24].

As any other data interchange enabling technology, the success of any development based on JSON relies on finding suitable ways of processing JSON documents in the resulting applications. For this purpose, multiple technologies for processing JSON documents have been proposed, which can be classified into two broad categories:

- *Specific processing technologies*. With these artifacts, it is possible to carry out specific-purpose processing tasks (e.g, querying and document transformation). Examples of these proposals are [5][10][18]. While these technologies are easy to use, due to their specific and task-oriented nature, the main drawback of this task-specific approach is the need to find suitable specific technologies for each particular processing task.
- *Generic processing technologies*. These technologies make it possible to achieve any processing task. They are provided by libraries and frameworks for JSON manipulation embedded as part of a general-purpose programming language. Examples of these technologies include those that perform marshalling and unmarshalling between JSON documents and data structures [23], and frameworks for parsing JSON documents [4][11][13][14][16][19][22][29]. In addition, although these technologies can be used to address any processing task, they are substantially more difficult than specific technologies, resulting in higher development and maintenance efforts.

Regardless of their scope of applicability, the aforementioned processing approaches are *data-oriented* in nature, in the sense of conceiving JSON documents as mere data containers, and JSON processing as the mapping of this data into data structures in the host languages. However, since JSON is a formal language, an alternative, language-oriented, approach is possible. This approach will be focused on computer language processing aspects instead of a data marshaling / un-marshaling perspective. In particular, it will be possible to characterize types of JSON documents as *formal grammars*, and then to orchestrate the processing of these documents according to a syntax-directed processing model. Indeed, the characterization of JSON documents as formal grammars is consistent with schema languages like JSON Schema [17]. Thus, the proposed language-oriented (or, more specifically, *grammar-oriented*) approach goes a step further, by conceiving processing tasks of JSON documents being carried out by syntax-directed language processors operating on these

978-83-60810-53-8/$25.00

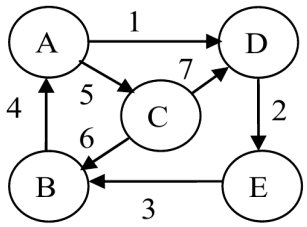
JSON documents. In turn, these language processors can be developed by using dedicated compiler construction tools (parser generators like JavaCC [21], ANTLR [27] or CUP [3], in particular). This approach exhibits the advantages of the variety and stability of these tools, the high level of abstraction to specify the processing (indeed, the approach brings the advantages of task-specific strategies to general-purpose processing settings), greater simplicity in application maintenance, and naturalness for addressing efficient stream-based processing.

This paper describes this grammar-oriented approach to the development of JSON processing applications. The rest of the paper is structured as follows: Section II provides a short introduction to JSON. Section III outlines the grammar-oriented approach. Section IV shows how the approach can be actually implemented by combining a concrete JSON processing framework (JSON-P) with a concrete parser generation tool (ANTLR). Section V illustrates how the approach can be applied to concrete scenarios with the development of a JSON-based application for playing human-computer dialogs. Finally, Section VI provides some conclusions and lines of future work.

II. JSON

As indicated earlier, JSON is a lightweight text-based notation for encoding data structures. Thus, this notation rules how to encode data structures as text entities, known as JSON *documents*. For this purpose, JSON distinguishes among the following kind of data:

(a)



(b)

```
{"nodes":["A","B","C","D","E"],
 "arcs":[
   {"source":"A","target":"D","label":"1"},
   {"source":"A","target":"C","label":"5"},
   {"source":"B","target":"A","label":"4"},
   {"source":"C","target":"B","label":"6"},
   {"source":"C","target":"D","label":"7"},
   {"source":"D","target":"E","label":"2"},
   {"source":"E","target":"B","label":"3"}]}
```

Figure 1. (a) A labelled directed graph, (b) a JSON encoding of the graph in (a).

- *Basic data:* (double precision floating-point) numbers, strings (double-quoted sequences of Unicode characters, with standard scape conventions), Booleans (true and false), and the `null` value.
- *Compound data: arrays* (ordered sequences of comma-separated values, delimited by `[` and `]`), and *objects* (unordered, comma-separated, collections of key-value pairs delimited by `{` and `}`; each key-value pair is in the form *key: value,* where *key* is, in turn, a string).

Using these somewhat simple conventions, JSON makes it possible to represent data structures of arbitrary complexity (it is very similar to what happens with s-expressions in LISP [1], or with XML markup). This flexibility, together with its seamless integration with JavaScript, explains the successful adoption of JSON as an enabling technology for web development, where, for instance, it has become a de facto standard for data exchange in RESTFul service-oriented architectures [30].

Figure 1 illustrates the use of JSON to represent a labeled directed graph with a JSON document. The encoding conventions followed should be apparent from the JSON document itself. It reveals another important feature of JSON: since it is a text-based format, with a little effort it can become understandable to developers. Thus, it facilitates making a good amount of system internals accessible both for humans and machines in terms of JSON documents.

III. The Grammar-Driven approach to the development of JSON applications

In addition to the textual encoding of data structures, JSON documents can be conceived as sentences in a formal language. Indeed, when JSON is used to encode a particular kind of data structure (e.g., labeled directed graphs, as in Figure 1), it is possible to distinguish a subset of JSON documents that meaningfully represents instances of such a data structure. This subset of documents, in turn, can be thought of as defining another formal language: the language of the JSON documents allowable in the particular application domain. Thus, it is possible to apply to JSON similar principles to those used in other analogous fields, like XML (i.e., distinction between *well-formed* and *valid* documents, and characterization of document types with formal grammars). In particular, the use of formal grammars to describe JSON documents in a given application domain acquires full meaning. This paradigmatic bias (i.e., going from a data-oriented perspective to a linguistic, grammar-oriented one) leads to the grammar-driven approach presented in this paper.

The grammar-driven approach can be derived by first considering the structure of a standard syntax-directed translator (Figure 2a). This structure comprises two basic components:

- The *scanner* that is in charge of tokenizing input sentences.
- The *translator,* a *parser* augmented with semantic actions that, when acting on the token sequence produced by the scanner, is able: (i) to recognize this sequence of tokens as belonging to the input language, or otherwise to reject it as invalid, (ii) to arrange it according to its underlying syntactic structure, and, (iii) to process it by firing the semantic actions.

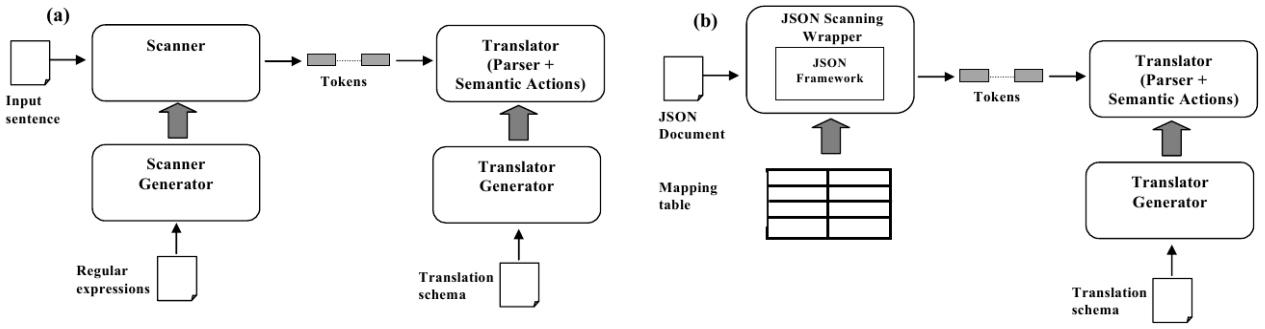


Figure 2. (a) Structure of a Syntax-Directed Translator and the automationaccomplish JSONof its development; (b) modification of the structure despicted in (a) to processing

As is widely acknowledged by the programming language community, this organization results in a processing model especially suited for stream processing, which, under reasonable assumptions, is able to behave in an extremely efficient way [2]. In addition, both the scanner and the translator can be automatically generated from high-level specifications (regular expression-based ones concerning the scanner; *translation schemata* –i.e., context-free grammars augmented with semantic actions, concerning the translator) [2]. Indeed, generation tools like JavaCC, ANTLR or CUP greatly facilitate this development task.

The next step is to adapt classic syntax-directed organization to JSON processing. For this purpose, the scanner in Figure 2a can be replaced by a new component: the *JSON scanning wrapper* (Figure 2b). When operating on JSON documents, this component will map the logical structure of these documents into sequences of tokens, as expected by a syntax-directed translator. It is important to notice that the provision of this component does not rely on the programming of a new generic JSON processor. On the contrary, this component can be meaningfully piggybacked on an existing JSON processing framework (like JSON-simple [19] or JSON-P [16]).

Once this replacement is accomplished, the rest of the organization remains unchanged, as evidenced by Figure 2b. In particular, it is still possible to specify processing (this time of JSON documents) by using high-level translation schemata, and to automatically turn these specifications into efficient implementations by using parser generation tools. Therefore, tools like JavaCC, ANTLR and CUP take a new and unpredicted role, as tools for developing efficient, stream-oriented, JSON processing applications.

Thus, notice that this grammar-driven development approach makes it possible to make up grammar-driven production environments for JSON processing applications by combining a suitable parser generation tool with a general purpose JSON processing framework. The adaptation between the two components will be performed by means of a JSON *scanning wrapper*, which will be dependent on the particular parser generation and processing framework. Beyond this specific component, the approach is nicely independent of the particular parser generator and processing framework chosen.

Concerning the use of this kind of grammar-oriented environments in the actual development of JSON applications, it involves:

- Customizing the JSON *scanning wrapper* to tokenize the logical structure of the JSON documents involved in the application. It can be readily done by providing a *mapping table* associating a distinct token with: (i) each key in each object, (ii) the object opening and closing marks (i.e., { and }), (iii) each possible basic value in the document (i.e., *number, string, true* and *false*). The other structure in the document (e.g., ordered sequences in lists) can be characterized in purely grammatical terms. For instance, Figure 3 despicts the mapping table for the example of labelled graphs in section II.

JSON Element	Token Kind
"nodes"	NODES
"arcs"	ARCS
"source"	SOURCE
"target"	TARGET
"label"	LABEL
{	OO
}	CO
string	STRING

Figure 3. Mapping table for documents like those of Figure 1.

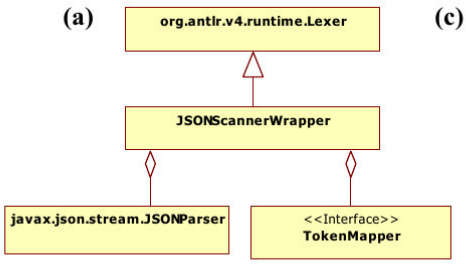
- Characterizing the grammatical structure of the source JSON documents. It can be done by using standard BNF or EBNF notation, augmented with some facilities for describing the structure of objects.

(a)
graph → {nodes: **nodes**, arcs: **arcs**}
nodes → (STRING)*
arcs → (**arc**)*
arc → {source: STRING, target: STRING, label: STRING}

(b)
arc → source: STRING, target: STRING, label: STRING |
source: STRING, label: STRING, target: STRING |
target: STRING, source: STRING, label: STRING |
target: STRING, label: STRING, source: STRING |
label: STRING, source: STRING, target: STRING |
label STRING, target: STRING, source: STRING

Figure 4. (a) Structure of graph-description JSON documents, (b) description of the structure of an arc object using standard EBNF notation.

(a)



(b)

```
public interface TokenMapper {
  int typeForKeyName(String keyName);
  int typeForObjectOpening();
  int typeForObjectClosing();
  int typeForStringValue(String data);
  int typeForNumericValue(String value);
  int typeForTrueValue();
  int typeForFalseValue();
  int typeForNullValue();
}
```

(c)

```
public Token nextToken() {
 try{
  if (parser.hasNext()) {
   JsonParser.Event eventCode=parser.next();
   while (parser.hasNext()&&
          eventCode!=JsonParser.Event.KEY_NAME &&
          eventCode!=JsonParser.Event.START_OBJECT &&
          eventCode!=JsonParser.Event.END_OBJECT &&
          eventCode!=JsonParser.Event.VALUE_NULL &&
          eventCode!=JsonParser.Event.VALUE_STRING &&
          eventCode!=JsonParser.Event.VALUE_NUMBER &&
          eventCode!=JsonParser.Event.VALUE_FALSE &&
          eventCode!=JsonParser.Event.VALUE_TRUE)
          eventCode=parser.next();
   if (eventCode == JsonParser.Event.KEY_NAME) {
        String name=parser.getString();
        JsonLocation location= parser.getLocation();
        return newToken(
                 tokenmapper.typeForKeyName(name),
                 name, location);}
   else if (eventCode == JsonParser.Event.VALUE_STRING) {
         String data = parser.getString();
         JsonLocation location = parser.getLocation();
         return newToken(
                  tokenmapper.typeForStringValue(data),
                  data, location);
    }
    else ...
```

Figure 5. (a) `JSONScannerWrapper` and its relationships with JSON-P and ANTLR, (b) the `TokenMapper` interface, (c) excerpt of `nextToken in JSONScannerWrapper`

In particular, we propose to describe objects by expressions in the form $\{k_1 m_1: V_1, \ldots, k_n m_n: V_n\}$, where each k_i is a distinct key name, each V_i is a EBNF expression characterizing the structure of the allowable values for k_i, and each m_i is a modifier controlling the ocurrence of key-value pairs of the kind k_i:v in actual documents. In this expression, the order of appearance of the key-value pairs does not matter. In addition, key-value pairs in the form k_i: v must occur (i) exactly one time if m_i is omitted, (ii) zero or one time if m_i is set to `?` , (iii) zero or more times if m_i is set to `*`, and (iv) one or more times if m_i is set to `+`. For instance, Figure 4a characterizes the grammatical structure of the documents involved in the graph example of the previous section using standard EBNF augmented with this convention.

- Encoding the grammatical structure in the parser generation tool. While in principle it could be possible to translate such a structure to pure EBNF (and thus, to pure BNF) notation(s), the lack of order of key-value pairs in objects can make this direct approach cumbersome, since it could involve enumerating all the possible permutations of key-value sequences (see Figure 4b). Thus, it is possible to use additional semantic facilities in the generator to facilitate such an encoding (e.g., validating semantic actions, semantic predicates …)
- Augmenting the grammar with semantic contexts and semantic actions in order to characterize the processing task as a syntax-directed translation process. The result is a translation scheme, which will be dependent on the parser generator adopted.
- Providing the additional machinery necessary to complete the processing application. Depending on the kind of application, it could include data visualization facilities, database support, a domain model to be instantiated as result of processing the JSON document, etc. In any case, it is interesting to provide a suitable façade in terms of which of the semantic actions in the translation scheme can be written. This façade will be called a *semantic module.*
- Generating the JSON processing component from its specification as a translation scheme. For this purpose, the parser generator is used.
- Gluing it all together in a suitable main program able to launch the application itself.

It is worthwhile to notice that, as a consequence of this grammar-oriented approach, applications are split into two well-differentiated layers:

- A *linguistic layer,* which is declaratively described as a translation scheme expressed in the specification language of the parser generator.
- An *application logic layer,* which is given in terms of conventional software components interfaced by the semantic module.

It leads to an interesting division of labor among developers specialized in JSON processing using formal grammars, and more conventional developers specialized in the development of more conventional application / business logics. The linguistic layer takes care of the orchestration of conventional application logic components, each of which can largely be provided in isolation from the others. In turn, this orchestration is directed by the grammatical structure that underlies the

JSON documents, and it can be described and maintained at a high level, using declarative, grammar-based, specifications, instead of being expressed in a more conventional general-purpose programming language.

IV. Grammar-Driven development with JSON-P and ANTLR

In this section we show how to enable the grammar-driven approach by combining JSON-P and ANTLR:

- JSON-P (Java API for JSON Processing) is a general-purpose JSON processing framework for Java [16]. It defines an API for mapping JSON documents into tree-like representations (the equivalent to DOM in the XML world), and another API to process JSON documents in a streaming fashion.
- ANTLR [27] is a multi-language parser generation tool, which is able to generate recursive descent parsers that combine many of the more recent parsing tendencies: the use of prediction automata for unlimited lookahead (achieved by the LL(*) parsing method), the use of semantic predicates, and the use of backtracking and tabulation to mimic *packrat* parsing [8] (see [28] for a more in-depth description of ANTLR internals). This combination of parsing technologies, together with their support for multiple implementation languages (among them, Java) makes this tool one of the more widely used worldwide.

Concerning JSON-P, this combination uses its facilities for JSON streaming processing. In particular, JSON-P provides a *pull* API similar to StAX in the XML world, which is especially well suited for its combination with ANTLR-generated parsers, since it can naturally work as a scanner for such a parser. In this way, the JSON *Scanning Wrapper* in this combination (see Figure 5a):

- Encloses a `JSONParser` instance (i.e., an instance of the *pull* streaming processing artifact provided by JSON-P)
- Can be customized by an instance of a suitable `TokenMapper` implementation, which actually characterizes the mapping tables (Figure 5b)
- Extends the ANTLR `Lexer` class. In particular, it implements the `nextToken` method to return ANTLR `CommonToken` instances representing the tokens associated with the JSON logical elements. Figure 5c shows an excerpt of this method in our combination.

```
arc locals [boolean sourceOn=false,
            boolean targetOn=false,
            boolean labelOn=false]:
 OC ( ({$sourceOn}? SOURCE STRING {$sourceOn=true;}) |
      ({$targetOn}? TARGET STRING {$targetOn=true;}) |
    ({$labelOn}? LABEL STRING {$labelOn=true;}) )* CC
  {$sourceOn && $targetOn && $labelOn}? ;
```

Figure 6. ANTLR encoding of the rule for `arc` in Figure 4a.

In this way, in the resulting environment:

- The customization of the JSON *Scanning Wrapper* involves: (i) providing a suitable implementation of the `TokenMapper` interface (each method in this interface determines how to map relevant JSON elements into types for ANTLR tokens), and (ii) specializing `JSONScannerWrapper` to use such an implementation as a customization table.
- The encoding of the grammatical structure can take advantage of ANLTR validating semantic predicates to simplify the description of object expressions in the augmented EBNF notation. Indeed, $\{k_1\ m_1\colon V_1, \ldots, k_n\ m_n\colon V_n\}$ is represented by $OC\ ((vp_1\ K_1\ V_1\ a_1) \mid \ldots \mid (vp_n\ K_n\ V_n\ a_n))^*\ CC\ v_f$ where: (i) K_i is the type of token corresponding to k_i, (ii) a_i is a semantic predicate registering the number of times that k_i has occurred, (iii) vp_i is a semantic predicate that validates whether K_i can occur, (iv) v_f is a semantic predicate validating whether all the mandatory key-value pairs have appeared, and (v) *OC* and *CC* are respectively the object opening and closing tokens. Figure 6 pro-

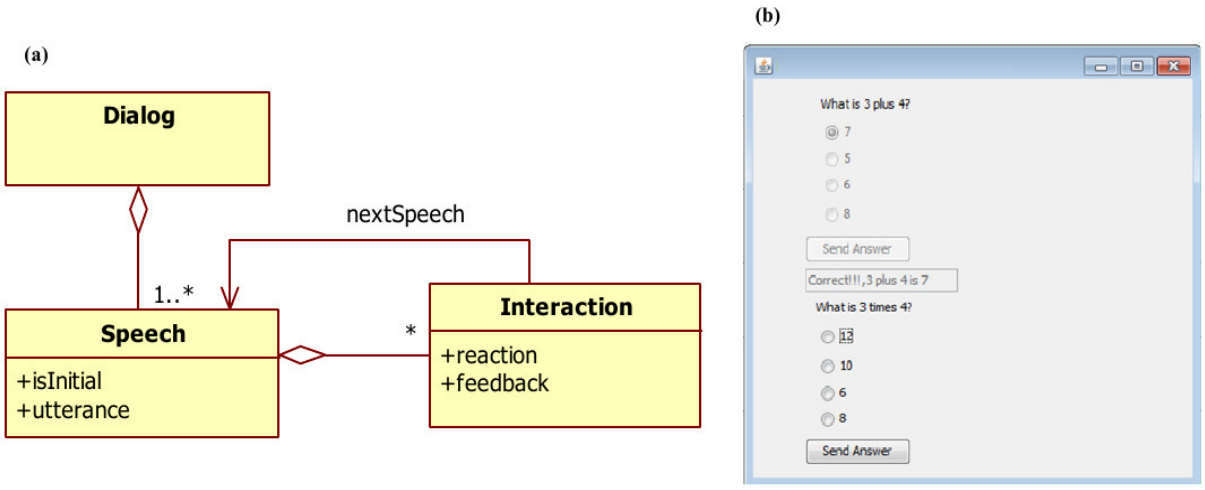


Figure 7. (a) Dialog semantic model;(b) Snapshot for the Dialog player.

vides an example concerning the EBNF structure provided in Figure 4a.
- Then, additional semantic context and semantic actions can be added to the resulting ANLTR grammar to configure the specification of the JSON processing component as a translation scheme. Once this translation scheme is processed with the ANTLR tool to yield the Java implementation, the corresponding *Lexer* class must be replaced by the customization of the JSON Processing Wrapper, in order to make the parser actually operate on the logical structure of the JSON documents.

V. Case Study: Grammar-Driven Development of a JSON-customizable Interactive Application

This section describes how we have applied the grammar-driven development model defined in the previous sections to the implementation of an interactive application oriented to play dialogs between the user and the computer[1]. These dialogs can be described using JSON documents. Subsection V.A describes how the interactive application behaves and how the dialog documents are structured. Then, subsection V.B details the grammar-driven development of this application.

A. The dialog player

The dialogs played by our application are based on the *Socratic Tutorials* developed by Prof. Alfred Bork's team during the eighties of the past century [6]. They obey the semantic model in Figure 7a. Thus, when playing a dialog (Figure 7b):
- The application proffers a *speech*. It is a chunk of text that can be read by the user.
- Then it displays a repertory of possible *interactions* and lets the user select one of them.
- When the user selects the interaction, the application gives him/her an associated *feedback.*
- Finally, it either continues with other speeches or ends the execution.

The application can be customized with dialogs described as JSON documents. Indeed, these documents are a possible concrete syntax for the semantic model depicted in Figure 7a. In this way:
- Dialogs are represented by objects with a "`Dialog`" key. The value of this key is a sequence of speeches.
- Each speech is, in turn, represented by an object that includes: (i) a mandatory "`idSpeech`" key, whose value identifies the speech in the JSON document (this value will be used for referencing the speech from other places in the document), (ii) an optional "`isInitial`" key, whose value, when `true`, indicates the speech starts the dialog, (iii) a mandatory "`utterance`" field that includes the text to be proffered by the machine, and (iv) an optional "`interactions`" field containing a sequence with all the possible interactions (if a speech without interactions is reached, the player ends the execution).
- Finally, interactions are represented by objects including: (i) a mandatory "`reaction`" key representing the actual text of the interaction, (ii) a mandatory "`feedback`" key representing the text of the feedback, and (iii) a mandatory "`nextSpeech`" representing the speech that continues the dialog; its value can be either another speech description, or the *id* of other speech in the dialog.

Figure 8 shows an excerpt of JSON document describing a dialog.

```
{"Dialog":[{
   "idSpeech":"1",
   "isInitial":true,
   "utterance":"what is 3 plus 4?",
   "interactions":[
          {
          "reaction":"7",
          "feedback":"Correct!!,3 plus 4 is 7.",
          "nextSpeech":{
                "idSpeech":"2",
                "isInitial":false,
                "utterance":"what is 3 times 4?",
                "interactions":[{
                        "reaction":"12",
                        "feedback":"Correct!!,3 times 4 is 12.",
                        "nextSpeech":3 },{
                        "reaction":"10",
                    "feedback":"Sorry!!, 3 times 4 is not 10. Try again",
                        "nextSpeech":2}, {
                        "reaction":"6",
                        "feedback":"Sorry!!, 3 times 4 is not 6.Try again"
                        "nextSpeech":2},
....
```

Figure 8. Excerpt of a Dialog Description JSON Document.

B. Grammar-Driven Development

The operation of the dialog player described in the previous subsection is as follows:
- It processes the input JSON document in order to instantiate the semantic model in Figure 7a.
- Then it plays the dialog by a direct interpretation of the semantic model instance.

While the interpretation stage is straightforward once the semantic model has been instantiated, the instantiation process is considerably more cumbersome, due in part to the changing and evolving nature of the concrete JSON encoding. Thus, the player can be meaningfully architected according to the grammar-driven approach as follows:
- The instantiation of the semantic model is developed in grammatical terms, using JSON-P and ANTLR.
- The semantic module is implemented as a façade class providing instantiation operations as methods, as well as a couple of tables required during the instantiation process: one table mapping *ids* into `Speech` instances, and another table mapping ids into `Interation` instances whose next speeches are those associated to such *ids.*
- The semantic model itself, along with the player shell, constitute the application-specific logic.

1It is actually a simplification of the real system in order to fit the space constraints of the paper. The actual system is closer to that described in [33]

(a)

```
public class DialogTokenMapper implements TokenMapper {
  public int typeForKeyName(String keyName) {
  if (keyName.equals("idSpeech"))
     return DialogParser.IDSPEECH;
  if (keyName.equals("isInitial"))
     return DialogParser.IS_INITIAL;
  ...
  }
  ...
}
```

  }
}
```

Figure 9. (a) Implementation of the mapping table for the Dialog case-study; (b) specialization of the JSONScannerWrapper ; (c) ANTLR grammar for the processing of JSON Dialog Documents; (d) semantic module.

- The main gluing program performs the instantiation, and then activates the player with the resulting semantic model instance.

Thus, the organization is very similar to that of applications built using DSL construction frameworks such as Eclipse XText [7] (in this case, input descriptions are encoded in JSON instead on a domain-specific syntax, however).

Concerning development details, Figure 9a shows an excerpt of the token mapping table. As indicated in Section IV, it involves implementing the `TokenMapper` interface, as made apparent in Figure 9a. Notice that, in this implementation, actual token codes are taken from the `DialogParser` class. This will be the parser class generated by ANTLR. Therefore, token names must be kept consistent throughout this mapping table and the subsequent ANTLR grammar.

Once the mapping table is available, it is possible to customize the JSON Scanner Wrapper. As indicated in Section IV it involves to subclass `JSONScannerWrapper` in order to install an instance of the mapping table provided (Figure 9b). The name given to this subclass must be consistent with the name of the lexer to be generated by ANTLR.

Next step, the most relevant one, is to characterize the syntactic structure of the JSON documents, then to encode this structure as an ANTLR grammar following the patterns given in Section IV, and finally to augment this grammar with suitable semantic actions. Figure 9c shows the resulting ANTLR translation scheme.

Then the semantic class that implements the semantic module can be provided (Figure 9d). In this class, in addition to creating a new speech, the `newSpeech` method back-patches all the interactions referring to such a speech, which is consistent with the usage of the operations in the ANTLR grammar.

Next step is to generate all the parsing code from the ANTLR grammar, and to replace the `DialogLexer` generated by that shown in Figure 9b. Finally, the application-specific logic and the main launching program must be provided, which constitutes a routine programming task.

VI. Conclusions And Future Work

In this paper, we have shown how to combine generic, stream-oriented, JSON processing frameworks with parser generators in order to facilitate the development of JSON processing applications. The resulting approach is aware of the grammatical nature of JSON documents and enables the specification of JSON processing tasks at a higher and more declarative level than that provided by general-purpose programming languages. Contrary to proposals like [9], formal grammars in our proposal operate on the logical structure of JSON documents instead of on the raw text of these documents. In this sense, our proposal is aligned with our previous works in XML processing [31][32], in which we proposed similar grammar-driven models for processing XML using grammars and parser generators.

Currently we are working on the implementation of an environment for providing more assistance to our grammar-driven development process model. We also are planning to use attribute grammars [20][26] as specification mechanisms of JSON processing tasks, paralleling our previous work in the XML world [31]. Finally, and although our firsts tests with developers are satisfactory, we plan to carry out a more systematic comparative study of our approach with more conventional approaches to JSON processing.

***Abstract*—The paper presents the semantics for the time version of the Alvis modelling language. Alvis combines possibilities of formal models verification with flexibility and simplicity of practical programming languages. The considered time Alvis language is suitable for formal verification of real-time systems. The paper contains description of: the Alvis time model, states and transitions between states and snapshot reachability graphs that represent models state spaces in the form of directed graphs.**

I. Introduction

COSTS of creating and maintaining embedded software draw attention of producers to formal methods. There are more and more attempts to provide methods and tools to improve the concurrent systems development [6], [9]. Alvis combines a formal approach with engineering-like look and style. It is hiding most of the formal side from users but not losing any part of it. Alvis is a modelling language being developed at AGH-UST in Krakow, Department of Applied Computer Science (*http://fm.kis.agh.edu.pl*).

Previous research on Alvis has been mainly concerned with the untimed version of the language with α^0 system layer (multiprocessor environments). The syntax of Alvis which is common for all language versions can be found in [21]. Formal semantics of the untimed version of Alvis has been presented in [22]. This version of Alvis has been successfully used for formal verification of concurrent systems e.g. for BPMN models [23] which may include rule-based systems [18] designed with the XTT2 method [11], [15] or as D-nets [24].

The aim of the paper is to present a draft of semantics for the time version of Alvis with α^0 system layer which allows users to assign to every model statement its duration. Then the set of reachable states of such a model is represented in the form of SR-graph and is used for its verification with model checking techniques [2]. SR-graphs provide the possibility of formal verification of real-time requirements. In contrast to other formalisms like time automata [1], Petri nets with time [10], [17] or multi-agent systems [5], Alvis syntax is very similar to procedural programming languages and the method of model states description is similar to information provided by software debuggers. The idea of SR-graphs has been shortly introduced in [19]. This paper contains formalised and more detailed description of it.

II. Alvis at a Glance

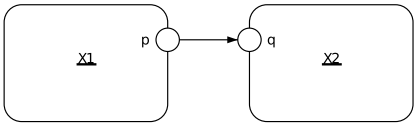
Alvis combines advantages of high level programming languages with a graphical language for modelling interconnections between subsystems (called agents) of a concurrent system. Agents are divided into *active* and *passive*. *Active agents* perform some activities and are similar to tasks in Ada programming language [4]. By contrast, *passive agents* do not perform any individual activities and are similar to protected objects (shared variables). Passive agents provide other agents with a set of procedures (services). An Alvis model is composed of three layers. A *communication diagram* (graphical layer) is used to describe a modelled system from the control and data flow point of view. Examples of such diagrams are given in Fig. 1 and 6. Active agents are drawn as rounded boxes while passive ones as rectangles. Ports used for communication are drawn as circles placed at the edges of the corresponding figures. Alvis agents communicate with each other using communication channels drawn as lines. The code layer is used to define behaviour of agents. It uses a set of Alvis statements and some elements of the Haskell functional programming language [16]. Despite of the fact that Alvis has its origin in the CCS process algebra [14] and the XCCS language [3], [20], it does not use algebraic equations to describe the behaviour of agents but a high level programming language. The *system layer* is predefined and defines the hardware environment for a model. In this paper we consider models with the α^0 *system layer* that denotes that each active agent has access to its own processor and if possible agents perform their steps concurrently. For more details see [21] or the project website.

An Alvis model semantics find expression in a *labelled transition system* (LTS graph). Execution of any language statement is expressed as a transition between formally defined states of such model. An LTS graph is an ordered graph with nodes representing states of the considered system and edges representing transitions among states. Examples of Alvis LTS graphs are given in Fig. 2, 3, 5 and 7. Alvis LTS graphs can be verified using the CADP toolbox [8]. We use CADP *evaluator* tool to check whether the model satisfies requirements given as regular alternation-free μ-calculus formulas [7], [13].

III. Alvis Time Model

The Alvis time model is based on the idea of a *global clock* used to measure the duration of model steps. The language provides carefully selected set of statements sufficient to describe the behaviour of individual agents. Each of them can have duration assigned which is provided by a user as

978-83-60810-53-8/$25.00



```
agent X1 { loop { out p; } }
agent X2 { loop { in q; } }
```

Figure 1. Communication between active agents

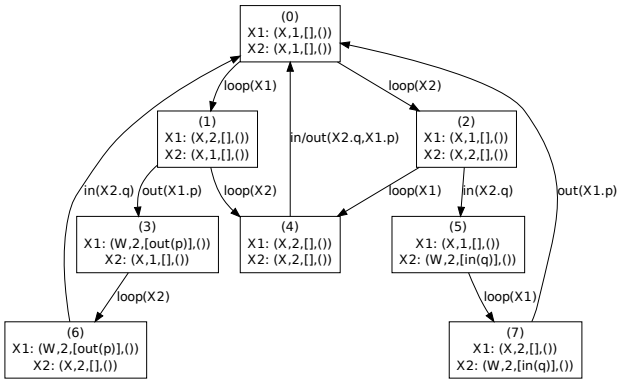


Figure 2. LTS graph for model in Fig. 1

a verification parameter. The time units used in a given model are strictly connected with the model interpretation.

Let us consider the simple model of two communicating active agents shown in Fig. 1. Each agent performs two steps: entering a loop and a communication. Agent $X1$ sequentially sends signals via port $X1.p$ ($X1.p$ denotes port p of agent $X1$), while agent $X2$ sequentially collects signals via port $X2.q$. If an untimed Alvis language is considered, the LTS graph represents all possible execution paths as shown in Fig. 2. The LTS graph labels point out steps performed by agents.

Definition 1: A *state of an agent* X is a tuple

$$S(X) = (am(X), pc(X), ci(X), pv(X)) \tag{1}$$

where $am(X)$, $pc(X)$, $ci(X)$ and $pv(X)$ denote *agent mode*, *program counter*, *context information list* and *parameters values* of the agent X respectively.

The following modes are possible. *Finished* (F) means that an agent has finished its work. *Init* (I) is the default mode for agents that are inactive in the initial state. *Running* (X) means that an agent is performing one of its statements. *Taken* (T) means that one of the passive agent procedures has been called and the agent is executing it. For passive agents *waiting* (W) means that the corresponding agent is inactive and is waiting for another agent to call one of its accessible procedures. For active agents the mode means that the corresponding agent is waiting either for a communication with another active agent or for a currently inaccessible procedure of a passive agent.

The *program counter* points out the current statement of an agent. The context information list contains additional

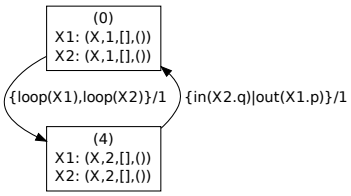

Figure 3. LTS graph for model in Fig. 1 – timed version

information about the current state e.g. if an agent is in the *waiting* mode, ci contains information about events the agent is waiting for. The set of admissible entries used in ci lists is given in Table II. The *parameters values list* contains the current values of the corresponding agent parameters, if such parameters (variables) have been defined in the agent code.

A state of a model is represented as a sequence of agents states [22], [12]. We will use letter S with possible index to denote states. If necessary am, pc, ci, pv will be indicated by indexes S, S' etc. to point out the state they refer to.

If durations of steps are taken under consideration, we cannot consider states of a system in the same way as previously. For example, state 3 in the untimed LTS graph shown in Fig. 2 represents the situation when agent $X1$ has already finished two of its steps, while agent $X2$ still remains in its initial state. Such situation is not possible in time models. Assume steps durations for all steps in the considered model are equal to 1. It means that both agents start execution of their first steps in the same time, so after 1 time-unit the system changes its state from 0 to 4. Finally, the LTS graph for the model is reduced to the one shown in Fig. 3. Labels of edges in the presented graph are of the form $steps/t$, where t stands for the duration of the steps performed simultaneously. The change of the state from 4 to 0 is the result of synchronous communication between agents which is denoted by symbol `|` used instead of a comma.

Alvis uses three statements that use time explicitly:

- **`delay`** `t` – postpones an agent for a given time;
- **`alt`**`(`**`delay`** `t) {...}` – defines a branch of the *select* statement that is open after the given time;
- **`loop`** `(`**`every`** `t) {...}` – repeats loop contents every specified number of time-units.

Let us focus on the *step* idea. It is necessary to distinguish between code statements and steps. Most of the Alvis statements e.g. *exec*, *exit*, etc. are *single-step* statements. By contrast, *if*, *loop* and *select* are *multi-step* statements. We use recursion to count the number of steps for multi-step statements. For each of them, the first step enters the statement interior. Then we count steps of statements put inside curly brackets. From theoretical point of view steps are described as transitions. The formal description of Alvis provides definitions of results of any transition execution. Such formal semantics for untimed models is presented in [22]. The time aspect of transitions is considered in Section IV.

Suppose the code layer for the communication diagram in Fig. 1 is implemented as shown in Fig 4. Agent $X1$ starts its

```
agent X1 {
  loop (every 10) { out p; }}        -- 1, 2

agent X2 {
  loop {                             -- 1
    select {                         -- 2
      alt (ready [in(q)]) {
        in q; delay 1; }             -- 3, 4
      alt (delay 2) { null; }}}}     -- 5
```

Figure 4. Communication between active agents version 2 – new code layer for communication diagram in Fig. 1

Table I
STEP DURATION FOR MODEL IN FIG. 4

Agent $X1$	Step duration	Agent $X2$	Step duration
loop every	1	*loop*	1
out	3	*select*	2
		in	2
		delay	1
		null	1

loop every 10 time-units and sends a signal via port p inside the loop. Behaviour of agent $X2$ is defined as an infinite loop with a **select** statement inside. The statement contains two branches. First one is open (can be performed) if port q can be immediately used to collect a signal (i.e. agent $X1$ has already sent a signal via port p which is connected with q). Inside the branch agent $X2$ collects a signal via port q and is postponed for 1 time-unit. Second branch is open 2 time-units after entering the **select** statement. Inside the branch agent $X2$ performs the empty statement.

Assume steps durations for all steps performed by agents $X1$ and $X2$ are defined as given in Table I. Let us focus on the initial state $S_0 = ((\mathsf{X}, 1, [\,], ()), (\mathsf{X}, 1, [\,], ()))$. When the α^0 system layer and timed Alvis language are considered it is assumed that agents execute their steps as soon as possible. Thus, both agents are running their first steps ($loopevery(X1)$ and $loop(X2)$) concurrently and after one time-unit the state $S_1 = ((\mathsf{X}, 2, [timer(1, 9)], ()), (\mathsf{X}, 2, [\,], ()))$ is received. The $timer(1, 9)$ entry used in $X1$ agent context information list points out that the next loop course can start after 9 time-units. There are two steps $out(X1.p)$ and $select(X2)$ enabled in the state 1. Because step $out(X1.p)$ takes 3 time-units, while $select(X2)$ takes 2 time-units, we cannot present the result of these transitions execution as a state similar to state 1. After 2 time-units the step $out(X1.p)$ is still under execution and after 3 time-units when step $out(X1.p)$ is finished, agent $X2$ could be executing another step – this is not the case in this model due to the lack of an open branch for the **select** statement. The solution for the problem is a *snapshot* [19] i.e. a state that presents the considered system with some steps under execution. We can take a snapshot every 1 time-unit but we are interested only in such snapshots when at least one step has finished its execution.

An LTS graph with snapshots will be called *snapshot reachability graph* or SR-graph for short. A part of the SR-graph for the model in Fig. 4 is shown in Fig. 5. State 2 represents the time point when agent $X2$ has finished step 2 and is waiting for an open branch of the **select** statement, while agent $X1$ is still performing step $out(X1.p)$. The $sft(n)$ (*step finish time*) entry used in $X1$ context information list points out the number of time-units necessary to finish the current step. State 4 represents the time point when agent $X1$ is waiting for a timer event to restart the loop. The event will be generated in 4 time-units. State 5 represents the time point when both agents are waiting for timers' events. Agent $X2$ is waiting for the end of the postpone time. The $time$ label of the edge from state 5 to 6 denotes the passage of time.

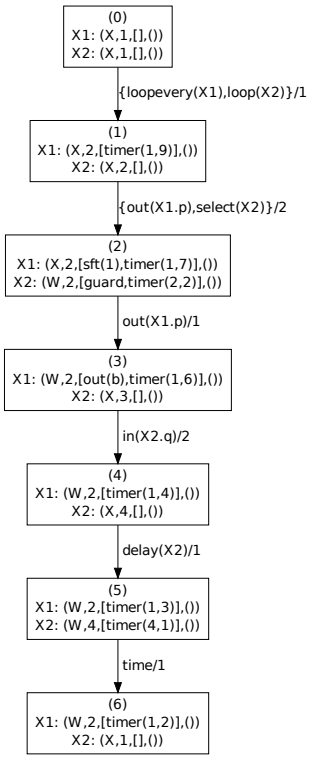

Figure 5. Part of SR-graph for model in Fig. 4

IV. TRANSITIONS

Let $\mathcal{P}$ denote the set of all model ports. For this paper we define Alvis models as follows [22].

Definition 2: A *communication diagram* is a triple $D = (\mathcal{A}, \mathcal{C}, \sigma)$, where: $\mathcal{A} = \{X_1, \ldots, X_n\}$ is the set of *agents* consisting of two disjoint sets, $\mathcal{A}_A$, $\mathcal{A}_P$ such that $\mathcal{A} = \mathcal{A}_A \cup \mathcal{A}_P$, containing *active* and *passive* agents respectively; $\mathcal{C} \subseteq \mathcal{P} \times \mathcal{P}$ is the *communication relation*, such that: (1) a connection cannot be defined between ports of the same agent; (2) procedure ports are either input or output ones i.e. ports defined as procedures are used to transfer signals (values) either to or from a passive agent; (3) a connection between an active and a passive agent must be a procedure call; (4) a connection between two passive agents must be a procedure call from a non-procedure port. Function $\sigma\colon \mathcal{A}_A \to \{False, True\}$ is the

start function that points out initially activated agents.

Definition 3: An Alvis *model* is a triple $\mathbf{A} = (D, B, \alpha^0)$, where $D = (\mathcal{A}, \mathcal{C}, \sigma)$ is a *communication diagram*, B is a syntactically correct *code layer*, and α^0 is the α^0 *system layer*. Moreover, each agent X belonging to the diagram D must be defined in the code layer and each agent defined in the code layer must belong to the diagram.

Definition 4: A *state* of a model $\mathbf{A} = (D, B, \alpha^0)$, where $D = (\mathcal{A}, \mathcal{C}, \sigma)$ and $\mathcal{A} = \{X_1, \ldots, X_n\}$ is a tuple $S = (S(X_1), \ldots, S(X_n))$. The *initial state* is defined as follows:

- $am(X) = \mathsf{X}$, for any active agent X such that $\sigma(X) = True$; $am(X) = \mathsf{I}$, for any active agent X such that $\sigma(X) = False$; $am(X) = \mathsf{W}$, for any passive agent X;
- $pc(X) = 1$ for any active agent X in the *running* mode and $pc(X) = 0$ for other agents.
- $ci(X) = [\,]$ for any active agent X; and $ci(X)$ contains names of accessible procedures for any passive agent X.
- For any agent X, $pv(X)$ contains X parameters with their initial values.

Table II contains all possible entries that can be included into a context information list and the relationships between the entries and an agent mode.

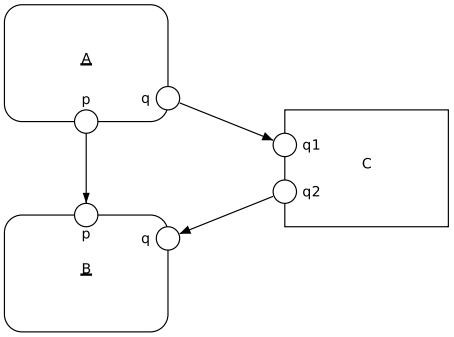
Let $B(X)$ denote an agent X code, $card(B(X))$ denote the number of *steps* in $B(X)$, $B_i(X) \in \{delay, exec, exit, if, in, jump, loop, loopevery, null, out, select, start\}$ denote the name of the agent X i-th step, and $\mathcal{N}(t)$ denote the name of the transition t (possible values are the same as for steps). The set of all transitions available for a particular model will be denoted by $\mathcal{T}$. Moreover, let $\Delta(X, k)$ denote the duration of the k-th step of agent X.

Let us consider the model given in Fig. 6. It contains two active agents A and B that can communicate directly or using passive agent C. Agent A inside the infinite loop performs a **select** statement and waits at most 3 time-units for a communication via port p. In case of a timeout, agent A sends a signal via port q. Agent B inside its periodic loop picks 0 or 1 at random and depending on the result collects a signal via port q or p. Agent C provides two procedures that are accessible depending on the value of parameter n. It works like a buffer for a single signal. The comments included into the code contain steps numbers and durations.

Definition 5: Assume $\mathbf{A} = (D, B, \alpha^0)$ is an Alvis model with the current state S and $X \in \mathcal{A}_A$. A transition $t \in \mathcal{T}$ is *enable* in the state S *with respect to* X if and only if X is in the *running* mode, the program counter points out step t, X has not called a procedure and the step t is not already in progress. The fact that a transition t is enabled in a state S with respect to an agent X and that a state S' is the result of executing t in S will be denoted by $S{-}t(X){\rightarrow}S'$.

The paper [22] contains formal description of all possible transitions for untimed Alvis models. In this section we will focus on description of the differences between untimed and time versions of the language.

Let $pv_S(X)|_{x=w}$ denote the list of parameters values $pv_S(X)$, but with the parameter x assigned to a new value w. If $X \in \mathcal{A}_A$, $S{-}t_{exec}(X){\rightarrow}S'$, and a parameter x is



```
agent A {
  loop {                                        -- 1/1
    select {                                    -- 2/1
      alt (ready [out(p)]) { out p; } -- 3/2
      alt (delay 3) {out q; } } } }    -- 4/2

agent B {
  i :: Int = 0;
  loop (every 6) {                              -- 1/1
    i = pick [0,1];                             -- 2/1
    if(i == 1) { in q; }          -- 3/1, 4/3
    else { in p; } } }                          -- 5/2

agent C {
  n :: Bool = False;
  proc q1 (n == False) {
    in q1; n = True; }            -- 1/2, 2/1
  proc q2 (n == True) {
    out q2; n = False; } }        -- 3/2, 4/1
```

Figure 6. A time model with a passive agent

assign a value w with the corresponding *exec* statement, then for an untimed model the state S' is defined as folows: $S'(X) = (\mathsf{X}, nextpc(S(X)), ci_S(X), pv_S(X)|_{x=w})$, if $nextpc(S(X)) \neq 0$, and $S'(X) = (\mathsf{F}, 0, [\,], pv_S(X)|_{x=w})$ otherwise, where $nextpc$ function determines the next program counter for an agent [22]. Moreover, $S'(Y) = S(Y)$ for any other agent Y.

The transition is defined in a similar way for the time Alvis language. The basic difference concerns ci list with entries referring to time. Let Δ denote the duration of the considered step. Then, in case of $nextpc(S(X)) \neq 0$, we have $S'(X) = (\mathsf{X}, nextpc(S(X)), update(ci_S(X), \Delta), pv_S(X)|_{x=w})$, where the function $update$ replaces entries $timer(s, n)$ with $timer(s, n - d)$ if $n > d$ and with $timeout(s)$ otherwise.

It should be stressed that the $update$ function must be applied to context information lists of all agents in the considered model but it is not enough to determine the new state for the model. If after an ci update the list contains a $timeout(s)$ entry and the agent is in the *waiting* mode in the current state, then the corresponding agent may change its mode (to *running*) and program counter. For example, after execution of the **delay** d statement, agent switches to the *waiting* mode. Then after d time-units (if the statement is not the last one in the main block or a procedural block) the agent switches back to the

Table II
RELATIONSHIPS BETWEEN THE MODE AND THE CONTEXT INFORMATION LIST OF AN AGENT

agent X	$am(X)$	$ci(X)$ entry	description
active passive	X T	$sft(n)$	the current step will be finished in n time-units
active	X, W	$proc(Y.b, a)$	X has called the $Y.b$ procedure via port a and this procedure is being executed in the X agent context
active passive	X, W T	$timer(n, t)$ $timeout(n)$	a time event for the step number n will be generated in t time-units a time event for the step number n has been generated but it has not yet been served
active passive	W T	$in(a)$, $in(a\|T)$ $out(a)$, $out(a\|T)$ $guard$	X waits for a communication via port a (a is the input port for the communication); T is the type of the expected value X waits for a communication via port a (a is the output port for this communication) X waits for an open branch of a *select* statement
passive	T	$proc(Y.b, a)$	X has called the $Y.b$ procedure via port a and this procedure is being executed in the same context as X
passive	W	$in(a)$ $out(a)$	input procedure a is accessible output procedure a is accessible

running mode, its program counter is set to the next value and the $timeout(s)$ entry associated with the considered statement is removed from the ci list. When the $timeout(s)$ entry is *consumed* immediately then it does not appear at all in the agent state in the SR-graph.

The process of a new state determination is complex due to necessity of consideration of all concurrent steps and optimisation of the number of states in the SR-graph. The optimisation refers to skipping snapshots that differ from their predecessors only in parameters of sft and $timer$ entries in the corresponding context information lists. We can distinguish the following stages of a new SR-graph node generation:

- determination of the set $\mathcal{T}_1$ of all transitions that are in progress;
- determination of the set $\mathcal{T}_2$ of all transitions that start performing a new step;
- determination of the new state S' on the assumption that all steps from $\mathcal{T}_1 \cup \mathcal{T}_2$ are performed concurrently.

A state S is called *dead*, iff sets $\mathcal{T}_1$ and $\mathcal{T}_2$ are empty in S and does not exist an agent with ci list containing a $timer$ entry.

Assume all steps have assigned non-zero durations. Firstly, we determine the new state S' as the state 1 time-unit later than S. If state S' differs from S only in parameters of sft and $timer$ entries (parameters are decreased by 1) then we skip that state and calculate the new state 2 time-units later than S, etc. Otherwise, the state S' is a new node in the SR-graph.

If we allow zero duration for at least one step then as additional state *separators* are used changes of agents program counters values. In other words, a label in an SR-graph cannot contain two steps performed by the same agent.

Let us focus on t_{delay} and $t_{loopevery}$ transitions. Suppose, $X \in \mathcal{A}_A$, $S{-}t_{delay}(X){\rightarrow}S'$, $d > 0$ is the argument of the **`delay`** statement and Δ is the duration of the considered step. Then: $S'(X) = (\mathsf{W}, pc_S(X), update(ci_S(X), \Delta) \oplus timer(pc_S(X), d), pv_S(X))$, where $\oplus$ adds the $timer$ entry at the end of the list.

Suppose, $X \in \mathcal{A}_A$, $S{-}t_{loopevery}(X){\rightarrow}S'$ and $d > 0$ is the loop period. Then: $S'(X) = (\mathsf{X}, nextpc(S(X)), update(ci_S(X) \oplus timer(pc_S(X), d), \Delta), pv_S(X))$.

Activity of passive agents is defined similarly as for active ones but a passive agent context (i.e. the active agent that called the procedure in progress) must be taken under consideration [22].

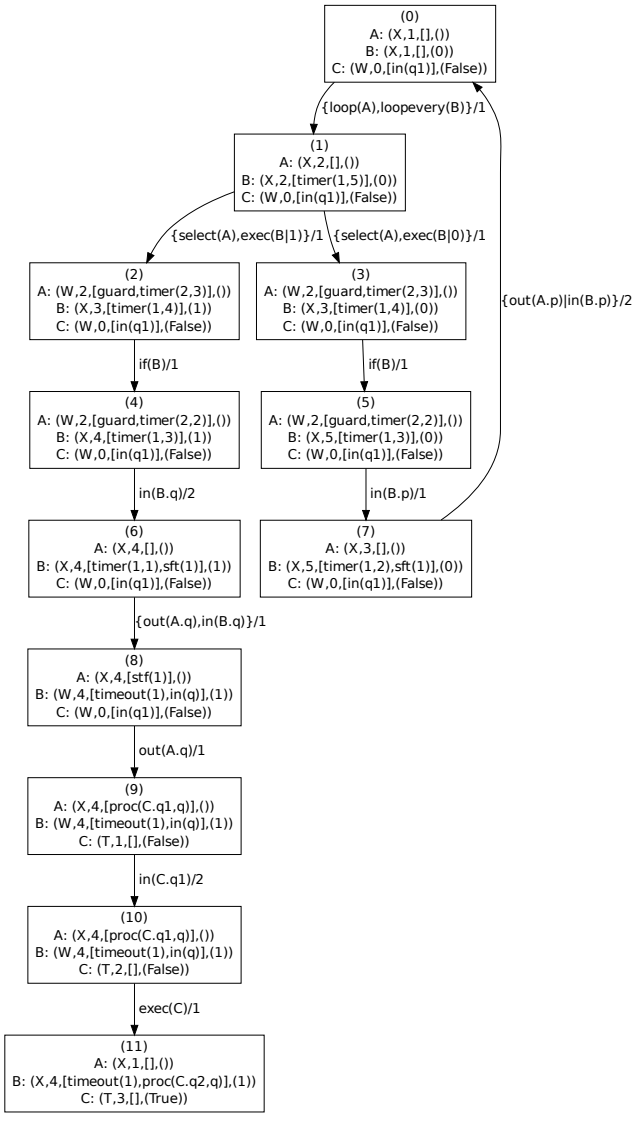


Figure 7. Time model – part of SR-graph

To illustrate presented definitions let us consider a part of the SR-graph for the considered model that is shown in Fig. 7. Let us consider sample states and transitions between them.

- Edge $0 \rightarrow 1$: Steps $loop(A)$ and $loopevery(B)$ are executed simultaneously.
- State 1: The ci list of agent B contains entry $timer(1,5)$ referring to the periodic loop.
- States 2 and 3: The states differ in the value of the parameter of agent B. After execution of **`select`** step, agent A switches to *waiting* mode, because all branches are closed; ci list contains $guard$ and $timer(2,3)$ entries, because A waits either for guard satisfaction or timeout.
- Edge $4 \rightarrow 6$: The duration of $in(B.q)$ step is 3 time-units, but state 6 is present in the SR-graph, because of agent A state change. After lapse of 2 time-units (referring to state 4) entry $timer(2,2)$ was updated to $timeout(2)$ and the agent switched mode to *running* and its program counter was set to 4. At the same time ci list of agent B contains $sft(1)$ entry.
- Edge $5 \rightarrow 7$: In the case of time models readiness of a port for a communication is stated just after commencement (rather than completion) of a communication via this port. After the lapse of 1 time-unit from starting executing $in(B.p)$ step, the condition of the first branch of **`select`** statement is satisfied, so agent A switches to *running* mode and performs steps from the branch.
- Edge $7 \rightarrow 0$: Steps $out(A.p)$ and $in(B.p)$ are performed at the same time as a synchronous communication. In time models communication is considered as synchronous, when intervals of execution of steps in and out overlap partially at least. Such communication is completed when both steps are finished.
- State 8: The $timer(1,1)$ entry in agent B context information list was updated to $timeout(1)$. The periodic loop cannot be restarted because agent B still waits for availability of the called procedure.
- Edge $10 \rightarrow 11$: The execution of agent C $exec$ step finishes procedure $q1$. Because procedure $q2$ has been already called agent C starts it immediately.

V. SUMMARY

The formal description of time Alvis models and the set of transition rules for such models have been considered in the paper. The transition rules provide in fact an algorithm for SR-graphs generation that represent state spaces for such models. It should be stressed that an SR-graph is strictly dependent on the steps duration. For example, if we change the integers presented in Table I we will receive another SR-graph with possibly another paths. An SR-graph enables to check whether a given path (a sequence of steps) is possible to be executed for a given steps durations. We can also determine the minimal and maximal times of passing between two given states, i.e. we can, for example, determine the maximal time of reaction of our system to an event. Moreover, SR-graphs enable us to verify all classic properties like live-locks, deadlocks, process starvation etc. What is more important, the verification of these properties takes time dependencies under consideration. The future work will focus on implementation of algorithms for verification time requirements automatically.

Relaxing Queries to Detect Variants of Design Patterns

***Abstract*—Design patterns codify general solutions to frequently encountered design problems. They also facilitate writing robust and readable code. Their usage happens to be particularly profitable if the documentation of the resulting system is lost, inaccurate or out of date. In reverse engineering, detection of instances of design patterns is extremely helpful as it aids grasping high level design ideas. However, the actual instances of design patterns can diverge from their canonical textbook templates. Useful pattern detection tools should thus be able to identify not only orthodox implementations but also their disparate variants. In this paper, we present a method to generate queries to detect canonical instances of design patters. We formulate these queries so that they are language-agnostic. They precisely reflect the intents of the canonical implementations of design patterns. However, they abstract from any peculiarities of programming languages. Next, we show a systematic technique to relax these queries so that they also cover variant implementations of patterns. We discuss our proof-of-concept implementation of this approach in our prototype tool D-CUBED. Finally, we report the results of an experimental comparison of D-CUBED and state-of-the-art detectors.**

I. Introduction

A DESIGN pattern [1] is a general reusable solution to a commonly occurring problem in software design. Design patterns facilitate forming quality designs. As well as being useful in the construction of software systems (forward engineering), they also aid analysing existing systems (reverse engineering).

Detection of design patterns is an important part of reverse engineering. There are a significant number of large software systems without proper documentation that nevertheless need to be maintained, extended, or modified. In such cases, reverse engineering is necessary. However, the process is usually time-consuming and error-prone, as most of the core analysis must be performed manually and some important aspects can be omitted. Detection of design patterns automates extraction of high-level design concepts, which helps gaining a better understanding of code and makes analysis more efficient in terms of time and cost. Moreover, detection of design patterns can aid documenting code (e.g., generating or verifying documentation) or assessing its quality (e.g., using metrics based on design patterns).

In recent years, we have observed a continual improvement in the field of automatic detection of design patterns in source code. Existing approaches [2]–[13] can detect a fairly broad range of design patterns, targeting structural as well as behavioural aspects of patterns. Until recently, the research in the field of pattern detection has focused on novel approaches. However, the papers [14], [15] highlight the importance of the accuracy (precision and recall) of detection methods.

To achieve high recall, we need to reduce the number of false negative results. For a design pattern detection method, this minimization of false negatives means that the method should be capable of detection of numerous implementation variants that preserve the meaning of a design pattern, even though the details of their implementations do not follow the canonical implementation. Therefore, following the advice of [14] that emphasises the importance of '*a common set of patterns, both structural as well as behavioural, with well-defined implementation variants*', we focus on a systematic approach to detect variants of design pattern.

The analysis of implementation variants revealed highly diverse ecosystem of possibilities. For a simple design pattern like the Singleton, we have identified 7 elemental variants as presented in [16]. For another design pattern like the Visitor, we have also identified several significantly different implementations as presented in [17]. Considering further combinations of those elemental variants, it seemed infeasible to enumerate all available variants of design patterns, thus we sought an automated way to generate them. As a starting point we assumed the canonical implementation of design patterns as described in [1]. In [18], we introduced *pattern-preserving transformations* that enable transforming an implementation variant of a design pattern into a new one while preserving the design pattern.

In this paper, we extend our method of detecting design patterns (based on first-order logic formulae as described in [13]) to include a systematic approach to relaxing queries capable of detecting implementation variants of design patterns.

Contributions of this paper are as follows:

1) We present a systematic approach to the construction of queries to detect implementation variants of design patterns. The approach is based on the application of specific and generic pattern-preserving transformations of a Prolog query representing the canonical variant of a design pattern.
2) As a proof-of-concept for Contribution 1, we present queries capable of detecting variants of the Singleton

978-83-60810-53-8/$25.00

design pattern.
3) We evaluate our prototype tool (D-CUBED) with relaxed variant queries and compare it with two state-of-the-art pattern detectors (PINOT, DPD Tool).

II. METHOD

Our method of detecting variants of design patterns consists of the following steps (see Figure 1):

1) A transformation of the UML class diagram of the canonical implementation of a design pattern to a logic query;
2) An application of specific pattern-preserving query transformations;
3) An application of generic pattern-preserving query transformations;

The starting point of the method is the UML class diagram of *the canonical implementation* of a design pattern. We define *a canonical implementation* as the original implementation provided by the authors of a design pattern (e.g., Gang of Four in their book [1]). Through a set of transformations applied to the UML diagram of the canonical implementation of a design pattern, we obtain a disjunction query used to detect the variants of this pattern.

In [18], we introduced the concept of *pattern-preserving code transformations*, i.e., code transformations that preserve the intent of a design pattern. They were used to generate the implementation variants of design patterns in order to create test cases for pattern detectors. Here, we introduce a corresponding concept of *pattern-preserving query transformations*, which relax queries to extend their capabilities of detecting more implementation variants of design patterns.

In Step 1: Direct Transformation of UML to Logic, we transform the class diagram of the canonical implementation of a design pattern represented in UML to a formula using our custom metamodel (see Section II-A) expressed in logic. The output formula is a conjunction of predicates from our metamodel, describing such features as classes along with their fields and methods. Occasionally, we may need to add additional clauses to a conjunction query in order to represent important implementation details of a design pattern which are described in UML comments, other UML diagrams, or in the description of the pattern.

In Step 2: Specific Pattern-Preserving Query Transformations, we apply *specific pattern-preserving query transformations* to the query constructed in Step 1. *Specific pattern-preserving query transformations* are based on the concept of *specific pattern-preserving transformations* introduced in [18]. Each of them is a code transformations characteristic to a particular design pattern that preserves its intent. If such a transformation is applied to a correct implementation variant of a design pattern, it will produce a new correct variant. Exemplary specific pattern-preserving query transformations can be found in Section III.

In Step 3: Generic Pattern-Preserving Query Transformations, we apply *generic pattern-preserving query transformations* to the queries obtained in Step 2. Similarly to a specific pattern-preserving transformation, a *generic pattern-preserving query transformation* is based on the concept of a *generic pattern-preserving transformation* introduced in [18]. It is a code transformation referring to generic programming (e.g., abstractness, invocation, access modifiers) that preserves the design intent. The detailed description of generic pattern-preserving query transformations can be found in Section II-D.

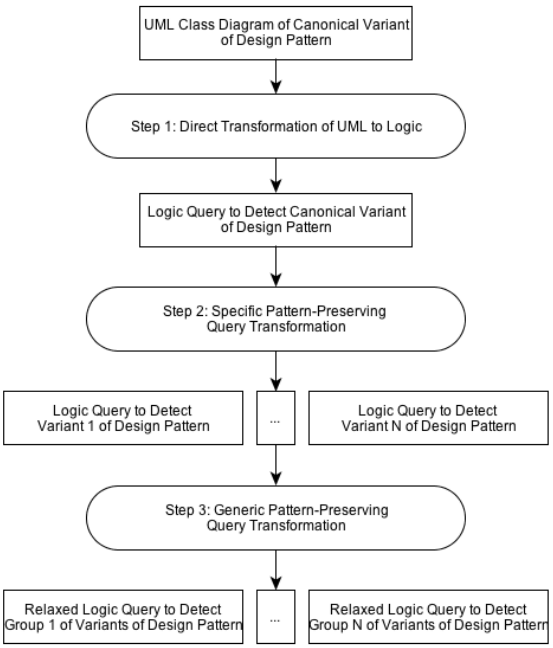

Fig. 1. The overview of the construction of the queries to detect the variants of a design pattern.

The final query to detect the variants of a given design pattern is the disjunction of the relaxed queries constructed in Step 3.

A. Program Metamodel

The program metamodel used in our detection method has been introduced in [13]. It consists of a set of core elements and a set of relationships among those elements, both structural and behavioural. The metamodel has been designed to be *"as simple as possible, but not simpler"*, yet it is powerful enough to model a large set of object-oriented languages.

The program metamodel consists of the following core elements (Figure 2): types, fields-or-variables, operations, and instances. Most of them have their obvious object-oriented meaning. A type denotes either a class, an interface or any other language-specific data type construct (like Java enum). A field-or-variable includes two cases: (1) an instance field or static field of a class or an interface, and (2) a variable that is not a field e.g. a global variable (irrelevant to Java but not to C++). Similar to the field-or-variable element, an operation also covers two cases: (1) a method declared in a type, and (2) a function e.g., a global function. An instance has been defined as an equivalence class of the relation "objects

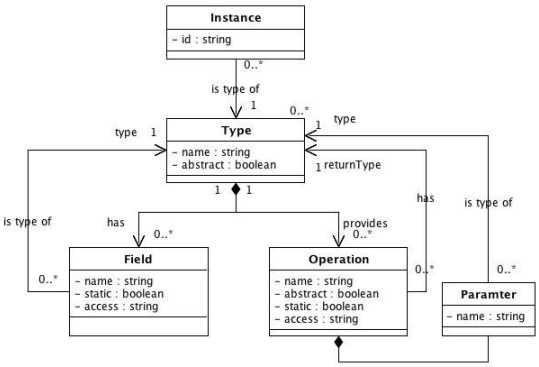

Fig. 2. The core elements of the program metamodel

constructed by the same `new`". All objects instantiated by the same `new` statement are treated as a single instance.

The extensional Prolog predicates describing core elements include: $isClass$, $isInterface$, $isEnum$, $isPrimitive$, $isType$, $isInstance$, $isField$, $isVariable$, $isFunction$, $isMethod$, $isParameter$, and others.

The elemental structural relations describe the relationships among core elements of a program, including memberships (i.e., fields and methods), modifiers (e.g., static, abstract, and access modifiers), and type system. The extensional Prolog predicates representing the elemental structural relations include: $isFieldOf$, $isMethodOf$, $hasParameter$, $hasReturnType$, $hasModifier$, $isTypeOf$, $isSubtypeOf$, and others. The intensional predicates $isTypeOf^*$ and $isSubtypeOf^*$ are the transitive closures of $isTypeOf$ and $isSubtypeOf$ respectively.

The elemental behavioural relations mostly refer to a data-flow and a call-flow, including instantiation as a specific call to a `new` operator. The extensional Prolog predicates representing the elemental behavioural relations include: $invokes$, $instantiates$, $hasInput$, $hasOutput$, and others. The intensional predicates $invokes^*$ and $instantiates^*$ are the transitive closures of $invokes$ and $instantiates$ respectively.

In order to illustrate the semantics of the predicates representing relations, here we present the definitions of $hasInput$ and $hasOutput$, two exemplary predicates related to the call-flow of a program:

$hasInput$

$hasInput(F, I)$, if and only if there is a potential execution path where the instance I is passed as one of the input parameters or as a part of an input parameter to the operation F.
$hasInput(F, T)$, if and only if $hasInput(F, I)$ and $isTypeOf^*(I, T)$.

$hasOutput$

$hasOutput(F, I)$, if and only if there is a potential execution path where the instance I is the output value or a part of the output value of the call to the operation F. The output means a return value as well as an output parameter.
$hasOutput(F, T)$, if and only if $hasOutput(F, I)$ and $isTypeOf^*(I, T)$.

B. UML to Logic Transformation

By a logic query we understand a set of Horn [19] clauses as used in logic programming. These logic queries operate on the program metamodel from Section II-A. We treat UML class diagrams of design patterns as inquires to a codebase. Therefore, we translate the codebase queries in the form of the UML class diagrams to the logic queries operating on the metamodel.

The algorithm to transform a class diagram to a logic query is as follows:

1) For each class and interface in a class diagram, we produce a conjunction of predicates, describing the type ($isClass$ or $isInterface$), its supertypes ($isSubtypeOf$), and its modifiers ($hasModifier$).
2) For each method in a class or interface, we produce a conjunction of predicates, describing its enclosing type ($isMethodOf$), its signature ($numberOfParameters$, $hasParameter$, $hasReturnType$), and its modifiers ($hasModifier$).
3) For each field in a class or interface, we produce a conjunction of predicates, describing its enclosing type ($isFieldOf$), its type ($isTypeOf$), and its modifiers ($hasModifier$).
4) We model additional information (e.g., comments) contained in a class diagram on per-case basis.
5) The output query is the conjunction of previously generated queries (i.e., class queries, method queries, field queries, additional information queries).

Optionally, we may need to transform to a logic query other UML diagrams (e.g., a sequence diagram) of a design pattern or encode features described purely textually.

C. Specific Query Transformations

A *specific pattern-preserving query transformation* is characteristic to a particular design pattern. It deals with, so-called, query logical fragments (i.e. parts of a query representing logical fragments of a pattern) transforming them into queries corresponding to different implementations valid in the context of a pattern.

A *pattern logical fragment* is a robust fragment of a design pattern which can be implemented using various programming techniques, e.g. the instantiation of a singleton instance (lazy or eager implementation). It is possible for a design pattern to have only one logical fragment (itself).

The identification of logical fragments of a design pattern as well as the transformations of these fragments are a purely manual process because they require understanding and abstraction of the semantics of a design pattern.

The application of the specific query transformations is an automated process, once we have query logical fragments and their transformations. Let us assume that we identified N logical fragments $F_i : 1 \leq i \leq N$ and for each fragment F_i we found a set of query transformations $T_{F_i} = T_j^i : 1 \leq j \leq K_i$. Then our algorithm to apply specific pattern-preserving query transformations is as follows:

1) We produce a Cartesian product of transformations over logical fragments, eliminating impossible combinations. As the result we obtain a set of possible transformation tuples $T = (t_1, ..., t_N) : t_i \in T_{F_i} \cup NONE$.
2) We apply the transformations tuples to the query obtained in Step 1.

D. Generic Query Transformations

Generic pattern-preserving query transformations are based on generic pattern-preserving code transformations. Figure 3 presents the generic pattern-preserving transformations as identified in [18]: (1) abstractness transformations, (2) invocation transformations, (3) inheritance transformations, (4) aggregation transformations, (5) method signature transformations, and (6) access transformations.

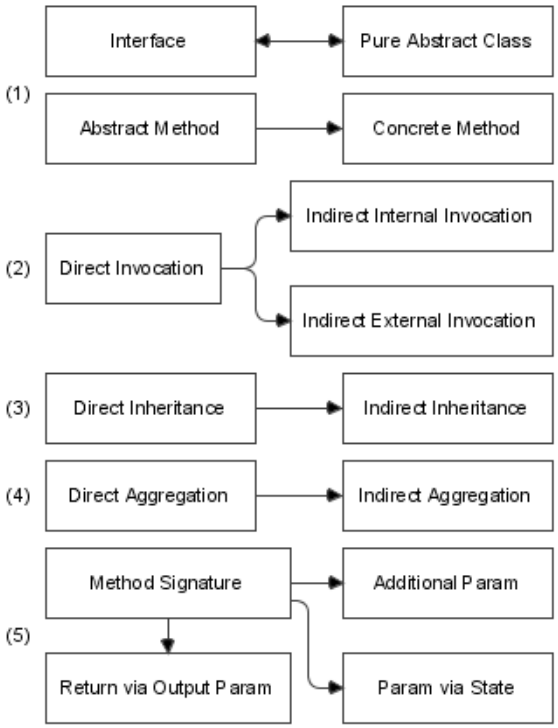

Fig. 3. The generic pattern-preserving code transformations.

a) Abstractness Transformations: These transformations refer to the property of being abstract for a class or a method. There is a two-sided transformation between interface and pure abstract class. This transformation is obvious since there exists a direct correspondence between these two constructs. They are often used interchangeably. The next transformation converts an abstract method to a concrete method. In our opinion this also is a natural transformation. It often happens that in the real world development programmers provide a default implementation instead of leaving a method abstract. By combining these transformations, we can transform an interface into a concrete class. Summing up, as long as we can take advantage of polymorphic calls, abstractness and concreteness do not impact the intent of a pattern code.

In terms of logic queries, the abstractness transformations lead to the following rewrite rules:

1) $isClass(Type) \rightarrow isClassOrInterface(Type)$
2) $isInterface(Type) \rightarrow isClassOrInterface(Type)$
3) $hasModifier(Class, 'abstract') \rightarrow true$
4) $hasModifier(Method, 'abstract') \rightarrow true$

b) Inheritance Transformations: The inheritance transformation introduces an intermediary level of inheritance, i.e. a direct subclassing is transformed into indirect. In real world software code such a construct can be the effect of a particular functional requirement or the complexity of a design problem. The length of an inheritance chain does not impact the intent of a pattern.

In terms of logic queries, the inheritance transformations lead to the following rewrite rule:

1) $isSubtypeOf(Type1, Type2) \rightarrow isSubtypeOf^*(Type1, Type2)$

c) Invocation Transformations: This group refers to transformations of invocation and instantiation statements. It is a popular refactoring. When a piece of code becomes complex, it is extracted into a separate method or class. This means that an invocation (or an instantiation), which remained direct until refactoring, is transformed into indirect. Depending on whether a new method or a new class is introduced, we call this indirect invocation internal or external respectively. Similarly to the length of an inheritance chain, the length of an invocation chain does not influence the logic of a pattern variant.

In terms of logic queries, the invocation transformations lead to the following rewrite rules:

1) $invokes(Method1, Method2) \wedge isMethodOf(Method1, Class) \wedge isMethodOf(Method2, Class) \rightarrow invokes^*(Type1, Type2) \wedge isMethodOf(Method1, Class)$
2) $invokes(Method1, Method2) \rightarrow invokes^*(Type1, Type2)$

d) Aggregation Transformations: These transformations follow the reasoning presented for invocations. Replacing a direct aggregation of an attribute (or a group of attributes) with an indirect aggregation does not influence the overall intent of a pattern implementation. Here is the example of such a transformation applied to the `observers` attribute:

```
class Observable {
    List<Observer> observers;
    ...
}
```

```
class Observable {
    ObserverList observerList;
    ...
}
class ObserverList {
    List<Observer> observers;
    ...
}
```

In terms of logic queries, the aggregation transformations lead to the following rewrite rule:

1) $isFieldOf(Field, Type) \rightarrow isFieldOfField^*(Field, Type)$

e) Method Signature Transformations: Here we present the transformations of method signatures. We have identified three such transformations:

- addition of a new (input) parameter,
- replacing the return value with an output parameter,
- passing an input value to a method via an object state instead of passing a parameter.

In terms of logic queries, the method signature transformations lead to the following rewrite rules:

1) $numberOfParameters(Method, N) \rightarrow true$
2) $isParameter(Param, Type) \wedge isParameterOf(Param, Method) \rightarrow hasInput(Method, Type)$
3) $hasReturnType(Method, Type) \rightarrow hasOutput(Method, Type)$

f) Access Transformations: These transformations relate to access modifiers of fields, methods, and classes. Basically, it means that access modifiers are not core elements of patterns and can be ignored during pattern detection. First of all, access modifiers are language-dependent feature. There are programming languages (e.g., JavaScript) that do not support access modifiers. Also, the semantics of the access modifiers may differ from one language to another (e.g., protected access in Java and C++). Therefore, we cannot rely on access modifiers and their semantics in a language-independent detection method. Moreover, there might be software requirements that limit the visibility of a field, method, or class (e.g., a Singleton class that is visible and accessible only in a package).

In terms of logic queries, the access transformations lead to the following rewrite rule:

1) $hasModifier(Element, Access) \rightarrow true$

III. Examples

This section describes the application of our method of query relaxation to the Singleton pattern.

The Singleton pattern is the most popular pattern detected by the existing detection approaches. Its canonical implementation is simple, and the intent seems straightforward. However, by carefully analyzing the structure of this pattern, we can identify some corner cases among its implementation variants as well as in the usage context. The standard variant of the Singleton is shown in Figure 4.

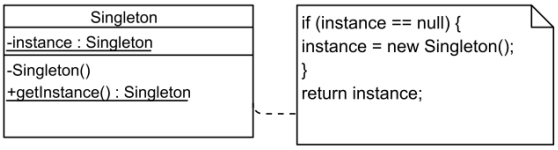

Fig. 4. The standard variant of the Singleton pattern.

A. Step 1: UML to Logic Query Transformation

Below we present the query that reflects the canonical implementation of the Singleton. As such, it can be used to detect orthodox implementations of this design pattern.

A singleton class:

$$isClass(S) \wedge hasModifier(S, 'public')$$

A singleton constructor:

$$isConstructor(SCtr) \wedge isConstructorOf(S) \wedge numberOfParameters(SCtr, 0) \wedge hasModifier(SCtr, 'private')$$

A singleton getter (access point):

$$isMethod(Get) \wedge isMethodOf(Get, S) \wedge numberOfParameters(Get, 0) \wedge hasReturnType(Get, S) \wedge hasModifier(Get, 'static') \wedge hasModifier(Get, 'public')$$

A singleton field:

$$isField(Field) \wedge isFieldOf(Field, S) \wedge isTypeOf(Field, S) \wedge hasModifier(Field, 'static') \wedge hasModifier(Field, 'private')$$

An approximation of a lazy instantiation block:

$$isCodeBlock(Code) \wedge isCodeBlockOf(Get) \wedge instantiatesOptionally(Code, Instance) \wedge isTypeOf(Instance, S) \wedge writesOptionally(Code, Field, Instance)$$

B. Step 2: Specific Query Transformations

In [18], we presented the logical fragments of the Singleton pattern along with the Singleton specific pattern-preserving code transformations. Here, we present the corresponding Singleton-preserving query transformations:

1) Instantiation: To Eager (A) – the lazy instantiation is replaced with an eager instantiation. The rewrite rule is as follows:
$$isCodeBlock(Code) \wedge isCodeBlockOf(Get) \wedge instantiatesOptionally(Code, Instance) \wedge isTypeOf(Instance, S) \wedge writesOptionally(Code, Field, Instance) \rightarrow isInitBlock(Code) \wedge instantiates(Code, Instance) \wedge isTypeOf(Instance, S) \wedge writes(Code, Field, Instance)$$
2) Placeholder: Inner Class (B) – the singleton instance is held as a static attribute of an inner class. The rewrite rule is as follows:
$$isFieldOf(Field, S) \rightarrow isFieldOf(Field, Inner) \wedge isClass(Inner) \wedge isMemberOf(Inner, S)$$

3) Placeholder: External Class (C) – the singleton instance is held as a static attribute of a class from within the same package. The rewrite rule is as follows:
$isFieldOf(Field, S) \rightarrow isFieldOf(Field, Outer) \wedge isClass(Outer) \wedge inPackage(S, P) \wedge inPackage(Outer, P)$
4) Access Point: Inner Class (D) – the public static method is moved to an inner class of a singleton. The rewrite rule is as follows:
$isMethodOf(Get, S) \rightarrow isMethodOf(Get, Inner) \wedge isClass(Inner) \wedge isMemberOf(Inner, S)$
5) Access Point: External Class (E) – the public static method is added to a newly created class in the same package. The rewrite rule is as follows:
$isMethodOf(Get, S) \rightarrow isMethodOf(Get, Outer) \wedge isClass(Outer) \wedge inPackage(S, P) \wedge inPackage(Outer, P)$
6) Access Point: Attribute (F) – the static singleton instance is made public (eagerly instantiated, with the access method removed). The rewrite rule is as follows:
$isMethod(Get) \wedge isMethodOf(Get, S) \wedge numberOfParameters(Get, 0) \wedge hasReturnType(Get, S) \wedge hasModifier(Get, 'static') \wedge hasModifier(Get, 'public') \rightarrow hasModifier(Field, 'public')$
7) Access Point: Protected (G) – the visibility of the access method is changed to protected. The rewrite rule is as follows:
$hasModifier(Get, 'public') \rightarrow hasModifier(Get, 'protected')$
8) Finality: Abstractness with Subclassing (H) – the Singleton class is made abstract and a concrete subclass is provided (the visibility of the Singleton constructor is changed to protected). The rewrite rule is as follows:
$isTypeOf(Instance, S) \rightarrow isTypeOf(Instance, CS) \wedge isClass(CS) \wedge isSubtypeOf(CS, S) \wedge hasModifier(S, 'abstract')$

C. Step 3: Generic Query Transformations

As in this paper it is infeasible to list all generated queries, we present the resulting query obtained after the application of the generic query transformations to the query being the result of the application of the specific query transformations $(A, NONE, NONE, NONE)$ (i.e., lazy instantiation changed to eager instantiation):

A singleton class:
$isClass(S)$
A singleton constructor:
$isConstructor(SCtr) \wedge isConstructorOf(S)$
A singleton getter (access point):
$isMethod(Get) \wedge isMethodOf(Get, S) \wedge hasOutput(Get, S) \wedge hasModifier(Get, 'static')$
A singleton field:
$isField(Field) \wedge isFieldOf(Field, S) \wedge isTypeOf(Field, S) \wedge hasModifier(Field, 'static')$
An approximation of an eager instantiation block:
$isInitBlock(Code) \wedge instantiates(Code, Instance) \wedge isTypeOf(Instance, S) \wedge writes(Code, Field, Instance)$

IV. Evaluation

We compared our prototype tool D-CUBED [20] with two state-of-the-art pattern detection tools: PINOT [21] and FUJABA 4.3.1 [2].

PINOT is a command-line tool written in C++ and based on jikes (the IBM Java compiler). PINOT is available as open source for custom compilation. PINOT ran smoothly, offering high performance in pattern detection tasks. The detection algorithms are hard-coded in PINOT, thus it is hard to experiment by modifying the detection approach. PINOT produces a useful, verbose report summarizing detected pattern instances.

FUJABA is a visually appealing graphic tool suite that provides pattern inference facilities as a plug-in (Inference Engine). There was no problem in launching FUJABA. It provides a UML-like language for user-defined patterns, and presents detected pattern instances as oval annotations on class diagrams. Even though this visual presentation helps in better understanding of diagrams, a summary report might be useful as well.

Similarly to PINOT, D-CUBED is a command line tool written in Java. However, contrary to PINOT, its detection queries are not hard-coded. Instead, we use XSB Prolog, a deductive database, as the data store for our program metamodel and Prolog as the query language. To generate a program metamodel from source code, we use Recoder (a front-end Java compiler) and a set of custom analyses to inspect in detail the call-flow and data-flow of a program.

We have tested these three tools against the source code of JHotDraw60b1 [22]. JHotDraw is a Java GUI framework for technical and structured graphics. It has originally been developed as a design exercise by Erich Gamma and Thomas Eggenschwiler.

Table I presents the results of the tests against JHotDraw. Unfortunately, FUJABA threw an exception during its static analysis. PINOT and D-CUBED performed their detection without any problems, however they produced significantly different results. PINOT did not report any Singleton instances, whereas D-CUBED recognized seven Singleton candidates:

1) *Clipboard* — a true positive; a singleton documented in source code.
2) *DisposableResourceManager* — a true positive; a singleton documented in source code; different placeholder;
3) *ResourceDisposabilityStrategy* — a true positive; analogous to *DisposableResourceManager*; different placeholder;
4) *CollectionsFactory* — a true positive; a singleton with subclassing and delegated construction;
5) *Alignment* — a true positive; a singleton with 6 instances;
6) *FigureEnumerator* — a false positive; there is a single static enumerator representing an empty enumerator,

though other instances are created as well;

7) *HandleEnumerator* — a false positive; there is a single static enumerator representing an empty enumerator, though other instances are created as well;

PINOT did not detect any singleton instance because its detection algorithm relies on the presence of the standard structure and a lazy instantiation block. *Clipboard* uses eager initialization (variant A), whereas two next singletons represent a different placeholder variant (variant C). *CollectionsFactory* represents a singleton with subclassing (variant H). As we did not impose an exactly one instance constraint, we also found the variant with several instances available (*Alignment*).

Unfortunately, query relaxation lead to two false positives. Therefore, the current method turned out to be too flexible. Our current goal, i.e. improving recall, decreased precision of the method. To achieve high precision, we need to filter out false positives. For a design pattern detection method, this minimization of false positives translates into understanding code constructs that violate the principles of a design patterns, even though the overall structure of a given piece of code resembles that of the design pattern. This is part of our undergoing research.

TABLE I
THE RESULTS OF SINGLETON DETECTION ON JHOTDRAW

	PINOT	FUJABA	D-CUBED
Singleton	0	×	7 (5 true positives)

× the tool raised an exception

V. RELATED WORK

There exists a number of proposed approaches to design pattern recognition, yet these approaches often lack in terms of accuracy, flexibility, or performance. A large number of approaches uses only structural information in order to detect design pattern instances (e.g. [23], [24]), but there also exist several approaches that exploit behavioural information contained in source code (e.g. FUJABA [2]–[4], Hedgehog [5], PINOT [6], [7]). We compare the existing detection methods to ours in terms of the concept of an approach, the architecture of a solution, and the mechanisms used to search for patterns.

A metamodel-based approach is not new. There exist several approaches that make use of a metamodel. Ptidej [10] is based on the PADL metamodel (the ancestor of PDL). However, a pattern in PADL is defined as a list of the required entities (a simple conjunction). Thus, it is hard to express more complex logic conditions. Moreover, it does not provide any support to data flow. SPQR [9] uses denotational semantics known as the ρ-calculus together with the set of elemental design patterns that capture call flow information. Similarly to PADL, there is no support to data flow. Hedgehog [5] utilises a Prolog-like language (Spine) to construct a pattern definition. Again, Spine's support to data flow is limited, but additional rules can be introduced. Also MAISA uses a metamodel. Its metamodel is UML and with its help it defines the structural patterns.

Current detection approaches utilise significantly different techniques to identify the instances of design patterns in source code. The most popular technique is the use of a logic inference system. This idea has been applied in Pat [25], where each structural pattern has been associated with a separated set of rules and Prolog interpreter has been used to search for patterns. Also [8] utilises a logic inference system to detect patterns in Java and Smalltalk based on a language-specific naming and coding conventions. SPQR and FUJABA also employ a logic inference engine to reason about the pattern instances.

Ptidej [10] uses a constraints solver with automatic constraint relaxation to detect sets of entities similar to a design pattern. A related work of Ptidej [26] utilises program metrics and a machine learning algorithm to fingerprint design motifs roles. One more approach that uses machine learning techniques is [27]. It enhances a pattern-matching system [11], [12] by filtering out false positives.

Numerous approaches simply navigate over a program abstract syntax tree to find the instances of patterns. They perform static or dynamic analyses to capture the behaviour of a program. Usually their detection algorithms are hard coded and tailored to a particular programming language. PINOT [6] performs static analysis to identify pattern-specific code-blocks. It is a lightweight solution performing recognition in an efficient manner. The approach described in [7] has two phases. In the first phase (the static analysis of the code structure) the abstract syntax tree is analysed in order to select the set of candidates to be pattern instances. In the second phase (the dynamic analysis of a program run) the messages passed are examined to check whether a candidate instance from the first phase is rejected or accepted.

Our approach and the prototype D-CUBED utilises structural information, but it extends the structure-driven approaches by targeting behaviour of the patterns. D-CUBED seems similar to the database driven approaches like DP++ [28] or SPOOL [29], but while these approaches address only the structural patterns, D-CUBED addresses the creational and behavioural patterns utilising the elemental relations to capture code intent.

A completely different approach is taken by the authors of DPJF [30]. They run a number of detection tools and the fuse their results. Such an approach may boost both precision and recall depending on the tuning of parameters. In this paper we focus on our specific method that can improve DPJF when their maintainers upload new version of D-CUBED.

VI. CONCLUSION

In this paper we proposed a general method to generate queries (logic programs) that detect disparate implementation variants of design patterns. First, we produce a strict query that reflect only the canonical textbook version of a design pattern. Then, we relax this query in order to allow multiple variants.

We implemented this approach in our prototype tool D-CUBED. We experimentally verified it with respect to state-of-

the-art detectors. The results are promising, since D-CUBED has detected several non-trivial variants of the Singleton that have not been revealed by other tools.

Apparently, our approach increases the recall of the detection process. However, higher recall may possibly imply lower precision. As the next step in our research, we plan to limit the number of false positives, i.e. detected instances that are not real incarnations of the design patterns. We will attempt tightening the detection queries by *adding* conditions that detect features that actually *violate* the intent of the given design pattern.

***Abstract*—Trustworthy system logs and application logs are crucial for digital forensics. Researchers have proposed different security mechanisms to ensure the integrity and confidentiality of logs. However, applying current secure logging schemes on heterogeneous formats of logs is tedious. Here, we propose FAL, a domain-specific language (DSL) through which we can apply a secure logging mechanism on any format of logs. Using FAL, we can define log structure, which represents the format of logs and ensures the security properties of a chosen secure logging scheme. This log structure can be later used by FAL to serve two purposes: it can be used to store system logs securely, and it will help application developers for secure application logging by generating required source code.**

***Keywords*-DSL, Secure Logging, Audit Trail, Digital Forensics**

I. Introduction

IN RECENT years, digital crime case has increased tremendously. An annual report of the Federal Bureau of Investigation (FBI) states that the size of average digital forensic case is growing 35% per year in the United States. From 2003 to 2007, it increased from 83 GB to 277 GB [1]. Various logs, e.g., network log, process log, file access logs, audit trail of application play vital role in a successful digital forensics investigation. System and application logs record crucial events, such as, user activity, program execution status, system resource usage, network usage, and data changes through which some important attacks can be identified, e.g., network intrusion, malicious software, unauthorized access to software, and many more. Log is also important to ensure the auditability of a system and auditability is a vital issue to make a system compliant with the regulatory acts, e.g., Sarbanes-Oxley (SOX) [2] or The Health Insurance Portability and Accountability Act (HIPAA) [3]. Keeping system audit trails and reviewing them in a consistent manner is recommended by NIST as one of the good principles and practices for securing computer systems [4].

While the necessity of logs and application audit trail are indisputable, the trustworthiness of this evidence will remain questionable if we do not take proper measures to secure them. In many real-world applications, sensitive information is kept in log files on an untrusted machine. As logs are crucial for identifying an attacker, attackers often attack the logging system to hide the trace of their presence in the attack or to frame an honest user. Very often, experienced attackers first attack the logging system [5], [6]. Malicious insider users colluding with the attacker can also tamper with logs. Moreover, forensics investigators can also alter evidence before presenting to court. To protect logs from these possible attacks, we must need a secure logging mechanism. Researchers have already proposed several secure logging schemes [7]–[9], which are designed to defend such attacks.

However, ensuring the privacy and integrity of the logs is costly given that it requires special knowledge and skill of developers. To implement a secure logging scheme, we need to give complete access of the logs to application developers. Providing full access of sensitive logs to developers definitely increases the attack surface. They can violate the privacy, sell sensitive business or personal information, and most importantly can keep a back door for future attack. Adding secure application audit trail can also be burdensome for developers, and increases the application development cost. On the other hand, system admins, who have access to network logs, process logs may not have sufficient knowledge for developing a securing logging scheme.

In this paper, we propose a DSL [10] to assist system admins and application developers for maintaining system logs and application audit trail securely, which is crucial for digital forensics investigation. A DSL is designed for a particular domain and has great advantages over general-purpose language for that specific domain. DSLs provide higher productivity by its greater expressive power, the ease of use, easier verification and optimization [10]–[12]. Using our proposed DSL *FAL*, system admins can define log structure and parse a log file according to the structure. They can also define the security parameters to preserve the integrity and confidentiality of logs. To accomplish this, they only need their domain knowledge related with system logs. Using FAL, a software security analyst can define the required audit trail structure and can generate code for a generic purpose language (GPL), e.g., Java, C# to store the audit logs securely.

Contribution. The contribution of this work is two-fold:

- We propose the first domain-specific language FAL, which can be used to ensure the security of system logs, and application audit logs.
- We show all the DSL development processes, which can be served as a guideline for future DSL development.

II. Background and Motivation

In this section, we present the necessity of secure logging scheme, common approaches for secure logging, and how a DSL can help to mitigate some challenges of secure logging.

A. Secure Logging

As logs are crucial for digital forensics investigation, this is often become the target of attacker. There can be two types of attacks on logs:

- **Integrity**: Integrity of logs can be violated in three ways – an attacker can remove log information, can re-order the log entries, and can add fake logs. A malicious user can launch these attacks to hide the trace of illegal activities from forensics investigation, or to frame an honest user. Timing of an incident is crucial for forensics investigation. Hence, re-ordering the log entries can be important for an attacker, which can give him a chance to produce some alibi.
- **Confidentiality**: From various system logs and application logs, we can identify the activity of users as well as sensitive private information about the users. From the application logs of a business organization, we can also trace out very sensitive business information. This information has high value to attacker. Hence, attack on the confidentiality of logs can be highly beneficial to attacker.

The above attacks can come from different types of attackers:

- **External Attackers**: An external attacker can be a malicious user intending to attack users' privacy from the logs, or try to modify logs to hide the trace of any attack (e.g., network intrusion, malware, spyware). A dishonest forensic investigator can also be an external attacker, as the investigator can alter the logs before presenting to court.
- **Internal Attackers**: A more crucial attack can come from insider attackers colluding with malicious users. A dishonest insider can be a system admin, database admin, or application developer. As system admins have access to all system logs, they can always tamper with logs. Application logs and some of the system logs can be stored in database. In this case, threats can come from database admin. A malicious database admin can modify logs without leaving any trace of the modification. Application developers can modify application logs, or can create a backdoor to collect the application logs. Besides tampering the logs, these insiders can also attack on the privacy of users. They can collect and sell sensitive business and personal information derived from the logs.

To defend the confidentiality and integrity of logs, researchers have proposed several secure logging schemes [7]–[9], [13]. The commonalities among these secure logging schemes are: encrypting sensitive fields to protect the confidentiality, and maintain a hash-chain of the logs to protect the integrity of logs. Hash-chain maintains the chronological information of data. Hence, if any log is missing from the chain or if there is a reordering of the logs then this alteration can be detected from the hash-chain. Hash-chain of one log entry is calculated using the hash of its previous entry. In this way, it preserves the sequence information.

B. Motivation

Though there are some proven secure logging schemes, developing and maintaining a scheme is always challenging because of the following reasons:

1) The first problem is logs are in heterogeneous format. Unfortunately, there is no standard of logs format. Hence, two types of systems logs can look completely different. Moreover, same log can vary by operating systems. For example, format of a process log entry is different in MacOS and Debian.
2) To build a secure logging scheme, we need to permit the logging scheme developers to access the logs. Developers' accessibility to crucial log information certainly increases the attack surface. Earlier, we only need to trust system admins; adding developers in the loop adds an extra level of trust. The developer might place a back door to collect plain log information and can violate the privacy of users.
3) For application logging, application developers need to add secure application logging code for every scenario. Most of the cases, we need to log the database operations – Add, Update, Delete. Through these logs, we can get who has done some specific operations on a specific data. Writing code for all of the possible scenarios is burdensome for developers, and skipping one important logging method may turn out to be crucial.

To resolve the above challenges, we suggest that a well-defined DSL should help. For system logs, with the help of a DSL, we can shift the responsibility of developing a secure logging scheme from programmers to system admins. Because systems admins already have the domain knowledge about system logs, and with the help of a DSL, they can easily define the required security parameters. In this way, we can minimize one level of attack surface. The DSL should also deal with the heterogeneous formats of logs. Hence, we do not need to re-implement a scheme when the log format changes because of any system migration. For application logs, a DSL can generate required application logging code to ease the life of application developers. However, using proprietary encryption and hashing algorithm cannot be adopted by a DSL. Hence, our proposed DSL can only handle established encryption and hashing algorithms.

III. The domain-specific-language FAL

A. Domain Analysis

The very first step of designing a DSL is the detailed analysis and structuring of the application domain [14], which is provided by domain analysis. Output of domain analysis is a Domain Model, which gives us commonalities and variabilities, semantics of concepts, and dependencies between properties. Among various schemes of domain analysis, we choose FODA

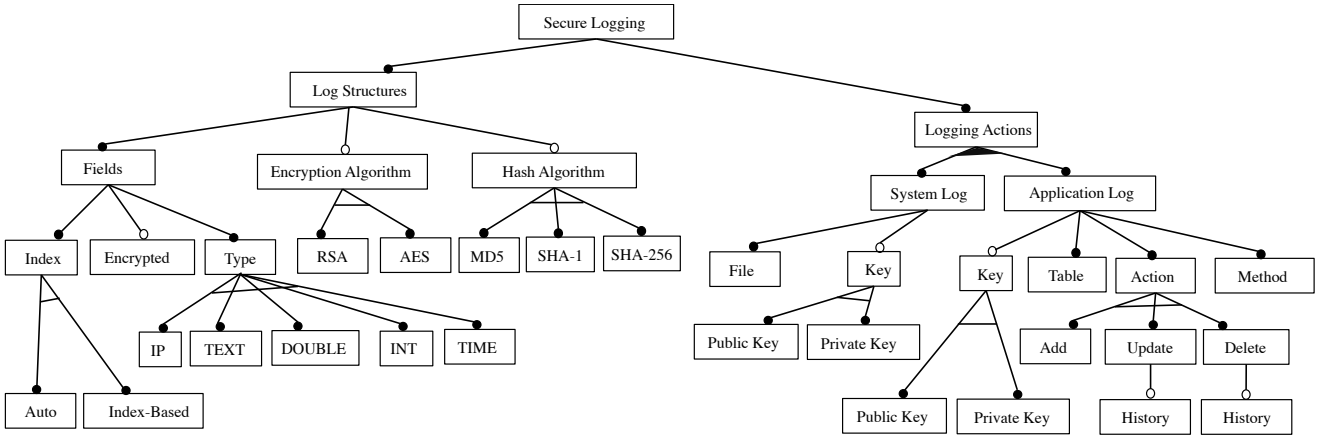

Fig. 1: The Feature Diagram of FAL

(Feature Oriented Domain Analysis). In FODA, the results of the domain analysis are obtained in a feature model [15]. One of the most prominent ways of describing feature model is by feature diagram (FD). The FD is represented as a tree with nodes as rectangles and arcs connecting the nodes. Nodes determine the features, while arcs determine the dependency between the features. The nodes can be mandatory or optional, which are denoted by closed dots, or open dots respectively. The FD of FAL is illustrated in Figure 1.

From Figure 1, it is clear that a secure logging scheme constitutes of log structure and logging action. Every log structure must have fields. Every field must have a type. According to the chosen secure logging scheme, a field can be encrypted or not. Fields may have an index attribute, which will be used to specify the location of a field in an input. The type of a field can be IP, Text, Double, Integer, or Time. Time can be auto-generated, i.e. current system time, or can be index-based. For index-based field, value will be extracted from input file or argument list according to the position defined by the index. For encryption, encryption algorithms, such as, RSA [16], AES [17] can be used. Some secure logging mechanisms use hashing, and hash-chain to ensure the integrity of the logs. Hence hashing algorithms, e.g., SHA-1[1], SHA-256[1], or MD5[2] can be used.

After defining a secure log structure, we need to use the structure for system or application logging. There can be two types of actions. First, for system logs, we need to parse the log files according to a pre-defined structure, and apply the security features while storing. Second, for application log, we need to generate GPL code. For system logs, we must have a file name, and we may have public or private key file. By encrypting with public key, we can ensure that only the private key owner can decrypt certain information. Private key is also needed to create a signature on certain data. Using the public key we can verify the signature. For application logging, we must have a table name, action, method, and may have public or private key file. Method is actually a method name of a GPL program, from where the action is called. An action can be adding a new record, update, or delete a record. For update and delete, we may want to save the history of previous records.

The FDs represent the common features, which always exist in a system (commonalities) and optional features, which may or may not exist in a system (variabilities). Some of the commonalities identified from the FD of FAL are *Fields*, *Type*, etc., and some variabilities are *Encryption Algorithm*, *Key*, etc. From FD, the variation points can be easily identified (optional, one-of and more-of features). After the domain analysis, we can gather the following information – terminology, concepts, and common and variable properties of concepts and their interdependencies.

B. The Abstract Syntax

After the domain analysis, the next step is to design the DSL, from which we will get syntax and semantics of the language. During the domain analysis using FODA, we identified several concepts in the application domain that needed to be mapped into DSL syntax and semantics. From the FD, we can notice the relationship between concepts/features in an application domain and non-terminals in a context-free grammar (CFG). Table I represents the mapping between application domain concepts and non-terminals in context-free grammars, which appears on the left hand side (LHS) and right-hand side (RHS) of CFG production.

Based on Table I, we define the abstract syntax of FAL, which is presented in Table II. The syntactic domains of variables are presented in Table III. A FAL program consists of Log structures LS, and logging actions LA. Log structure LS defines field description F and security parameter S. There can be one or more LS. The field description F specifies field type, id, index I, and encrypted status. There can be one or more fields in a log structure. Index I is either an integer number, or auto. Security parameter S defines encryption and hashing algorithm. Logging action LA can be either System logging action SLA or Application logging action ALA. There can be one or more logging actions. SLA specifies the system log file

[1]http://www.itl.nist.gov/fipspubs/fip180-1.htm
[2]http://tools.ietf.org/html/rfc1321

TABLE I: Translation of the application domain concepts to a context-free grammar

Application domain concepts	LHS non-terminal	RHS structure
Secure Logging	P	Description of Log structure, and logging action
Log Structure	LS	Description of fields and security parameters
Fields	F	Field id, type (IP, Text, Double, Integer, Time), indexing feature, encrypted (or not encrypted)
Index	I	Position of a field in input, or auto.
Security Parameters	S	Description of encryption and hashing algorithm
Logging Action	LA	Description of system logging, or application logging statement.
System logging	SLA	File name to be parsed to store securely, and encryption key.
Application log	ALA	Database operation, table id, GPL method name, encryption key, and history preservation option.

name and encryption key. ALA specifies the database action name, database table name, GPL method name, encryption key, and history preservation option.

TABLE II: Abstract syntax of FAL

P ::= LS LA
LS ::= lid F S |LS1; LS2
F ::= type fid I encrypted |type fid I |F1; F2
S ::= encAlg hashAlg |encAlg |hashAlg |ϵ
I ::= n |Auto
LA ::= SLA |ALA |LA1; LA2
SLA ::= file key |file
ALA ::= action tid key m withhistory |action tid m key |
action tid m history |action tid m

TABLE III: Syntactic Domains

P ∈ Pgm	LS ∈ LogStructure
F ∈ Field	LA ∈ LogAction
I ∈ Index	S ∈ SecAttrs
SLA ∈ SystemLog	ALA ∈ AppLog
n ∈ Num	file ∈ FileSpec
type ∈ {IP, Text, Double, Integer, Time}	fid ∈ FileIdentifier
tid ∈ TableIdentifier	m ∈ MethodName
action ∈ {Add,Update,Delete}	key ∈ KeyFileSpec
lid ∈ LogStructureIdentifier	encAlg ∈ {RSA,AES}
hashAlg ∈ {MD5, SHA-1,SHA-256}	

C. The Concrete Syntax

After defining the abstract syntax, we experimented with various forms of concrete syntaxes to see how various constructs might look. For example, a log structure with two field *fromip* and *user* can be defined using the concrete syntax as described in Listing 1.

Listing 1: FAL Log Structure

```
1: Define netlog {
2:     IP fromip Index 0 Encrypted;
3:     TEXT user Index 1;
4:     Use Encryption With RSA;
5:     Use Logchain With SHA_1;
6: };
```

Here, *fromip* field has data type IP, and *user* is of TEXT data type. The *Index* attribute represents the position of a field in the network log file. The *Encrypted* attribute states that the field will be encrypted according to the encryption algorithm defined in line 4. If there are multiple encrypted fields, all the fields will be encrypted using the same encryption algorithm. Line 5 adds the flexibility of choosing any hash function.

After defining a log structure a log action will be defined, which uses the pre-defined log structure. A concrete example of storing a network log file securely can be defined as follows (Listing 2):

Listing 2: FAL Logging Action

```
1: Watchfile network.log Using netlog
2: {
3:     Privatekey private.key;
4: }
```

The *Watchfile* statement uses the predefined 'netlog' structure to parse the 'network.log' file and provides the required encryption key to start the process of preserving logs securely.

Listing 3: FAL Program for System and Application Log

```
 1: SampleProgram[
 2:     Define netlog {
 3:         IP fromip Index 0 Encrypted;
 4:         TEXT user Index 1;
 5:         Use Encryption With RSA;
 6:         Use Logchain With SHA_1;
 7:     }
 8:     Define patientlog{
 9:         TIME logtime Auto;
10:         TEXT user Index 0 Encrypted;
11:         INT refid Index 1;
12:         TEXT message Index 2 Encrypted;
13:         Use Logchain With SHA_256;
14:     }
15:     Watchfile network.log Using netlog {
16:         Privatekey private.key;
17:     }
18:     Watchtable Patient Using patientlog {
19:         Action Edit Withhistory;
20:         Method updatepatient;
21:         Publickey public.key;
22:     }
23: ]
```

When a language designer is satisfied with the look and feel of the language's syntax, and possible additional constraints from domain experts or language end-users are fulfilled, the concrete syntax can be finalized. In Listing 3, a complete example of FAL program for secured system and application logs is described. We finalized the concrete syntax on the basis of several example programs. Finalizing the concrete syntax process can be executed in parallel with defining language semantics. In Table IV, the FAL concrete syntax is given.

TABLE IV: The concrete syntax of FAL

```
Program := #CCStart [LOG_STRUCT LOG_ACTION]
LOG_STRUCTS := LG_STRUCTS
LG_STRUCTS := LG_STRUCTS LG_STRUCT |LG_STRUCT
LG_STRUCT:= Define #Id {DEF}
DEF := FIELDS SEC_ATTRS
FIELDS := FIELDS FIELD |FIELD
FIELD := #Type #Id IND_BASE ENC ;
IND_BASE := Index #Number |Auto
ENC := Encrypted |ϵ
SEC_ATTRS := SEC_ATTRS SEC_ATTR |ϵ
SEC_ATTR := Use SEC_STMT ;
SEC_STMT := ENC_STMT |HASH_STMT
ENC_STMT := Encryption With #EncAlgorithm
HASH_STMT := Logchain With #HashAlgorithm
LOG_ACTION := LG_ACTIONS
LG_ACTIONS := LG_ACTIONS LG_ACTION |LG_ACTION
LG_ACTION := SYS_ACT |APP_ACT
SYS_ACT := Watchfile #FileName Using #Id {ENC_KEY}
ENC_KEY := PUB_KEY |PRIV_KEY |ϵ
PUB_KEY := Publickey #FileName;
PRIV_KEY := Privatekey #FileName;
APP_ACT := Watchtable #CCStart Using #Id {PARAM}
PARAM := DB_ACTION GPL_MTHD ENC_KEY
DB_ACTION := Action ACT_NAME ;
ACT_NAME := Add |ACT_HSTRY
ACT_HSTRY := ACT_HSTRY_NAME HISTRY_STMT
ACT_HSTRY_NAME := Edit |Delete
HISTRY_STMT := Withhistory |ϵ
GPL_MTHD := Method #Id ;
```

D. Translational Semantics

The advantages of using formal description for semantics of DSL (e.g., attribute grammars, denotational semantics, operational semantics) have been previously discussed in [10], where an ability to find problems in semantics before a DSL is actually implemented was exposed. In this work, we used translational semantics, which is simpler to define then denotational and operational semantics, and it is often used for defining semantics of domain-specific modeling languages [18]. Due to space considerations, only the translational semantics for log structures is presented in Listing 4 (translational semantics for logging actions is omitted from this paper). For each non-terminal in CFG, (Table II) a translational function is defined, which maps syntactic domains (Table III) to their meanings – generated code in Java using a specialized API for secure logging. In particular, the meaning of non-terminal LS is defined by translational function TLS, which maps $LogStructure$ to $code$. Two different forms of LS exist (see abstract syntax in Table II). Hence, two translational functions TLS are defined (lines 4 and 5 in Listing 4). The first translational function TLS (line 4 in Listing 4) maps syntactic structure $lid\ F\ S$ into several Java statements: declaration of new object as an instance of class $LogStructure$, setting a name to the newly created object by calling $setName$ method, and additional Java statements, which will be generated by applying translational functions TF and TS on non-terminals F and S representing fields and security attributes, respectively. Whilst, the second translational function TLS (line 5 in Listing 4) define the meaning of sequence of log structures ($LS1; LS2$). The generated code for $LS1$ is simply concatenated with generated code for $LS2$ (line 5 in Listing 4). In similar manner, other translational functions are defined.

Listing 4: Translational Semantics

```
1:  TP : Pgm → Code
2:  TP⟦LS LA⟧ = TLS⟦LS⟧ + TLA⟦LA⟧
3:  TLS : LogStructure → Code
4:  TLS⟦lid F S⟧ = "LogStructure " + lid + " = new LogStructure();" +
    lid+".setName(" + lid + ");" + TF⟦F⟧ lid + TS⟦S⟧ lid
5:  TLS⟦LS1; LS2⟧ = TLS⟦LS1⟧ + TLS⟦LS2⟧
6:  TF : Field → lid → Code
7:  TF⟦type fid I encrypted⟧ = lid+".addField(FieldType." + type + "," +
    fid + "," + TI⟦I⟧ + ", true);"
8:  TF⟦type fid I⟧ = lid+".addField(FieldType." + type + "," + fid + "," +
    TI⟦I⟧ + ", false);"
9:  TF⟦F1; F2⟧ = TF⟦F1⟧ + TF⟦F2⟧
10: TI : Index → Code
11: TI⟦n⟧ = "true, " + n
12: TI⟦Auto⟧ = "false, INTEGER.MAX_VALUE"
13: TS : SecAttrs → lid → Code
14: TS ⟦encAlg hashAlg⟧ = lid + ".setEncryptionAlgorithm("+ encAlg
15:     + ");" + lid + ".setHashingAlgorithm("+ hashAlg + ");"
16: TS ⟦encAlg⟧ = lid + ".setEncryptionAlgorithm("+ encAlg +");"
17: TS ⟦hashAlg⟧ = lid + ".setHashingAlgorithm("+ hashAlg + ");"
18: TLA : LogAction → Code
19: ...
```

E. Implementation

Various implementation techniques to implement a DSL exist, such as preprocessing, embedding, compiler/interpreter, compiler generator, extensible compiler/interpreter, commercial off-the-shelf, and hybrid approaches [10]. Kosar et al. [19] suggested focusing end-user usability while implementing a DSL. One implementation approach can be good in terms of effort needed to implement a DSL. However, the same approach may not be suitable for end-users. End-users may need extra effort to rapidly write correct programs using the DSL. If only DSL implementation effort is taken into consideration, then the most efficient implementation technique is embedding. However, the embedding approach might have significant penalties when end-user effort is taken into account (e.g., DSL program size, closeness to original notation, debugging and error reporting). To minimize end-user effort, building a DSL compiler [19] is most often a good solution, but this process costs most from an implementation point of view. However, the implementation effort can be greatly reduced, but not as much as with embedding, especially if compiler generators (e.g., LISA [20], ANTLR [21], Silver [22]) are used.

To implement FAL, we depend on source-to-source transformation technique. To transform a FAL program into an intermediate Java program, we build a FAL compiler using LISA, which has proven itself useful in many other DSL projects [23], [24]. The intermediate program uses a pre-build Java API. The design of the API is illustrated in Figure 2.

Fields are represented by *Field* class. The *LogStructue* has a list of Field object, and the security attributes. The name field of *LogStructure* is used to map with the database table name. *LogAction* is an Abstract class with the abstract method *execute*, and it also has an instance of *LogStructure*. *FileWatcher* extends the *LogAction* class and implements the execute method. The execute method is responsible to parse a log file and store it to database with the help of LogStructure and Field. *TableWatcher*

also extends the *LogAction* class and implements the execute method, which generates application logging code for developer. The *SecurityUtil* class defines all the required encryption and hashing methods.

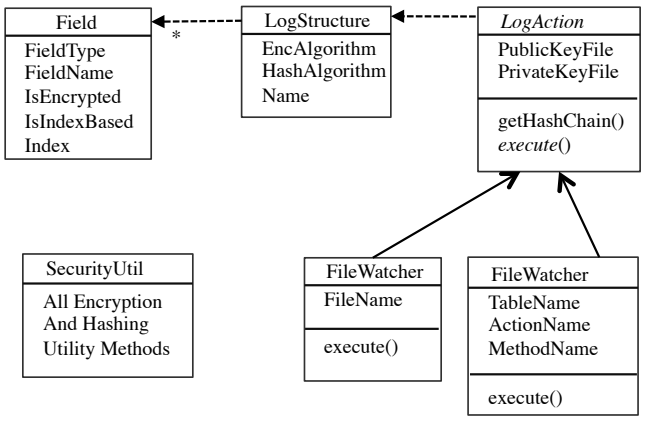

Fig. 2: Design of the API for FAL

After finalizing the Java API, we now know what the intermediate program will be. The FAL compiler will generate this intermediate program from a FAL program. To transform the FAL program to Java program correctly, we use the attribute grammar based approach and LISA specifications are based on attribute grammars [25], [26]. It is capable to generate the compiler from formal attribute grammar-based language specifications.

The first task to implement the compiler is to define the lexicon. Defining the lexicon in Lisa is straightforward. It is showed in Listing 5.

Listing 5: Lexical specification for FAL in LISA.

```
1:  lexicon {
2:      Number [0-9]+
3:      Id [a-z][a-z0-9_]*
4:      Type IP |TEXT |INT |TIME |DOUBLE
5:      EncAlgorithm RSA |AES
6:      HashAlgorithm MD5 |SHA_1 |SHA_256
7:      keywords Define |Use |Encryption |With |Logchain |Index |
8:          Auto |Encrypted |Watchfile |Using |Publickey |Privatekey |
9:          Watchtable |Action |Withhistory |Method |Parameter
10:     FileName [a-z][a-z0-9_]*.[a-z]*
11:     CCStart [A-Z][a-z0-9_]*
12:     ActionName Add |Edit |Delete
13:     Separator \; |\{ |\} |\, |\[ |\]
14:     ignore [ \0x09\0x0A\0x0D\]+
15: }
```

To write the attribute-based semantic rules, first, we need to identify the required attributes for proper semantic analysis. Listing 6 presents the attributes that we used. *code* is the main synthesized attribute that produces the targeted GPL program. *ivar* is an inherited attribute that is used to propagate the variable name down the parse tree. *envs* is a synthesized attribute and *envi* is an inherited attribute; both were needed to maintain a HashSet of already defined variables. *errorMsg* is a synthesized attribute required to report FAL error message to users. *ok* is a synthesized attribute that indicates whether a FAL program is correct or not. Finally, *PROGRAM.file* attribute is used to write the generated GPL program in a file.

Listing 6: Attributes for FAL in LISA.

```
1:  attributes String *.code;
2:      String *.ivar;
3:      String *.errorMsg;
4:      HashSet *.envs;
5:      HashSet *.envi;
6:      boolean *.ok;
7:      BufferedWriter PROGRAM.file;
```

An implementation of translational semantics (Listing 4) using LISA is a straightforward task. The implementation of translational function TF (Line 7 in Listing 4) is presented in Listing 7. Note, how closed both notations are.

Listing 7: Semantic Rules in LISA.

```
1:  rule field {
2:      FIELD ::= #Type #Id IND_BASE ENC \; compute {
3:          FIELD.code = FIELD.ivar + ".addField( FieldType." +
4:              #Type.value() + ",\"" + #Id.value()+"\", " +
5:              IND_BASE.code + "," + ENC.code+");";
6:      };
7:  }
8:  rule ind_base {
9:      IND_BASE ::= Index #Number compute {
10:         IND_BASE.code = "true,"+ #Number.value();
11:     }
12:     |Auto compute {
13:         IND_BASE.code = "false,Integer.MAX_VALUE";
14:     };
15: }
16: rule enc {
17:     ENC ::= Encrypted compute {
18:         ENC.code = "true";
19:     }
20:     |epsilon compute {
21:         ENC.code = "false";
22:     };
23: }
```

After compiling a FAL program, a required Java code is automatically generated, which uses previously defined APIs to store logs, and generate audit trail code for ensuring the integrity and confidentiality of the logs.

IV. Practical Experience

The goal of this section is to acquaint the reader with the practical experiences that were obtained by using FAL. We have therefore selected two case studies of FAL applications:

- Preserve snort log securely using FAL.
- Generate application logging code for a patient information update method in Java.

A. Preserve Snort log

Snort[3] is a free lightweight network intrusion detection system. The network logs generated by Snort plays vital role in network forensics. Hence, preserving the confidentiality and integrity of Snort logs is crucial from digital forensics perspective. Here is a sample Snort log:

```
11/19-13:43:43.222391 11.1.0.5:51215 ->
74.125.130.106:80  TCP TTL:64 TOS:0x0 ID:22101
```

[3]http://www.snort.org

```
IpLen:20 DgmLen:40 DF  ***A***F Seq: 0x3EA405D9
Ack: 0x89DE7D Win: 0x7210 TcpLen: 20''
```

This log tells that the machine with IP 11.1.0.5 performed an http request to machine 74.125.130.160 at time 11/19-13:43:43.222391. Hence, when a machine attacks another machine, we can identify the attacker machine IP from the snort log. Let's assume that a system admin decides to store the 'from IP', 'to IP', and time of network request securely. To protect the confidentiality of logs, among these three fields, the admin decides to encrypt 'from IP', and 'to IP' by the public key of law enforcement agencies using RSA algorithm. To protect the integrity of the logs, the system maintains hash-chain of the logs using SHA-256 hash function. The FAL program described in Listing 8 can be used to ensure all the properties.

Listing 8: FAL Program for Snort Log

```
SnortParser[
    Define snortlog {
        IP fromip Index 1 Encrypted;
        IP toip Index 3 Encrypted;
        Time logtime Index 0;
        Use Encryption With RSA;
        Use Logchain With SHA_256;
    };
    Watchfile snortnetwork.log Using snortlog {
        Publickey lawpublic.key;
    }
]
```

The above FAL program will generate Java code as follows (Listing 9):

Listing 9: Translated Java Code from FAL

```
LogStructure snortlog = new LogStructure();
snortlog.setName("snortlog");
snortlog.addField(FieldType.IP,"fromip",true,1,true);
snortlog.addField(FieldType.IP,"toip",true,2,true);
snortlog.addField(FieldType.TIME,"logtime",true,0,false);
snortlog.setEncryptionAlgorithm("RSA");
snortlog.setHashingAlgorithm("SHA_256");
FileWatcher snortlogFileWatcher = new FileWatcher();
snortlogFileWatcher.setLogStructure(snortlog);
snortlogFileWatcher.setFileName("snortnetwork.log");
snortlogFileWatcher.setPubicKeyFile("public.key");
snortlogFileWatcher.execute();
```

Executing the Java code (Listing 9) will parse the snort log file and store them with the security parameter. However, FAL users do not need to understand the underlying API or the intermediate Java code generated by FAL.

B. Application Logging

Application log is crucial for many applications including business and health care sector. The methods that directly communicate with database need to be logged. From these logs, later we can identify who added a new record, or who updated or deleted some record, etc. Application developer needs to integrate this logging feature with every method that updates database. FAL can generate the necessary logging code for application developer.

Here, we present a hypothetical scenario of a health care application, where we can use FAL for secure application logging. In the application, there is a Patient table, and we want to store logs whenever any update is operated on patient's record. The log will include the user name of the application, patient id is being updated, a description of the operation, and time of operation. The security analyst of the application decides to encrypt user name, and the operation description using AES encryption algorithm and SHA-1 hash function to maintain the hash-chain of logs. The FAL program described in Listing 10 can be used to generate necessary application logging code.

Listing 10: FAL Program for Application Logging

```
PatientAppLog [
    Define useraudit {
        TIME logtime Auto;
        TEXT username Index 0 Encrypted;
        INT refid Index 1;
        TEXT message Index 2 Encrypted;
        Use Encryption With AES;
        Use Logchain With SHA_1;
    };
    Watchtable Patient Using useraudit {
        Action Edit Withhistory;
        Method updatepatient;
        Privatekey serveraes.key;
    }
]
```

The translated Java code from FAL program (Listing 10) will generate the application logging method as described in Listing 11.

Listing 11: Generated Code For Application Logging

```
public void auditPatientEdit(String username, int refid, String message,
String logtime)
{
    try {
        String rowValue = username + refid + message + logtime;
        String currHashs = getHashChain("useraudit","id",rowValue,
            "SHA-1");
        String aesKey = HandleKey.readAESKey("serveraes.key");
        username = HandleKey.aesEncrypt(username +"", aesKey);
        message = HandleKey.aesEncrypt(message +"", aesKey);
        String query = "insert into useraudit( username, refid,
            message, logtime, tablename, actionname, methodname,
            logchain, withhistory) values("' + username
            + "'," + refid + ",'" + message + "','" + logtime +
            "','Patient','Edit','updatepatient','"+currHashs+"',true)";
        DBHandler dbHandler = new DBHandler();
        dbHandler.insertData(query);
    }catch (Exception e) { e.printStackTrace();}
}
```

V. Related Work

There has been a lot of prior research on secure logging, because of its vital role in digital forensics. Schneier et al. proposed a secure audit logging scheme, which can detect any modification of logs after a machine got compromised [27]. It also preserves the confidentiality of logs. Zawoad et al. proposes a secure logging scheme for cloud computing environment where the cloud service provider itself can be dishonest and can try to alter original logs [9]. Though there are no DSL for secure logging, there are some DSLs for providing access control facility on the audit logs or provenance

record and also for general-purpose access control. Ni et al. provided a XML-based access control language for general provenance model [28]. Using this language, users can define and evaluate access control policies on application audit logs. It also supports specifying policies to a particular record and its fields. Weissmann proposed ACS [29], an access control language for specifying access control policy, which especially resolves undecidability of granting or denying access, and incapability of editing control policy without changing the model. Ribeiro et al. provided SPL, an access control language for security policies with complex constraints [30]. SPL supports simultaneously multiple complex policies by resolving conflicts between two active policies. Beyond the permission / prohibition, they also showed how to express and implement the obligation concept.

VI. Conclusion and Future Work

For proper digital forensics investigation, maintaining the trustworthiness of logs is compulsory, and for this, we need a proper secure logging mechanism. To address the problem of secure logging mechanism, we have designed and implemented the domain-specific language FAL with the following benefits:

- Shifting the responsibility of developing a secure logging schemes from application programmers to security experts, which in turn increases trustworthiness.
- Required code to use specialized API for secure application logging is automatically generated. Hence, the effort and cost for developing secure logging scheme is lower.
- Heterogeneous formats of logs with any secure logging schemes can be easily handled.
- Detail understanding of specialized API for secure logging is not needed for FAL users.

We are working to add user specified delimiter feature with FAL. In future, we will add a user-friendly error reporting. Another important future feature is to incorporate timing option with system logging action. With this feature, users can define for how long they want to run system logging option. We will also work towards making FAL more robust so that it can generate audit-trailing code for all popular GPLs. Finally, FAL's design needs to be validated by end-users by performing usability studies and control experiments.

Dynamic loop reversal - the new code transformation technique

I. Šimeček, P. Tvrdík
Department of Computer Systems, Faculty of Information Technology,
Czech Technical University in Prague Prague, Czech Republic Email: xsimecek,pavel.tvrdik@fit.cvut.cz

***Abstract*—In this paper, we describe a new source code transformation called *dynamic loop reversal* that can increase temporal and spatial locality. We also describe a formal method for predicting the cache behaviour and evaluation results of the accuracy of the model by measurements on a cache monitor. The comparisons of the numbers of measured cache misses and the numbers of cache misses estimated by the model indicate that model is relatively accurate and can be used in practice.**

I. Introduction

LINEAR codes for dense linear algebra consist mainly of loops. A number of source code transformations techniques have been developed and used in the state-of-the-art compilers. In this paper, we consider the following standard techniques: *loop unrolling*, *loop blocking*, *loop fusion*, and *loop reversal* [1], [2], [3]. The main result of this paper is a description of a new transformation technique, called *dynamic loop reversal*, shortly *DLR*, to improve temporal and spatial locality.

Models for predicting the number of cache misses have also been developed for standard source code transformations [4], [5], [6], [7]. In order to incorporate the DLR into compilers, we propose such a model for the DLR in Section IV-B .

II. Terminology

Throughout the paper, we assume that indexes of vectors and matrices start from 1, all elements of vectors and matrices are of type *double* and that all matrices are stored in the row-major format.

A. The cache architecture model

We consider a *set-associative cache*. The number of sets is denoted by h. One set consists of s independent *blocks*. The size of the data part of a cache in bytes is denoted by DC_{S}. The cache block size in bytes is denoted by B_{S}. Then $DC_{\mathrm{S}} = s \cdot B_{\mathrm{S}} \cdot h$. The size of type `double` is denoted by S_{D}. We consider only *write-back* caches with *LRU block replacement* strategy.

B. The compressed sparse row (CSR) format

A matrix A is *dense* if it contains $\Theta(n^2)$ nonzero elements and it is *sparse* otherwise. In practice, a matrix is considered sparse if the ratio of nonzero elements drops bellow some threshold. The most common format (see [8], [9], [10]) for storing sparse matrices is the *compressed sparse row* (CSR) format. The number of nonzero elements is denoted by NZ_A. A matrix A stored in the CSR format is represented by three linear arrays $Elem_A$, $Addr_A$, and Ci_A. Array $Elem_A[1,\ldots,NZ_A]$ stores the nonzero elements of A, array $Addr_A[1,\ldots,n]$ contains indexes of initial nonzero elements of rows of A, and array $Ci_A[1,\ldots,NZ_A]$ contains column indexes of nonzero elements of A. Hence, the first nonzero element of row j is stored at index $Addr_A[j]$ in array $Elem_A$. The density of the matrix A (denoted by $density(A)$) is the ratio between NZ_A and n^2.

III. Code restructuring

In this section, we propose a new optimization technique called *dynamic loop reversal* (or alternatively *outer-loop-controlled loop reversal*).

A. Standard static loop reversal

In the standard loop reversal, the sense of the passage through the interval of a loop iteration variable is reversed. This rearrangement changes the sequence of memory requirements and reverses data dependencies. Therefore, it allows further loop optimizations in general.

Example code 1

```
1: for i ← n, 2 do
2:     B[i]+ = B[i − 1];
3: for i ← 2, n do
4:     A[i]+ = B[i];
```

Example code 1 represents a typical combination of data-dependent loops whose data dependency can be recognized automatically by common compiler optimization techniques. However, the first loop is *reversible* (it means that it is possible to alternate the sense of the passage). The reversal of the second loop and loop fusion can be applied and the reuse distances (see Section IV-A for the definition of the reuse distance) for memory transactions on array B are decreased.

Example code 2 Loop reversal and loop fusion applied to Example code 1

```
1: for i ← n, 2 do
2:     B[i]+ = B[i − 1];
3:     A[i]+ = B[i];
```

In Example code 3, data-dependency analysis reveals that the two loops are also reversible.

978-83-60810-53-8/$25.00

Example code 3

```
1: for i ← 1, n do                    ▷ Loop 1
2:     s+ = A[i] ∗ A[i];
3: norm = √s;
4: for i ← 1, n do                    ▷ Loop 2
5:     A[i]/ = norm;
```

However, the application of the loop reversal to the second loop decreases the reuse distances.

Example code 4 Loop reversal applied to Example code 3

```
1: for i ← 1, n do                    ▷ Loop 1
2:     s+ = A[i] ∗ A[i];
3: norm = √s;
4: for i ← n, 1 do                    ▷ Loop 2
5:     A[i]/ = norm;
```

The problem is that in this case (and in other similar cases), the compiler heuristics for the decision which loop to reverse to minimize reuse distances is complicated.

B. The effect of the static loop reversal on cache behaviour

If the size of array A is less than the cache size ($nS_{\mathrm{D}} \leq DC_{\mathrm{S}}$), then Example codes 3 and 4 are equivalent as to the cache utilization. However, if the size of array A exceeds the cache size, then no elements of A are reused in Example code 3,whereas the last $k = \frac{B_{\mathrm{S}}}{S_{\mathrm{D}}}$ elements of A are reused within the second reversed loop in Example code 4. So, the loop reversal improves the temporal locality (see Figures 1 and 2).

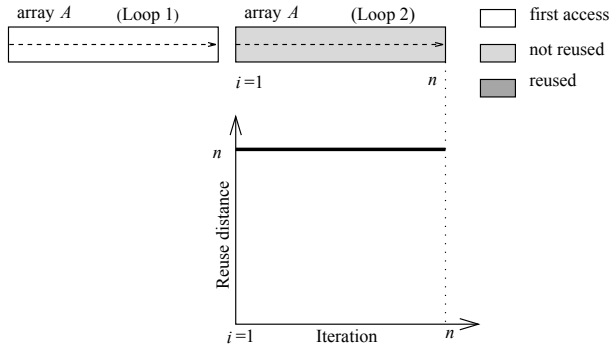

Fig. 1. The reuse distances in Example code 3.

C. Dynamic loop reversal

The static loop reversal is used to reverse data-dependency in one dimension. This has motivated us to generalize this idea and we have designed another optimization for nested reversible loops based on loop reversal. Consider the following code:

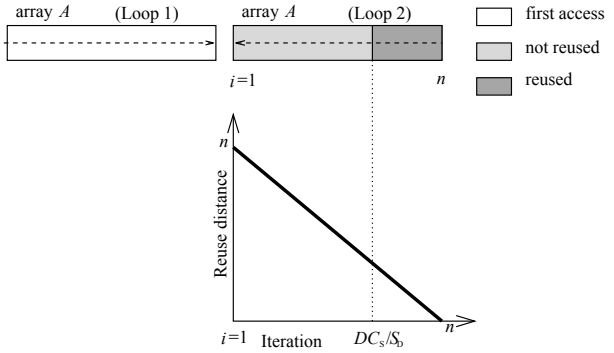

Fig. 2. The reuse distances in Example code 4.

Example code 5

```
1: for i ← 1, n do
2:     s = 0;
3:     for j ← 1, n do
4:         s+ = A[i][j] ∗ x[j];
```

The direction of the inner loop can be alternated forward and backward in even and odd iterations of the closest outer loop. In this way, we can use the positive effect of a loop reversal in every iteration of the outer loop. This is why we call it a *dynamic loop reversal*, or *DLR* for short. Example code 5 is a candidate for such a transformation.

Example code 6 DLR applied to Example code 5

```
1: for i ← 1, n do
2:     s = 0;
3:     if i is odd then
4:         for j ← 1, n do
5:             s+ = A[i][j] ∗ x[j];
6:     else
7:         for j ← n, 1 do
8:             s+ = A[i][j] ∗ x[j];
```

We will denote this transformation by DLR($i \rightarrow j$). For large arrays, this transformation leads to even better temporal locality than the original Example code 5, because it reduces the reuse distances and data reside in the cache from the previous iteration. On the other hand, the saving of the number of cache misses in one iteration of the outer loop is bounded by $DC_{\mathrm{S}}/B_{\mathrm{S}}$. So, the *DLR* has a significant effect if the cache size is comparable to the sum of affected arrays sizes in one iteration of the outer loop. The necessary condition for applying the *DLR* is that the inner loop must be reversible.

D. The application of DLR on triple-nested loops

In the previous text, the DLR was applied to double-nested loops, but it can also be applied to triple-nested loops. Consider the following code skeleton:

Example code 7

```
1: for i ← 1, n do
2:     for j ← 1, n do
3:         for k ← 1, n do
4:             (* loop body *)
```

In Example code 7, there are three options how the DLR can be applied:

- on the i-loop: DLR($i \to j$),
- on the j-loop: DLR($j \to k$),
- both transformations: DLR($i \to j$) and DLR($j \to k$).

The last option means composition of two transformations DLR($i \to j$) and DLR($j \to k$). This composition we will denoted by DLR($i \to j \to k$). In this case, the effect of DLR is twofold: DLR($i \to j$) (on the outer pair of loops) can improve temporal locality inside the L2 cache and DLR($j \to k$) (on the inner pair of loops) can improve temporal locality inside the L1 cache.

E. Comparison and possible combinations of DLR and other loop restructuring techniques

In this section, we describe some loop restructuring techniques (for details see [11], [12], [13], [14], [15]), compare them with DLR, and discuss their possible combinations with DLR.

1) Loop unrolling: Loop unrolling has two main effects. Firstly, it makes the sequential code longer, so it may improve data throughput, because the instructions could be better scheduled and the internal pipeline could be better utilized. Secondly, the number of test condition evaluations drops according to the unrolling factor. In general, the loop unrolling concentrates on maximizing the machine throughput, not on improving the cache behaviour.

2) Loop tiling (blocking): Loop tiling (sometimes called loop blocking or iteration space tiling) is one of advanced loop restructuring techniques. A compiler can use it to increase the cache hit rate. One possible motivation for using this technique is that the *loop range* (e.g., the size of the array traversed repeatedly within the loop) is too big and exceeds the data cache size DC_{S}. Thus, the loop should be split into two loops: the outer loop is the out-of-cache loop and the inner one is the in-cache loop. The value B_f is called the *tiling or block factor* and its optimal value depends on the size of the cache.

The loop tiling and DLR can be easily combined. DLR can be applied on every pair of immediately nested loop, but its useless to apply it for in-cache loops (i-loop, j-loop, and k-loop). We consider loop tiling as a competitor for DLR and we have performed experiments with both. These quantitative measurements of effects of these techniques are presented in Section VI-D.

IV. An Analytical Model of the Cache Behavior for the DLR

The *polytope model* (for details see [3], [6]) is used by modern compilers for an estimation of the parameters for loop restructuring techniques. We will present two cache behaviour models based on reuse distances (shortly RD).

A. A cache miss model with reuse distances

This model is inspired by the model introduced in [16]. We will call it the *basic RD model*.

Definition Consider an execution of an algorithm on the computer with load/store architecture and assume that addresses of memory transactions during this execution form a sequence $P[1,\ldots,n] = [addr_1,\ldots,addr_n]$. Then P is called a **sequence of memory access addresses** and $P[i] = addr_i$ is the i-th transaction with memory address $addr_i$. The **reuse distance** $RD(t)$, where $t \in \langle 1, n\rangle$, is the number of **different** memory addresses accessed between two uses of the address $P[t]$. Formally, if $P[t] = addr_t$ and $\epsilon(t) > 0$ is the minimal integer number such that $P[t-\epsilon(t)] = addr_t$, then $RD(t) = |\{P[t-\epsilon(t)],\ldots,P[t-1]\}|$. If such an $\epsilon(t)$ does not exist, then $RD(t) = \infty$, otherwise $RD(t) \le \epsilon(t)$.

The notion of reuse distances can be used for developing a simple cache miss model based on estimating the numbers of thrashing misses in fully-associative ($h = 1$) caches. If $RD(t) > DC_{\mathrm{S}}/S_{\mathrm{D}}$, then the content of the cache block from the memory address $P(t)$ is replaced by some new value and a cache miss occurs. If $RD(t) = \infty$, then a compulsory miss occurs, otherwise a thrashing miss occurs. Recall that we assume only caches with LRU block replacement strategy.

In this basic RD model, the spatial locality of the cache memory is not considered, i.e., it is assumed that a cache block contains exactly one array element ($B_{\mathrm{S}} = S_{\mathrm{D}}$). However, $B_{\mathrm{S}} = c \cdot S_{\mathrm{D}}$, where c is typically 4 or 8 in modern processors, and therefore, spatial locality must be taken into account in order to have a more realistic model.

B. A simplified cache miss model for the DLR

Even the basic RD model is too complicated for modelling the cache behavior of DLR in real applications. Hence, we introduce another model that is even more simplified. We call this model *simplified RD model*. We use this model for enumeration cache misses saved by DLR. To derive an analytical model of the effect of the DLR on the cache behaviour, consider the following code skeleton representing most often memory access patterns during a matrix computation:

Example code 8

```
1: statement_1;
2: for i ← i_1, i_2 do
3:     statement_2;
4:     for j ← j_1, j_2 do
5:         statement_3;
6:         = B[j];          ▷ Memory operation of type α
7:         = B[i];          ▷ Memory operation of type β
8:         = A[i][j];       ▷ Memory operation of type γ
9:         = A[j][i];       ▷ Memory operation of type δ
10:    statement_4;
11: statement_5;
```

We consider the following simplifying conditions:

A1 We assume that all matrices are stored in the row-major order.

A2 We assume that *statements*$_{1-5}$ contain only local computation with register operands. That is, we assume that *statements*$_{1-5}$ have negligible cache effects and the only memory accesses are memory operations of type $\alpha - \delta$.

A3 We assume that the reuse distances depend on the exact ordering of memory operations (inside the j-loop) only slightly and so do the number of cache misses.

A4 We do not distinguish between load and store operations.

A5 We assume that the cache memory is big enough to hold all the data for one iteration of the (inner) j-loop.

A6 We assume that the cache memory is not able to hold all the data for one iteration of the outer i-loop. Otherwise, the DLR has no effect in comparison to standard execution.

A7 This model is derived only for immediately nested loops.

Let us now analyse the effect of DLR($i \to j$) on individual memory operations.

- A memory operation of type α is affected by the DLR, because its operand (or its part) can be reused. The effect of DLR can be estimated by the RD analysis.
- A memory operation of type β is not affected by the DLR, because it returns the same value (in the j-loop). It is usually eliminated by an optimizing compiler.
- A memory operation of type γ is not affected by the DLR, because its operand cannot be reused due to the row-major matrix format assumption.
- A memory operation of type δ is affected by the DLR, due to its spatial locality.

1) Evaluation of simplified RD model: The number of cache misses during one execution of Example code 8 is denoted by X. The number of cache misses during one execution of Example code 8 with DLR($i \to j$) is denoted by Y. The reduction of the number of cache misses during one execution of Example code 8 due to the DLR($i \to j$) is denoted by μ_{saved} and it is equal to $X - Y$. The value of μ_{saved} has an upper bound

$$\mu_{\text{saved}} \leq (i_2 - i_1) \cdot DC_{\text{S}}/B_{\text{S}}.$$

This general upper bound can be reached only for loops where all memory operations are affected by the DLR. In practical cases, the reduction of the number of cache misses is smaller. To estimate the reduction of the number of cache misses during an execution of Example code 8 with the DLR, we need to count the number of iterations of the j-loop that can reside in the cache. We will denote this number by N_{iter}

$$N_{\text{iter}} = \frac{DC_{\text{S}}}{B_{\text{S}} \sum_m SCMO(m)}, \quad (1)$$

where

- m is a memory operation (of type $\alpha - \delta$) in the j-loop,
- $SCMO(m)$ is the probability that memory operation m loads data into a new cache block.

$$SCMO(m) = \begin{cases} 1 & \text{if } m \text{ is a memory operation of types } \beta \text{ or } \delta \text{ which are accessed in column-like pattern.} \\ S_{\text{D}}/B_{\text{S}} & \text{if } m \text{ is a memory operation of types } \alpha \text{ or } \gamma \text{ which are accessed in row-like pattern.} \end{cases} \quad (2)$$

If $N_{\text{iter}} < 1$, then the assumption (A5) is not satisfied and $\mu_{\text{saved}} = 0$.
If $N_{\text{iter}} \geq (j_2 - j_1)$, then the assumption (A6) is not satisfied and $\mu_{\text{saved}} = 0$.

We can also estimate probability (denoted by $PDLR(m)$) that the memory location accessed by memory operation m is reused using DLR.

$$PDLR(m) = \begin{cases} 0 & \text{if } m \text{ is a memory operations of types } \beta \text{ or } \gamma \text{ (i.e., it is not affected by the DLR;)} \\ 1 - S_{\text{D}}/B_{\text{S}} & \text{if } m \text{ is a memory operation of type } \delta \text{ (i.e., it is affected by the DLR, for column-like access, the last element in cache-line is not counted;)} \\ 1 & \text{if } m \text{ is a memory operation of type } \alpha \text{ (i.e., it is affected by the DLR,for row-like access.)} \end{cases} \quad (3)$$

Finally, the number of cache misses saved by the DLR applied to the i-loop can be approximated by

$$\mu_{\text{saved}} = (i_2 - i_1) \cdot N_{\text{iter}} \sum_m \big(PDLR(m) \cdot SCMO(m)\big), \quad (4)$$

where m is a memory operation in the j-loop.

Comparisons of the numbers of estimated and measured cache misses are presented in Section VI-C3.

V. Experimental evaluation of the DLR

A. Testing codes

For measuring of the effect of DLR (performance, cache miss rate, and so on), we use two simple codes:

- matrix-matrix multiplication (MMM for short),
- multiplication of two sparse matrices (spMMM for short).

We have deeply studied characteristics of these codes in following sections:

- For performance results, see Section VI-A.
- For cache utilization results, see Section VI-B.
- We also evaluate precision of our analytical model for MMM_STD code, see Section VI-C.
- We also combine effects of DLR and loop tiling for MMM_STD code, see Section VI-D.

1) Matrix-matrix multiplication: We consider input real square matrices A and B of order n. A standard sequential pseudocode for matrix-matrix multiplication $C = A \cdot B$ is the following:

```
1: procedure MMM_STD(in A,B;out C)
2:     for i ← 1, n do
3:         for j ← 1, n do
4:             sum = 0;
5:             for k ← 1, n do
6:                 sum+ = A[i][k] * B[k][j];
7:             C[i][j] = sum;
8:     return C;
```

2) Multiplication of two sparse matrices: We consider input real square sparse matrices A and B of order n represented in the CSR format (see Section II-B), output matrix C is a dense matrix of order n. A standard sequential pseudocode for the sparse matrix-matrix multiplication $C = A \cdot B$ can be described by the following pseudocode:

```
1: procedure SPMMM_CSR(in A,B;out C)
2:     for y ← 1, n do
3:         for i ← A.Addr[y], A.Addr[y + 1] − 1 do
4:             x = A.Ci[i];
5:             for j ← B.Addr[x], B.Addr[x + 1] − 1 do
6:                 x2 ← B.Ci[j];
7:                 C[y][x2]+ = A.Elem[i] * B.Elem[j];
8:     return C;
```

B. Configuration of the experimental system

All cache events were evaluated by our software cache emulator [17] and verified by the Intel Vtune tool. The experiments were performed on the Pentium 4 Celeron at 2.4 GHz, 512 MB, running OS Windows XP Professional, with the following cache parameters:

- L1 data cache with $DC_S = 8K$, $B_S = 32$, $s = 4$, $h = 64$, and LRU strategy.
- L2 unified cache with $DC_S = 128K$, $B_S = 32$, $s = 4$, $h = 1024$, and LRU strategy.

We used the Intel compiler version 7.1 with switches:
`-O3 -fno_alias -xK -ipo`

VI. The Results of Experimental Evaluation

A. Performance evaluation of testing codes

We count every floating point operation (multiplication, addition and so on). The performance in MFLOPS is then defined as follows:

$$\text{MFLOPS(MMM\_STD)} = \frac{2n^3}{\text{execution time } [\mu\text{s}]}$$

$$\text{MFLOPS(SPMMM\_CSR)} = \frac{2 \cdot NZ_A \cdot NZ_B}{n \cdot \text{execution time } [\mu\text{s}]}$$

The graph in Figure 3 illustrates the performance with or without DLR. These graphs illustrate that the DLR increases the code performance due to better cache utilization. There

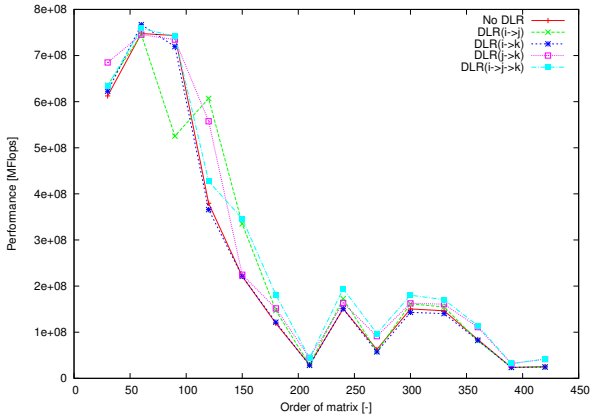

Fig. 3. Performance of MMM_STD.

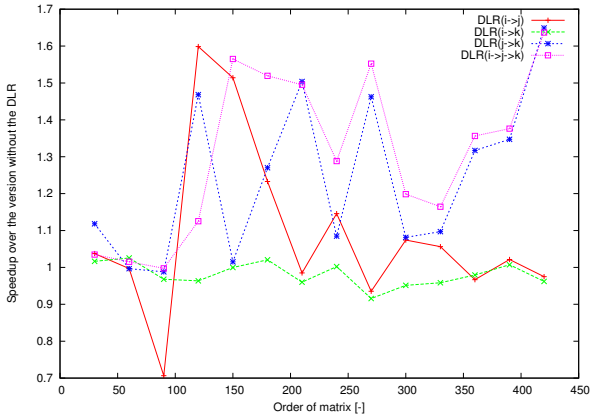

Fig. 4. Speedup of MMM_STD

is a performance gap (for example for $n = 120$ for the MMM_STD), which DLR can overcome. The graph in Figure 4 shows the speedup over the version without the DLR. We can conclude that the fastest code is the version with DLR($i \to j \to k$) for the MMM_STD code. We can also conclude that the average measured speedup is more than 20% in the measured set for the MMM_STD code.

For small matrices, a small slowdown was measured. While the DLR can improve the cache hit rate, it has more overhead due to more conditional loops. This effect becomes even more important for the DLR on triple loops.

B. Cache miss rate evaluation

The cache utilization is enumerated according to the following definitions. Let us define "relative number of cache misses" as the ratio between the number of cache misses with DLR and the number of cache misses without DLR.

The graphs on Figures 5 and 6 illustrate the number of cache misses occurring during one execution of the MMM_STD pseudocode. We can conclude that

- the DLR effect depends on the value of the parameter n and on the cache memory size (this observation proves the results of the analytical model from Section IV-B)

- except for few cases, the DLR transformation has a positive impact on cache utilization.

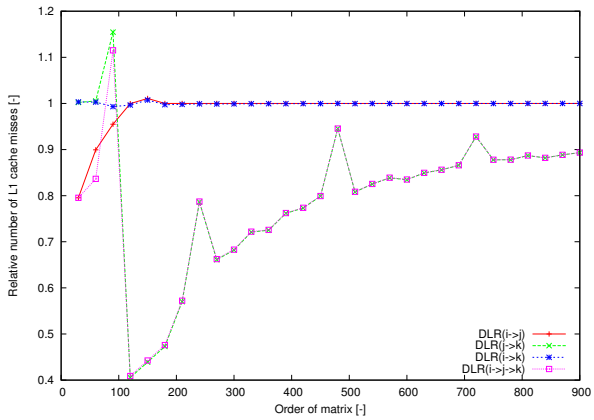

Fig. 5. Relative number of cache misses during MMM_STD for L1 cache

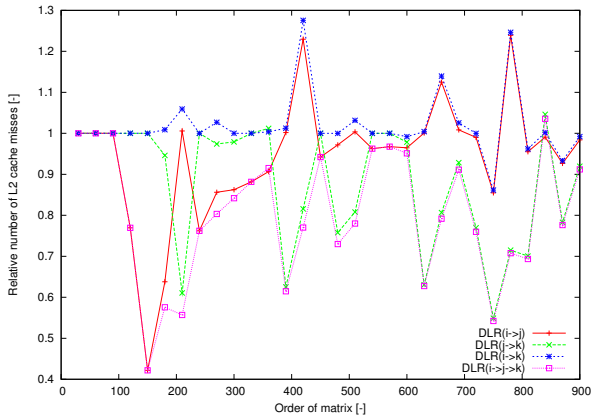

Fig. 6. Relative number of cache misses during MMM_STD for L2 cache

C. Evaluation of simplified RD model

1) Analytical cache model for MMM_STD*:* To analyse this algorithm, we omit accesses in array C at code line 7, because they are much less frequent. In this simplified model, the algorithm contains the following types of memory accesses:

- If DLR($i \to j$) is applied, then memory operations with $A[i][k]$ are of type β and memory operations with $B[k][j]$ are of type α.
- If DLR($j \to k$) is applied, then memory operations with $A[i][k]$ are of type α and memory operations with $B[k][j]$ are of type δ.

2) Analytical cache model for SPMMM_CSR*:* Analysis of cache behaviour and DLR effects for this algorithm are beyond the scope of the compiler due to its irregular memory pattern.

3) An example of evaluation of the cache analytical model: We apply DLR($j \to k$) on the MMM_STD pseudocode. In this case as we stated above, memory operations with $A[i][k]$ are of type α and memory operations with $B[k][j]$ are of type δ.

Firstly, we must count how many iterations of the j-loop can reside in the cache. From the types of memory operations (Eq. (2)), we can derive that

$$SCMO(A[i][k]) = S_{\mathrm{D}}/B_{\mathrm{S}}, \quad PDLR(A[i][k]) = 1.$$

$$SCMO(B[k][j]) = 1, \quad PDLR(B[k][j]) = 1 - S_{\mathrm{D}}/B_{\mathrm{S}}.$$

So, the number of iterations is (from cache parameters in Eq. (1)

$$N_{\mathrm{iter}} = \frac{DC_{\mathrm{S}}}{B_{\mathrm{S}}(1 + S_{\mathrm{D}}/B_{\mathrm{S}})}.$$

The number of cache misses saved by DLR(k, j) per one iteration of the j-loop (Eq. (4)) is $\mu_{\mathrm{saved}} = N_{\mathrm{iter}}$.

The total number of cache misses saved by DLR($j \to k$) during one execution of the MMM_STD pseudocode is

$$\text{total } \mu_{\mathrm{saved}} = n^2 N_{\mathrm{iter}}.$$

For the given cache configuration, it gives the following results:

- for L1 cache: $N_{\mathrm{iter}} = 228$.
- for L2 cache: $N_{\mathrm{iter}} = 3640$.

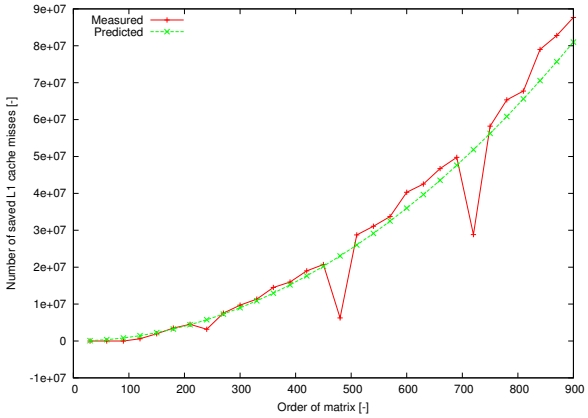

Fig. 7. Comparison of the numbers of estimated and measured cache misses (μ_{saved}) saved by the DLR during the execution of MMM_STD for L1 cache.

Comparisons of the numbers of estimated and measured cache misses are shown in Figures 7 and 8.

4) Discussion of the precision of the simplified RD model: Our analytical model is derived from the RD, which is based on fully-associative cache memory assumption. This assumption is the main source of errors in predictions. The errors are higher for L2 caches due to their lower associativity.

D. Evaluation of combination of DLR and loop tiling

We have also measured the performance and cache utilization for pseudocode MMM_STD with loop tiling and effects of the DLR transformation on this code. Graphs on Figures 9 and 10 illustrate the fact that loop tiling can greatly improve the cache utilization. On the other hand, the tiling factor must be chosen very carefully, because the number of cache misses grows quickly with the distance of the tiling factor from the

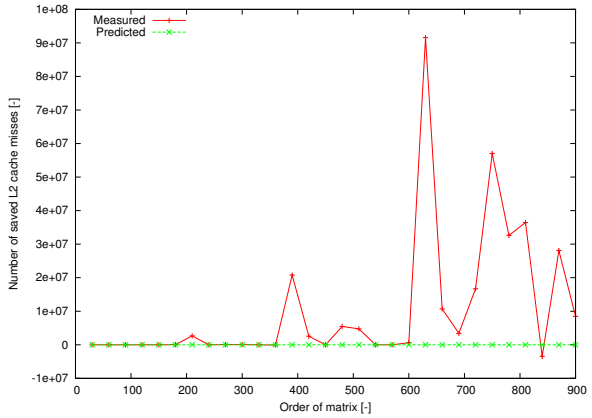

Fig. 8. Comparison of the numbers of estimated and measured cache misses (μ_{saved}) saved by the DLR during the execution of MMM_STD for L2 cache.

optimal value. When the DLR is applied, the growth is more smooth, so the code is less sensitive to the tiling factor value. Hence, the DLR technique is useful in cases when it is hard to predict a good value for the tiling factor.

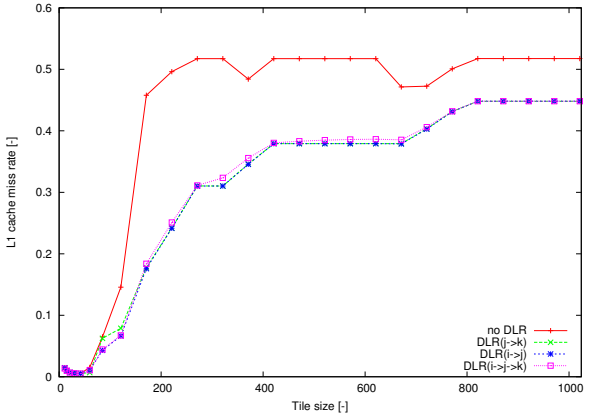

Fig. 9. The L1 miss rate for MMM_STD code with loop tiling (for n=1024) for different values of the tile size.

E. Evaluation of the DLR for the SPMMM_CSR code

The SPMMM_CSR code is a simple example of an irregular code. For the testing purposes, we always generate five sparse matrices with random locations of nonzero elements with given properties (order of matrix, number of nonzero elements or density). The average value of these five measurements were taken as a result. In this code, the memory access pattern is hard to predict on the compiler level and loop tiling is excluded. Thus the DLR is usable and the application of this technique can save reasonably large number of cache misses (see Figures 11,12, and 13).

VII. Automatic compiler support of the DLR

The DLR transformation brings new possibilities to optimize nested loops.

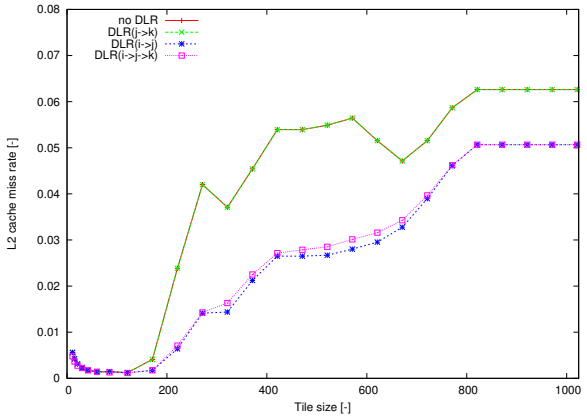

Fig. 10. The L2 miss rate for MMM_STD code with loop tiling (for n=1024) for different values of the tile size.

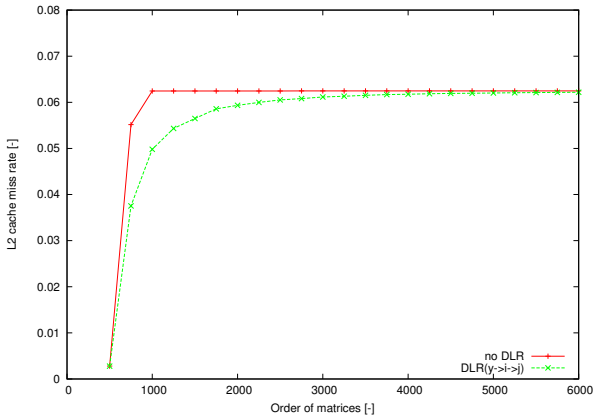

Fig. 11. The L1 and L2 miss rate for SPMMM_CSR algorithm (for $density(A) = 7\%$ and $density(B) = 21\%$)

A. A proposed algorithm of automatic compiler support of the DLR

Let $\mathcal{L}_{1\ldots b}$ represent a hierarchy of immediately nested loops ($\mathcal{L}_1$ is the outermost loop, $\mathcal{L}_b$ is the innermost loop). The control variable for the loop $\mathcal{L}_i$ is denoted by $\mathcal{C}_i$. We propose the following function that returns a list of loop numbers that can profit from the DLR application and that can be implemented into compiler to support the DLR application automatically.

1: **procedure** DLR_APPLICATION(in $b, \mathcal{L}, \mathcal{C}$)
2: $res = []$;
3: **for** $i \leftarrow 1, b-1$ **do** ▷ here we consider application of DLR($\mathcal{C}_i \rightarrow \mathcal{C}_{i+1}$)
4: **if** this DLR application is possible **then**
5: compute μ_{saved} from the proposed cache model;
6: compute overhead of this DLR application;
7: **if** this DLR application pays-off **then**
8: add i to the res;
9: **return** res;

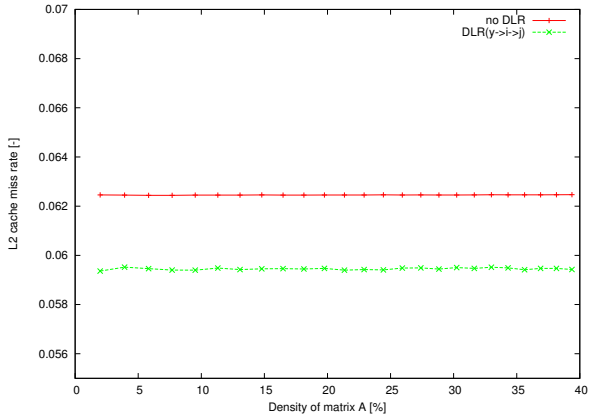

Fig. 12. The L2 miss rate for algorithm SPMMM_CSR (n=2200 and $density(B) = 17\%$)

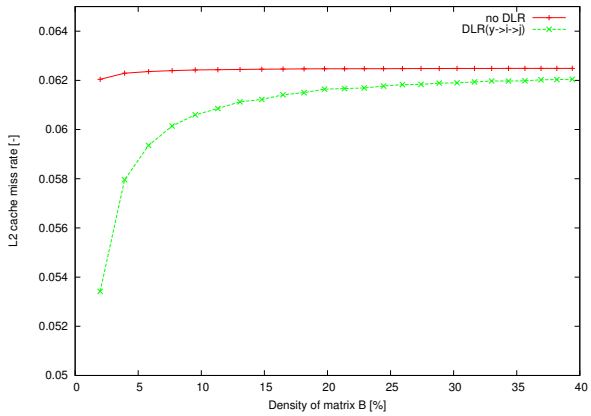

Fig. 13. The L2 miss rate for algorithm SPMMM_CSR (n=3700 and $density(A) = 10\%$)

If this function returns empty list, then DLR does not pay-off for any loop in $\mathcal{L}$. In other case, it returns a list (res) of loop number x such that the DLR should be applied to $\mathcal{L}_x$, i.e., DLR($\mathcal{C}_x \rightarrow \mathcal{C}_{x+1}$) to increase the code performance.

B. Discussion of applicability of the DLR inside compilers

The function in Section VII-A is very general. The real incorporation of the DLR into existing compilers (like GCC or LLVM) must address more issues:

- Where can be the DLR applied? The DLR can be applied on the nested reversible loops. This condition can be easily checked by the compiler.
- Where should be DLR applied? The DLR should be applied on a pair or triple of loops that causes its maximal effect (mentioned in Section III-C). This compiler decision is very similar as for loop tiling.
- Has DLR significant effect? Yes. In most cases, higher speedups are achieved by loop unrolling or loop tiling. But the DLR can be combined with these techniques (see Section VI-D) and also the DLR can be applied on some codes where loop tiling could not (for example sparse matrix operations).

VIII. Conclusions

We have described a new code transformation technique, the dynamic loop reversal, whose goal is to improve temporal locality. This transformation seems to be very useful for codes with nested loops. We have demonstrated significant performance gains for two basic algorithms from linear algebra.

We have also developed a probabilistic analytical model for this transformation and compared the numbers of measured cache misses and the numbers of cache misses estimated by the model. The inaccuracies of the model are due to some simplifying assumptions.

This work is to contribute to the development of more efficient compiler techniques.
