Dear Reader, it is our pleasure to present to you Proceedings of the 2014 Federated Conference on Computer Science and Information Systems (FedCSIS), which took place in Warsaw, Poland, on September 7–10, 2014. Each of the papers, found in this volume, was refereed by at least two referees and the acceptance rate of full (regular) papers was 34.88% (150 papers out of 430 submissions).

FedCSIS 2014 was organized by the Polish Information Processing Society (Mazowsze Chapter), Warsaw University of Technology, Wrocław University of Economics and Systems Research Institute Polish Academy of Sciences. FedCSIS was organized in technical cooperation with: IEEE Computer Society, IEEE Region 8, Computer Society Chapter Poland, Gdańsk Computer Society Chapter, Poland, Polish Chapter of the IEEE Computational Intelligence Society (CIS), ACM Special Interest Group on Applied Computing, International Federation for Information Processing (IFIP), European Alliance for Innovation (EAI), Łódź ACM Chapter, Informatics Europe, Asociación de Técnicos de Informática, Committee of the Computer Science of the Polish Academy of Sciences, Polish Society for Business Informatics, Polish Chamber of Information Technology and Telecommunications, Polish Chamber of Commerce for High Technology, Mazovia Cluster ICT and Eastern Cluster ICT Poland. Furthermore, the 9th International Symposium Advances in Artificial Intelligence and Applications (AAIA'14) was organized in technical cooperation with: International Rough Set Society, International Fuzzy Systems Association and Polish Neural Networks Society.

FedCSIS 2014 consisted of the following events:

- **AAIA'14—9th International Symposium Advances in Artificial Intelligence and Applications**
  - AIMA'14 – 4th International Workshop on Artificial Intelligence in Medical Applications
  - ASIR'14 – 4th International Workshop on Advances in Semantic Information Retrieval
  - CEIM'14 – 1st Complex Events and Information Modelling
  - WCO'14 – 7th Workshop on Computational Optimization
- **CSS—Computer Science & Systems**
  - CANA'14 – 7th Computer Aspects of Numerical Algorithms
  - MMAP'14 – 7th International Symposium on Multimedia Applications and Processing
  - ScoDiS-LaSCoG'14 – 2nd Workshop on Scalable Computing in Distributed Systems and 7th Workshop on Large Scale Computations on Grids
- **ECRM—Education, Curricula & Research Methods**
  - E2LP Workshop Application of Innovative Teaching Methods in Embedded Engineering
  - ISEC'14 – Information Systems Education & Curricula Workshop
- **iNetSApp—Innovative Network Systems and Applications**
  - EAIS'14 – Emerging Aspects in Information Security
  - SoFAST-WS'14 – 3rd International Symposium on Frontiers in Network Applications, Network Systems and Web Services
  - WSN'14 – 3rd International Conference on Wireless Sensor Networks
- **IT4MBS—Information Technology for Management, Business & Society**
  - ABICT'14 – 5th International Workshop on Advances in Business ICT
  - AITM'14 – 12th Conference on Advanced Information Technologies for Management
  - ISM'14 – 9th Conference on Information Systems Management
  - IT4L'14 – 3rd Workshop on Information Technologies for Logistics
  - KAM&AI4KM'14 – 20th Conference on Knowledge Acquisition and Management and 2nd Workshop on Artificial Intelligence for Knowledge Management
- **Joint Agent-oriented Workshops in Synergy (JAWS)**
  - MAS&M'14 – International Workshop on Multi-Agent Systems and Simulation
  - SEN-MAS'14 – 3rd International Workshop on Smart Energy Networks & Multi-Agent Systems
- **SSD&A—Software Systems Development & Applications**
  - ATSE'14—5th International Workshop Automating Test Case Design, Selection and Evaluation
  - MDASD'14 – 3rd Workshop on Model Driven Approaches in System Development

Furthermore, an AAIA'14 Data Mining Competition, focused on key risk factors for the Polish State Fire Service has been organized. This competition was an integral part of the 1st Complex Events and Information Modeling workshop, while its results constitute a separate section in these proceedings. Awards for the winners of the contest were sponsored by: Dituel Ltd. and F&K Consulting Engineers Ltd.

Each event constituting FedCSIS had its own Organizing and Program Committee. We would like to express our warmest gratitude to members of all of them for their hard work attracting and later refereeing 430 submissions.

FedCSIS 2014 was organized under the auspices of Prof. Lena Kolarska-Bobińska, Minister of Science and Higher Education, Dr Rafał Trzaskowski, Minister of Administration and Digitization, Prof. Michał Kleiber, President of the Polish Academy of Sciences, Major General Wiesław Leśniakiewicz, Chief Commandant of the State Fire Service, Prof. Hanna Gronkiewicz-Waltz, Mayor of the Capital City of Warsaw, Prof. Jan Szmidt, Rector of Warsaw University of Technology, Gen. Prof. Zygmunt Mierczyk, Rector of Military Technical Academy, and Prof. Andrzej Gospodarowicz, Rector of Wroclaw University of Economics.

FedCSIS was sponsored by the Ministry of Science and Higher Eduction, Intel, Orange Polska S.A. and Samsung.

***Abstract*—Fog Computing is a paradigm that extends Cloud computing and services to the edge of the network. Similar to Cloud, Fog provides data, compute, storage, and application services to end-users. In this article, we elaborate the motivation and advantages of Fog computing, and analyse its applications in a series of real scenarios, such as Smart Grid, smart traffic lights in vehicular networks and software defined networks. We discuss the state-of-the-art of Fog computing and similar work under the same umbrella. Security and privacy issues are further disclosed according to current Fog computing paradigm. As an example, we study a typical attack, man-in-the-middle attack, for the discussion of security in Fog computing. We investigate the stealthy features of this attack by examining its CPU and memory consumption on Fog device.**

***Index Terms*—Fog Computing, Cloud Computing, Internet of Things, Software Defined Networks.**

I. Introduction

CISCO recently delivered the vision of fog computing to enable applications on billions of connected devices, already connected in the Internet of Things (IoT), to run directly at the network edge [1]. Customers can develop, manage and run software applications on Cisco IOx framework of networked devices, including hardened routers, switches and IP video cameras. Cisco IOx brings the open source Linux and Cisco IOS network operating system together in a single networked device (initially in routers). The open application environment encourages more developers to bring their own applications and connectivity interfaces at the edge of the network. Regardless of Cisco's practices, we first answer the questions of what the Fog computing is and what are the differences between Fog and Cloud.

In Fog computing, services can be hosted at end devices such as set-top-boxes or access points. The infrastructure of this new distributed computing allows applications to run as close as possible to sensed actionable and massive data, coming out of people, processes and thing. Such Fog computing concept, actually a Cloud computing close to the 'ground', creates automated response that drives the value.

Both Cloud and Fog provide data, computation, storage and application services to end-users. However, Fog can be distinguished from Cloud by its proximity to end-users, the dense geographical distribution and its support for mobility [2]. We adopt a simple three level hierarchy as in Figure 1.

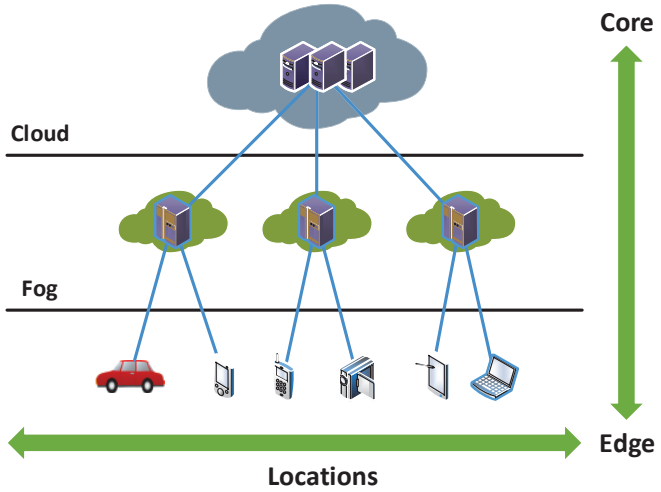

Fig. 1. Fog between edge and cloud.

In this framework, each smart thing is attached to one of Fog devices. Fog devices could be interconnected and each of them is linked to the Cloud.

In this article, we take a close look at the Fog computing paradigm. The goal of this research is to investigate Fog computing advantages for services in several domains, such as Smart Grid, wireless sensor networks, Internet of Things (IoT) and software defined networks (SDNs). We examine the state-of-the-art and disclose some general issues in Fog computing including security, privacy, trust, and service migration among Fog devices and between Fog and Cloud. We finally conclude this article with discussion of future work.

II. Why Do We Need Fog?

In the past few years, Cloud computing has provided many opportunities for enterprises by offering their customers a range of computing services. Current "pay-as-you-go" Cloud computing model becomes an efficient alternative to owning and managing private data centres for customers facing Web applications and batch processing [3]. Cloud computing frees the enterprises and their end users from the specification of many details, such as storage resources, computation limitation and network communication cost. However, this bliss becomes

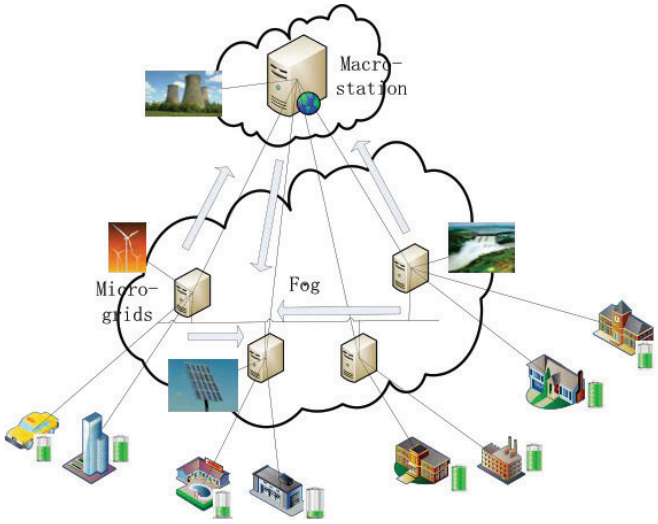

Fig. 2. Fog computing in smart grid.

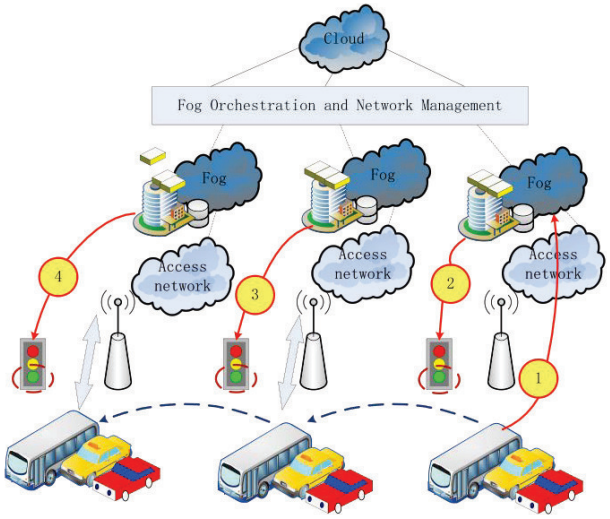

Fig. 3. Fog computing in smart traffic lights and connected vehicles.

a problem for latency-sensitive applications, which require nodes in the vicinity to meet their delay requirements [2]. When techniques and devices of IoT are getting more involved in people's life, current Cloud computing paradigm can hardly satisfy their requirements of mobility support, location awareness and low latency.

Fog computing is proposed to address the above problem [1]. As Fog computing is implemented at the edge of the network, it provides low latency, location awareness, and improves quality-of-services (QoS) for streaming and real time applications. Typical examples include industrial automation, transportation, and networks of sensors and actuators. Moreover, this new infrastructure supports heterogeneity as Fog devices include end-user devices, access points, edge routers and switches. The Fog paradigm is well positioned for real time big data analytics, supports densely distributed data collection points, and provides advantages in entertainment, advertising, personal computing and other applications.

III. What Can We Do With Fog?

We elaborate on the role of Fog computing in the following six motivating scenarios. The advantages of Fog computing satisfy the requirements of applications in these scenarios.

Smart Grid: Energy load balancing applications may run on network edge devices, such as smart meters and micro-grids [4]. Based on energy demand, availability and the lowest price, these devices automatically switch to alternative energies like solar and wind. As shown in Figure 2, Fog collectors at the edge process the data generated by grid sensors and devices, and issue control commands to the actuators [2]. They also filter the data to be consumed locally, and send the rest to the higher tiers for visualization, real-time reports and transactional analytics. Fog supports ephemeral storage at the lowest tier to semi-permanent storage at the highest tier. Global coverage is provided by the Cloud with business intelligence analytics.

Smart Traffic Lights and Connected Vehicles: Video camera that senses an ambulance flashing lights can automatically change street lights to open lanes for the vehicle to pass through traffic. Smart street lights interact locally with sensors and detect presence of pedestrian and bikers, and measure the distance and speed of approaching vehicles. As shown in Figure 3, intelligent lighting turns on once a sensor identifies movement and switches off as traffic passes. Neighbouring smart lights serving as Fog devices coordinate to create green traffic wave and send warning signals to approaching vehicles [2]. Wireless access points like WiFi, 3G, road-side units and smart traffic lights are deployed along the roads. Vehicles-to-Vehicle, vehicle to access points, and access points to access points interactions enrich the application of this scenario.

Wireless Sensor and Actuator Networks: Traditional wireless sensor networks fall short in applications that go beyond sensing and tracking, but require actuators to exert physical actions like opening, closing or even carrying sensors [2]. In this scenario, actuators serving as Fog devices can control the measurement process itself, the stability and the oscillatory behaviours by creating a closed-loop system. For example, in the scenario of self-maintaining trains, sensor monitoring on a train's ball-bearing can detect heat levels, allowing applications to send an automatic alert to the train operator to stop the train at next station for emergency maintenance and avoid potential derailment. In lifesaving air vents scenario, sensors on vents monitor air conditions flowing in and out of mines and automatically change air-flow if conditions become dangerous to miners.

Decentralized Smart Building Control: The applications of this scenario are facilitated by wireless sensors deployed to measure temperature, humidity, or levels of various gases in the building atmosphere. In this case, information can be exchanged among all sensors in a floor, and their readings can be combined to form reliable measurements. Sensors will use distributed decision making and activation at Fog devices to

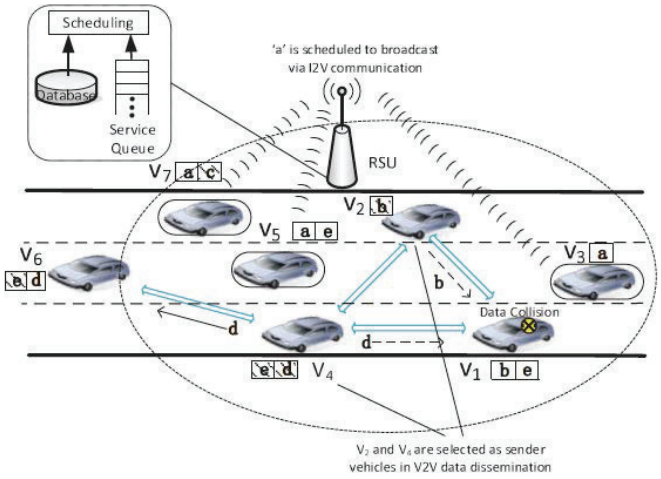

Fig. 4. Fog computing in SDN in vehicular networks [6].

react to data. The system components may then work together to lower the temperature, inject fresh air or open windows. Air conditioners can remove moisture from the air or increase the humidity. Sensors can also trace and react to movements (e.g, by turning light on or off). Fog devices could be assigned at each floor and could collaborate on higher level of actuation. With Fog computing applied in this scenario, smart buildings can maintain their fabric, external and internal environments to conserve energy, water and other resources.

IoT and Cyber-physical systems (CPSs): Fog computing based systems are becoming an important class of IoT and CPSs. Based on the traditional information carriers including Internet and telecommunication network, IoT is a network that can interconnect ordinary physical objects with identified addresses [5]. CPSs feature a tight combination of the system's computational and physical elements. CPSs also coordinate the integration of computer and information centric physical and engineered systems. IoT and CPSs promise to transform our world with new relationships between computer-based control and communication systems, engineered systems and physical reality. Fog computing in this scenario is built on the concepts of embedded systems in which software programs and computers are embedded in devices for reasons other than computation alone. Examples of the devices include toys, cars, medical devices and machinery. The goal is to integrate the abstractions and precision of software and networking with the dynamics, uncertainty and noise in the physical environment. Using the emerging knowledge, principles and methods of CPSs, we will be able to develop new generations of intelligent medical devices and systems, 'smart' highways, buildings, factories, agricultural and robotic systems.

Software Defined Networks (SDN): As shown in Figure 4, Fog computing framework can be applied to implement the SDN concept for vehicular networks. SDN is an emergent computing and networking paradigm, and became one of the most popular topics in IT industry [7]. It separates control and data communication layers. Control is done at a centralized server, and nodes follow communication path decided by the server. The centralized server may need distributed implementation. SDN concept was studied in WLAN, wireless sensor and mesh networks, but they do not involve multi-hop wireless communication, multi-hop routing. Moreover, there is no communication between peers in this scenario. SDN concept together with Fog computing will resolve the main issues in vehicular networks, intermittent connectivity, collisions and high packet loss rate, by augmenting vehicle-to-vehicle with vehicle-to-infrastructure communications and centralized control. SDN concept for vehicular networks is first proposed in [6].

IV. State-of-the-Art

A total of eight articles were identified on the concept of Fog computing [1], [2], [8], [9], [10], [11], [12], [13], [14]. There are some other concepts, not declared as Fog computing, fall under the same umbrella. We will also discuss these work in the subsection of similar work.

A. Related Work

K. Hong et al. proposed mobile Fog in [11]. This is a high level programming model for geo-spatially distributed, large-scale and latency-sensitive future Internet applications. Following the logical structure shown in Figure 1, low-latency processing occurs near the edge while latency-tolerant large-scope aggregation is performed on powerful resources in the core of the network (normally the Cloud). Mobile Fog consists of a set of event handlers and functions that an application can call. Mobile Fog model is not presented as generic model, but is built for particular application, while leaving out functions that deal with technical challenges of involved image processing primitives. Fog computing approach reduces latency and network traffic.

B. Ottenwalder et al. presented a placement and migration method for Cloud and Fog resources providers [13]. It ensures application-defined end-to-end latency restrictions and reduces the network utilization by planning the migration ahead of time. They also show how the application knowledge of the complex event processing system can be used to reduce the required bandwidth of virtual machines during their migration. Network intensive operators are placed on distributed Fog devices while computationally intensive operators are in the Cloud. Migration costs are amortized by selecting migration targets that ensure a low expected network utilization for a sufficiently long time. This work does not optimize workload mobility because Fog devices are also able to carry computationally intensive tasks. It also does not optimize the size of control information or mobility overhead, and does not describe network control policies for finding optimal paths for different applications.

In [11], K. Hong et al. proposed an opportunistic spatio-temporal event processing system that uses prediction-based continuous query handling. Their system predicts future query regions for moving consumers and starts processing events early so that the live situational information is available when

the consumer reaches the future location. Historical events for a location are processed before the mobile user arrives at that location. Live event processing begins at the moment the user arrives. To mitigate large speed of mobile user, authors propose using parallel resources to enable pipeline processing of future locations in several time steps looking ahead. Further, they proposed taking several predictions for each time step and opportunistically compute the events for all of those locations. When the user arrives at that time, the prediction among those that is closest to truth will be selected and its events returned.

J. Zhu et al. applied existing methods for web optimization in a novel manner [14]. Within Fog computing context, these methods can be combined with unique knowledge that is only available at the Fog devices. More dynamic adaptation to the user's conditions can also be accomplished with network edge specific knowledge. As a result, a user's Web page rendering performance is improved beyond that achieved by simply applying those methods at the Web server.

In the mobile Cloud concept [12], pervasive mobile devices share their heterogeneous resources and support services. Neighbouring nodes in a local network form a group called a local Cloud. Nodes share their resources with other nodes in the same local Cloud. A local resource coordinator serving as Fog device is elected from the nodes in each local Cloud. The work [12] proposed an architecture and mathematical framework for heterogeneous resource sharing based on the key idea of service-oriented utility functions. Normally heterogeneous resources are quantified in disparate scales, such as power, bandwidth and latency. However, authors in [12] present a unified framework where all these quantities are equivalently mapped to "time" resources. They formulate optimization problems for maximizing the sum and product of the utility functions, and solve them via convex optimization approaches.

The work [10] first reviews the reliability requirements of Smart Grid, Cloud, and sensors and actuators. This work then combines them towards reliable Fog computing. However, it only concludes that building Fog computing based projects is challenging and does not offer any novel concept for the reliability of the network of smart devices in the Fog computing paradigm.

B. Similar Work

BETaaS [15] proposed replacing Cloud as the resident for machine-to-machine applications by 'local Cloud' of gateways. The 'local Cloud' is composed of devices that provide smart things with connectivity to the Internet, such as smart phones, home routers and road-side units. This enables applications that are limited in time and space to require simple and repetitive interactions. It also enables the applications to respond in consistent manner.

Demand Response Management (DRM) is a key component in the smart grid to effectively reduce power generation costs and user bills. The work [16] addressed the DRM problem in a network of multiple utility companies and consumers where every entity is concerned about maximizing its own benefit. In their model, utility companies communicate with each other, while users receive price information from utility companies and transmit their demand to them. They propose a Stackelberg game [17] between utility companies and end-users to maximize the revenue of each utility company and the payoff of each user. Stackelberg equilibrium of the game has a unique solution. They develop a distributed algorithm which converges to the equilibrium with only local information available for both utility companies and end-users. Utility companies play a non-cooperative game. They inform users whenever they change price, and users then update their demand vectors and inform utility companies. This iterates until convergence. The main drawback of this algorithm is a significant communication overhead between users and utility companies. Though DRM helps to facilitate the reliability of power supply, the smart grid can be susceptible to privacy and security issues because of communication links between the utility companies and the consumers. They study the impact of an attacker who can manipulate the price information from the utility companies, and propose a scheme based on the concept of shared reserve power to improve the grid reliability and ensure its dependability.

The work [18] investigated how energy consumption may be optimized by taking into consideration the interaction between both parties. The energy price model is a function of total energy consumption. The objective function optimizes the difference between the value and cost of energy. The power supplier pulls consumers in a round-robin fashion, and provides them with energy price parameter and current consumption summary vector. Each user then optimizes his own schedule and reports it to the supplier, which in turn updates its energy price parameter before pulling the next consumers. This interaction between the power company and its consumers is modelled through a two-step centralized game, based on which the work [18] proposed the Game-Theoretic Energy Schedule (GTES) method. The objective of the GTES method is to reduce the peak to average power ratio by optimizing the users energy schedules.

The closest work for SDN in vehicular networks are several implementations in wireless sensor network and mesh networks [19], [20]. Moreover, B. Zhou et al. studied adaptive traffic light control for smoothing vehicles' travel and maximizing the traffic throughout for both single and multiple lanes [21], [22]. In addition, the work [23] proposed a three-tier structure for traffic light control. First, an electronic toll collection (ETC) system is employed for collecting road traffic flow data and calculating the recommended speed. Second, radio antennas are installed near the traffic lights. Third, road traffic flow information can be obtained by wireless communication between the antennas and ETC devices. A branch-and-bound-based real-time traffic light control algorithm is designed to smooth vehicles' travels.

V. Security and Privacy in Fog Computing

Security and privacy issues were not studied in the context of fog computing. They were studied in the context of smart grids [24] and machine-to-machine communications [25].

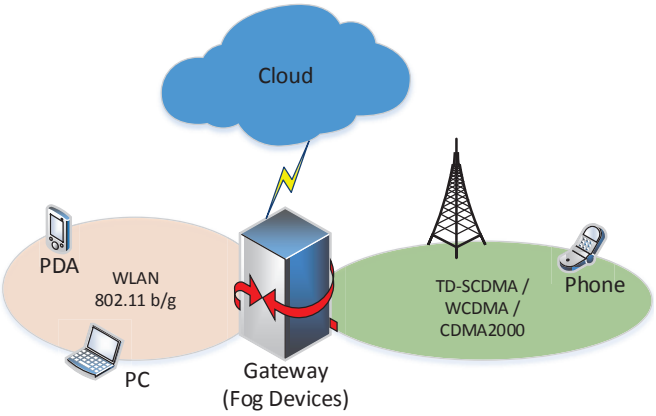

Fig. 5. A scenario for a man-in-the-middle attack towards Fog.

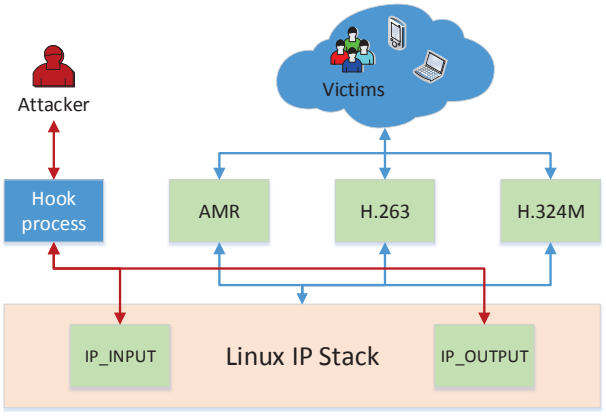

Fig. 6. A system design of man-in-the-middle-attack in Fog.

There are security solutions for Cloud computing. However, they may not suit for Fog computing because Fog devices work at the edge of networks. The working surroundings of Fog devices will face with many threats which do not exist in well managed Cloud. In this section, we discuss the security and privacy issues in Fog Computing.

A. Security Issues

The main security issues are authentication at different levels of gateways as well as (in case of smart grids) at the smart meters installed in the consumer's home. Each smart meter and smart appliance has an IP address. A malicious user can either tamper with its own smart meter, report false readings, or spoof IP addresses. There are some solutions for the authentication problem. The work [26] elaborated public key infrastructure (PKI) based solutions which involve multicast authentication. Some authentication techniques using Diffie-Hellman key exchange have been discussed in [27]. Smart meters encrypt the data and send to the Fog device, such as a home-area network (HAN) gateway. HAN then decrypts the data, aggregates the results and then passes them forward.

Intrusion detection techniques can also be applied in Fog computing [28]. Intrusion in smart grids can be detected using either a signature-based method in which the patterns of behaviour are observed and checked against an already existing database of possible misbehaviours. Intrusion can also be captured by using an anomaly-based method in which an observed behaviour is compared with expected behaviour to check if there is a deviation. The work [29] develops an algorithm that monitors power flow results and detects anomalies in the input values that could have been modified by attacks. The algorithm detects intrusion by using principal component analysis to separate power flow variability into regular and irregular subspaces.

B. An Example: Man-in-the-Middle Attack

Man-in-the-middle attack has potential to become a typical attack in Fog computing. In this subsection, we take man-in-the-middle attack as an example to expose the security problems in Fog computing. In this attack, gateways serving as Fog devices may be compromised or replaced by fake ones [30]. Examples are KFC or Star Bar customers connecting to malicious access points which provide deceptive SSID as public legitimate ones. Private communication of victims will be hijacked once the attackers take the control of gateways.

1) Environment Settings of Stealth Test: Man-in-the-middle attack can be very stealthy in Fog computing paradigm. This type of attack will consume only a small amount of resources in Fog devices, such as negligible CPU utilization and memory consumption. Therefore, traditional anomaly detection methods can hardly expose man-in-the-middle attack without noticeable features of this attack collected from the Fog. In order to examine how stealthy the man-in-the-middle attack can be, we implement an attack environment shown in Figure 5. In this scenario, a 3G user sends a video call to a WLAN user. Since the man-in-the-middle attack requires to control the communication between the 3G user and the WLAN user, the key of this attack is to compromise the gateway which serves as the Fog device.

Two steps are needed to realize the man-in-the-middle attack for the stealth test. First, we need to compromise the gateway, and second, we insert malicious code into the compromised system. For susceptible gateways, we can either refresh the ROM of a normal gateway or place a fake active point in

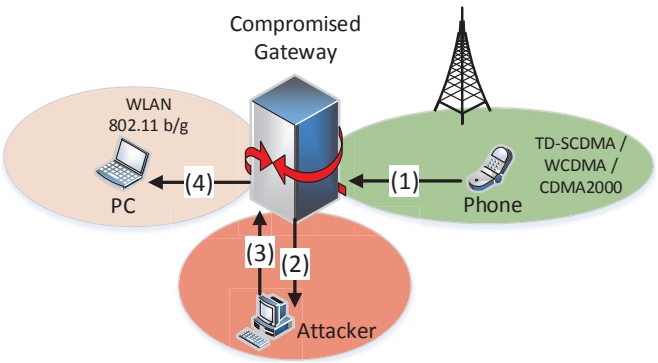

Fig. 7. The hijacked communication in Fog (e.g. from phone to PC).

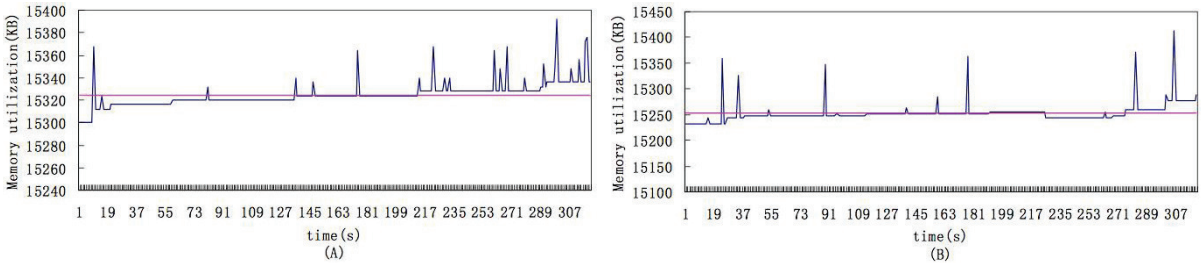

Fig. 8. Memory Consuming of man-in-the-middle-attack in Fog.

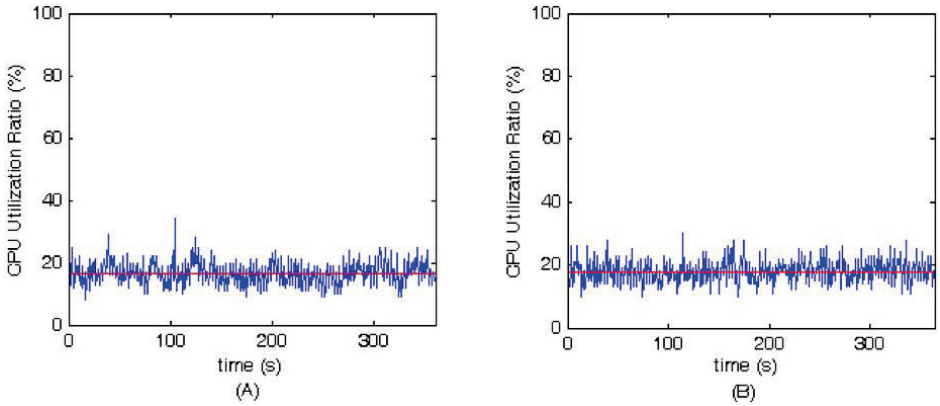

Fig. 9. CPU consuming of man-in-the-middle-attack in Fog.

the environment. Both methods can be easily implemented in the real world, such as in the KFC or Star Bar environments. In our experiment, we choose the former and use Broadcom BCM5354 as the gateway [31]. This device has a high-performance MIPS32 processor, IEEE 802.11 b/g MAC/PHY and USB2.0 controller. Video communication is set up on BCM5354 between a 3G mobile phone and a laptop which adopts Wifi for connection. We refresh the ROM of BCM4354 and update its system to the open-source Linux kernel 2.4.

In order to hijack and replay victims' video communication, we insert a hook program into the TCP/IP stack of the compromised system. Hook is a technique of inserting code into a system call in order to alter it [32]. The typical hook works by replacing the function pointer to the call with its own, then once it is done doing its processing, it will then call the original function pointer. The system structure is implemented in Figure 6. We further employ the relevant APIs and data structures in the system to control the gateway device, such as boot strap, diagnostics and initialization code. The IP packets from WLAN will be transferred to and processed in 3G related modules. We plug a 3G USB modem on BCM5354 device, on which we implement H.324M for video and audio tunnel with 3G CS. H.263 and AMR functions are also implemented as the video and audio codec modules in the system.

2) Work Flow of Man-in-the-Middle Attack: The communication between 3G and WLAN needs a gateway to translate the data of different protocols into the suitable formats. Therefore, all the communication data will firstly arrive at the gateway and then be forwarded to other receivers.

In our experiment, the man-in-the-middle attack is divided into four steps. We illustrate the hijacked communication from 3G to WLAN in Figure 7. In the first two steps, the embedded hook process of the gateway redirects the data received from the 3G user to the attacker. The attacker replays or modifies the data of the communication at his or her own computer, and then send the data back to the gateway. In the final step, the gateway forwards the data from the attacker to the WLAN user. In fact, the communication from the WLAN user will also be redirected to the attacker at first, and then be forwarded by the hook in the gateway to the 3G user. We can see clearly from Figure 7 that the attacker can monitor and modify the data sent from the 3G user to the WLAN user in the 'middle' of the communication.

3) Results of Stealth Test: Traditional anomaly detection techniques rely on the deviation of current communication from the features of normal communication. These features include memory consumption, CPU utilization, bandwidth usage, etc. Therefore, to study the stealth of man-in-the-middle attack, we examine the memory consumption and the CPU utilization of gateway during the attack. If man-in-the-middle attack does not greatly change the features of the communication, it can be proofed to be a stealthy attack. For simplicity, we assume the attacker will only replay the data at his or her own computer but will not modify the data.

Firstly, we compare the memory utilization of gateway before and after a video call tunnel is built in our experiment.

The results are shown in Figure 8, and the red line in plots indicates the average amount of memory consumption. We can see clearly that man-in-the-middle attack does not largely influence the video communication. In Figure 8(A), the average value is 15232 K Bytes, while after we build the video tunnel on gateway, the memory consumption reaches 15324.8 K Bytes in Figure 8(B). Secondly, we show the CPU consumption of gateway in Figure 9. Based on the results in Figure 9, we can also see that man-in-the-middle attack does not largely influence the video communication. In the Figure 8(A), the average value is 16.6704%, while after the video tunnel is built, the CPU consumption reaches 17.9260%. We therefore conclude that man-in-the-middle attack can be very stealthy in Fog computing because of the negligible increases in both memory consumption and CPU utilization in our experiments.

Man-in-the-middle attack is simple to launch but difficult to be addressed. In the real world, it is difficult to protect Fog devices from compromise as the places for the deployment of Fog devices are normally out of religious surveillance. Encrypted communication techniques may also not protect users from this attack since attackers can set up a legitimate terminal and replay the communication without decryption. Particularly, complex encryption and decryption techniques may not be suitable for some scenarios. For example, the encryption and decryption techniques will consume lots of battery power in 3G mobile phones. In fact, this attack is not limited to the scenario of our experiment environment. We can find many applications running in Fog computing are susceptible to man-in-the-middle attack. For example, many Internet users communicate with each other using MSN (Windows Live Massager). The communication data of MSN is normally not encrypted and can be modified in the 'middle'. Future work is needed to address the man-in-the-middle attack in Fog computing.

C. Privacy Issues

In smart grids, privacy issues deal with hiding details, such as what appliance was used at what time, while allowing correct summary information for accurate charging. R. Lu et al. described an efficient and privacy-preserving aggregation scheme for smart grid communications [33]. It uses a super-increasing sequence to structure multi-dimensional data and encrypt the structured data by the homomorphic cryptogram technique. A homomorphic function takes as input the encrypted data from the smart meters and produces an encryption of the aggregated result. The Fog device cannot decrypt the readings from the smart meter and tamper with them. This ensures the privacy of the data collected by smart meters, but does not guarantee that the Fog device transmits the correct report to the other gateways. For data communications from user to smart grid operation center, data aggregation is performed directly on cipher-text at local gateways without decryption, and the aggregation result of the original data can be obtained at the operation center [33]. Authentication cost is reduced by a batch verification technique.

VI. Conclusions and Future Work

We investigate Fog computing advantages for services in several domains, and provide the analysis of the state-of-the-art and security issues in current paradigm. Based on the work of this paper, some innovations in compute and storage may be inspired in the future to handle data intensive services based on the interplay between Fog and Cloud.

Future work will expand on the Fog computing paradigm in Smart Grid. In this scenario, two models for Fog devices can be developed. Independent Fog devices consult directly with the Cloud for periodic updates on price and demands, while interconnected Fog devices may consult each other, and create coalitions for further enhancements.

Next, Fog computing based SDN in vehicular networks will receive due attention. For instance, an optimal scheduling in one communication period, expanded toward all communication periods, has been elaborated in [6]. Traffic light control can also be assisted by the Fog computing concept. Finally, mobility between Fog nodes, and between Fog and Cloud, can be investigated. Unlike traditional data centres, Fog devices are geographically distributed over heterogeneous platforms. Service mobility across platforms needs to be optimized.

***Abstract*—The Smart Grid is the vision underlying the evolution the power grid is currently undergoing. Its pillars are increased efficiency, self-healing, operation automation, and renewable energy integration obtained through real-time control and digitalization of the infrastructure. Thus, an important ingredient—if not the main one—is information technology support for power transmission and distribution. Given the size of the power grid, its pervasiveness, and the need for its availability, it is easy to imagine that any serious ICT infrastructure dealing with it will have to manage a great deal of rapidly forming data. Now the question is whether the amount, diversity, and uses of such data put the smart grid in the category of Big Data applications, followed by the natural question of what is the value of such data. To provide an initial answer to this question, we analyze the current state of data generation of the Dutch grid, its evolution towards a smart grid, and a future realistic scenario. The scenario considered shows that the amount of data generated is comparable to some of today's social media and "classic" Big Data examples.**

***Index Terms*—smart grid; power systems; Big Data**

I. Introduction

THE EVOLUTION of the power grid towards a smart grid is based on a massive deployment of Information and Communication Technology (ICT) in sensing, analyzing and controlling the operations of the power grid, from generation to utilization. This shift to a more information technology-based power grid will require considerable amounts of data to be produced by the sensing equipment, and by the new generation of (smart) meters. Thus, setting a challenge for the current ICT architectures of utilities and electricity distribution companies. If this trend is underway now, it is especially because the diffusion of renewable generation sources at all levels of the power grid calls for timely and precise monitoring of the infrastructure. In addition metering equipment is more affordable and reliable.

If the shift towards a smart digitalized grid is broadly accepted, little is known about the actual data generation potential of the future grid and on the management and utilization of large electricity data streams. The few works in the literature provide only a qualitative analysis of the amount of data that the smart grid is likely to generate with almost no results of quantitative experiences and field tests. To fill such knowledge gap, with the current treatment, we assess the amenability of the Big Data definition to the smart grid considering mainly the volume and velocity features of smart grid data. We perform such assessment by comparing the amount of data produced and transmitted in today's prominent Big Data examples, coming from the areas of social media and Internet based services. For the comparison, we use information coming from the Dutch power grid. The Netherlands has one of the infrastructures with one the highest availability in Europe with the electrical system being in 2012 99,99486% of the time available [1]. Moreover, The Netherlands plans to have a full rollout of smart meters by 2018 and a standard for the information to be read and exchanged by smart meters is currently being finalized.

The rest of the paper is organized as follows: Section II briefly defines the Big Data concept and offers some examples of today's sources of data. Section III provides a description of the concept of smart grid, while Section IV provides a quantitative analysis of the amount of data generated by a smart grid infrastructure with special focus on the Dutch grid as concrete example. A survey of related work is presented in Section V and the concluding remarks complete the paper, Section VI.

II. Big Data Examples

Big Data refers to information systems characterized by having to manage high volumes of data, which is rapidly created and that potentially has added value. It is common practice to refer to the *5Vs* when talking about Big Data. The *5Vs* stand for *Volume, Velocity, Variety, Value and Veracity*: big quantity of information that moves fast on a network; data that are diverse and provide relevant facts (implicit) in the information they carry, while being reliable as data sources.

Communication capacity: The telecom sector has seen an exponential growth in its infrastructure. The Internet alone in the short time span of 7 years (2000-2007) has increased network utilization by 29 times, with the necessity of transmitting 65 exabytes per year (optimally compressed) [2]. Cisco computed a monthly IP traffic of 43 exabyte for 2012 and lead to an almost 30% increase rate till 2016 reaching 110 exabytes/month and 1.3 zettabytes/year [3].

Prominent examples of Big Data today have to do with social media, where billions of users interact by exchanging data in various forms. Let us consider YouTube and Facebook as representative examples of the trend.

978-83-60810-58-3/$25.00

YouTube: YouTube is an on-line user-based broadcasting service where every user can watch and publish videos. Some key-facts numbers from YouTube's statistics[1]: more than 1 billion unique users visit YouTube monthly, over 4 billion hours of video are watched each month on YouTube, and 72 hours of video are uploaded to YouTube every minute.

Facebook: Facebook is the best-known social platform having recently passed the 1 billion users mark. The statistics concerning the amount of data that Facebook deals with are quite impressive: more than 500 terabytes of new data every day, 300 millions photo uploads, 2.7 billions 'Likes' each day[2]. It is then no wonder that with all these data Facebook requires an Hadoop Distributed File System cluster with more than 100 petabytes of physical space.[3]

Many more examples exist. E.g., computational science projects such as the data obtained from the Large Hadron Collider experiments; the astronomic images collected by (radio) telescopes; data generated on stock markets and used, for instance, for algorithmic trading; private businesses having 1 million transactions per hour, such as, Walmart, or the almost 500 transactions per second managed during peaks at Amazon.

III. The Smart Grid

The term smart grid does not yet have a unique definition [4], rather the various stakeholders and scientific disciplines involved have their own point of view on the area. From a physical and technical perspective, the system has always to satisfy the equilibrium between energy supply and demand in order to keep the correct operations and safety of the system. The information flow related to the operations of the grid is the real innovation of the Smart Grid. The grid will become more and more digital with information recorded by the sensors and the digital meters deployed at users' premises and along the grid and power stations. The benefit is to have enriched information of the performance of the system, its stability, and customer consumption. Another important motivation that drives the modernization of the grid lies in the ability to accommodate more renewable sources [5]. With more and more unpredictable (renewable) power sources, the electrical system needs more flexibility in managing the demand and supply equilibrium. One of the mechanisms to achieve such flexibility is through the use of variable electricity tariffs. These tariffs vary even several times per day and are transmitted to the users that are able to react to them by increasing or decreasing their consumption. For example, on a very windy day the wind energy production surges and in order to keep the balance of the grid, tariffs are lowered to incentivize the use of electricity. Naturally, to have such real-time flexibility, information has to be exchanged with the users both in terms of dynamic tariffs and energy used at a given price to enable the accounting.

An essential component in this scenario is the smart meter. It has the same primary duty of the traditional analog meter, but in addition it has a memory to store information, a processor, a digital clock, it can use multiple tariffs, it is able to measure bidirectional power flows (i.e., consumed and produced energy), and it is connected with a telecommunication link to the utility. All these features let us talk today of Advanced Metering Infrastructure (AMI).

TABLE I: 2012 Dutch smart grid data.

Metering	
Metered customers	7,827,350
Installed smart meters	450,000
Smart meter sampling period (min)	86,400 (by law 2 months)
Smart Devices	
Electric vehicles	6,275
Battery packs	N/A
Intelligent appliances per household	0
Grid Infrastructure	
Nodes HV (380/220kV)	36
Nodes MV/LV	155,000

IV. The Smart Grid and Big Data

Taking The Netherlands as our case study, we consider the current and a possible future situation for the power grid, specifically considering the amount of generated data. We have chosen The Netherlands because the electrical system is very reliable, with just an average of 27 minutes downtime per year per customer [1], because it has a modern infrastructure with an unbundled energy market, and because it is going fast towards a digitalization of the electrical system.

A. Volume and Velocity

Volume and velocity are the most two prominent aspects of the transition towards a smart grid.

Metering and Smart Buildings: In the last years in The Netherlands, a compulsory smart meter roll-out had been planned and then canceled due to privacy concerns [6]. Thus, currently smart meters are only partially installed in the country and the approach is first to test the AMI in controlled settings and in pilots before proceeding to a massive roll out, expected to cover the country by 2018.

In our quest for Big Data, we consider the current situation of advancement of the AMI and smart grid in The Netherlands and we compare it to two realistic scenarios of the near future. The current situation is synthesized in Table I. To date, in The Netherlands only about 5% of the meter installations are smart. Furthermore, the data measuring capabilities of the meter is only partially used, since current law mandates that they can only be read once every two months. A number of *smart devices* might also interact and exchange information with the grid about tariffs or the power use. Most notably, electric vehicles, batteries in residential premises and intelligent home appliances contribute to the picture [7]. Weather information represents another essential source in the future smart gird. Knowing the weather in advance allows an home energy management system to forecast how much energy will be produced by user's solar panels or small wind turbines, and the internal needs for heating and cooling.

TABLE II: Near future scenario (e.g., one decade).

Metering	
Metered customers	8,000,000
Installed smart meter	8,000,000
Smart meter sampling period (min)	15
Smart Devices	
Electric vehicles	790,000
Battery packs	45,000
Intelligent appliances per household	10
Grid Infrastructure	
Nodes HV (380/220kV)	45
Nodes MV/LV	158,419

TABLE III: Far future scenario (e.g., four/five decades).

Metering	
Metered customers	9,000,000
Installed smart meter	9,000,000
Smart meter sampling period (min)	5
Smart Devices	
Electric vehicles	3,950,000
Battery packs	135,000
Intelligent appliances per household	20
Grid Infrastructure	
Nodes HV (380/220kV)	60
Nodes MV/LV	178,221

Table II shows a short-medium term scenario for the same objects, when the roll-out of the smart meters will be completed. The 100% penetration is based on the commitment of the European Union to deploy smart meters to at least 80% of all customers (c.f. EU directives 2009/72/EC and 2009/73/EC) and the commitment of the Dutch government. As a sampling period we consider 15 minutes. This is the time interval used in many of the AMI installations and tests (e.g., CenterPoint AMI in Texas.[4] We envision most of the advancements in the adoption of smart devices with almost 800,000 electric vehicles (equal to 10% of the passenger vehicles in 2012), 45,000 battery packs for local energy storage (based on the figures of solar capacity installed till 2011) and the penetration of home intelligent appliances of 10 per metering point (as about half of the average number of appliance per family).

Table III provides a long term vision, say few decades. We consider that the fully digital smart meter infrastructure reaches 9 millions customers throughout the whole country. As sampling period we consider an infrastructure that is closer to real-time measurement with 5 minutes interval. We suppose that smart appliances become the norm, therefore with 20 smart devices on average in each home or office leading to a total of 180 millions devices. The number of electric passenger vehicles reaches 3.95 millions (equal to 50% of the passenger vehicles in 2012), while the battery packs increase threefold. This last assumption is based on the estimate of the increase in distributed generation capacity by three times compared to the 2011 figures.

The Power Grid: Complementary to the users and metering of the electricity, there is the transmission and distribution infrastructure. In the bottom of Tables I, II, and III we report

[4]http://goo.gl/MzGPX

TABLE IV: Data size for various parameters/devices/services in bytes per sample.

Data Use in Metering	**Size**
Consumption only	193
Consumption/production	245
Consumption/production, instantaneous power (3-phase), and current	530
Consumption/production, instantaneous power (3-phase), current, failures, and gas metering	1,100
Data Use in Smart Devices	**Size**
Electric vehicle consumption only	193
Electric vehicle consumption/feed-in	245
Electric vehicle consumption/feed-in, instantaneous power (3-phase), and current	530
Electric vehicle consumption/feed-in, instantaneous power (3-phase), current, failures, and gas metering	1,100
Battery	200
Intelligent appliances	200
Data Use in Weather Forecast	**Size**
Essential weather parameter	13,000
Improved weather parameter	15,000
Advanced weather parameter	20,000

on the current size of the Dutch power grid, size that we do not expect to increase dramatically in the medium-long period. We consider the nodes (e.g., power and transformation station) since these contain the equipment and the sensors that monitor the status of the power assets and the lines. Considering the high voltage, the current number of nodes is provided in the work of Rosas-Casals and Corominas-Murtra [8], whereas the information concerning the medium and low voltage nodes is provided by the various distribution utilities of the Netherlands.[5] For the high voltage grid, we consider a moderate evolution based on the public plans of the transmission operator (TenneT[6]). In considering the evolution, we make the conservative assumption that the ratio between the medium-low voltage nodes and the metered customers is constant and equal to the current ratio. That means that the total number of medium-low voltage nodes is 158,419 and 178,221 in the short term and long term future scenario, respectively.

Data Size: The Dutch Smart Meter requirement document [9] defines the size and function of the information sent. Based on this information we consider the user generated data: data from self generation, failure statistics, additional energy metering (e.g., 3-phase installation, gas metering) as shown on the top of Table IV. In the current situation, the amount of data produced by the Dutch smart grid is extremely limited as shown in Figure 1. The most parsimonious case entails just a yearly amount of about 500 megabytes, while measuring the whole set of parameters requires almost 3 gigabytes.

Things change when considering future scenarios where the diffusion of smart meters, electric vehicles and appliances will be pervasive. As shown in the central part of Table IV, we consider four categories of data generation related to the

[5]http://www.energieleveranciers.nl/netbeheerders/overzicht-netbeheerders
[6]http://www.tennet.eu

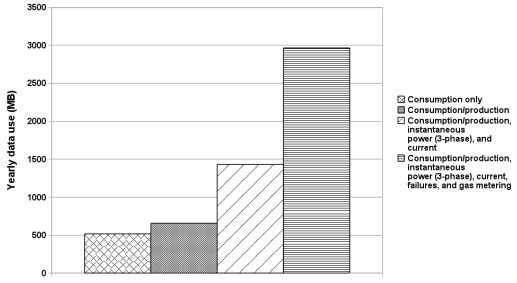

Fig. 1: Current Dutch AMI yearly data generation.

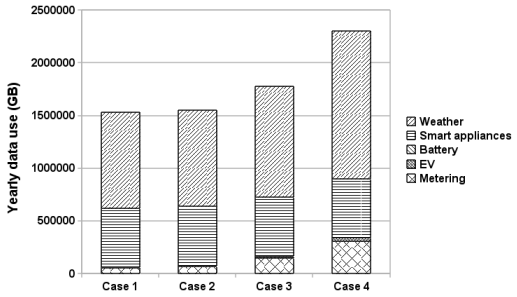

Fig. 2: Near future Dutch smart grid yearly data generation.

electric vehicles. In essence, an electric vehicle is not much different from a house metering point. Another similarity is in the possibility of feeding energy to the grid when required, thus acting as a production unit. In this future scenario, we also consider the interaction with meteorological services that provide weather information and forecast which influences users energy behavior, their energy production units, and the schedule of their appliances. The last three lines of Table IV show the amount of data required by a weather service. The National Oceanic and Atmospheric Administration (NOAA) provides eXtensible Markup Language based information regarding temperature, wind speed, and cloud coverage conditions up to 1 week forecast. The 'improved' and 'advanced' weather service data are considered for improved weather services with meteorological information with fine grain timescale. This granularity of information is essential for reliable forecasting of local production of energy, and therefore needed in the smart grid.

For the big data estimation, we identify four cases. Each case has increasing data quantities as more units are involved. The generated data can come from:

- *Case 1:* Consumption data from smart metering and electric vehicles; data from batteries and intelligent appliances; essential weather data.
- *Case 2:* Data for consumption/feed-in from smart metering and electric vehicles; data from batteries and intelligent appliances; essential weather data.
- *Case 3:* Data for consumption/feed-in, instantaneous power, and current from smart metering and electric vehicles; data from batteries and intelligent appliances; rich weather data.
- *Case 4:* Data for consumption/feed-in, instantaneous power, failures from smart metering and electric vehicles; data from gas metering; data from batteries and intelligent appliances; rich weather data.

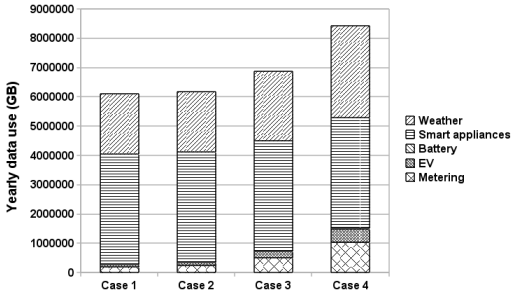

Fig. 3: Far future Dutch smart grid yearly data generation.

Considering the near future scenario for full smart grid implementation the amount of data produced yearly for the whole of The Netherlands starts to assume the connotation of "Big Data" (Figure 2). We remark that the sampling frequency is 15 minutes for metering whereas the weather information are provided every hour. In the most conservative scenario (Case 1) the data reaches the amount of 1.5 petabytes. Case 2 is similar in data generation having a total amount again close to 1.5 petabytes. Case 3 is close to 1.8 petabytes due to the increased information recorded and more comprehensive weather information. In Case 4 we note that more than half of the data generated comes from the meteorological information. The actual metering accounts for about 300 terabytes, while the electric vehicles are about 10% of this figure. The high number of smart appliances considered in a full fledged implementation of the smart grid, makes them responsible of the generation of more than half a petabyte of data.

Considering a future scenario with even higher penetration of smart devices and higher sampling rates, the amount of data naturally grows (Figure 3). We assume a sampling period of 5 minutes for metering-related data, and 30 minutes for weather. In the first case (most conservative), the data reaches the 6 petabytes value. Case 2 is almost as data rich as Case 1, whereas Case 3 reaches almost 7 petabytes. In all the cases the source that causes the most of data are smart appliances responsible of a little less than 4 petabytes of data. In Case 4 one reaches the level of about 8.5 petabytes, distributed between smart appliances (almost 3.8 petabytes), weather information (about 3 petabytes), and smart meters (1 petabyte).

Before concluding the analysis of the volume and, to some extent, of the velocity of the data that can come from the future smart grid users, we analyze the data generating potentials of the power grid infrastructure itself. Table V provides the values for the high voltage and the low voltage grid for the current situation and for the near and far future scenarios. For each of the three temporal variants, we consider the percentage of

TABLE V: Data for grid monitoring.

Type of Power Station	% of Station Monitored	Sampling period (min)	Data Size (byte)

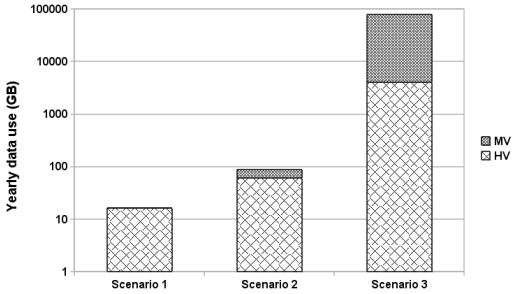

Fig. 4: Dutch power grid data generation.

monitored infrastructure, the sampling period and the size of the data.

Today, with very few exceptions, the medium/low voltage stations have manual switching device operations and therefore no data or remote monitoring is in place. The sampling period will shorten in the future and we assume to go from days to 5 minutes. Regarding the data size, we consider the data involved in the query and response of a distribution relay which is 40 bytes following the Modbus standard[7] that is a typical standard for electrical equipment monitor. We assume that in the far future scenario the data will be increased to 4,000 bytes per sample. The assumption is based on the presence of more sensing equipment and richer protocols. Considering the high voltage stations, they are already fully monitored; we consider only a decrease in the period of monitoring from 15 to 5 and 1 minute in the three scenarios. The amount of data required is based on the study of Sanchez *et al.* on the implementation of telecontrol functions for electrical stations using IP technologies, by considering just one picture frame per monitoring function [10]. Even here, we keep the current and the near future value constant and increase 100 folds the situation for the far future since we assume more equipment and richer protocols.

Based on these projections, we report the expectations for how much data is generated by the Dutch power grid in Figure 4. One notices an important growth for the high voltage related data, though what is remarkable is the important appearance of the distribution grid (medium and low voltage) data. In fact, this is where the smart grid concept will mostly change the current status quo.

B. Variety

Several standardization bodies and international organizations are working to provide new standardization documents to guarantee the interoperability between electric and electronic equipment in the context of the (smart) grid. To date IEEE alone has more than 100 standardization initiatives. IEC is going in the same direction with more than 100 relevant standards involving the smart grid in its various domains. These standards are not all related to data transmission and information-oriented aspects, since there are also aspects inherited by the electric aspects. In general, the application domains can be divided into different portions where standards and information exchanges can be considered. In the IEC representation are defined: the IEC-61850 that describes the communication networks and systems inside a substation; the IEC-61968 describes the information exchange in the electricity distribution system; the IEC-61970 describes the common information model (CIM) used in the control center to interoperate with the components and equipments outside the control center. Security aspects of the various communications are addressed in the IEC-62351.

In addition to technical aspects, it is important to consider the data exchange factor related to the market. The efforts of two standardization bodies (IEC and NIST) and State Grid Corporation of China are compared in [11] where similarities and differences in the approach are compared and a probabilistic model on the amount of development is provided. IEC-62325 deals with the market aspects putting the accent on deregulation. The market efforts are also addressed by the OASIS technical committee for the smart grid. Both the OASIS Energy Inter-operation specifications and the OASIS Market Information Exchange provide a framework for standardization where energy interactions are considered as transactions, i.e., energy is an operation comprising a price, a quantity and a date of delivery that can be negotiated on the market.

The home automation setting [12] is also a rich one in terms of data variety. There are many technologies and protocols for home energy saving and many initiatives are underway in relation to the smart grid. Zigbee Alliance Smart Energy Profile provides the protocol stack (based on the IP protocol) to have smart grid application at home such as meter reading, and appliance automation in response to changing energy prices. In order to enable a true interoperability between so many different and heterogeneous services, the tendency is that of using solutions that are based on services available through the Internet [13]. In summary, many standards are appearing with different data specifications and formats.

C. Veracity

In the broad panorama of the smart grid, the problem of having accurate and meaningful data is essential. Having so many different sources and levels of aggregation requires a fine grained filtering to ensure that data are consistent and

[7] www.modbus.org/

that no compromised or mistaken data are present. In addition to the traditional mechanism of error correction coding [14], one of the issues that are highly debated about the smart grid is the security of a digital power grid infrastructure. There are several possible attacks, ranging from the acquisition of private user data, to tampering the energy bills, to modifying the data recordings of the equipment of the grid, to malware injection into general purpose and embedded computers, modifications of the demand-response mechanism creating imbalances in the production and consumption and therefore compromising the stability of the grid [15]. Therefore accuracy, integrity, confidentiality, and authenticity have to be all satisfied to guarantee the safe operations of the smart grid. The cyber-security aspects of the future power grid are a source of concern. Solutions to the security issues are under investigation for instance by NIST that has established a Cyber Security Working Group on the smart grid topic. In [16] the proposed solution is based on technologies already applied to ICT domains such as public key infrastructure for providing a secure way of authentication and authorization. Encryption based on AES or 3DES algorithms can provide a solution to guarantee privacy. In order to guarantee the trust in a system made of many different components (several thousands to millions) with different technologies and several manufacturers, the solution proposed by Metke and Ekl [16] uses trust anchor security i.e., a series of chains of certification authorities and at the end of the chain a digitally signed certificate for a piece of equipment or device in the smart grid is provided. Among the different security concerns of the smart grid analyzed in [17] some are definitely related to the data: security of devices and their communication interactions, and privacy of the users whose energy consumption is digitally metered.

D. Value

It is difficult to give a value to information regarding an infrastructure not yet in place and which is managed as a monopoly in most countries, or at most as a slightly unbundled market. However, we can estimate the value of the smart grid data considering some of the actors involved and the benefits they can achieve with an accessible and rich digital infrastructure.

The end user can obtain value by energy saving and appropriate planning of its energy use. This can be done only with an automation system in place and would be even more profitable with a dynamic tariff system, as shown in [7]. The value can be even greater if a totally open energy market existed where end-users could trade their excess and stored energy freely with any other partner, a scenario we depicted in [18].

The value for the energy utilities will be manyfold. First, the AMI provides accurate measure of power consumed thus a more accurate billing for the end user. Second, the AMI and the data flow of a smart meter helps to discover and fight electricity thefts and have better revenues. Worldwide estimations of electricity thefts account for 25 billion dollars [19]. Third, energy utilities with smart grid data are able to early diagnose problems (especially at distribution level) in the network and provide a fast solution, which results in less customer interruptions and therefore less penalties for service interruption. Fourth, and most importantly, precise knowledge of energy flows allows utilities to better plan the generation of energy and save money, since energy production costs are not a linear function of the amount, but rather a convex one. Fifth, the inclusion of renewables requires a better prediction of the distributed generation to keep the demand-response balance.

With the smart grid concept, there is also the possibility that new actors can find value in the power grid (Big) data. New companies are emerging (e.g., Opower) that work for the utilities in smart meters data analytics, to motivate the customer in energy conservation, dynamic tariffs usage, and energy efficiency through automation. Furthermore, several benefits are achievable through smart appliances. In fact, they enable totally new scenarios of use of the home environment. The home appliances of the next generation will receive a configuration by the user who sets the preferences of the usage time and tariffs limits to be used [20]. These appliances will interact with the home energy management system, with the utilities that might directly control them, and with the manufacturer that receives logs about the appliance life conditions. Electric vehicles will also interact with the utilities, to provide a balancing capacity for the network, therefore they will participate in the demand response functionality receiving energy tariff information, remotely provide the battery status to the user and the log of anomalies to the vehicle manufacturer. Utilities and energy services companies can take advantage of energy analytics to develop new tailor made products. The approach will be similar to the personalized offers that Amazon or other on-line retailers offer to the customers having a more detailed set of information concerning the products that the customer likes or visits frequently. Utilities will provide energy offers based on the energy consumption patterns of customers, on the appliance usage and charging time of the electric vehicle.

V. Related Work

The smart grid is a new industrial and research theme open to exploration. The impact of data production and management is still under investigation. The few related works on the topic consider the amount of data generated to be huge, but very few provide actual numbers not to mention field experiences.

The direction towards an electricity sector that is more complex is synthesized by Rusitschka *et al.* [21]. The idea is to exploit cloud and a service-oriented approaches for processing power grid data. The paper does not provide an estimation of the amount of data that the smart grid is going to generate. The authors take for granted that the amount will be big: “The smart grid will be the largest increase in data any energy company has ever seen.” [21].

Parikh *et al.* [22] investigate the appropriate wireless technology to be used for the smart grid. The various solution proposed range between WiMAX and cellular for long distance communication to the wireless LAN, ZigBee and Bluetooth to more short distance applications. The review is interesting,

though the paper only considers the theoretical bandwidth of the technologies without considering the data size and sampling requirement of the smart grid.

The important problem of privacy in metering is addressed in [23] where the authors propose an anonymization mechanism for smart metering data. The approach considers two types of metering services a *high frequency* and a *low frequency*. The solution proposed appears effective and able to actually solve the main privacy concerns. The authors only refer to high frequency of sampling without giving any quantitative aspects on the amount of data. Another interesting aspect to be investigated is the amount of overhead in data size necessary to guarantee privacy.

The authors of [24] propose a new communication infrastructure to deal with the enhanced amount of data that will be generated by the smart grid. The infrastructure is a distributed one. The authors explicitly state that the new smart grid infrastructure will generate a significant amount of data given the increased sampling frequency of the grid sensing equipment (e.g., phasor measurement units) and that the current infrastructure is not ready to handle them. The authors do not provide any quantitative value concerning the data generated by the current or the future grid. Only a table shows the main characteristic of the sampling rate of part of the today's sensing and actuating infrastructure.

The concept of a distributed control for the power grid in the future evolution of the grid is illustrated also in [25]. The authors consider that the system will evolve from a mechanical-electrical control system to a fully electronics based one. They also state that more computation will take place locally on the grid with agent-based technologies operating within substations. Again, no sizing concerning the communication infrastructure to enable this additional information exchange between the substations is provided, thus difficult to have a quantitative picture of the Big Data of the smart grid.

In order to test the new scenarios of the data generation of the smart grid, EDF has estimated in its French network 35 millions smart meters and a sampling frequency of 10 minutes to have a total amount of data about 120 terabytes/year [26]. In that report, the authors show how a solution based on Hadoop and an accurate optimization in the data modeling, partitioning, and compression can improve the performance of the system that manages these data.

The IBM white paper on Big Data and smart grid provides some quantitative insights on the amount of data that utilities are going to deal in a smart grid future [27]. With a smart meter infrastructure and a 15 minutes sampling period, IBM forecasts a 3000 fold increase in the amount of data compared to the current monthly metering situation. Another quantitative example that is provided in the report to show the goodness of the IBM data management solution shows that in a 31-day period the total amount of storage required in a 100 millions meter scenario was less than 4 terabytes. The report explicitly emphasizes that the volume of data will not reach the same amount as for traditional data intensive industries, though in the power systems utilities world the projected amount could be overwhelming. The report also emphasizes that in addition to the *velocity* characteristic of the smart grid data in collection, processing, and use, the utility will have to deal with the *variety* of the data to handle from power control system data, to surveillance videos, to geographical and meteorological data, to social media mining.

The literature provides good examples of how the power grid will evolve. For instance, in [28] we look at the topological aspects of the distribution grid through the lenses of complex network analysis [29]. In general, all the works agree that additional amount of computation will be required to monitor the supplementary information coming from more sensors deployed in the grid. However, the studies never provide quantitative information concerning the amount of data that AMI or data gathered at substation level will produce. Only few studies try to provide indication of the communication infrastructure required, but in a coarse way.

VI. Concluding Remarks

Given the current state of affairs, the smart grid, or better said AMI, is not amenable to be referred to as an example of Big Data, not in the Netherlands, not in other countries. However, when more and more houses and businesses will be equipped with smart meters and the sampling period will be reduced, then the Dutch smart grid will become closer to be a Big Data system. If we compare the absolute numbers of the Big Data examples that we have analyzed in Section II, then there is no competition with the annual amount of data generated by social media or video repositories. However, to make the comparison fair considering Facebook, for example, if we account the the traffic generated by the more than 8 millions Dutch users of Facebook,[8] they are responsible for about 1.6 petabytes a year. We indeed note that the amount of data produced by the future Dutch smart grid is similar to the amount of data that the Dutch users produce each year on Facebook.

The numbers provided in this paper should be taken with a grain of salt. For instance, the Dutch smart meter standard is not yet finalized, therefore the amount of data and information metered could change, thus increasing or decreasing the data required. One aspect that we have not considered in our investigation is the overhead required by the communication infrastructures (i.e., the extra data in addition to the application layer that need to be considered) that could be a substantial burden. Further, all the data containing user and privacy related information will need to be protected by an additional layer of security (e.g., encryption) that require even more bits to be transmitted and stored. On the other hand, we have not considered any compression level possible for the smart grid data, but the figures here presented are raw data. Compression both in the communication and storage of data has achieved remarkable results [30]. For the protocols to control the grid we have considered one for the high

[8] http://goo.gl/HyKzxQ

voltage (IEC 60870-5 [10]) and one for medium/low voltage (Modbus) among many others available and in use.

Utilities are likely to have to face a number of data related issues in the short and medium term. In the implementation of big-scale AMIs utilities will deal with ICT challenges that are not the core of their business. In addition to a secure telecommunication infrastructure to transfer the metered data and other information, the utilities will have to deal with the storage and management of that data. Of course this is not a big problem from a technical perspective, similar solutions exist in the financial sector. However, the smart grid will require a modernization of the utilities that in addition to the energy orientation will have to become also information oriented. The power industry from a fully analog business where consumer data was recorded annually with pen and paper is going to become the most data intensive industry with enormous quantity of data generated every day.

In this paper, we have made projections and calculations on how the relatively small grid of The Netherlands could become a Big Data generator similar to Facebook. Certainly, sensing more data along the grid to monitor its performance is essential for the utilities and provides an improvement in their operation, it will also ease the billing process and it will help the inclusion of renewable sources. Interesting challenges are not only in the management of the future smart grid data, but also on how to extract value from this data and on novel business models based on the availability of Big Data.

ACKNOWLEDGEMENTS

9th International Symposium
Advances in Artificial Intelligence and Applications

THE AAIA'14 will bring researchers, developers, practitioners, and users to present their latest research, results, and ideas in all areas of artificial intelligence. We hope that theory and successful applications presented at the AAIA'14 will be of interest to researchers and practitioners who want to know about both theoretical advances and latest applied developments in Artificial Intelligence. As such AAIA'14 will provide a forum for the exchange of ideas between theoreticians and practitioners to address the important issues.

Topics

Papers related to theories, methodologies, and applications in science and technology in this theme are especially solicited. Topics covering industrial issues/applications and academic research are included, but not limited to:

- Knowledge Management
- Decision Support Systems
- Approximate Reasoning
- Fuzzy Modeling and Control
- Data Mining
- Web Mining
- Machine Learning
- Combining Multiple Knowledge Sources in an Integrated Intelligent System
- Neural Networks
- Evolutionary Computation
- Nature Inspired Methods
- Natural Language Processing
- Image Processing and Interpreting
- Applications in Bioinformatics
- Hybrid Intelligent Systems
- Granular Computing
- Architectures of Intelligent Systems
- Robotics
- Real-world Applications of Intelligent Systems
- Rough Sets

Professor Zdzislaw Pawlak Best Paper Awards

We are proud to announce that we will continue the tradition started during the AAIA'06 Symposium and award two "Professor Zdzislaw Pawlak Best Paper Awards" for contributions which are outstanding in their scientific quality. The two award categories are:

- Best Student Paper - for graduate or PhD students. Papers qualifying for this award must be marked as "Student full paper" to be eligible for consideration.
- Best Paper Award for the authors of the best paper appearing at the Symposium.

Candidates for the awards can come from AAiA and all workshops organized within its framework (i.e. AIMA, ASIR, CEIM, TAIE, WCO)

In addition to a certificate, each award carries a prize of 300 EUR provided by the Mazowsze Chapter of the Polish Information Processing Society.

IFSA Award for Young Scientist

During the Advances in Artificial Intelligence and Applications (AAIA) Symposium, the International Fuzzy Systems Association (IFSA) Best Paper Award for Young Scientist, will be presented.

Candidates for the awards can come from AAiA and all workshops organized within its framework (i.e. AIMA, ASIR, CEIM, TAIE, WCO)

***Abstract*—A new method to solve the inverse problem of electrical capacitance tomography is proposed. Our method is based on artificial neural network to estimate the radius of an object present inside a pipeline. This information is useful to predict the distribution of material inside the pipe. The capacitance data used to train and test the neural network is simulated on Matlab using the electrical capacitance tomography toolkit ECTsim. The provided accuracy is promising and shows efficiency to solve the inverse problem in a simple manner and on reduced computational time about 120 times when compared to the existing Landweber iterative algorithm for tomographic image reconstruction that can be encouraging for dynamic industrial applications.**

***Index terms*—Electrical Capacitance Tomography, Inverse Problem, Artificial Neural Networks, Gravitational Flow of Solids.**

I. Introduction

ELECTRICAL Capacitance Tomography (ECT) is a non-invasive technique used to image the spatial distribution of merged materials with different dielectric properties inside a pipe [1]. The spatial distribution is determined by measuring the capacitances between all pairs of electrodes placed around the vessel containing the process to be examined [2]. The provided measurements depend on the electrical permittivity value of the combined materials and their spread inside the isolated pipe. Studying the relationship between capacitance records and permittivity distribution and converting them to an ECT image has been an attractive research era since 1980's [13, 15, 16]. Researchers are still investigating to improve the performances of this technique and agree on the complexity of the task due to the difficulties with inverse problem solution, nonlinearity of the system and the limited number of obtained capacitances. Typical used sensors are with N electrodes (e.g. N=8, 12, 16) lead to M capacitance measurements (M= 28, 66, 120) respectively and typical generated 2D ECT image with resolution of 32x32 pixels, which in turn makes the inverse problem ill-posed.

Forward and inverse problems are in fact the two main tasks in tomography visualization. First one is looking for the measurement records given permittivity distribution (in case of ECT tomography) while the later one is nothing else but looking for a relationship of the measurement (result) with the source data (cause) that is looking for the cause, which gives the measurement. In most cases, a forward problem is solved by numerical methods with the finite elements method (FEM) being the most popular one. FEM allows calculating the inter-capacitance values relying on the known permittivity distribution.

Typical results of inverse problem solution are the reconstructed images of ECT sensor space. Depending on type of the applied reconstruction algorithm the image quality can vary. Choice of appropriate reconstruction method for industrial application is limited by time of calculation in real time. In the case of iterative reconstruction methods the reconstructed image is updated iteratively until reaching a satisfactory error based on the difference between the calculated and real capacitances.

Authors in [4] reviewed various Iterative ECT methods: Newton–Raphson, Landweber iteration and Algebraic Reconstruction Techniques. Evaluation and simulations results highlighted the superiority of the performances of Landweber iterative algorithm in terms of lowest capacitance calculation errors comparing to the other cited algorithms. Artificial Neural Networks (ANN) have been used for solving both ECT problems since they represent a powerful and effective tool to dealing with complex and non-linear computations. The type of the applied neural network differs depending on the purpose of investigations. A multi-layer Feed-Forward Network (FFN) was applied to solve the forward problem. The network was trained to predict capacitance data from different permittivity distributions and then when integrated with Landweber iteration method provided a satisfactory quality of reconstructed image [3]. 313 parallel multi-layer perceptron with 2 hidden layers each

of which were applied in [5] to reconstruct different ECT image pixels and visualize the oil distribution inside a pipe.

Large radial basis function (RBF) neural network is used in [7], with 66 nodes, representing the measured capacitances, in the input layer and 804 neurons in the output layer to flow patterns image reconstruction. The 804 outputs of the network correspond to the mesh grid elements considered to model the ECT phantoms in an earlier step.

In our present work we propose to use a Multi-Layer Perceptron with one hidden layer to estimate the radius of an object present inside the sensor and thus reconstruct the tomographic image. Our approach has the advantage to have a simple neural network with simplified structure: 66 capacitances form the input layer and one neuron at the output which corresponds to the radius of the phantom. The performance rate is set at 0.004 while it was equal to 0.3 in [7].

II. ECT INVERSE PROBLEM

Electrical capacitance tomography inverse problem is to, by means of appropriate algorithm; determine permittivity distribution based on measured capacitances into a form of a tomographic image [10, 14]. Fig. 1 shows a schematic of an image reconstruction process in ECT

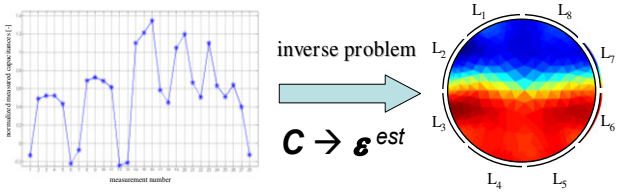

Fig. 1.Example of a graph of normalized measured capacitances and corresponding reconstructed tomography image following the solving of permittivity matrix using the inverse problem method.

Two major characteristic obstacles of inverse problem are: its ill-posed and non-linear properties. The first refers to the limited number of measured capacitances compared to the number of pixels to be reconstructed while the relationship between capacitance and permittivity distribution nonlinearity is modeled by the Gauss Law, [11, 13, 14] (Eq.1):

$$C = \frac{Q}{V} = -\frac{1}{V}\iint_{\Gamma} \varepsilon(x,y)\nabla\phi(x,y)\,d\Gamma, \quad (1)$$

where Q is the electric charge; V the potential difference between two electrodes, ε(x,y) denotes the permittivity and φ(x,y) represents the electrical potential distributions. Γ stands for the electrode surface and $d\Gamma$ an element orthogonal to this surface.

A discrete linear approximation of the previous equation is formulated as following (Eq. 2):

$$C = \mathbf{S}\,\varepsilon, \quad (2)$$

where C is a vector of measured capacitances, **S** linearized sensitivity matrix and ε is a vector of permittivity distribution. The problem of image reconstruction is then reduced to solving the linear discrete form (2) which is still challenging and attracting researchers 'efforts. The problem of image reconstruction is then reduced to solving equation (3) represented:

$$\varepsilon = S^{-1}\,C \quad (3)$$

The inverse of **S** does not exist; because **S** is not a square matrix (number of measurements is not equal of number of pixels in image). Instead of having its inverse S^{-1}, the pseudo-inverse **S*** must be calculated, for instance, using an approximated solution. Other important problem in image reconstruction procedure is the dependence of the sensitivity matrix on the permittivity distribution, what causes that the inverse problem is non-linear. A lot of publications where different kind of methods to solve the inverse problem (linear, non-linear, directly methods and iterative methods) are presented in literature [3]. Depending on computational method, the algorithm generates images with different levels of quality, in the case of LBP algorithm or much higher quality, using iterative or non-linear methods. In the case of iterative and non-linear methods, high image quality is occupied by long computational time.

The Landweber iterative algorithm is one of the most popular methods in the field of ECT image reconstruction. The iteration process, in Landweber algorithm is governed by the following formula [8, 14]

$$\varepsilon_{k+1} = \varepsilon_k - l\,S^T(S\varepsilon_k - C) \quad (4)$$

where ε_{k+1} and ε_k are the estimated permittivity distributions at the k^{th} and $(k+1)^{th}$ iterations respectively, S is the calculated sensitivity matrix and l is a relaxation parameter of Landweber algorithm.

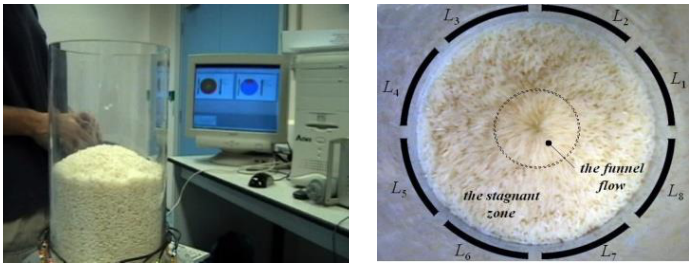
The method cited above owns the advantages of easy implementation and low computational complexity but suffers from the numerical optimization point of view as it possess a relatively low convergence rate and hardly provides a global optimization solution, [12].

Artificial Neural Network constitutes a competitive optimization based- method applied in the same research era [3, 17].

III. PROBLEM STATEMENT

The extraction of industrial process characteristic parameters gives possibility of predicting unwanted incidents and feasibility of in depth exploration of dynamic spatial temporal phenomena occurring during industrial process such as flows [13, 15, 16, 18-20]. Visualization of flow processes by means of tomography image reconstruction gives a non-invasive tool for extraction of these parameters and given sufficient reconstruction time combined with fast image processing algorithms can promise on-the-fly flow characterization.

One of the examples of successful ECT application for dynamic flow is hopper gravitational discharging process [19, 20]. Model of such process is depicted on Fig. 2. where the laboratory setup photograph is presented. The mentioned type of flow is widely present in a range of branches such as pharmaceutical, chemical, food processing, construction and others. Processing of 2D reconstructed images allowed examination of hopper discharging funnel type of flow parameters. The set of parameters such as solids concentration in funnel and funnel area size characterize the dynamics of hopper flow [18]. This knowledge gives the information about correct/incorrect hopper flow.



a) b)

Fig. 2. Photos of the hopper flow model. Photos of the hopper model: a) side view of the hopper and the image reconstruction visualisation; b) top view of the container with 8 sensor electrodes depicted around the silo.

The so-called funnel flow occurring during the silo discharging process not obvious to be analysed in its full volume since the non-transparent nature of the process. Hence, ECT is the ultimate tool to examine this flow on the base of reconstructed image where funnel area, in the center of silo, with the smaller material concentration value than rest of the sensor space can be observed (Fig. 3)

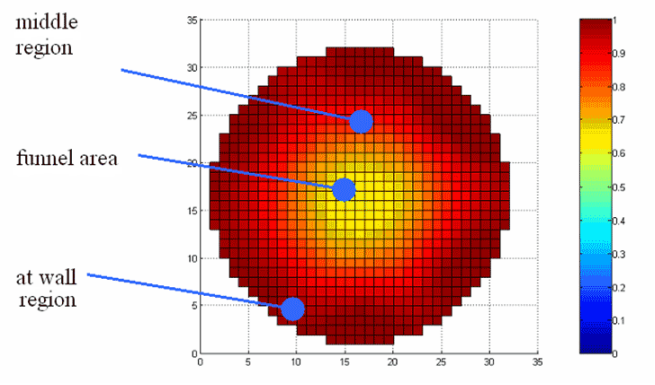


Fig. 3. Basic ECT tomographic image reconstructed for funnel hopper flow with characteristic flow areas indicated.

In order to develop the method for calculating these characteristic parameters a scheme of data processing was proposed. It allows estimating the radius of the object of a different permittivity inside a sensor cross-section space. As a proof-of-concept study we present a simulation with a phantom as useful information to predict the distribution inside the vessel knowing the capacitance measurements. A uniform distribution inside a circular sensor and a circular object is situated at the center of the vessel was assumed for calculations as shown in Fig. 4.

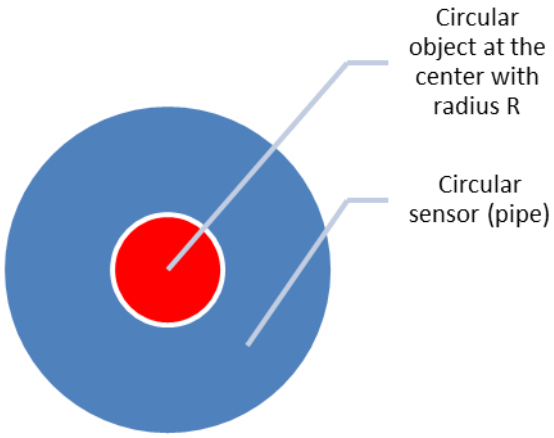

Fig. 4. Phantom considered with circular sensor and circular object in the center.

We present, in the following sections, the ECT inverse problem solving by use of Artificial Neural Networks, an evaluation of our method by comparing it to Landweber iterative approach and mention further works.

IV. ARTIFICIAL NEURAL NETWORKS

An artificial neural network is a powerful information processing tool recognized for its abilities to model complex input/output relationships and to learn these relationships directly from the data being modeled. They are principally designed to mimic the human brain functions in the following two ways: they acquire knowledge through a learning process, and the knowledge is stored within inter-neuron connection strengths known as synaptic weights, [6].

Two learning approaches are available: the first one is supervised and the second is unsupervised. A supervised learning, mostly applied, requires a desired output in order to learn. To perform the task of learning a training algorithm is applied in order to adjust the synaptic weights of the network in an orderly fashion so as to generate a model that maps the input to the output using historical data. The provided model can then be generalized to produce the output when the desired output is unknown. In addition to a powerful training algorithm, a neural network needs to have an appropriate structure to deal with the complexity of the problem to be solved. The most commonly used network structure, which has been also used in the presented approach, is the Multi-Layer Perceptron (MLP). An example of a MLP network is shown in figure 5.

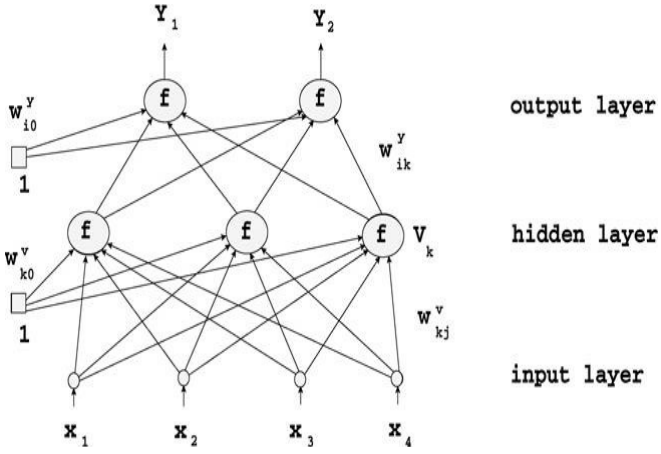

Fig.5. An example of multilayer perceptron network with one hidden layer.

The inputs are fed into the input layer and get multiplied by interconnection weights as they are passed from the input layer to the hidden layer. Within the hidden layer, they get summed then processed by a nonlinear function called activation function. The data is multiplied by interconnection weights then processed one last time within the output layer to produce the neural network outputs. A mathematical representation of the signal of i−th network output Yi is given by the Eq. (5):

$$Y_i = f\left(\sum_{k=0}^{M} \omega_{ik}^{y}\, y_k\right) = f\left(\sum_{k=0}^{M} \omega_{ik}^{y}\, f\left(\sum_{j=0}^{N} \omega_{kj}^{v}\, x_j\right)\right) \quad (5)$$

Where: N—number of inputs, M—number of neurons in the hidden layer, w_{kj}—weight of kth neuron in the hidden layer for the j th input, w_{yik}—weight of ith neuron in the output layer for the signal y_k, which is the output of the kth neuron

The activation function f (·) may be a simple linear or a non-linear function. The most commonly used activation functions are: threshold function, sigmoidal function, hyperbolic tangent function and radial basis function. In our case we used the sigmoidal function in both hidden and output layers. Sigmoidal function is mathematically expressed as:

$$f(z) = \frac{1}{1+e^{-z}} \quad (6)$$

ANN-based inverse model is built on the basis of relations between the network input and output vectors. The knowledge about the inverse mapping is stored within the network structure and network connection weights [6,22]. Sixty six values of capacitances **C**= [$C_{1,\ldots}$, C_{66}] constitute the network input vector. The approximated values of the corresponding radius $\hat{R}$ are calculated at the network output. An unknown mapping of the input vector to the output vector is approximated in an iterative procedure known as neural network training [5]. The objective of the learning algorithm is to adjust network weights on the basis of a given set of input-output pairs for a given cost function to be minimized. Back propagation algorithm, a supervised learning network algorithm, uses the gradient of the performance function to determine how to adjust the weights to minimize performance. In back propagation, the error data is propagated from the output layer backwards through the network. The effected computations allow the update of the incoming weights at each layer. In our present approach, during the network learning phase the error is propagated until a set value of the training error is reached.

V. EXPERIMENTAL PART

A. Description

We treat on our present work the inverse problem which aims to determine the material distribution relying on measured capacitances. The simulation is done using ECTSIM Matlab's toolbox, [8, 21]. ECTSIM was designed to evaluate existing image reconstruction algorithms applied on the field of ECT like Landweber algorithm and LBP method. Our work can be described on 2 main steps: (1) Sensor Modeling and capacitances measurement (2) Image Reconstruction using Artificial Neural Network: A multi-layer Perceptron (MLP) is applied to determine the phantom radius). We enclose the experimental part by comparing the obtained results with our method with others obtained with Landweber algorithm. Computations were performed on PC computer with Intel(R) Xeon(R) CPU E5630 @ 2.53GHz processor and 24,0 GB RAM. The different algorithms were implemented in MATLAB.

We detail on the following paragraphs the steps mentioned above.

B. Sensor Modeling and capacitances measurement

The current work is done under the 2D version of the ECTSIM toolbox using the circular sensor model. The provided sensor model is composed of four layers: pipe layer, electrode layer, insulation layer and the screen layer as shown on Fig.3. As the user of the toolbox is able to set the different parameters of each layer like thickness, electrical permittivity of insulation material and number of electrodes, we chose a sensor with 12 electrodes (N= 12) placed inside the pipe (inner insulator thickness=0), background permittivity =1 and elements' permittivity =3. The field of view diameter was set to 84 mm. The sensor field of the view was then divided into 96x96 square meshes. For each phantom the simulated capacitances is calculated using the discrete linear approximation of Gauss Law (Eq.2).

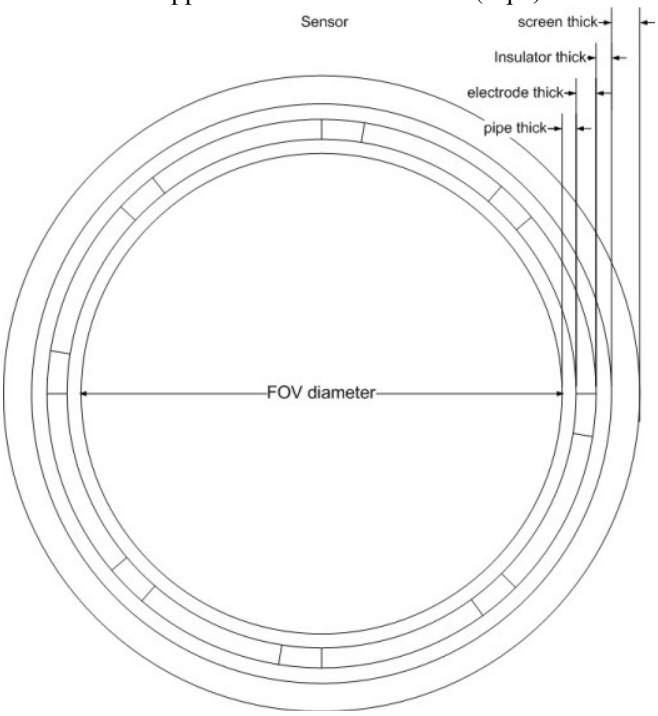

Fig.6. Sensor's diagram used for simulation [21].

We varied the diameter of the object present inside pipe in order to generate the phantoms to train and test the ANN in a farther step.

C. Image Reconstruction using Artificial Neural Network

For the given parameters we generated 320 phantoms divided into 241 training examples and 80 test examples. A Multi-Layer Perceptron with a single hidden layer is applied to estimate the radius of the object inside the pipe. The number of nodes in the input layer is given by the number of measured capacitances L= N (N-1)/2 = 66 and one neuron at the output layer. The network was trained using the back propagation algorithm with a training error set to E= 1/240=0.004. We made several experiences to determine the number of nodes in the hidden layer. Table1 summarizes the obtained testing errors with different numbers of hidden neurons.

We consider on the selection of the appropriate structure of MLP :

- Number of iterations at the learning phase
- Mean Square Error (MSE) during the test process:

$$\text{MSE} = \frac{1}{n}\sum_{i=1}^{n}(R - \widehat{R})^2 \quad (7)$$

- Mean testing error:

$$\text{Mean} = \frac{1}{n}\sum_{i=1}^{n}|e_i|$$

where $e_i(R) = (R - \hat{R})$ (8)

We designate by R the desired MLP output / desired radius, $\hat{R}$ the estimated radius at the testing phase and n the number of testing examples. Table1 summarizes the obtained testing errors with different numbers of hidden neurons.

TABLE 1.
TESTING ERRORS AND NUMBER OF ITERATIONS WITH DIFFERENT MLP STRUCTURES

Network structure	Testing error		Number of iterations (learning)
	MSE	Mean	
(66-10-1)	**0.1670**	**0.2839**	**1080885**
(66-20-1)	0.1688	0.3148	1419490
(66-30-1)	0.1721	0.2846	1815935
(66-66-1)	0.1832	0.4086	1225485

The provided results show that minimum testing errors MSE=0.1670 and Mean=0.2839 are obtained for a network structure with 10 hidden neurons (66-10-1). The maximum errors were obtained with 66 neurons in the hidden layer. The use of both Mean Square Error and the Mean Error was beneficial to decide the best structure to retain for the reconstruction phase since the obtained MSE errors were close for the two first structures (66-10-1) and (66-20-1). The learning process was the fastest for the given structure and was the slowest for the structure (66-30-1) as the smaller the network structure is the less numerical complexity we have.

To consider the MLP structure (66-10-1) the appropriate structure to solve our handled problem, the process of learning and testing the selected was repeated several times and results uphold that 10 neurons in the hidden layer are sufficient to estimate the radius of the object inside the pipe.

A second attempt to evaluate the performances of the proposed method is to compare the reconstructed images from ANN with images reconstructed with Landweber algorithm under the ECTsim toolbox.

TABLE. 2.
RECONSTRUCTED IMAGES FROM MLP AND LANDWEBER ALGORITHM

Desired Phantom / Distribution	**Image reconstructed from MLP**	**Image reconstructed from Landweber/ Time elapsed for reconstruction (in s)**
			time elapsed for reconstruction (in s) 0.070273	time elapsed for reconstruction (in s) 10.22
			time elapsed for reconstruction (s) 0.075846	time elapsed for reconstruction (s) 9.910792
			time elapsed for reconstruction (s) 0.082285	time elapsed for reconstruction (s) 10.112285

D.Evaluation of the proposed method

We present in table2. the reconstructed images from MLP network and Landweber algorithm for different radius taken from the neural network test base. The reconstruction from MLP is performed by drawing the circular object with the estimated radius. The elapsed time included one iteration to estimate the radius from the capacitances fed to the input of the MLP with the retained structure (66-10-1) and the time to draw the outer circular sensor and the object inside. The number of iterations to reconstruct the same object, using Landweber algorithm, with the same radius is set equal to 100.

The obtained images from the neural network method present satisfactory shape with small relative radius estimation error. The circular shape is better maintained with MLP based method especially in boundaries. Other advantage of the proposed methods is better estimation of permittivity value for object. In the case of MLP the relative permittivity value is much closer to the prepared simulated phantom than for Landweber algorithms. Next aspect is the time calculation. The phantom reconstruction with MLP method is about 120 times faster than with Landweber iteration algorithm.

The relative testing error for different values of radius was calculated based on formula:

$$E_R = \frac{R-\hat{R}}{R} \quad (9)$$

where R is desired radius and $\hat{R}$ is the estimated radius.

The results are shown in Fig.7. The error is significant, for small values of radiuses - about 1 mm. For R<5 mm the relative error value is still negative which means that the estimated value is bigger than the real value. For 5mm<R< 15mm, the relative error value becomes positive and the gap between the desired and estimated values is smaller. For radius values higher than 15 mm the relative testing error is near to zero. The high pic of relative error could be referred either to the capacitances measurement process (i.e. the difficulty to sense the permittivity distribution in a very small objects) or to the lack of training examples for this interval of radii. Providing more training examples for small objects (R<15mm) would improve the performances of our neural network.

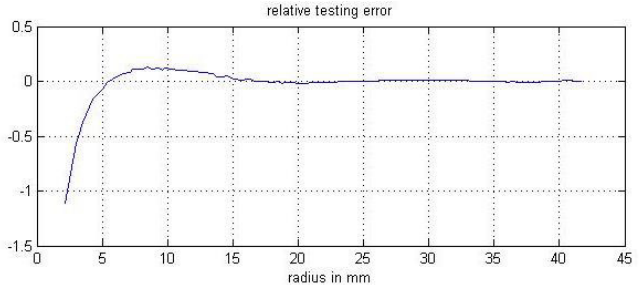

Fig. 7. Relative testing error in term of the object radius.

VI. CONCLUSION

The aim of the work was to estimate the radius of the object present inside a circular cross section ECT sensor based on neural network technique. The calculated radius was then used to image the distribution of content inside the sensor. The different steps for solving the inverse ECT problem were depicted. The obtained results are promising especially under a simple MLP structure (66-10-1) and back-propagation training algorithm. The provided accuracy is satisfactory and ANN based approach allowed to solve the inverse problem in a simple manner and on reduced computational time about 120 times when compared to the existing Landweber iterative algorithm. Results revealed potential to estimate flow patterns such as funnel-type hopper flow with reconstruction speed sufficient for on-the-fly industrial applications. Possibility to estimate more than one useful parameter (such as radius and permittivity) and generalization of the pattern of phantoms will be the subject to further work.

***Abstract*—In this paper we consider a problem of automatic labeling of textual data with concepts explicitly defined in an external knowledge base. We describe our tagging system and we also present a framework for adaptive learning of associations between terms or phrases from the texts and the concepts. Those associations are then utilized by our semantic interpreter, which is based on the Explicit Semantic Analysis (ESA) method, in order to label scientific articles indexed by our SONCA platform. Apart from the description of the learning algorithm, we show a few practical application examples of our system, in which it was used for tagging scientific articles with headings from the MeSH ontology, categories from ACM Computing Classification System and from OECD Fields of Science and Technology Classification.**

***Keywords*—semantic indexing; Explicit Semantic Analysis; Adaptive Semantic Analysis; multi-label tagging; adaptive learning;**

I. Introduction

THE MAIN idea of a keyword search is to look for texts (documents) that contain one or more words specified by a user. Then, using a dedicated ranking algorithm, relevance of the matching documents to the user query is predicted and the results are served as an ordered list [1]. In contrast, semantic search engines try to improve the search accuracy by understanding both, the user's information need and the contextual meaning of texts, which are then intelligently associated [2].

From the data processing point of view, the semantic search engine may be divided into three main components: semantic text representation module, interpretation and representation of a user query, and an intelligent matching algorithm [3]. The scope of the first two modules may be categorized as a semantic data representation [4]. In opposite to the keyword search, the semantic data representation, and thus the semantic indexes, cannot be calculated once and then utilized by intelligent matching algorithms. The text representation, as well as a query interpretation should be assessed with respect to the type of the users' group, a context of the words in the query and many others factors [5].

This work is partially supported by the National Centre for Research and Development (NCBiR) under Grant No. SP/I/1/77065/10 by the Strategic scientific research and experimental development program: "Interdisciplinary System for Interactive Scientific and Scientific-Technical Information" and by Polish National Science Centre (NCN) grants DEC-2011/01/B/ST6/03867 and DEC-2012/05/B/ST6/03215.

The better part of current search engines is based on a combination of a keyword search and sophisticated document ranking methods [1]. Only some of them process search queries, analyzing both, a query and documents' content with respect to their meaning, and return the semantically relevant search results [2]. However, even this approach becomes insufficient. The process of information retrieval needs to be made intelligently in order to help users in finding relevant information. The key role in this process is the recognition of the users' information needs and collecting feedback about the search effectiveness. The gathered information should be utilized to improve search algorithms and forge better responses to user requirements. Those challenges are in the scope of studies on adaptive search engines which interact with experts (users) and operate in a semantic representation space [6].

The SONCA (Search based on ONtologies and Compound Analytics) platform [7] is developed at the Faculty of Mathematics, Informatics and Mechanics of the University of Warsaw. It is a part of SYNAT project focusing on development of Interdisciplinary System for Interactive Scientific and Scientific-Technical Information (www.synat.pl). SONCA aims at extending the functionality of search engines by more efficient search of relevant documents, intelligent extraction and synthesis of information, as well as a more advanced interaction between users and knowledge sources.

Within the SYNAT project, some successful methods for the semantic text representation and indexing have already been developed [4], [8]. In this paper we discuss an adaptive learning model of terms-to-concepts associations which can be treated as an extension of the Explicit Semantic Analysis (ESA) method [9], [10]. By an analogy, we call it Adaptive Semantic Analysis (ASA). The main purpose of this model is to adjust the links between words and well-defined concepts. Those links are automatically derived from natural language definitions of the concepts which are stored in an external knowledge base. The associations are then used for labeling and indexing scientific articles. The definitions of the concepts can be extracted from different knowledge sources such as domain ontologies. In our experiments we show how the model can be constructed using descriptions of the concepts in a natural language and how it can be improved by using feedback from domain experts. We also show how to deal with a lack of concept descriptions in a case when there is available a sufficient number of training examples of labeled articles. Finally,

978-83-60810-58-3/$25.00

we present our most recent developments and improvements to the model, which are related to a problem of deciding how many concepts should be associated with a given document. As case studies we use a task of tagging biomedical articles from the PubMed repository with concepts from the MeSH ontology [11], a task of labeling abstracts of computer-science-related documents with terms from ACM Computing Classification System [12] and a problem of assigning the OECD Fields of Science and Technology Classification categories to articles from the Infona system (www.infona.pl).

II. Explicit Semantic Analysis

Explicit Semantic Analysis (ESA) proposed in [9] is a method for automatic tagging of textual data with Wikipedia concepts. It utilizes natural language texts of Wiki articles as textual representations of the corresponding concepts. It is assumed that the Wiki articles contain definitions of the concepts and describe their semantic. Those representations are regarded as a regular collection of texts and are matched against documents to find the best associations [10].

In ESA, the semantic relatedness between concepts and documents is computed two-fold. First, after the initial processing (tokenization, stemming, stop words removal), the corpus and the concept definitions are converted to the *bag-of-words* representation. Each of the distinct terms in the documents is given a weight expressing a strength of its association to the text. Assume that after the initial processing of a corpus consisting of M documents, $D = \{D_1, \ldots, D_M\}$, there have been identified N distinct terms (e.g. words, stems, n-grams) $t_1, \ldots, t_N$. Any text D_i in the corpus D can be represented by a vector $W_i = \langle w_{1,i}, \ldots, w_{N,i} \rangle \in \mathbb{R}_+^N$, where each coordinate $w_{j,i}$ expresses a value of some relatedness measure for j-th term in vocabulary (t_j), relative to this document. The most common measure used to calculate $w_{j,i}$ is the *tf-idf* (term frequency-inverse document frequency) index [1], defined as:

$$w_{j,i} = tf_{i,j} * idf_j = \frac{n_{i,j}}{\sum_{k=1}^{N} n_{i,k}} \log\left(\frac{M}{|\{i : n_{i,j} \neq 0\}|}\right), \quad (1)$$

where $n_{i,j}$ is the number of occurrences of the term t_j in the document D_i.

In the second step, the bag-of-words representation of the concept definitions is transformed into an inverted index that maps the terms $t_1, \ldots, t_N$ into lists of K concepts $C_1, \ldots, C_K$, described in an external knowledge source. The inverted index can be used as a semantic interpreter. Given a document from the corpus D, we may iterate over terms from the text, retrieve the corresponding entries from the inverted index and merge them into a vector of concept weights that represents the analyzed document.

Let $W_i = \langle w_{1,i}, \ldots, w_{j,i}, \ldots, w_{N,i} \rangle$ be a bag-of-words representation of an input document D_i, where $w_{j,i}$ is the tf-idf index of t_j defined by the formula (1). We can analogically quantify the association between the term t_j and the k-th concept C_k by computing the *bag-of-words* representations of the concept descriptions. Those associations constitutes the inverted index. Let $inv_{j,k}$ be the inverted index entry for the term t_j and the concept C_k. For convenience, all the weights $inv_{j,k}$ can be arranged in a sparse matrix structure with N rows and K columns, denoted by INV, such that $INV[j,k] = inv_{j,k}$ for any pair (j,k), such that $j = 1, \ldots, N$ and $k = 1, \ldots, K$. The new vector representation of D_i will be denoted by $V_i = \langle v_{1,i}, \ldots, v_{K,i} \rangle$ where:

$$v_{k,i} = \sum_{j : t_j \in D_i} w_{j,i} * inv_{j,k}. \quad (2)$$

In other words, the above equation expresses a standard dot product of the k-th column of the matrix INV and the vector W_i. This new representation will be called a *bag-of-concepts* of a document D_i.

For practical reasons it may also be useful to represent documents only by the most relevant concepts. In such a case, the association weights can be used to rank the concepts and to select only the top concepts from the ranked list. One can also apply some more sophisticated methods that involve utilization of internal relations in the knowledge base (e.g. for semantic clustering of concepts and assigning only the most representative ones to the documents).

The original purpose of Explicit Semantic Analysis was to provide means for computing semantic relatedness between texts. However, an intermediate result – weighted assignments of concepts to documents (induced by the term-concept weight matrix) may be naturally utilized in document retrieval as a semantic index [3], [5]. Although originally ESA was meant to utilize the Wikipedia articles as the external knowledge source, it seems reasonable that for specialized tasks, such as indexing articles from a specific branch of science, it is better to use concepts described in dedicated knowledge bases or ontologies. A user (an expert) may query a document retrieval engine for documents matching a given ontology concept. If the concepts are already assigned to documents, this problem is conceptually trivial. However such a situation is relatively rare, since the employment of experts who could manually labeled documents from a huge repository is expensive. On the other hand, the utilization of an automatic tagging method, such as ESA, allows to infer a labeling of previously untagged documents or at least it can support the experts in that task.

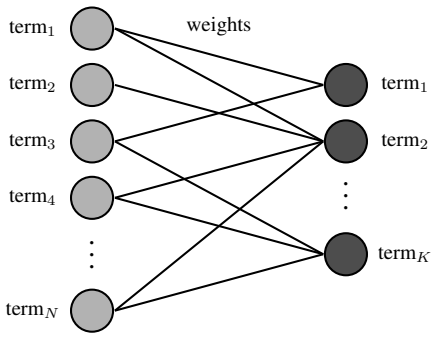

Fig. 1. A schema of the inverted index utilized by ESA.

III. The Adaptive Learning Algorithm

During our research on the automatic tagging methods we noticed that the structure of the inverted index used by ESA resembles a structure of an artificial neural network [13]. This network consists of a single layer of perceptrons (neurons)

that correspond to the different concepts and their inputs correspond to the distinct terms from the concept definitions. However, unlike in a classical neural network, in the case of ESA the inputs are not connected with every neuron. In fact, the net of the connections is rather sparse, since only a small fraction of terms appears in a single description of a concept. Each connection has a non-negative weight from the inverted index, which quantifies the association between the term and the concept. Such a schema of the inverted index structure is depicted in Figure 1.

In the classical neural networks, the activation of each neuron is determined by computing a value of, so called, an activation function. This function takes as its argument a weighted sum of input values and returns a real-valued output. In ESA the activation function corresponds to the identity function. Nevertheless, it is possible to use other types of functions, including those which are typically used in perceptrons (e.g. sigmoid, hyperbolic tangent [13]), in order to scale the association values into a desired range. We can also easily modify the network structure from Figure 1 by adding an additional input, connected to each of the neurons. This input will be treated as an activation threshold. We will assign a concept C_k to a document D_i only if its association $v_{k,i}$ exceeds the corresponding activation threshold a_k, $k = 1, \ldots, K$.

Since the model resembles a neural network, in our previous research [8] we proposed to use a simple learning algorithm for the adaptation of weights from the inverted index to a feedback regarding the tagging quality, obtained from domain experts. The algorithm was based on a typical perceptron learning schema, namely the error backpropagation approach [14]. It is shown in Figure 2. Here we present an improved version of this algorithm that does not require a prior information regarding a number of concepts that should be assigned to each document. For this purpose, we first need to discuss the types of errors that can be made in predicting a set of labels that should be assigned to a given document.

Let us denote by $esa(D_i, INV, A)$ a set of concepts assigned by ESA to a document D_i, using the inverted index INV and the vector of activation thresholds A. This set consists of those concepts whose associations to D_i exceeded the activation threshold values, i.e., $esa(D_i, INV, A) = \{C_k : v_{k,i} > a_k, k = 1, \ldots, K\}$. We assume that there is available a corpus D of training documents, for which we can get the sets of truly related concepts. Since those sets of reference labels usually have to be obtained from domain experts, we will denote them by $exp(D_i)$.

Knowing the sets $esa(D_i, INV, A)$ and $exp(D_i)$ we can divide their union into three mutually disjoint subsets: $TP_i = esa(D_i, INV, A) \cap exp(D_i)$, $FP_i = esa(D_i, INV, A) \setminus exp(D_i)$ and $FN_i = exp(D_i) \setminus esa(D_i, INV, A)$. They can be interpreted as the sets of *Truly Positive*, *Falsely Positive* and *Falsely Negative* cases in the classical machine learning theory [13]. The set TP_i contains truly relevant concepts which were assigned by ESA. Since we want to maximized its cardinality, in every iteration of the learning algorithm we will increase the weights of the connections between the terms t_j from D_i and the concepts from TP_i. The update will be proportional to the association strength between the terms and D_i, which is quantified by the values of $w_{j,i}$. Analogically, we will increase the weights of the concepts from FN_i and decrease those of the concepts from FP_i. At the same time we will be updating the activation thresholds in order to move the concepts from FN_i into TP_i and to remove the FP_i concepts from the set $esa(D_i, INV, A)$. Details of this procedure are explained by Algorithm 1. We call it Adaptive Semantic Analysis (ASA) by an analogy to the ESA algorithm.

We impose one constraint on the weight refinement procedure. Only the available concept descriptions determine the network structure of the inverted index. During the learning procedure we do not construct any new connections in the network, i.e. we restrict the weights $inv_{j,k}$ equal zero to remain zero for a whole learning process. Moreover, the updates in our algorithm are multiplicative, which guarantees that $inv_{j,k} \geq 0$ for every j and k. This restriction is motivated by an intuition that the original concept descriptions, which are usually provided by domain experts, contain sufficient vocabulary to characterize the concepts, thus they define a good model of the terms-to-concepts relations. Additionally, by tuning a large number of weights it is possible to fall into a trap of over-fitting the inverted index to the reference data. Moreover, the reduced number of connections in the inverted index makes the learning more efficient, since there are needed considerably less updates at every iteration of the ASA algorithm.

In the algorithm, the activation thresholds are tuned along the concept weights. In practice, however, they do not need to be updated in every iteration. In order to speed up the learning process, the line number **(31)** of Algorithm 1 can be executed periodically, with the length of the period controlled by an additional parameter.

IV. Experiments

We tested our multi-label tagging system on three different problems, namely automatic labeling of biomedical articles from the PubMed Central repository with headings from the MeSH ontology, assigning categories from ACM Computing Classification System (ACM CCS) to articles from ACM Digital Library and labeling research papers from the Infona repository [6] with the OECD Fields of Science and Technology Classification (OECD FOS) categories. In all those experiments we followed the same testing methodology. We split the available corpus into a training and a test set. We use the training data for adaptive learning of the associations between terms and concepts with the proposed ASA algorithm (see Section III), and then we verify the performance of our tagging system on the test data. We repeat the whole procedure several times with different divisions of the data and report the average results. As the quality measures we use average values of the F_1-$score$, $Precision$ and $Recall$, obtained for all the test documents by comparing the predicted tags to those which were assigned by experts or authors. This type of evaluation of a tagging quality is popular for the multi-label classification problems [15].

A. Experiment on Biomedical Articles

In our first series of experiments we performed the tests on a corpus from the PubMed Central repository [16], consisting of roughly $38,000$ publicly available articles. As the external knowledge base we used the MeSH ontology [11],

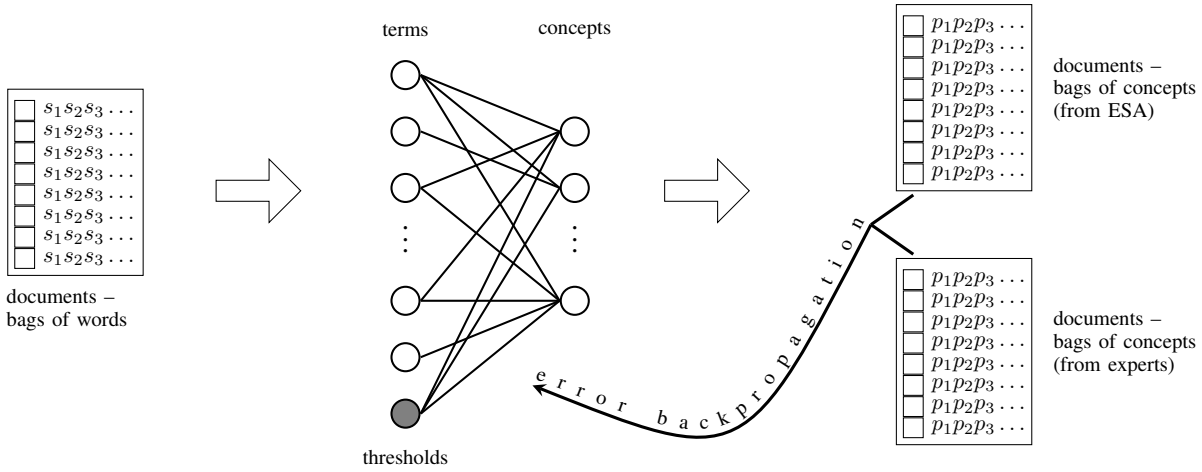

Fig. 2. The learning schema for Adaptive Semantic Analysis.

which is also employed by PubMed to index articles and to facilitate search through its resources. We adapted the ESA method to enable tagging documents from the corpus with the MeSH concepts (also known in MeSH terminology as the headings). In the MeSH ontology, each heading is accompanied by a descriptor data record prepared by domain experts. We composed the final natural language description of the MeSH headings by concatenating the following elements of the corresponding MeSH record: *MESH HEADING* (the name), *MESH SCOPE NOTE* (a short textual description), *ENTRY* (synonyms), *PREVIOUS INDEXING* (previous naming) and *PHARMACOLOGICAL ACTION* (known pharmacological activity). We processed those descriptions using text mining tools in order to determine the initial inverted index structure of our model (i.e. relations between the terms and concepts) and the initial values of the weights. In the experiments we used the edition of MeSH from the year 2012, which contained records on 26.142 main concepts (the headings).

Additionally, for each document in the corpus we obtained sets of MeSH headings assigned by experts from the U.S. National Library of Medicine. The average number of tags assigned to a single article by the NLM experts was ≈ 13.5. We treat those tags as a reference and we utilize them for improving the terms-to-concepts associations with the adaptive learning algorithm described in Section III. We also used those tags for the evaluation purpose. In the tests, we run the adaptation of the inverted index on randomly selected $20,000$ documents and then we use it to tag the remaining part of the corpus. As the starting activation thresholds we use a vector with all coordinates equal 5. This value was chosen using a common sense, based on an observation of a distribution of the concept associations for several exemplary documents. We assess the quality of the tagging by computing the average values of F_1-$score$, $Precision$ and $Recall$ measures. Results of those tests are shown in Figure 3.

The results of the tests turned out to be very promising. On the test data we observed a significant improvement of performance over the regular ESA (the iteration number 0 in the plots) in terms of the computed statistics. For instance, F_1-$score$ value improved by approximately 160% (from ≈ 0.15 to ≈ 0.39). Even a greater improvement was noticed with regards to the values of $Recall$. After the last iteration, its average value exceeded 0.43 while for the regular ESA the average $Recall$ was ≈ 0.16. This however, can be partially explained by the fact that in the initial learning iterations the resulting tagging model usually returned a lower number of labels than the experts.

B. Experiment on Papers from ACM Digital Library

This experiment was conducted on a corpus consisting of publicly available meta-data entries for articles from ACM Digital Library. The corpus contain information on approximately $400,000$ research papers from the field of computer science. The available meta-data included a title, an abstract and in some cases a list of key phrases assigned by authors. We concatenated those information for each document into a single text and we used it to compute its bag-of-words representation. Additionally, the data contained a list of associated ACM CCS categories which also were inputted by the authors. On average, every article was associated with only three out of 1571 possible categories.

The task in this experiment was to label the articles with the ACM CCS categories based on the remaining meta-data. Unlike in the previous experiment, however, this time we did not possess any additional knowledge base with natural language descriptions of the concepts. To deal with this problem we had to slightly modify the procedure of our experiment. After the initial division of the data into the training and test sets (in proportion of 1:1), we divided the training data into two separate sets. For each of the ACM CCS categories we concatenated into a single text the meta-data of all articles that were labeled with this category by the authors. In this way we obtained the textual representation of the categories that could be used for the computation of the initial term-to-concepts associations for our tagging system.

In the second step, we used those associations as a starting point for the ASA algorithm. We performed the adaptive learning of the associations on the remaining part of the training data. We initiated the learning process with the activation thresholds set to 0.30 for all the categories. The starting value of this parameter was much lower than in the experiments

Algorithm 1: Computation of a new inverted index matrix INV^{l+1} and activation thresholds A^{l+1} in the l-th iteration of the adaptive learning algorithm (ASA).

Input: A corpus $D = \{D_i : i \in 1, \ldots, M\}$; INV^l; activation thresholds $A^l = \langle a_1, \ldots, a_K \rangle$;
Output: An updated matrix INV^{l+1}; a vector A^{l+1};

begin
  Initiate ΔINV and CU as empty $N \times K$ matrices;
  Initiate ΔA as a zero vector of length K;
  for $i = 1$ **to** M **do**
    $TP_i = esa(D_i, INV^l, A^l) \cap exp(D_i)$;
    $FP_i = esa(D_i, INV^l, A^l) \setminus exp(D_i)$;
    $FN_i = exp(D_i) \setminus esa(D_i, INV^l, A^l)$;
    foreach $C_k \in esa(D_i, INV^l, A^l) \cup exp(D_i)$ **do**
      $tIds = \{j : t_j \in D_i \wedge INV^l[j,k] > 0\}$;
      $wSum = \sum_{j \in tIds} w_{j,i}$;
      if $C_k \in FP_i$ **then**
        foreach $j \in tIds$ **do**
          $\Delta INV[j,k] = \Delta INV[j,k] - INV^l[j,k] * w_{j,i} / wSum$;
          $CU[j,k] = CU[j,k] + 1$;
        $\Delta A[k] = \Delta A[k] + A^l[k] * \left(1 - \frac{|TP_i|}{|TP_i \cup FP_i|}\right)$;
      else
        foreach $j \in tIds$ **do**
          $\Delta INV[j,k] = \Delta INV[j,k] + INV^l[j,k] * w_{j,i} / wSum$;
          $CU[j,k] = CU[j,k] + 1$;
        $\Delta A[k] = \Delta A[k] - A^l[k] * \left(1 - \frac{|TP_i|}{|TP_i \cup FN_i|}\right)$;
  foreach (j,k) *such that* $CU[j,k] > 0$ **do**
    $\Delta INV[j,k] = \Delta INV[j,k] / CU[j,k]$;
  $INV^{l+1} = INV^l + \Delta INV$;
  $A^{l+1} = A^l + \Delta A / M$;
  return INV^{l+1} *and* A^{l+1}

on biomedical articles due to a fact that this time we had to operate on significantly shorter texts. We measured the quality of our tagging system by comparing the labels assigned to the test articles with the labels which were given by the authors. The results of those comparisons in the consecutive iterations of the learning algorithm are depicted on Figure 4.

Similarly to the previous experiments, the results clearly show that the learning algorithm significantly improves the quality of the tagging system in comparison to the standard ESA (the iteration number zero on the plots). In the test, the highest F_1-$score$ on the test set was ≈ 0.20. It was obtained in the last iteration (50-th) of the algorithm, which suggests that it would be possible to slightly improve the results by giving the algorithm some more time for learning. There is also a noticeable difference between the results on the training and test sets. The highest training F_1-$score$ exceeded 0.33, which is over 50% higher than the corresponding test score. On one hand this difference may be partially explained by the fact that authors do not follow any strict rules or guidelines when they assign the categories to their papers. It makes the assigned labels very subjective. As a consequence, the prediction of the ACM CCS categories becomes a very difficult task. On the other hand, the differences in the tagging quality for the training and test data may be caused by the way we generated the textual descriptions of the ACM CCS categories. The concatenation of many article abstracts had to result in the inclusion of many highly specialized terms into the descriptions. Such terms often allow to identify individual papers, thus their presence may lead to the over-fitting of the learning algorithm to the training data.

C. Experiment on Data from the Infona System

The last series of experiments was conducted on a corpus obtained from the Infona repository [6]. Infona contains meta-data of over 1.8 million articles from a wide range of science fields. However, in our experiments we were restricted to only a small sample of all the data from this repository, i.e. our corpus contained information from 1000 meta-data entries. Each entry consisted of an article title in English, author names and an English abstract. Additionally, for many entries there were available key phrases assigned by the authors. Similarly as in the previous experiments, for each article we concatenated the available meta-data (we skipped the information regarding the authors) to create their textual representation.

The task in those experiments was to learn how to tag the documents from Infona with the categories from the OECD FOS classification. This classification system consists of 42 main categories grouped into six different upper-level categories, namely *Natural sciences*, *Engineering and technology*, *Medical and Health sciences*, *Agricultural sciences*, *Social sciences* and *Humanities* [17]. In order to construct

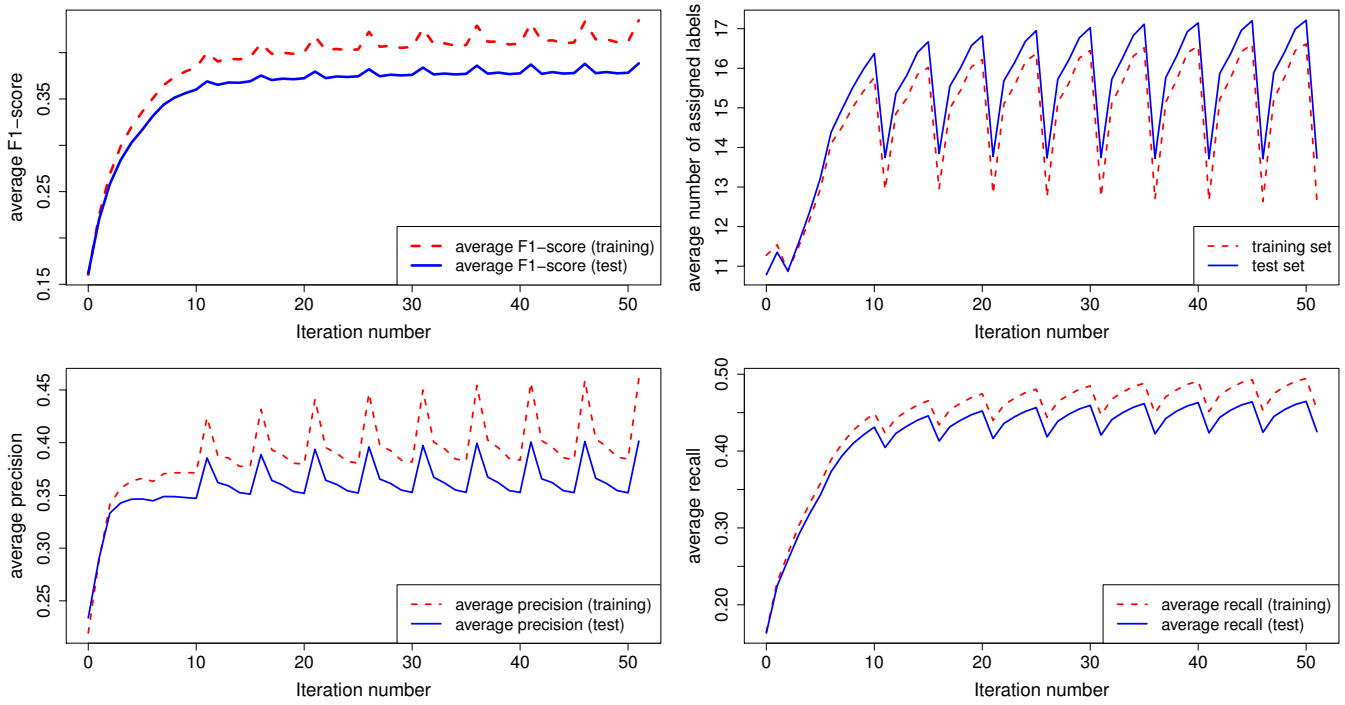

Fig. 3. Results of the adaptive learning algorithm on the PubMed Central corpus (50 iterations). The documents were labeled with the concepts from the MeSH ontology. For each learning iteration the average F_1-$score$, $Precision$, $Recall$ and a number of assigned categories is shown. The results in the iteration number 0 correspond to the standard ESA algorithm. The activation thresholds in those experiments were updated in every fifth iteration of the algorithm.

the textual descriptions for all the 42 categories we manually selected a number of related English Wikipedia articles and we concatenated their content.

The size of the corpus for those experiments was limited by the availability of the expert knowledge. Infona did not provide us any information about the OECD FOS categories of the documents. In order to create a reference set of labeled documents we had to ask volunteers to manually tag the data. In this way we obtained a total of 1000 labeled meta-data entries which we could use in the experiments. A single document on average was assigned to 1.7 categories. Approximately 30% of the documents were labeled by more than one person. In this way we could check how difficult this task is and get a good estimation of a reference quality assessment. It turned our that the average cross-expert F_1-$score$ merely exceeds 0.51, while the average $Precision$ and $Recall$ values are about 0.55. It means that on average, two different experts agree only on about a half of the assigned categories, thus we should not expect a better result from an automatic tagging method.

In the experiments we used 800 documents as a training set and the remaining 200 served as a test set. Due to the small size of the test sets, we repeated the testing procedure 20 times on different divisions of the data in order to get reliable estimations of the tagging quality. Similarly as in the case of the ACM Digital Library corpus, we set the initial values of the activation thresholds to a low value, i.e. they were all equal 0.25. The average results of those tests for the consecutive iterations of the ASA algorithm are presented in Figure 5. In those plots, the values of the cross-expert quality estimations are marked by the thick black lines.

The experimental results once again clearly demonstrate usefulness of our learning algorithm. The average F_1-$score$ value obtained using the adapted inverted index was greater by over 40% than the score of the standard ESA algorithm. For ASA it was approximately 0.47. It is worth noting that this improvement was possible, even though the number of available training documents was very limited. The best F_1-$score$ on the test set was usually achieved around thirtieth iteration of the algorithm and after that point we noted a slight decrease in the results. Since the scores obtained on the training set systematically grew and often exceeded 0.8, this can be most likely explained by the over-fitting problem. Nevertheless, the score achieved using ASA was very close to the cross-expert F_1-$score$ which confirms the effectiveness of the proposed adaptive learning algorithm.

V. Conclusions

In the paper we discussed an adaptive learning framework, called Adaptive Semantic Analysis, which can be utilized for improving the terms-to-concepts associations from the inverted index of the ESA algorithm. We described in details the learning procedure and we showed its effectiveness in dealing with real-life problems. In particular, we presented results of experiments on three document corpora, in which the ASA algorithm was used to facilitate the automatic tagging of documents with concepts from different knowledge bases.

We hope that in a future our automatic tagging module can become a part of a larger scientific article repository platform. We are currently trying to integrate our SONCA platform with the Infona repository. This may enable an

For each learning iteration the average F_1-$score$, $Precision$, $Recall$ and a number of assigned categories is shown. The results in the iteration number 0 correspond to the standard ESA algorithm. The activation thresholds in those experiments were updated in every fifth iteration of the algorithm.

efficient and automatic semantic indexing of Infona's resources which would allow to better fulfill the information needs of Infona's users. Apart from the direct use as an indexing module of the search engine, the tags returned by our system could be utilized for, e.g., improving the clustering of search results or assigning comprehensible names to document clusters.

***Abstract*—This paper introduces a new type of brain emotional learning inspired models (BELIMs). The suggested model is utilized as a suitable model for predicting geomagnetic storms. The model is known as BELPM which is an acronym for Brain Emotional Learning-based Prediction Model. The structure of the suggested model consists of four main parts and mimics the corresponding regions of the neural structure underlying fear conditioning. The functions of these parts are implemented by assigning adaptive networks to the different parts. The learning algorithm of BELPM is based on the steepest descent (SD) and the least square estimator (LSE). In this paper, BELPM is employed to predict geomagnetic storms using the Disturbance Storm Time (Dst) index. To evaluate the performance of BELPM, the obtained results have been compared with the results of the adaptive neuro-fuzzy inference system (ANFIS).**

I. Introduction

THE geomagnetic storm, which originates from the solar wind, disturbs the Earth's magnetosphere and has caused harmful damage to the ground based communication, electricity power network, etc. Therefore, developing alert systems for geomagnetic storms is essential in order to prevent these harmful effects [1]-[6].

The disturbance storm time, Dst, is one of the main indices of a geomagnetic storm and was defined by Bruce Tsurutani [1], [5]-[6]. It is a measurement to count 'the number of solar charged particles that enter the Earth's magnetic field' [6]. The Dst index has been proposed to characterize the phases of geomagnetic storms i,e., the initial phase, main phase and recovery phase and has been recorded by several space centers such as the World Data Center for Geomagnetism, Kyoto, Japan.

Different machine learning methods e.g., linear input-output techniques or linear prediction filtering neural networks [8][9], neurofuzzy methods [2],[4], have been investigated for predicting geomagnetic storms using the Dst index [1]-[4], [6]-[12]. Amongst them, neural networks and neuro-fuzzy models have shown high generalization [13],[14] capabilities to model nonlinear behavior of the Dst index .

Recently, inspiration from the mammalian emotional systems to develop emotion-based models has received fairly good attention [15]-[25]. The emotion-based models that were proposed in [15]-[17] have been developed by a limited modification of a computational model of emotional learning that is referred to as 'amygdala-orbitofrontal system'; this computational model simulates the emotional learning in the amygdala (i.e.,one region of the mammalian brain) [26]. The obtained results from [15]-[17] verify that there are not able to accurately predict chaotic behavior of nonlinear systems.

This paper suggests a new instance of Brain Emotional Learning-Inspired Models (BELIMs) that are emotion-based models. The suggested model is applied to predict the Dst index of geomagnetic storms. So far different variations of BELIMs have been [18]-[25] examined for forecasting solar activity and geomagnetic storms.

The main contribution of this paper is to present a new version of BELIMs to be used as an accurate prediction method for the long horizon prediction of the Dst index. Another contribution of this paper is to provide comparative results when predicting the Dst index.

The rest of the paper is organized as follows: Section II reviews related works to emotions. Section III describes the structure, function and learning algorithm of the BELPM (Brain Emotional Learning Based Prediction Model). Section IV reviews the related studies in predicting the Dst index and the results of BELPM to predict the Dst index are described. Finally, conclusions about the performance of BELPM and the further improvements to the suggested model are discussed in Section V.

II. Related Works To 'Emotions'

Neuroscientists and psychologists have tried to describe emotions on the basis of different hypotheses, e.g., psychological, neurobiological, philosophy, and learning hypotheses [27]. Cognitive neuroscientists have also tried to describe the neural system underlying the emotional process. One of the earlier works is the 'Papez circuit' (See Fig. 1) that was proposed by Jamez Papez. As Fig. 1 shows, this circuit includes the 'hypothalamus, anterior thalamus, cingulate gyrus and hippocampus' [27].

978-83-60810-58-3/$25.00

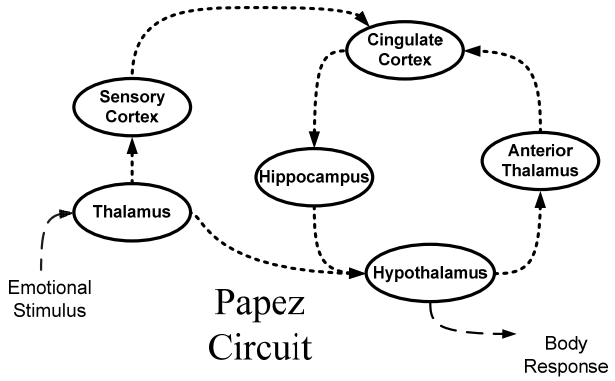

Fig.1. The Papez Circuit and its component.

MacLean modified the Papez circuit and proposed the limbic system theory to describe the regions of the brain that are responsible for emotional processing. The limbic system includes the hippocampus, amygdala, thalamus and sensory cortex [27]. Later, neuroscientists rejected the limbic system theory and stated that different parts of the brain are responsible for different emotional behavior [28]. Fear is a common emotional behavior that exists as well for humans as animals. Fear conditioning has been defined as a 'behavioral paradigm' which means learning fearful stimuli to predict aversive events [28].

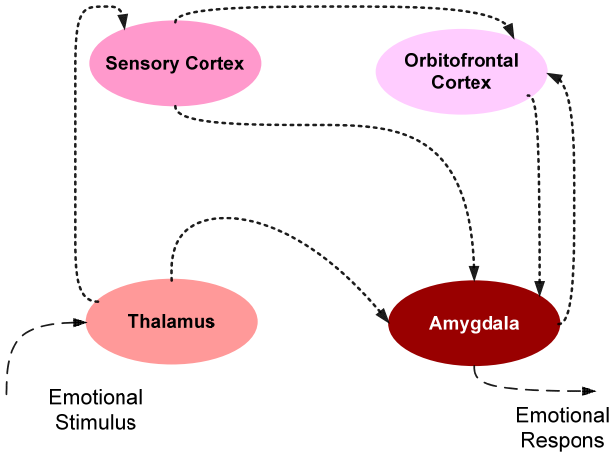

Fig. 2. A schematic of the brain's parts and their interconnections in fear conditioning.

Figure 2 displays how the amygdala and other parts of the brain, thalamus, sensory cortex and orbitofrontal cortex connected to process a fearful stimulus in the mammalian brain. As the diagram indicates, the amygdala is the central part to process the emotional stimulus. The neural structures of emotional behavior have been the foundation of the computational model of emotional learning.

Computational models of emotion [23],[25],[26] are computer-based models that have been developed to simulate different aspects of the emotional system. A good example of computational models is a model that is referred to as amygdala-orbitofrontal system and has been proposed to simulate emotional learning in the amygdala [26].

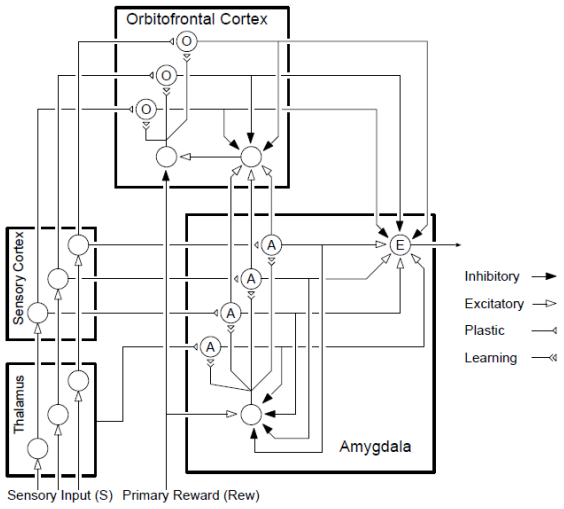

Fig.3. The Amygdala-orbitofrontal system [26].

Figure 3 depicts the internal structure of the amygdala-orbitofrontal system and describes that orbitofrontal cortex and amygdala consists of several nodes; the output of each node of the amygdala is represented as A_i while the output of each node of the orbitofrontal cortex is represented as O_i. The overall output of the model is represented as **E** and it is formulated as equation (1) [26].

$$\mathbf{E} = \sum_i A_i - \sum_i O_i \tag{1}$$

Here A_i and O_i are the output of the i^{th} node of the amygdala and the orbitofrontal cortex, respectively. The updating rules of the model are based on the reinforcement signal **REW**. The updating rules are formalized as equations (2) and (3) and are utilized to adjust the weights **V** and **W** that are associated with the nodes of the amygdala and the orbitofrontal part, respectively [26]. Here s_i is the input stimulus for the i^{th} node of the amygdala and the orbitofrontal cortex [26].

$$\Delta V_i = \alpha(S_i \times \max(0, \mathbf{REW} - \sum_i A_i)) \tag{2}$$

$$\Delta W_i = \beta(S_i \times (\sum_i O_i - \mathbf{REW})) \tag{3}$$

The amygdala-orbitofrontal model [26] has a simple structure and has been used as a foundation for numerous l emotion-based models [15]-[25],[29]-[33]. As was discussed earlier, the emotion-based models in [15]-[16] were proposed as chaotic time series prediction models. The foundation of these models is amygdala-orbitofrontal system; however they were developed by changing the updating rules of amygdala-orbitofrontal system. These models have not shown good results to accurately predict chaotic time series [15]-[16]. In [17], another modification of amygdala-orbitofrontal system was proposed by changing the input vector of the thalamus and the amygdala part; in addition, the updating rules of amygdala and orbitofrontal cortex were modified. The model that is named 'ADBEL'[17]

(adaptive brain emotional decayed learning) was applied to predict the hourly Dst index; however, the obtained results verify the ADBEL could not accurately predict chaotic behavior of the Dst index.

The Emotion-based controllers [29]-[33] have also been developed by imitating the structure of the amygdala-orbitofrontal.

This paper presents a new type of emotion-based prediction models. Although the general structure of this model is similar to the amygdala-orbitofrontal system, the internal structure of this model is different from the amygdala-orbitofrontal system.

III. Brain Emotional Learning-Based prediction Model

The Brain Emotional Learning-Based Prediction Model (BELPM) is a type of Brain Emotional Learning-Inspired Model (BELIM) which is a new category of computational intelligence models. The general structure of a BELIM is an extension of the amygdala-orbitofrontal system by adding new internal parts that have been inspired by the neural structure of one of the emotional systems in the brain. Different types of BELIM: Brain Emotional Learning-based Fuzzy Inference System (BELFIS), Brain Emotional Learning-based Recurrent Fuzzy System (BELRFS) and Emotional Learning Inspired Ensample Classifier (ELiEC) [18]-[25] have been proposed as prediction models and classification models.

A. Structural Aspect of BELPM

Figure 4 depicts the structure of BELPM and shows that it consists of four main parts: TH, CX, AMYG and ORBI which refer to the THalamous, sensory CorteX, AMYGdala, and ORBItofrontal cortex, respectively. The structure of BELPM copies the interconnection of those parts (THalamous, sensory CorteX, AMYGdala, and ORBItofrontal cortex) that are responsible to process the emotional stimuli. It should be noted that these regions of the brain are very complex and there is no intention to mimic their functionality and all their connections in detail.

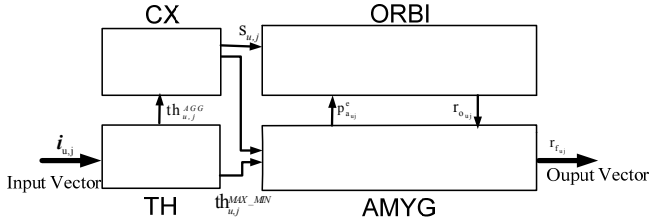

Fig. 4. The structure of BELPM.

The following steps describes the input and output of each part of BELPM; when it receives an input as $i_{u,j}$ from the training data set, $\mathbf{I}_u = \{\mathbf{i}_{u,j}\}_{j=1}^{N_u}$.

1. First, $\mathbf{i}_{u,j}$ the j^{th} input vector from $\mathbf{I}_u = \{\mathbf{i}_{u,j}\}_{j=1}^{N_u}$ (taking the assumption that the number of training samples is equal to N_u ; the subscript u has been used to determine the input data is chosen from the training data set) enters the TH, which provides two outputs, $\mathbf{th}_{u,j}^{Max\_Min}$ and $\mathbf{th}_{u,j}^{AGG}$ which are sent to the AMYG and the CX, respectively.

2. The CX provides $\mathbf{s}_{u,j}$ and sends it to both the AMYG and the ORBI.

3. The AMYG receives two inputs: $\mathbf{th}_{u,j}^{Max\_Min}$ and $\mathbf{s}_{u,j}$. It provides the primary output, $r_{a_{u,j}}$, and expected punishment, $p^e_{a_{u,j}}$, that is sent to the ORBI (the subscript a has been used to show the outputs of AMYG).

4. The ORBI receives $\mathbf{s}_{u,j}$ and $p^e_{a_{u,j}}$. It provides the secondary output, $r_{o_{u,j}}$, and sends it to the AMYG. 5. The AMYG receives $r_{o_{u,j}}$ and provides the final output, $r_{f_{u,j}}$ (the subscript f has been used to show the final outputs).

B. Functional Aspect of BELPM

The function of BELPM is implemented by assigning adaptive networks to different parts. Figure 5 describes how the adaptive networks can be assigned to each part to implement the functionality of that part.

The adaptive network (see Fig. 6) consists of a number of nodes that are connected by directional links. The nodes of the adaptive network can be classified into circle and square nodes. A circle node has a function without adjustable parameters; in contrast, the square nodes have been defined by a function with the adjustable parameters. The learning parameters of an adaptive network are a combination of linear and nonlinear parameters and can be adjusted by using a learning algorithm.

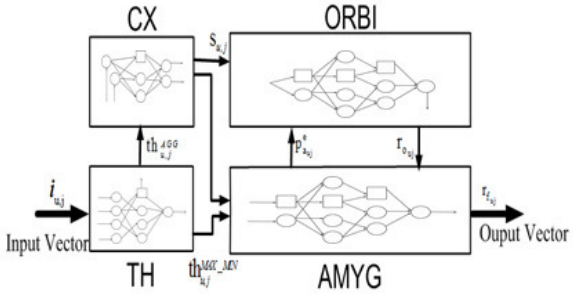

Fig. 5. Assigning different adaptive networks to different parts of BELPM.

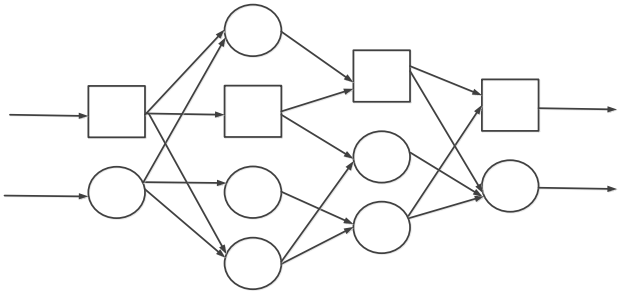

Fig. 6. A structure of an adaptive network.

C. A Weighted k-Nearest Neighbor based Adaptive Network

In BELPM, weighted k-nearest neighbor based adaptive networks are assigned to the AMYG and the ORBI. This adaptive network has been developed on the basis of weighted k-Nearest Neighbor (Wk-NN). Figure 7 describes a simple Wk-NN based adaptive network and shows that it is divided into four layers. In the following, the function, the input and the output of each layer has been explained.

The first layer consists of k square nodes with K(.) function (kernel function). Note that in Fig.7, k is equal to three. This layer has an input vector as $\mathbf{d}_{\min} = \{d_{\min,m}\}_{m=1}^{k}$. The $\mathbf{d}_{\min}$ is a set of k minimum distances of $\mathbf{d} = \{d_j\}_{j=1}^{N_u}$. The distances vector $\mathbf{d} = \{d_j\}_{j=1}^{N_u}$ can be calculated as Euclidean distances between a new input as $\mathbf{i}_{c,j}$ and the training data as $\{\mathbf{i}_{u,j}\}_{j=1}^{N_u}$. The output vector of the m^{th} node of the first layer is calculated using equation (4). Here, the input to the m^{th} node is $d_{\min,m}$.

$$n_m^1 = K(d_{\min,m}) \tag{4}$$

In general, the kernel function for the m^{th} node can be one of the functions that have been defined as equations (5), (6), and (7). The input and the parameter of K(.) of m^{th} node can be determined using d_m and b_m .

$$K(d_m) = \exp(-d_m b_m) \tag{5}$$

$$K(d_m) = \frac{1}{(1+(d_m b_m)^2)} \tag{6}$$

$$K(d_m) = \frac{\max(\mathbf{d}) - (d_m - \min(\mathbf{d}))}{\max(\mathbf{d})} \tag{7}$$

The second layer is a normalization layer and has k nodes (fixed or circle), which are labeled N to calculate the normalized values of $\mathbf{n}^1$ using (8). The input vector of this layer is $\mathbf{n}^1$ and the output of m^{th} node in this layer can be calculated as (8)

$$\bar{n}_m^1 = \frac{(n_m^1)}{\sum_{m=1}^{k} n_m^1} \tag{8}$$

The third layer has k circle nodes; the function of m^{th} node of this layer is given in (9). This layer has two input vectors, $\bar{\mathbf{n}}^1$ and $\mathbf{r}_{\min,u}$; the latter is a vector that is extracted from $\mathbf{r}_u = \left[r_{u,1}, r_{u,2}, ..., r_{u,N_u}\right]$ and is related to the target outputs of the k samples of $\{\mathbf{i}_{u,j}\}_{j=1}^{N_u}$ that have minimum distances with the new input $\mathbf{i}_{c,j}$. The output of this layer is $\mathbf{n}^3$.

$$n_m^3 = \frac{(n_m^1)}{\sum_{m=1}^{k} n_m^1} \times r_{u,m} \tag{9}$$

The fourth layer has a single node (circle) that performs the summation of the input vector, $\mathbf{n}^3$ to produce $\mathbf{r}$.

The above explanation has illustrated the function of a simple Wk-NN based adaptive network. It should be noted that in BELPM, the AMYG and the ORBI are assigned this type of adaptive network.

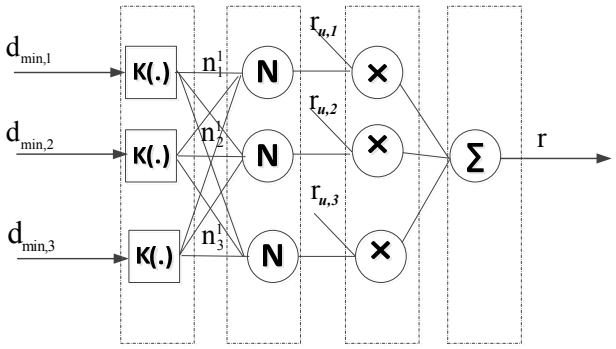

Fig.7. A weighted k-Nearest Neighbor adaptive network.

D. Learning Aspect of BELPM

To adjust the linear and nonlinear learning parameters, a hybrid learning algorithm that consists of the steepest descent (SD) and the least-squares estimator (LSE) is used. The SD updates the nonlinear parameters in a gradient related direction to minimize the loss functions, which are defined based on the outputs of the adaptive networks. The LSE is applied to update the linear parameters. The learning algorithm has been explained in detail in [25].

IV. Related work to Predict Geomagnetic Storms

As was previously discussed, developing an alert system for geomagnetic storms is essential. The Dst index that has been defined to measure the intensity of geomagnetic storms has been utilized by many data driven models. The following subsection reviews several studies that have been used to predict geomagnetic storms.

A. Related works to Predict Geomagnetic Storm

A good review of earlier studies related to use the Dst index to predict geomagnetic storms have been done in [6]. The authors of [6] provided a survey of using the Dst index to predict geomagnetic storms; they also proposed a neural network-based prediction model to predict the minimum

values of the Dst index. The model was successfully evaluated to predict geomagnetic storms of 1980 and 1989. In [9], a recurrent neural network was introduced to predict one hour step of Dst from 2001. The authors of [9] also showed that combining principal component analysis (PCA) and NN could significantly increase the accuracy of prediction of a geomagnetic storm. The damage and harmful effects of geomagnetic storms were reviewed in [10]. The authors of [10] studied the effect of the embedding dimension on the chaotic behavior of the Dst time series; the proposed model in [10] was is study tested for two super storms: 13 March 1989 and 11 January 1997. In [2] a combination of Singular Spectrum Analysis (SSA) and locally linear neuro-fuzzy model was proposed as a useful methodology to increase the accuracy of long term prediction of Dst time series. Specifically, this method was examined to predict ten steps ahead of extracted Dst time series between 1988 and 1990, Within this time window the geomagnetic storm damaged Quebec's power grid and caused a blackout in Quebec [10] is included. A nice review of the Dst index prediction models and the benefits of prediction of the Dst index was presented in [12]. The authors of [12] also proposed a long term prediction model that is known as 'Anemomils'[12] and tested it for three geomagnetic storms of 2001, 2005 and 2012.

B. Evaluating the BELPM's Performance on the Dst index

This subsection evaluates BELPM's performance by examining it on two sets of the Dst index. The code of BELPM has been written in MATLAB and the Dst index can be downloaded from the World Data Center for Geomagnetism, Kyoto, Japan.

The first data set is related to the Dst index of the super storm that occurred in March 1989. The value of the Dst index on the 13th March of 1989 reached to '-589 nanotesla (nT)'. Figure 8 depicts the hourly DST index during January1988 to January 1990.

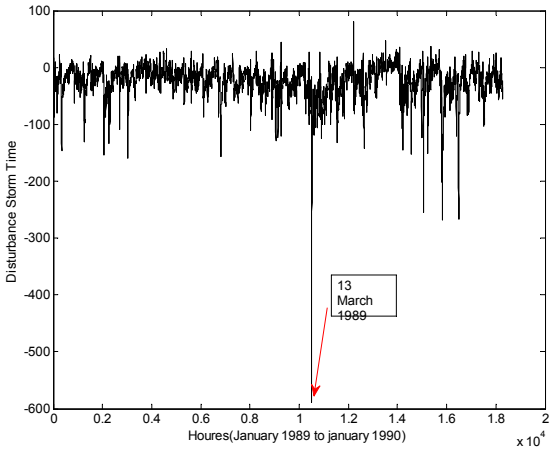

Fig. 8. The hourly Dst index from January 1988 to January 1990.

The second data set is related to the geomagnetic super storm which occurred on July 15th to 17th ; the minimum of the Dst index was – 301 nanotesla (nT). Figure 9 depicts the hourly DST index during the days of July 2000.

To provide a careful comparison with other methods, this paper utilizes two error measures: normalized mean square error (NMSE) and the correlation coefficient $\rho_{y,\hat{y}}$ that are given as equations (10) and (11).

$$\mathrm{NMSE} = \frac{\sum_{j=1}^{N}(y_j - \hat{y}_j)^2}{\sum_{j=1}^{N}(y_j - \bar{y}_j)^2} \tag{10}$$

$$\rho_{y,\hat{y}} = \frac{\mathrm{Cov}(y,\hat{y})}{\sigma_y \sigma_{\hat{y}}} \tag{11}$$

The parameters $\hat{\mathbf{y}}$ and $\mathbf{y}$ refer to the predicted values and desired targets, respectively. The parameter $\bar{\mathbf{y}}$ is the average of the desired targets.

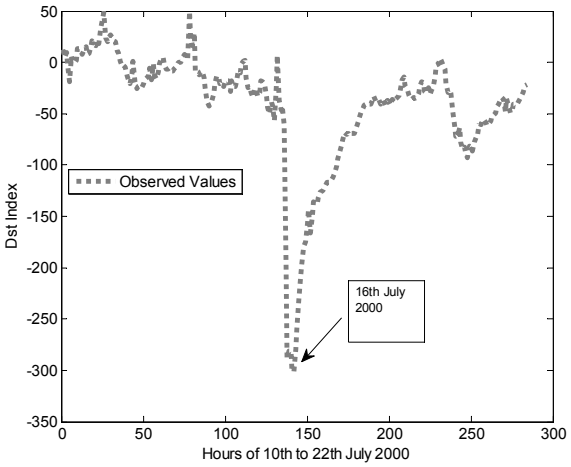

Fig.9. The hourly Dst index for July 2000.

As was mentioned earlier, in the first experiment, BELPM is tested to model the Dst time series between january1988 to January 1990. The Dst time series is related to one of the harmful geomagnetic storms which occurred during solar cycle 22 and caused severe damage to Quebec's electricity power system. In this case, the embedded dimension is selected as three. Figure 10 shows the inputs and output of BELPM as a black box to predict the Dst time series.

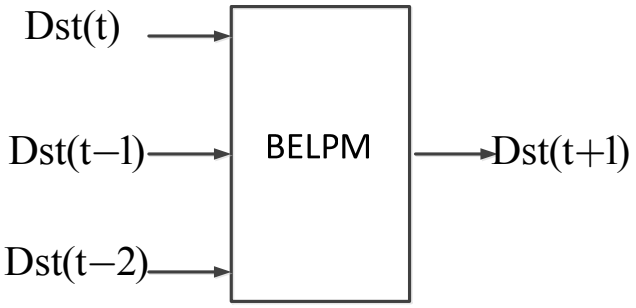

Fig.10. A black box of the BELPM to receive the Dst index and predict one step ahead of the Dst index.

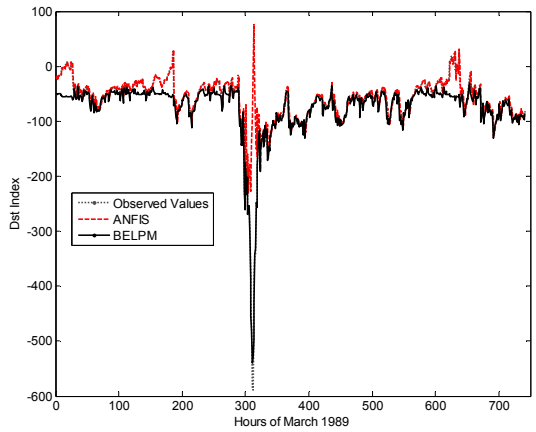
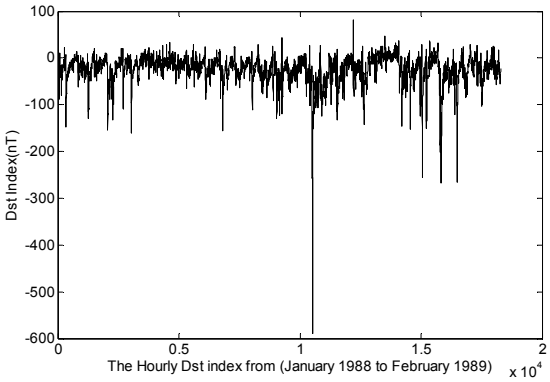
The predicted values of the Dst index versus the observed values of the first data set includes the Dst index of 13th March 1989 which has been described in Fig.11(a). The training data samples of Dst index has been depicted in Fig. 11(b). This figure shows that BELPM can outperform ANFIS in modeling the Dst index.



(a)



(b)

Fig.11. (a). The observed values and predicted values by ANFIS and BELPM. (b). The training data samples.

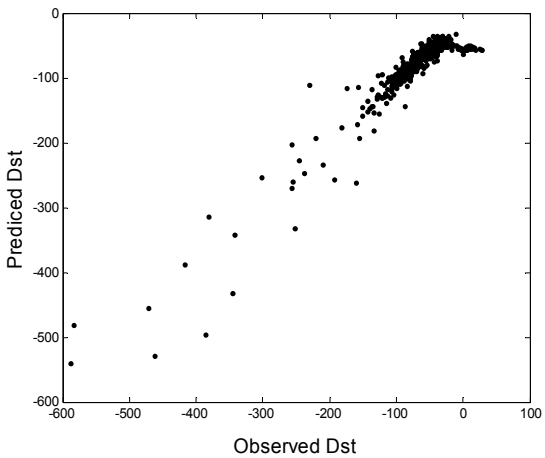


Fig.12. The correlation between the predicted values and the observed values of March 1989.

The correlation between the predicted values and the observed values are shown in Fig.12. The obtained NMSE of BELPM is 0.1041; while the NMSE index of ANFIS is more than 0.15.

For the second data set, BELPM is tested for multi-step ahead prediction of the Dst values. The main goal of this case is to evaluate the performance of BELPM for long term prediction of the Dst index. Figure 13. shows the predicted values by BELPM versus the observed values. For one step ahead prediction of the Dst index from 10th to 22nd of July 2000, the NMSE index of BELPM equals to 0.0593; while the NMSE index of ANFIS is equal 0.112. As this figure describes BELPM could predict the Dst index better than ANFIS. Figure 14 shows how increasing the prediction horizon causes increases in the prediction errors of BELPM and ANFIS. It is notable that the values of the NMSE index of BELPM are lower than the values of the NMSE index of ANFIS.

Tabel I compares the performance of three methods on six -steps ahead prediction of the Dst index. It is notable that the BELPM outperforms ANFIS and a neural network method in terms of NMSE and correlation coefficent.

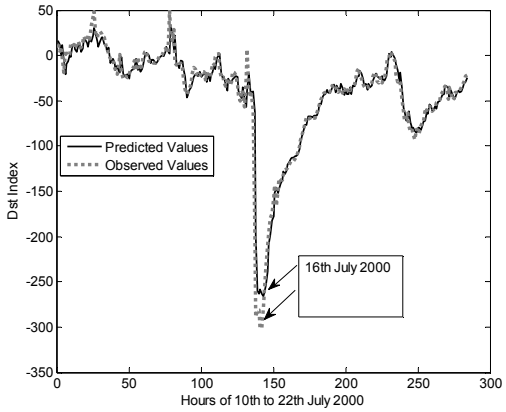

Fig.13.The predicted values of Dst index of 2000

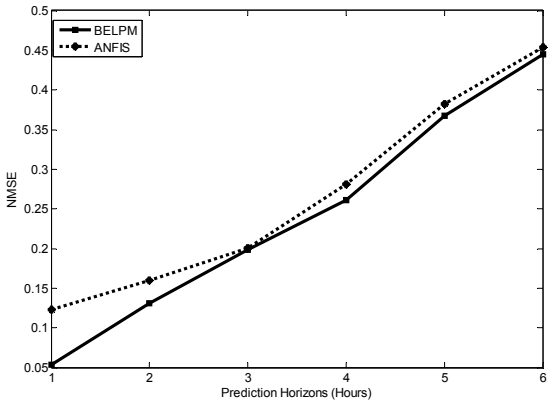

Fig.14. The values of NMSE index versus the prediction horizon of the Dst time series.

TABLE I
A COMPARISON BETWEEN BELPM, ANFIS AND ANN

Method	NMSE	Correlation
ANN[13]	-----	0.75
BELPM	0.44	0.75
ANFIS	0.45	0.74

V. CONCLUSION

This study has suggested another model of BELIMs that is referred to as Brain Emotional Learning-based Prediction Model (BELPM). This paper examined this model (BELPM) to model the Dst index and has been tested for prediction geomagnetic storms using two data sets of the Dst index. The results have verified that the proposed model can be used for long-term prediction of geomagnetic storms.

As future work, the authors consider adding an evolutionary-based optimization method e.g., genetic algorithm to find optimal values of the fiddle parameters, e.g., the number of neighbors and the initial values of nonlinear parameters. Other improvements in the model would be made on the basis of kd-Tree data structure to address "the curse of dimensionality" problem and decrease the computational time complexity of BELPM. To adjust the nonlinear parameters, different types of optimization methods (e.g., Quasi-Newton or Conjugate Directions) may be utilized. The good results obtained when employing the BELPM for predicting geomagnetic storms are a motivation for applying this model to classify patterns as well as to identify complex systems.

ACKNOWLEDGEMENT

The authors are grateful for accessing the Dst index provided by NOAA and World Data Center for Geomagnetism and Space Magnetism, Kyoto University

***Abstract*—The aim of this paper is to propose a new method of solving feature selection problem. Foundations of presented algorithm lie in the theory of rough sets. Feature selection methods based on rough sets have been used with success in many data mining problems, but their weakness is their computational complexity. In order to overcome the above-mentioned problem, researches used diverse approximation techniques. This paper presents a new approach to approximation of reducts.**

Particle swarm optimization (PSO) is a stochastic meta-heuristic similar to genetic algorithms. The idea is to see each potential solution as a particle with certain velocity flying through the problem space. The PSO finds optimal solutions by interactions of individuals in population. The main advantage of the PSO over genetic algorithms, is that PSO does not require complex operators such as crossover or mutation. It only uses simple mathematical operators to update position and velocity of each particle, which makes PSO computationally inexpensive in terms of both memory and runtime.

The presented feature selection algorithm treats each feature subset as separate particle. Optimal subset, in terms of selected measure, is discovered as particles fly within the problem space. In order to speed up calculations and balance usage of hardware resources (processors, memory), parallel asynchronous version of PSO is applied. It is based on scheduling calculations of complex fitness function on slave processors, while the main one is responsible for updating particles data and checking algorithm's convergence. Applied approach scales well and provides balanced usage of given resources even if it is not feasible to use the same computational power of every processor, for instance when used resources are not homogeneous.

Proposed method was tested on selected set of data sets from the UCI repository and results were compared to some of the classical algorithms.

***Index Terms*—Feature Selection, Rough Sets, Particle Swarm Optimization, Parallel Asynchronous Particle Swarm Optimization**

I. Introduction

FEATURE selection is one of phases in data mining. The idea is to select subset of attributes, which preserves knowledge for given information or decision system. There are two main reasons for doing it. Firstly, it is some kind of data compression which eases comprehension of analysed data. Secondly, most classifiers are better trained on non-redundant data (compare with [6]). Moreover, removal of superfluous attributes leads to smaller data, which will quicken classifier training.

There are many algorithms for feature selection. Some of them are simple filters concerning every attribute separately. The more useful ones try to rank sets of attributes. They have also high computational complexity (see [1]). One of methods for finding „good" subset of attributes is calculating reducts. It is based on rough sets theory. The reduct is a set of attributes which: preserve information contained in full set of attributes and is minimal, i.e. removing one attribute from reduct leads to losing some knowledge about data. Unfortunately, calculating reducts is quite complex [7].

Feature selection algorithms can be divided into two groups: *filters* and *wrappers* ([2] and [3]). The most standard filters select attributes based on some measure and are classifier agnostic. On the other hand, wrappers use selected classifier accuracy as a measure of quality of subset of attributes. By doing that, they are somewhat „tied" to used classifier and their results will probably not work well with other learning algorithms.

The aim of this paper is to present a new feature selection algorithm. It is wrapper algorithm, that uses classical, exhaustive method for finding reducts and inducing decision rules from them. Because reducts are induced on a subset of attributes, time of their calculations should be smaller than time for obtaining reducts from all attributes. Finding new candidates for reducts is done by using particle swarm optimization. The idea was inspired by work presented in [4]. Particle swarm optimization is meta-heuristic originally developed as a simulation of birds flocking. Because it is a little simpler to apply and implement than genetic algorithms, it has gained researchers attention lately. In order to further speed up the approximation, parallel asynchronous version of particle swarm optimization ([14]) was applied.

The rest of this paper is divided as follows. Section II contains basic information about rough sets theory and reducts calculations. In section III particle swarm optimization has been presented. Above-mentioned section also contains com-

978-83-60810-58-3/$25.00

parison of synchronous and asynchronous versions of this meta-heuristic. Subsection III-C of section III contains detailed information about algorithm presented in [4]. Proposed algorithm for feature selection is described in section IV, where it is also compared with method from [4]. In the same section, experimental results: comparison of reducts and found attributes subsets, as well as parallelization gains are also presented. Section V contains conclusions and possible extensions to presented research.

II. Rough Sets

The development of rough sets theory was started by professor Z. Pawlak in 1981 [5]. Its main purpose is to deal with uncertainty of information or decision systems. *The information system* $\mathcal{A}$ is a pair of a non-empty, finite set of objects U called *universe* and a non-empty, finite set of their *attributes* A (see equation 1).

$$\mathcal{A} = (U, A) \tag{1}$$

An attribute is a function $a : U \to V_a,\ \forall_{a \in A}$, where set V_a is called a value set of a. *The decision system* is an information system extended by one distinguished attribute $d \notin A$ called *decision*.

As objects in information system are described only by attributes, two cases can occur:

- different objects can have the same values on all attributes, or
- some attributes can be superfluous.

To deal with the former case, an indiscernibility relation is used. More formally:

$$IND_{\mathcal{A}}(B) = \left\{(x, x') \in U^2 : \forall_{a \in B} a(x) = a(x')\right\} \tag{2}$$

The $IND_{\mathcal{A}}(B)$ from equation 2 is called *B-indiscernibility relation*. If $(x, x') \in IND_{\mathcal{A}}(B)$, then objects x and x' are indiscernible from each other by attributes from B. The equivalence classes of the B-indiscernibility relation are denoted $[x]_B$.

For a subset of objects $X \in U$ and a subset of attributes $B \in A$, X can be approximated only by attributes from B by constructing its *lower approximation* $\underline{B}X = \{x : [x]_B \subseteq X\}$ and its *upper approximation* $\overline{B}X = \{x : [x]_B \cap X \neq \emptyset\}$. The objects in $\underline{B}X$ are certainly in X basing on knowledge in B, whereas objects from $\overline{B}X$ can be classified only as possible elements of X on the basis of knowledge in B. The set $BN_B(X) = \overline{B}X \setminus \underline{B}X$ is called a B *boundary region of* X, and consists of objects which we cannot decisively classify into X on the basis of knowledge in B. A set is said to be *rough* (respectively *crisp*) if the boundary region is non-empty (respectively empty).

In order to speed up classification and clarify knowledge about data, redundant attributes can be removed. To do so, one can keep only those attributes, which preserve indiscernibility relation and hence set approximation. Rejected attributes were redundant since their removal has not worsened classification accuracy. There are usually several such subsets and those which are minimal in terms of cardinality are called *reducts*. It can be shown that the number of reducts of an information system with m attributes may be equal to $\binom{m}{\lceil \frac{m}{2} \rceil}$. Moreover, finding minimal reduct, i.e. a reduct the cardinality of which is the smallest among other reducts, is NP-hard [7].

In my experiments I have used classical algorithm for calculating reducts. Its detailed description can be found in [7]. The algorithm is executed in two steps: calculating a *discernibility matrix* and finding all prime implicants of a *discernibility function* induced from the discernibility matrix. Obtaining decision rules from reducts is straightforward: for each pair of object and reduct those attributes and their values are taken from object, that are also in reduct. Such pairs create conditional part of the rule. The decision part is made from decision for analysed object.

For the information system $\mathcal{A}$ with n objects, the *discernibility matrix* is a symmetric $n \times n$ matrix with entries given in equation 3.

$$\forall_{i,j \in \{1,2,\ldots,n\}}\ c_{ij} = \{a \in A : a(x_i) \neq a(x_j)\} \tag{3}$$

The *discernibility function* $f_{\mathcal{A}}$ for an information system $\mathcal{A}$ is a Boolean function of m Boolean variables $a_1^*, a_2^*, \ldots, a_m^*$, which correspond to attributes $a_1, a_2, \ldots, a_m$, defined as on equation 4, where $c_{ij}^* = \{a^* : a \in c_{ij}\}$.

$$f_{\mathcal{A}}(a_1^*, a_2^*, \ldots, a_m^*) = \bigwedge \left\{ \bigvee c_{ij}^* : i, j \in \{1, 2, \ldots, n\} \wedge c_{ij}^* \neq 0 \right\} \tag{4}$$

The set of all prime implicants determines the set of all reducts of $\mathcal{A}$.

III. Particle Swarm Optimization

Particle swarm optimization is a stochastic meta-heuristic developed by Eberhart and Kennedy in 1995 [11]. It was originally created to graphically model behaviour of bird flocking or fish schooling. Initial simulations were transformed into optimization algorithm, and later enhanced by introducing inertia weight [12].

A. Synchronous Particle Swarm Optimization

Particle swarm optimization is an algorithm similar to genetic algorithm [15]. In both cases solutions are mapped into parts of population: in case of particle swarm optimization population consists of particles, whereas in genetic algorithms there are individuals or phenotypes who form population. In both cases near-optimal solution is found as an individual which is the best fitted one, where fitness measure is the optimized function. Individuals in a new population are created by interactions between parts of the previous one.

Particle swarm optimization is initialized with a random set $P = \{p_1, p_2, \ldots, p_k\}$ of particles. Each particle $p_i, i \in \{1, 2, \ldots, k\}$ has:

- a position x_i in S dimensional space,
- a velocity v_i,
- memory of personal best position $best_i$.

There is also stored position $best_g$ of the best particles found so far.

In each population, all particles' positions are updated with formula 5 and particles' new fitnesses are calculated.

$$x_i(t+1) = x_i(t) + v_i(t) \tag{5}$$

Best positions: $best_g$ and $best_i$ are updated if necessary. Particles accelerate according to a formula 6.

$$\begin{aligned} v_i(t+1) = w(t) \cdot v_i(t) + \\ c_1 \cdot rand_1() \cdot (best_i - x_i) + \\ c_2 \cdot rand_2() \cdot (best_g - x_i) \end{aligned} \tag{6}$$

Velocities cannot be larger than some constant v_{max}. If they were, particles would fly too fast and probably miss subspaces containing optimal solutions. The v_{max} constant should be large enough, to allow particles to escape regions with sub-optimal solutions.

The $rand_1$ and $rand_2$ are uniformly distributed random functions in $[0, 1]$. Algorithm's parameters: c_1 and c_2 define particles' acceleration constants. Their high values correspond to high attraction of past sub-optimal solutions, whereas low values allow particles to roam far from target regions. The c_1 constant corresponds to personal best solution, and the c_2 determines how firmly particle follows the flock.

The w in equation 6 is called inertia [12]. It is positive linear function of time. Choosing proper inertia is crucial for providing balance between local and global exploration, thus to ensuring that optimal solution is found in small number of iterations.

In equation 6 one can distinguish three parts. The first one corresponds to particle's „memory". The second one, controlled with c_1 constant, is linked to particle's „cognition". The third part, which is governed by constant c_2, describes „social" behaviour of particle. It is responsible for collaboration among particles.

When all particles in the population are updated, particle swarm optimization algorithm checks its convergence. If the best solution found so far is good enough, then calculations are stopped. If found solution is not good enough, then the whole process of moving particles and obtaining their statistics is repeated.

B. Asynchronous Particle Swarm Optimization

In order to speed up particle swarm optimization algorithms, there were proposed many parallelization strategies. Some of them were based on communication strategies similar to ones used with genetic algorithms [13]. In [14] authors proposed significant change to particle swarm optimization algorithm: asynchrony. By making algorithm asynchronous, authors made it converge faster to some optimal solution. It is worth noting, that above-mentioned change created algorithm, whose results will probably be different from the ones obtained from the classical version.

In the asynchronous version of particle swarm optimization, after obtaining fitness for one particle, convergence check and updates are done. It leads to dynamically updated global best position, which can be modified after updating one particle and not after updating whole population as in synchronous version of algorithm.

It is noteworthy that asynchronous version of particle swarm optimization running sequentially will produce different results than classical particle swarm optimization. The cause of that difference is the above-mentioned difference in strategies for updating data of global best particle. If the global best position would be updated in the middle of processing one population, then the rest of population would move differently in asynchronous than in the synchronous version of particle swarm optimization.

Parallelization of asynchronous particle swarm optimization is straightforward, when done in master-slave architecture. The master processor is responsible for updating particles, checking convergence and scheduling fitness calculations on slave processors. Slave processor evaluates fitness of given particle's position and returns obtained value to master processor. Communication between master processor and slave ones is done with use of first-in-first-out task queue. As master processor process one particle, the one from the front of the task queue, at time and later schedules its data to slave processor, dynamic load balancing is done implicitly. If some slave processor is slower or more loaded, then it will calculate fitness slower than other ones. It will lead to scheduling more work on faster or less busy processors, because they will more often get tasks from master processor.

C. Feature Selection using Particle Swarm Optimization and Rough Sets

In [4], feature selection algorithm based on particle swarm optimization and rough sets theory was presented. In order to exploit particle swarm optimization for finding relevant attributes, some adaptations were necessary.

1) Representation of Position: For decision system with m attributes particle position was coded as a binary bit string of length m. If i-th attribute ($i \in \{1, 2, \ldots, m\}$) was chosen, then i-th bit of position string was set to 1. Otherwise, it was set to 0. More formally, there was defined bidirectional mapping from a power set $\mathcal{P}(A)$ of the set of attributes A into space of binary string of length m: $\mathcal{M} : \mathcal{P}(A) \longrightarrow \{0, 1\}^m$, such that for $R \subseteq A$, the condition from equation 7 holds.

$$\forall_{i \in \{1,2,\ldots,m\}} \mathcal{M}(R)_i = \begin{cases} 0 & a_i \notin R \\ 1 & a_i \in R \end{cases} \tag{7}$$

The movement of particle corresponds to modifying subset of attributes in order to find a better subset. If i-th bit of particle's position was set from zero to one, then the i-th attribute was added to subset. It i-th bit was set to zero, then the i-th attribute was removed. If proper representation of velocity and fitness measure were chosen, then particles flying towards the best position will correspond to finding subsets of A with most relevant attributes.

2) Representation of Velocity: The speed of particle was represented as a positive integer, varying from 1 to v_{max}. Value of the velocity shows how many bits of particle's position

should be changed in the particular moment of time to be the same as in the global best position. In other words, particles fly through problem space towards the current best position.

In order to update particles' speeds and positions, the authors of [4] proposed notion of positions difference. The *difference of positions* is equal to component-wise difference of positions seen as two vectors in m-dimensional space. For instance, if $a = [1, 0, 1, 0, 1]$ and $b = [1, 1, 0, 0, 0]$, then: $a - b = [0, -1, 1, 0, 1]$. The 1's' in difference correspond to those bits, which should be set in b to make b equal to a. Similarly, the -1's denote which bits in b should be unset. To use positions' difference in equation 6, it should be converted to integer. To do so, the authors of [4] proposed sum of all difference's components. In the previous example, it is: $|a - b| = \sum_{j=1}^{m} (a - b)_j = 1$. If updated speed was smaller than one, it was set to 1.

Formulae for updates of particle's velocity is presented on equation 8. The $i \in \{1, 2, \ldots, k\}$ on equation 8 denotes particle's index.

$$\begin{aligned} v_i(t+1) = \min(v_{max}, \max(1, \\ w(t) \cdot v_i(t) + \\ c_1 \cdot rand_1() \cdot \sum_{j=1}^{m} (best_i - x_i)_j + \\ c_2 \cdot rand_2() \cdot \sum_{j=1}^{m} (best_g - x_i)_j \\ )) \end{aligned} \tag{8}$$

As it is mentioned above, particle's position is updated to move particle towards the global best position. The two cases are possible:

1) $v_i \leq |best_g - x_i|\,,\ i \in \{1, 2, \ldots, k\}$,
2) $v_i > |best_g - x_i|\,,\ i \in \{1, 2, \ldots, k\}$.

In the first case, v_i random bits, which are different than the ones in $best_g$, are changed. That way, particle flies towards the global best position, but doing random search instead simply being the same as the best. In the second case, apart from flipping all of the bits which are different from the ones in the $best_g$, the $v_i - |best_g - x_i|$ the similar ones are also flipped. It can be interpreted as a particle flying past the best position and exploring more regions.

3) Fitness function: The fitness function used in [4] is presented on equation 9.

$$\mathcal{F}(p_i) = \alpha \cdot \gamma_R(d) + \beta \cdot \frac{m - |R|}{m} \tag{9}$$

The α and β are two parameters corresponding to the importance of classification and subset length, $\alpha \in [0, 1]$, $\beta = 1 - \alpha$. The $\gamma_R(d)$ is classification quality of condition attribute set R, relative to decision d, $|R|$ is its cardinality and $m = |A|$.

To measure classification quality of a condition attribute set R, the authors of [4] used the LEM2 algorithm ([8]) for inducing rules from set R and rule negotiation in classification ([9]). The final score was obtained by doing ten-fold cross validation.

IV. Proposed algorithm and conducted experiments

A. Proposed algorithm

Proposed algorithm is a fusion of two above-mentioned methods. It is slightly changed algorithm presented in [4], which is shortly described in section III-C. Instead of the LEM2 algorithm, exhaustive algorithm for finding reducts (see section II) has been used. Encoding particle's position, velocity and their update strategies was the same, as presented in section III-C1 and III-C2. The fitness function was also the same as the one shown in section III-C3.

The main advantage of proposed method over the one presented in [4], is usage of asynchronous particle swarm optimization. Every time particle fitness is obtained, that particle data are updated. After update, algorithm checks convergence and, if necessary, updates the global best position. Because of frequent updates, particles react more dynamically to finding new best solution. But the main trait of proposed change is to allow exploitation of parallel architecture of modern processors. I have used parallel asynchronous particle swarm optimization [14] and fused it with algorithm presented in [4].

B. Experimental results

1) Experimental setting: The sixth version of the Java language was chosen as an implementation language for proposed algorithm. The Rseslib library was used as a source of implementation of exhaustive algorithm for reducts calculation, inducing classifier (see section II for algotithm's details) and doing cross validation. As in [4], ten-fold cross validation was used. The parallel asynchronous particle swarm optimization [14] was implemented within Data Mining EXpressions Library (dmexl), which provides framework for implementing parallel data mining algorithms, especially the ones for feature selection. The dmexl library is being developed by the author of this paper.

Most of the algorithm's parameters were set to be equal to ones presented in [4]. The α was set to 0.9, and β – to 0.1, as in [4]. See section III-C3 and equation 9 for detailed description of above-mentioned parameters. Acceleration constants: c_1 and c_2 were both set to 2. As in [4], the v_{max} parameter was chosen to be equal to $\frac{m}{3}$. The value of minimal fitness, which could stop algorithm execution before reaching requested number of populations, was set to 0.85.

The inertia weight (see equation 6) was the same as in [4] and it is presented on equation 10.

$$w(t+1) = (w(t) - 0.4) \cdot \frac{P_{no} - t}{P_{no} + 0.4} \tag{10}$$

The P_{no} in equation 10 is the number of populations to simulate. The inertia weight is linear function which decreases with time, and varies between 1.4 and 0.4.

http://www.oracle.com/technetwork/java/javase/overview/index-jsp-136246.html

http://rseslib.mimuw.edu.pl/

https://github.com/mateka/dmexl

Experiments were conducted on a personal computer equipped with: Intel Core i7-4700HQ quad core CPU and 32GB of RAM. Amount of runtime memory available to java virtual machine was limited to 6GB.

2) Used data tables: Tests were conducted on set of fifteen data tables from UCI repository [16]. Selected tables are listed on table I. Statistics for selected tables are presented on table II.

For all data tables three experiments were made in RSES (see [10]). All of them were ten-fold cross validation classifications. In the first case, exhaustive reducts calculation algorithm was used. There was no rule shortening and conflicts were resolved by „simple voting". This case is denoted by *Exhaustive 1* on Table III. Two other experiments used rule shortening with rule shortening ratio set to 1.0 and conflicts were resolved by „standard voting". These are a default settings in RSES. Algorithms used with these settings were: exhaustive algorithm (*Exhaustive 2*) and LEM2 algorithm. All obtained classification accuracies are presented on table III. Even with 16GB of RAM, RSES was unable to calculate reducts and rules for Lung Cancer and Promoters tables when using exhaustive algorithms, with or without shortening obtained rules.

3) Algorithm's accuracy: Proposed algorithm was executed sixty times on each data table. Half of experiments were sequential and thirty were parallel. In each algorithm's execution, there were 20 particles and at most 100 populations. Statistics for obtained accuracies are presented on table IV. The first thing to note, is that both: sequential and parallel version of algorithm have roughly the same accuracies (see Figure 1). Unfortunately, their accuracies are much lower than those of LEM2 from RSES. On average, proposed algorithm had more stable accuracy than exhaustive one from RSES. It is probably due to working on subsets of attributes. It is also important to remember, that in RSES rules were shortened whereas in proposed algorithm they were not. It probably led to overfitting rules in experiments with proposed algorithm.

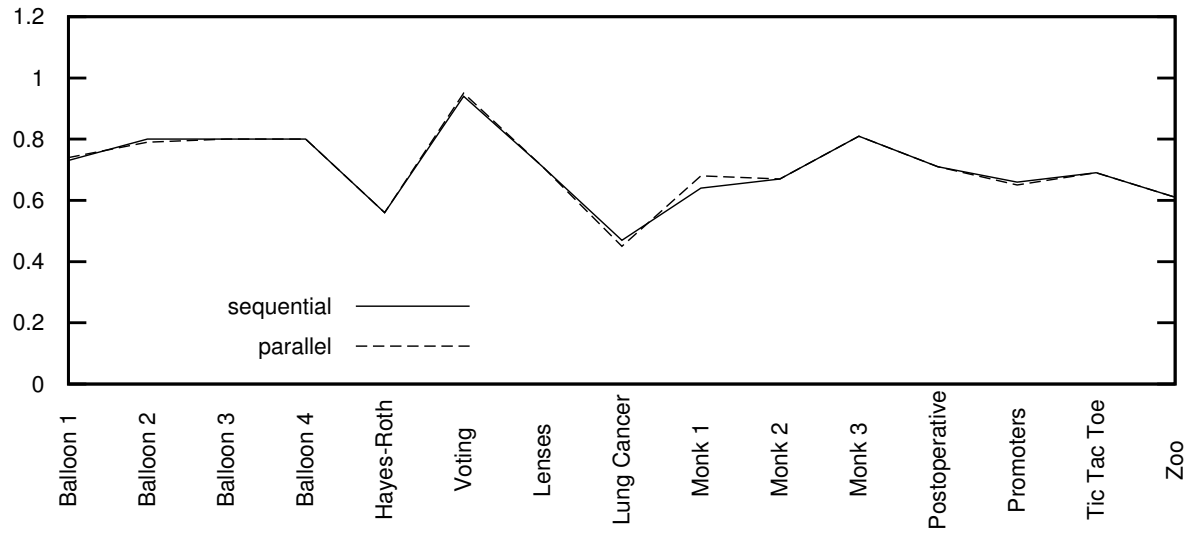

Fig. 1. Accuracies of sequential and parallel versions of proposed algorithm

The interesting conclusion can be drawn from comparing results of exhaustive algorithm without rule shortening and the proposed one. The proposed algorithm performed in all except three cases better than the exhaustive algorithm without rule shortening from RSES. Probably, due to working on smaller sets of attributes, which lead to creation of shorter reducts and rules. The next step in my research is testing proposed algorithm with rule shortening.

Comparison of obtained accuracies from proposed algorithm, exhaustive one from RSES with turned off rules shortening and LEM2 with default settings is presented on Figure 2.

It seems that number of decision classes had no impact on proposed algorithm accuracy, as it was quite stable between different experiments.

TABLE V
SPEEDUP AND EFFICIENCY

Table name	Speedup	Efficiency

4) Algorithm's performance: For execution times: T_1 – sequential and T_c – parallel on c processors, *seedup* $S_c = \frac{T_1}{T_c}$ and *efficiency* $E_c = \frac{T_1}{T_c \cdot c}$ are measures for expressing parallelization gains. Those measures for proposed algorithm are shown in table V. The presented values are mean values of all executions for each table. It is worth noting, the number of threads of execution for parallel version of algorithm was set to $4 \cdot c$ in order to fully utilize a given processor. That is the reason why efficiency may be greater than 1. There was an interesting case with Voting table. The sequential version of proposed algorithm have reached maximum number of populations four times, whereas the parallel version reached it only one. That is the reason why speedup for Voting table is so enormous.

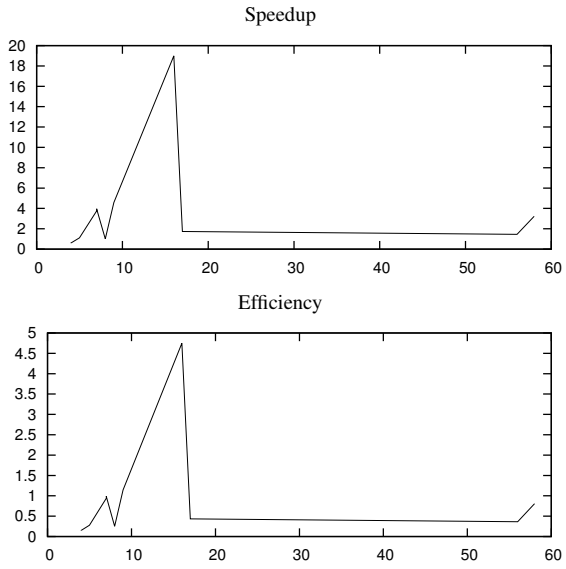

Fig. 3. Relationship between number of attributes and speedup or efficiency

The relationship between the number of attributes and speedup or efficiency is shown on Figure 3. X-axis shows

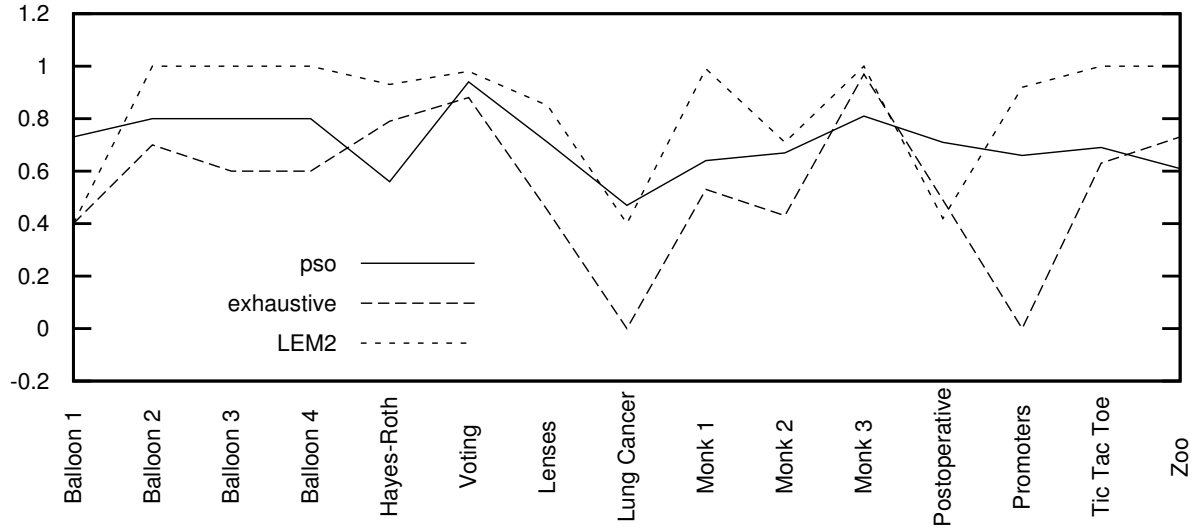

Fig. 2. Accuracies of proposed algorithm (pso), exhaustive one and LEM2

the number of attributes and y-axis shows:

- speedup for the first graph,
- efficiency for the second graph.

Although, with an increasing number of attributes speedup and efficiency are generally growing, the tendency is not clear.

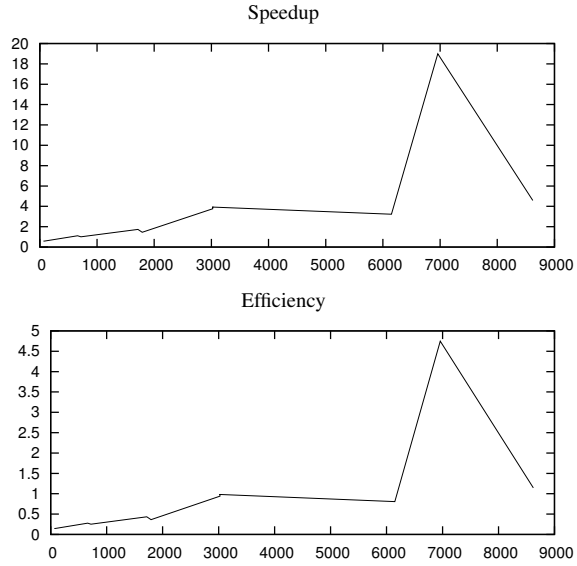

Fig. 4. Relationship between size of table and speedup or efficiency

On Figure 4 the relationship between the size of table and speedup or efficiency is shown. The horizontal axis corresponds to the table size, i.e. the number of attributes multiplied by the number of objects. Similarly to Figure 3, vertical axes correspond to speedup and efficiency. On Figure 4 it can be almost clearly seen, that, with an increasing size of data table, speedup and efficiency grow. The trend is only disturbed by the case of the Voting table, which was already described.

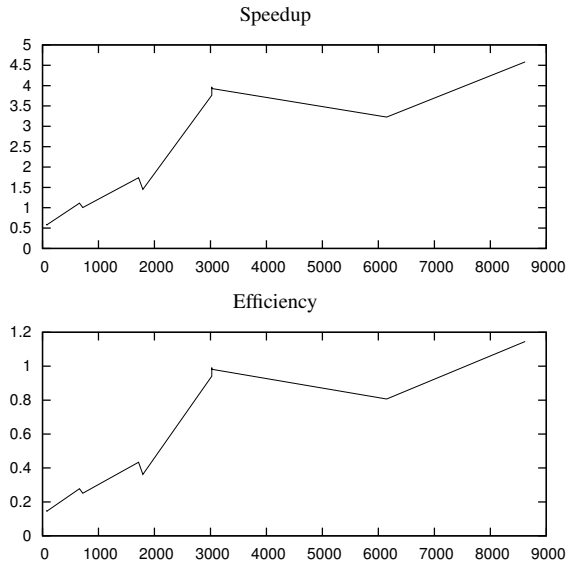

Fig. 5. Relationship between size of table and speedup or efficiency with Voting table removed

Relationship between size of table and speedup or efficiency, with removed the Voting table statistics, is shown on Figure 5. Graphs on Figure 5 clearly show upward trend in speedup and efficiency of proposed algorithm with the growth of the size of the table. When overhead of managing threads and parallelism is compensated by the table size, a parallel version of proposed algorithm performs better than the sequential one.

If there is any relation between the number of decision

classes and performance of proposed algorithm, it cannot be induced from gathered results. The main parameters, which can help to decide if a parallel or sequential version should be used, are: the number of attributes and the number of objects.

V. Conclusion

Although the presented algorithm was not able to achieve astonishing accuracy, it was on par with the ones implemented in RSES system used with default settings. As with all settings, they can be tuned to selected problem to achieve better results. It is noteworthy, that proposed algorithm performed better in most cases than exhaustive algorithm from RSES with rule shortening turned off and simple voting as a method for solving conflicts.

Particle swarm optimization is said to be simpler to apply in purely numerical optimization problems than genetic algorithms. It is due to its straightforward application and there is no need to define complex operators, as in genetic algorithms. Unfortunately, applying particle swarm optimization to feature selection and calculating reducts is not as straightforward as applying it to numerical optimization problems. Coding attributes subsets as binary strings and updating particles' speed and position turned out to be as complicated as when calculating operators in genetic algorithms.

The performance of parallel version of presented algorithm is promising. With growing size of data tables, algorithm's speedup and efficiency were raising. Although, these are optimistic results, there should be examined what impact on these coefficients would have adding more cores or processors.

The performance results are even more optimistic, as presented algorithm is a part of a *Data Mining EXpression Library* (dmexl). The dmexl library is a framework for easier development of data mining algorithms. Currently, efforts are taken into providing building blocks for feature selection algorithms. From the user's perspective, library enables writing complex algorithms as a simple expression. By selecting executor object, the user decides if algorithm should be executed sequentially or in parallel. Some examples can be seen in library's source code, which is available on the Internet: https://github.com/mateka/dmexl.

Another interesting research topic, would be using modification of proposed algorithm to execute feature selection in the context of clustering. As a classification accuracy would be unavailable, some other measure should be used to grade obtained particles. One possibility is to use a measure of coherence of resulting clusters. If this approach is sensible and applicable, further research has to be done.

***Abstract*—Web personalization becomes essential in industries and specially for the case of users with special needs such as visually impaired people. Adaptation may very much speed up the navigation of visually impaired people and contribute to diminish the existing technological gap. This work is the first stage of a web mining process carried out in discapnet: a website created to promote the social and work integration of people with disabilities where slow navigation has been detected. Based on observation in-use where behaviours emerge applying a web mining process to server log data, we designed a system to generate user navigation profiles and adapt to the web site through link prediction. Two approaches for user profiling were implemented: a global system built based on the complete database and a modular approach carried out discovering the navigation profiles within different zones. Although both approaches are effective, the modular approach outperforms. When 25% of the navigation of the new user has happened the designed system is able to propose a set of links where nearly 60% of them (2 out of 3) is among the ones the new user will be using in the future. This will definitely make the navigation easier saving a lot of time.**

I. Introduction

THE success of electronic commerce, especially for the less well-known companies, is largely dependent on the appropriate design of their website [1]. Chaffey et al. [2] stated in their work that a good website should begin with the users and understanding how they use the channel. This confirms that understanding the needs and preferences of the website audience will help to answer questions about what the content of the website should be, how it should be organized and so on. Organizations have to respond not only by adopting new technologies, but also by interpreting and using the knowledge created by Internet users.

In the last decades, the trends have led to a dramatic increase in the amount of information stored in the web, which often makes the information intractable for users. As a consequence, the general need for websites to be useful in an efficient way for users has become especially important. There is a need for easier access to the required information and adaptation to the users' preferences or needs. Web personalization thus becomes essential in industries and specially for the case of users with special needs such as visually impaired people.

However, little is known about the navigation tactics employed by screen reader users when they face problematic situations on the Web. Modelling the navigation of users is of utmost importance as it allows not only to predict interactive behaviour, but also to assess the appropriateness of the content in a link, the information architecture of a site and the design of a web page [3].

Navigating through audio web interfaces is a challenging task mainly because content is serially rendered. Content serialisation has several negative implications: users cannot get an overview of the page, entailing that users can only catch a glimpse of the page as long as they scan through the document. Consequently navigation across different web pages is a time consuming task and web page exploration is a resource intensive activity that requires a dedicated attention span [3].

The sequential access of screen readers means that visually impaired users take up to five times longer than sighted users to explore a web page [4]; the screen reader itself requires an additional cognitive effort [5] and, moreover, inter-page and intra-page navigation problems are some of the problems that need to be faced when working with visually impaired users [3].

As a consequence, in the case of users with disabilities, adaptation becomes crucial and may very much speed up the navigation and contribute to diminish the existing technological gap. In order to be able to model the user, the modelling component must collect information about a number of observable parameters such as interest, characteristics, etc. This information can be requested to the user in a previous session, but this is annoying, disruptive and can produce false assumptions. Another option is to collect this information in-use while the user is accessing the web, and therefore, to build a non invasive system able to model the users in the wild. In this way the system can learn its interests, likes, etc.

According to Pierrakos et al. [6] web personalization can be defined as the set of actions to dynamically adapt the presentation, the navigation schema and the contents of the website, based on the preferences, abilities or requirements of

978-83-60810-58-3/$25.00

the user. Nowadays, as Brusilovsky et al. [7] describe, many research projects focus on this area, mostly in the context of e-Commerce [7] and e-learning [8]. Important websites such as Google and Amazon are clear examples of this trend.

In any web environment, the contribution of the knowledge extracted from the information acquired from observation in-use is twofold:

- It can be used for web personalization (i.e. for the adaptation of the website according to the user requirements).
- It can also be used to extract knowledge about the interests of the people browsing the website or about the possible design mistakes.

Data mining for web personalization has many advantages. It is not disruptive, it is based on statistical data obtained by real navigation data (decreasing the possibility of false assumptions) and is itself adaptive (when the characteristics of the user change, collected data allows the automatic change of the interaction schema). When the user is a person with physical, sensory or cognitive restrictions, data mining is the easiest (and frequently almost the only) way to obtain information about the uses of the person.

Data mining in this context has also some drawbacks. The most important one is its impact over privacy, due to the need of storing large quantities of data about the users. Diverse laws in different countries protect user rights for privacy. Even if it is difficult to reach a balance among privacy and personalization, some appealing proposals have been recently published.

Web mining can be defined as the application of data mining techniques to data from the Internet. This process has three main stages:

- The data acquisition and pre-processing stage.
- The pattern discovery and analysis phase to find groups of web users with common characteristics related to the Internet and the corresponding patterns or user profile. Machine learning techniques are mainly applied in this phase.
- Finally, the patterns detected in the previous steps are used in the operational phase to adapt the system and make navigation more efficient for new users or to extract important information for the service providers.

This work is the first stage of a web mining process carried out in discapnet website *www.discapnet.es* where we analysed the navigation of users (web usage mining) and built user navigation profiles that provide a tool to adapt the web to new users while they are navigating (through link prediction). Being discapnet website addressed to people with disabilities, mainly to visually impaired people, link prediction will be specially important in the system. This is corroborated somehow because a preliminary analysis of the web logs showed that the time spent in link type or hub type pages is considerably longer than it would be expected to; it is longer than the one spent in pages devoted to content (content pages) and dynamic pages which are mainly related to news. This makes us suspect that the implementation of an efficient link prediction system will definitely help to make navigation easier, and as a consequence, diminish the time spent in link type pages.

So that the link prediction system is efficient, it is important for it to be based on observation in-use. This way behaviours emerge from the obtained data instead of looking for predefined models. Web logs are the most simple in-use information and the ones applicable to the wider set of users. Other more complete tools [9] capturing longitudinally low-level interaction unobtrusively limit the public to be used in the modelling process.

Summarizing, the aim of this paper is to design a link prediction system which contributes to make the navigation of users navigating in discapnet easier. The proposed system is based on observation in-use; behaviours emerge applying a web mining process to the obtained data, web server log data. The web mining process has required a thorough analysis of the environment and the data, a selection of the machine learning tools to be used and, finally, a design and evaluation of the system. After this process, we developed two approaches for user profiling: a global system built based on the complete website and a modular approach carried out discovering the navigation profiles within each zone. Both systems show to be useful for link prediction but the values of the evaluation measures are a bit higher for the modular approach. We consider that the inclusion of the described system in discapnet will contribute to improve inter-page navigation within the website and diminish the times spent in link type pages.

The paper describes the discapnet website and its main characteristics in Section II and the preprocess applied to the data in Section III. Section IV describes the machine learning techniques used for user navigation profile generation whereas Section V is devoted to describing the two profiling options implemented for discapnet. The evaluation of the two systems and their use for link prediction are presented in Section VI. Finally, Section VII summarises the conclusions and future work.

II. Discapnet website analysis

Discapnet is an initiative created to promote the social and work integration of the people with disabilities financed jointly by the Fundación ONCE [10] and Technosite. It contains two main action lines:

- An information service for organizations, professionals, people with disabilities and families.
- A platform to develop actions to promote the involvement of people with disabilities in the economic, social and cultural life.

Technosite provided us the server logs of two serves that store the activity generated in some areas of the web discapnet. The transferred data was basic anonimized server log data in Common Log Format [11] (see Figure 1). It contained all the requests served by two of the servers hosting discapnet website from the 2nd February 2012 to the 31st December 2012.

Fig. 1. Sample lines of a log file in CLF.

Fig. 2. Appearance of the front page of discapnet website.

In this context, the next stage of our research consisted on analysing the structure and content of the site. Figure 2 shows the appearance of the front page of discapnet.

The site is divided in different areas being main ones:

- *Areas Temáticas*
- *Comunidad*
- *Actualidad*

Some of these parts, such as, *Actualidad* (actuality) and *Noticias* (news) are very dynamic and can hardly be used for link prediction because it is impossible to build the models according to news that will be generated in the future. From the rest of the zones in the website, the experts in Technosite considered that *Areas Temáticas* (excluding *Salud*) and *Canal Senior* within *Comunidad* were the most interesting zones for modelling and introducing adaptation tools. And, as a consequence the provided data was limited to these zones.

The direct consequence of the previous assertion is that the built user models and link prediction system will be mainly limited to *Areas Temáticas* (see Figure 3).

Therefore, it shouldn't be forgotten that the provided sequences might not be complete user sessions what limits the data mining process and, as a consequence, the quality of the obtained profiles.

Finally, before starting with the modelling process we evaluated the accessibility of each of the pages of discapnet. We found this an important starting point because we considered that being discapnet a website addressed to people with special requirements, accessibility of the pages might become a source of problems. Therefore, accessibility was evaluated using EvalAccess [12]; the Automatic Accessibility Evaluator developed by EGOKITUZ according to the design guidelines published by WAI [13] and devoted to help designers to produce web sites that are accessible. The study showed that the accessibility rate was in average near 90% and this means that each individual page in discapnet was designed taking into account the accessibility guidelines.

III. Data Preprocessing

After the preliminary analysis the logs must be preprocessed to extract the useful information. Web server log files follow a standard format called Common Log Format [11]. This standard specifies the fields all log files must have for each request received: remotehost, rfc931, authuser, date, request, status and bytes. The fields we used for this work are: the

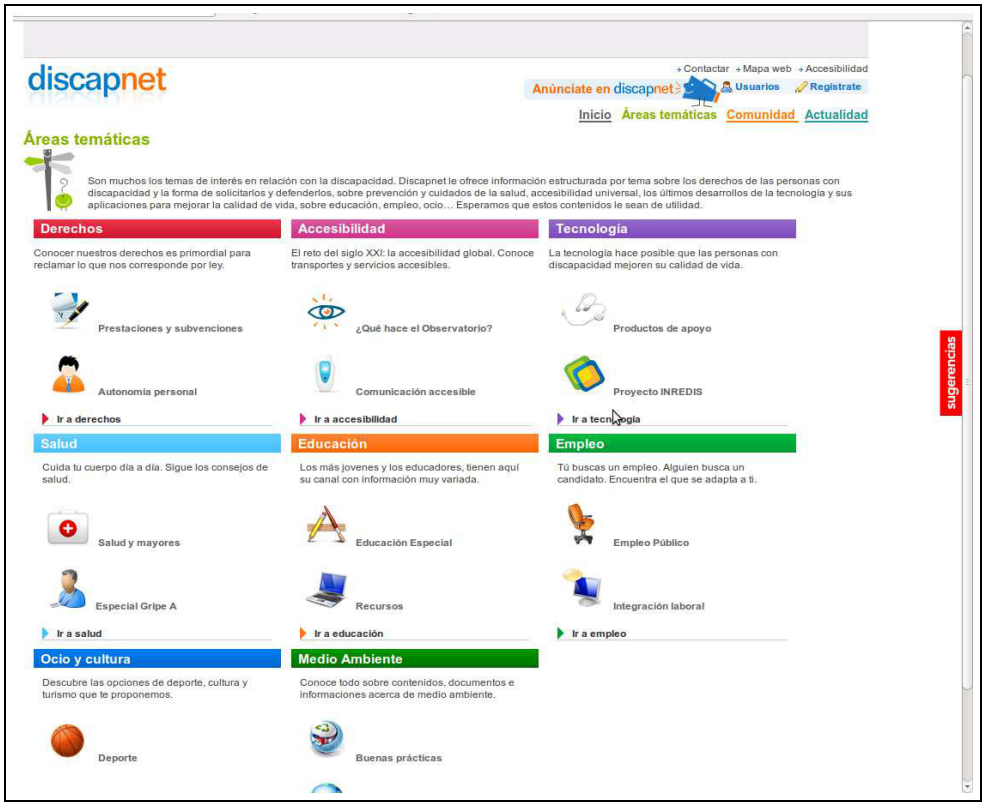

Fig. 3. Appearance of *Areas tematcias* within discapnet website.

code given by the anonymization process to remote host IP addresses, the time the request was recorded, the requested URL and the status field that informs about the success or failure when processing the request.

The log files used in this work contained 157,527,312 requests, which were reduced to 13,352,801 after the data preparation or data preprocessing phase described in the following lines. First of all we removed erroneous requests, those that had an erroneous status code (client error (4xx) and server error (5xx)). Therefore, we only took into account successfully processed requests. The next step consisted of selecting the requests directly related to the user activity. User clicks indirectly send many web browser requests to complete the requested web page with images, videos, style (css) or functionalities (scripts) for example. All these indirect requests were removed.

We then carried out session identification: we fixed the expiry time of each session to 10 minutes of inactivity [14] obtaining a total amount of 907,404 sessions.

A. Session Representation

Once the database to be used for the process has been selected in the filtering and preprocessing steps, we need to decide how to represent the information to be used in the machine learning algorithms. Being the aim of this work to detect sets of users with similar navigation patterns and to use them to make the navigation of future users easier, we represented the information corresponding to each of the sessions as a clickstream or sequence of clicks preformed in different URLs. Since we want to build user navigation profiles the order of the visited URLs will be important.

We selected the most relevant sessions (those with a minimum activity level; 3 or more clicks) and removed the longest sequences (those with their length out of the 98 percentile) with the assumption that long sequences are outliers and might be caused by some kind of robot, such as crawlers, spiders or web indexers.

IV. Pattern Discovery

This is the stage that, taking as input the user click sequences, is in charge of modelling users and producing user profiles. Most commercial tools perform statistical analysis over the collected data. They extract information about most frequently accessed pages, average view times, average lengths of paths, etc. that are generally useful for marketing purposes. But the knowledge extracted from this kind of analysis is very limited. Machine learning techniques are in general able to extract more knowledge from data. In this context unsupervised machine learning techniques have shown to be adequate to discover user profiles [6]. We have used a crisp clustering algorithm to group users that show similar navigation patterns.

A. Clustering

In this work, in order to grouping into the same segment users that show similar navigation patterns, we need a clustering algorithm that is able to deal with sequences and an adequate distance to compare sequences. Based in our experience in previous works, as clustering algorithm, we selected *PAM (Partitioning Around Medoids)* [15] [16] which is similar to k-means but uses medoids or examples as centres instead of centroids what makes it suitable for cases where the examples are represented as sequences. Furthermore, we selected a Sequence Alignment Method, Edit Distance [17][18], as a metric to compare sequences. As it happens with most clustering algorithms, *PAM* requires the K parameter to be estimated. This parameter is related to the specificity of the generated profiles, when greater its value is more specific the profiles will be. We didn't have prior knowledge of the structure of the data, that is, we have no idea of the number of different user profiles. Therefore we performed an analysis to try to find the value of K that is enough to group the sessions with common characteristics but does not force to group examples with not similar navigation patterns in the same cluster (the range of values tested for K will be described in Section VI).

B. Profile Generation

The outcome of the clustering process is a set of groups of user sessions that show similar behaviour. But we intend to model those users or to discover the associated navigation patterns or profiles for each one of the discovered groups. The model will be composed by the common click sequences appearing among the sessions in a cluster. We used SPADE (Sequential PAttern Discovery using Equivalence classes) [19], an efficient algorithm for mining frequent sequences, used to extract the most common click sequences of the cluster. SPADE uses combinatorial properties to decompose the original problem into smaller sub-problems, that can be independently solved in main-memory. All sequences are discovered in only three database scans.

In order to build the profiles of each cluster using SPADE we matched each user session with a SPADE sequence, with events containing a single user click. The application of SPADE provides for each cluster a set of URLs that are likely to be visited for the sessions belonging to it. The number of proposed URLs depends on parameters related to SPADE algorithm such as minimum support and maximum allowed number of sequences per cluster. We fixed the value for the minimum support to 0.2 and limited the amount of proposed URLs to 3 because proposing too many could disturb the user.

V. DISCAPNET USER NAVIGATION PROFILE DISCOVERY

We are aware that nowadays navigation in a website can be difficult for any type of users but this is still harder for users with special requirements. As a consequence, an adaptive system able to propose the adequate links to the user during her navigation would be specially helpful for them.

TABLE I
SIZES AND CHARACTERISTICS OF DATABASES USED FOR THE MODULAR SYSTEM AND THE GLOBAL SYSTEM.

Website zone	User Sessions	Average length	K
Accesibilidad	10,259	5.08	90
Derechos	22,561	4.78	80
Educación	1,773	4.27	27
Empleo	4,720	3.89	60
Medioambiente	852	5.05	20
Ocio y cultura	3,603	4.86	50
Tecnología	3,954	4.54	50
canal senior	338	4.60	13
Global	48,060	4.63	130

The structure of each of the subtopics within *Areas Temáticas* is very different and this will probably affect to the navigation the users do within them. Moreover a preliminary analysis of the sequences showed that nearly 50% of the user sessions extracted from the database belonged to navigations in a single zone. We considered those sessions representative of the navigation within each zone and decided to build the link prediction system based on them. After selecting the most relevant sessions and removing the longest sequences from it, the database contains 48,060 user sessions. We used two approaches to face the problem:

- The design of a global system using the data of all the analysed zones (see Figure 4).
- A modular system which builds profiles independently for each of the navigation zones (see Figure 5).

A. Global approach

The global system consists on applying the clustering and profiling processes as described in Section IV to the complete database; the 48,060 user sessions; the patterns are grouped using PAM clustering algorithm and the profile for each of the clusters discovered based on SPADE. The schema of the system is represented in Figure 4.

B. Modular approach

Being the structure of each zone different, we decided to build a modular approach to the user navigation profiling within discapnet. This means to build the profiles focusing on each of the possible analysis zones for user navigation profile discovery. With this aim, instead of working with the whole database, we worked with the user sessions located in a single web zone. That is we divided the database according to navigation zones and we worked with 8 different subsets; one for each of the zones where user navigation profile discovery will be carried out. Table I summarizes the sizes of each subset and Figure 5 shows the schema of the system where it can be observed that the profile discovery process within each zone was carried out as described in Section IV.

The set of profiles in the modular approach will be composed by the set of profiles generated for each one of the 8 zones.

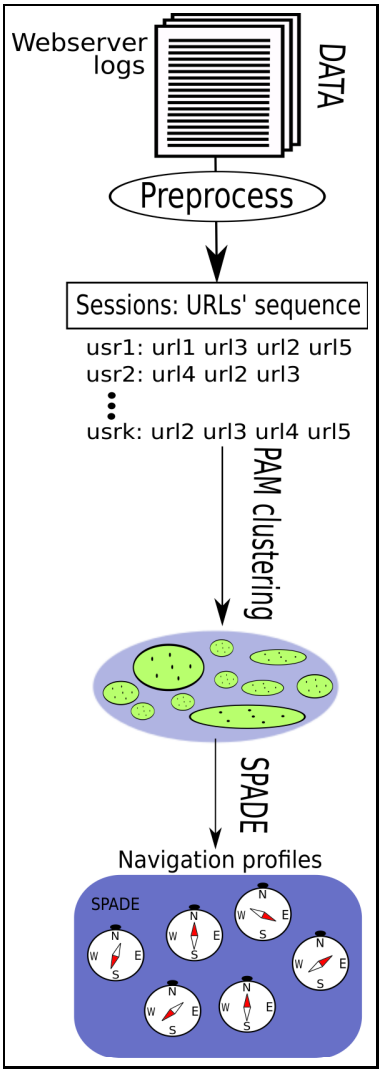

Fig. 4. Global approach to user profile discovery.

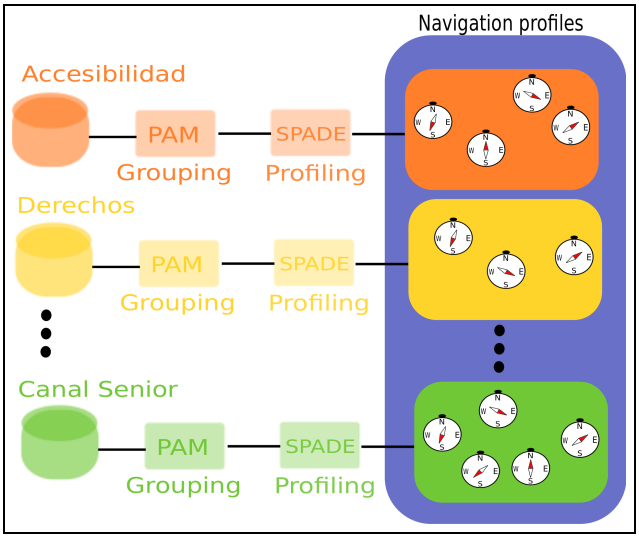

Fig. 5. Modular approach to user profile discovery.

VI. Evaluation and Link Prediction

Before the system is used in any real application the generated profiles need to be evaluated; i.e., we need to compare the generated profiles with the profiles of new users navigating the website and measure their similarity. We first generated user profiles by combining PAM with SPADE and compared these profiles to those for new users navigating the website. The evaluation procedure was exactly the same for the two approaches used to build the model: the modular approach and the global approach.

In order to carry out this evaluation we used a hold-out methodology, dividing each folder into a training set (70% of the examples), validation set (20% of the examples) and test set (10% of the examples). We used the validation set to select K (the number of clusters) and the test set to evaluate the performance of the system.

The internal structure of the data is completely unknown and we therefore tried a wide range of values for K to select the optimum number of clusters. Based on the usual exploration limit for the number of clusters, $\sqrt{n}$, in each of the databases we tried the following 5 values: $\sqrt{n}/4$, $\sqrt{n}/3$, $\sqrt{n}/2$, $2*\sqrt{n}/3$ and $\sqrt{n}$. Obviously, being the sizes of the subsets very different, the number of clusters or user profiles generated in each of them has been different; Table II shows in column K the number of profiles generated in each of the modules according to the evaluation carried out using the validation set. This number has been selected using the validation set to evaluate results the same way the test set has been used to evaluate the final system. The procedure is explained in the following lines (although the explanation is given for the test the procedure used with the validation set is exactly the same).

The generated profiles were evaluated by comparing them to new users navigating the website (test set). With this aim, the system needs to select a profile for the new users which will then be compared to their click sequence. The selection is done according to a distance calculation. This can be done at any stage of the navigation process; i.e. from the first click of the new user to more advanced navigation points. The hypothesis is that the navigation pattern of the user will be similar to the user profiles of its nearest clusters. As a result, the system will propose to the new user the set of links that models the users nearest clusters.

In order to simulate a real situation we need to take into account that when a user starts navigating only the first few clicks will be available to be used for deciding the corresponding profile. We simulated this real situation using 25% of the test sequences to select the profile for the new user according to the built model (between 1 and 2 links, because, as it is shown in column average length of Table I, the click sequences have in average near 5 links).

According to previous works found in the bibliography [20], new users might not be identical to any of the profiles

TABLE II
SUMMARY OF THE RESULTS.

		Validation			Test		
	k	Pr	Re	F.5	Pr	Re	F.5
Global system	130	0.55	0.40	0.51	0.55	0.40	0.51
Modular system	49	0.58	0.44	0.54	0.58	0.44	0.54
Improvement%		5.65	9.06	6.10	6.49	8.97	6.70

discovered in the training set; their profile might have similarities with more than one profile and, as a consequence, the diversification helps; it is better to build the profiles of the new users dynamically based on some of their nearest profiles. We propose the use of the k-Nearest Neighbour (k-*NN*) [21] supervised learning approach to calculate the distance from the click sequence (Edit Distance to the medoid) of the new users to the clusters generated in the previous phase. Due to its characteristics, the k-*NN* algorithm allows to select naturally the set of profiles generated in the training phase with higher similarity to the new user, and moreover, it showed to have good performance in previous works [20]. We used 2-*NN* to select the nearest clusters and combined the profiles of the two nearest clusters with defined profiles, weighting URL selection probabilities according to their distance. We combined these to propose profiles containing at most 3 URLs; those with the highest support values. If there are not enough URLs exceeding the minimum support value the profiles could have less than 3 URLs.

We computed performance metrics based on the results obtained for each of the new users of the test set. We compared the number of proposed links that are actually used in the test examples (hits) and the number of proposals that are not used (misses) and calculated precision (percentage of clicks used among the proposed ones), recall (percentage of clicks proposed among the used ones) and F.5-measure (a relationship between precision and recall giving more importance to precision).

The greater the number of URLs proposed as profiles the smaller will be the significance of some of them and the risk taken by the system will thus be greater. As a consequence, the values for precision will probably drop. Furthermore, by limiting the maximum number of URLs proposed for each profile to 3 the recall values will never reach 1. Since the average length of the sequences is near 5, if we propose a profile (3 URLs) based on 25% of the navigation sequence (between 1 and 2 URLs), we would be proposing less links than the really used ones, what makes impossible for the recall to achieve the highest values. We consider that in the concrete environment we are working it is really important to propose links that the user finds interesting because other proposed links would probably disturb the user. As a consequence, it is more important for the proposed links to be of good quality (precision) than guessing more of the used links (recall). This is why we used F.5-measure.

Table II shows the average results (precision, recall and F.5-measure) obtained for the test and validation sets in both cases: with the global system, and the modular system. The numbers show that the modular approach achieves better results than the global one, obtaining improvements of around 9% in recall and around 6.5% in precision and F.5-measure. Furthermore, results are similar for both, the validation set and the test set what means that the concrete data used to evaluate the system does not severely affect to the obtained performance.

The values obtained for the modular system show that if we would use the profiles for link prediction, nearly 60% (precision=0.58) of the proposed links (tending to 2 out of 3) would be among the ones used by the new user. This could probably make the user navigation easier.

Note that these results should be seen as lower bounds because, although not appearing in the user navigation sequence, the proposed links could be interesting and useful for them. Unfortunately, their usefulness/relevance could only be evaluated in a controlled experiment, by using user feedback.

Moreover, taking into account that the preliminary analysis showed that the time spent in hub pages is longer than usual we could assert that using those profiles for link prediction would save a big part of the time spent by users in their navigations.

The designed system seems to obtain near balanced values for precision and recall. Therefore analysing the recall we could state that nearly 45% of the links used by the new users would be among the ones proposed by the system (recall=0.44).

We need to take into account that this is a very strict evaluation of the models because, in a real situation, although not used during the navigation, some of the proposed links might also interest to the new users.

The main use of navigation profiles is link prediction and our system could be directly used for link prediction following the methodology described in the evaluation procedure.

VII. CONCLUSIONS

Web personalization becomes essential in industries and specially for the case of users with special needs such as visually impaired people. Adaptation may very much speed up the navigation of visually impaired people and contribute to diminish the existing technological gap. This work is the first stage of a web mining process carried out in discapnet: a website created to promote the social and work integration of people with disabilities. Based on observation in-use where behaviours emerge applying a web mining process to server log data, we designed a system to generate user navigation profiles and propose adaptations to the site through link prediction. The work was limited to the most static zones of the website.

We used *PAM (Partitioning Around Medoids)* clustering algorithm and Edit Distance to group into the same segment users with similar navigation patterns and SPADE (Sequential PAttern Discovery using Equivalence classes) to extract the user profiles from the cluster. These techniques were used to implemented two approaches: a global system built based on the complete website and a modular approach carried out discovering the navigation profiles within different zones of

the website. We then used a k-*NN (k-Nearest Neighbour)* based heuristic for link prediction.

Using a hold-out strategy and precision, recall and F.5-measure as performance measures for evaluation, we could deduce that both approaches showed to be effective for link prediction but the modular approach outperforms obtaining values of nearly 60% for precision and 45% for recall. This means that when 25% of the navigation of the new user has happened the designed system is able to propose a set of links where nearly 60% of them (2 out of 3) is among the ones the new user will be using in the future and this will definitely make the navigation easier saving a lot of time.

Being this a preliminary work, the system is open and many new ideas to be implemented in the future appeared during its development. First of all, the introduction of the designed link prediction system in the website and its evaluation in a real experiment would be the best way to discover the efficiency of the system. On the other hand, based on the web server log data provided by discapnet, other types of characteristics of the user sessions could be extracted which would allow to analyse the use of the website from another point of view mainly for problem detection.

***Abstract*—Often in multi-agent systems, agents interact with other agents to fulfill their own goals. Trust is, therefore, considered essential to make such interactions effective. This work describes a trust model that augments fuzzy logic with Q-learning to help trust evaluating agents select beneficial trustees for interaction in uncertain, open, dynamic, and untrusted multi-agent systems. The performance of the proposed model is evaluated using simulation. The simulation results indicate that the proper augmentation of fuzzy subsystem to Q-learning can be useful for trust evaluating agents, and the resulting model can respond to dynamic changes in the environment.**

I. Introduction

A MULTI-AGENT Systems (MAS) involves multiple autonomous, self-interested, and goal-driven interacting intelligent agents [1]. An open MAS is a class of these systems in which agents can freely enter and leave at any time [2]. As each agent has only limited capabilities, it may need to rely on the services or resources from other agents in order to accomplish its goals [3]. Agents cannot assume that other agents share the same core beliefs about the system, or that other agents make accurate statements regarding their competencies and abilities. In addition, agents must accept the possibility that other agents may intentionally spread false information, or otherwise behaving in a harmful way, to achieve their own goals [1]. Therefore, agents should be equipped with a strong trust assessment model that is capable of maximizing the benefit, also referred to as utility gain (UG), of interacting with other agents. The estimation should be accurate enough that allows trust evaluating agents, also referred to as trustors (TRs), to identify the most beneficial trustee (TE) in their systems. The trust estimation model should consider all relevant factors, which affect the trust that an agent has about other agents. Failure to gather those factors would lead to compute a non-accurate trust value, which could explicitly affect agent's outcome [4]. Moreover, the model should dynamically update agents' belief sets to capture new characteristics of the environment, and should not rely on any centralized entities. Furthermore, the failure or takeover of any node must not lead to the failure of the whole system.

Trust has been defined in many ways in different domains [5]. For this work the definition used in [4] for trust in MASs, will be adapted. An agent's trustworthiness is considered as a measurement of the agent's possibility to do what it is supposed to do. In this work, we describe a trust model for MAS that combines the advantages of both: fuzzy logic and reinforcement learning for trust modeling in MAS. Moreover, we use a suspension technique in combination with reinforcement-learning to speedup the response of the model to dynamic changes in the system.

The paper is organized as follows: the related work is presented in section II followed by a general overview about fuzzy logic systems and reinforcement learning in section III. Section IV presents the details of the proposed model, while performance analysis is presented in section V. The last section presents conclusions and future work

II. Related Work

According to [3], most existing research on trust evaluation models can be divided into four main categories: direct trust evaluation models, that depends on past experience, indirect or reputation-based trust evaluation models, that depends on third-party testimonials from other agents in the same environment, socio-cognitive trust evaluation models, that depends on examining the social connections among agents to determine their trustworthiness, and organizational trust evaluation models, that depends on some organizational affiliations or endorsements issued by some trusted third-party to determine the trustworthiness of agents

FIRE [2] is a well-known decentralized trustworthiness estimation model for open MASs. The model categorizes trust components into direct experience called Interaction trust, Witness reputation, Role-based trust and Certified reputation. The model assumes that witnesses are honest and willing to cooperate and uses weighted summation to aggregate trust components.

Fuzzy logic offers the ability to handle uncertainty and imprecision effectively, and is therefore ideally suited to reasoning about trust [6]. Fuzzy inference copes with imprecise inputs and allows inference rules to be specified using imprecise linguistic terms, such as "very high" or "slightly low" [6].

FuzzyTrust [7] uses fuzzy logic inferences to estimate trust based on direct experience and witnesses testimonials taking into consideration uncertainties and incomplete information in a peer to peer system. The authors compare the performance of FuzzyTrust with the well known EigenTrust algorithm

978-83-60810-58-3/$25.00

[8], over the public domain transaction data from eBay, and demonstrated that it is more effective than EigenTrust.

A reinforcement learning (RL) based trustworthiness estimation model for buying and selling agents in an open, dynamic, uncertain and untrusted e-marketplace is described in [9] and further elaborated in [10], where buyers model the trustworthiness of the sellers as trustworthy, untrustworthy and neutral sellers. A buying agent chooses to purchase from a trustworthy seller. If no trustworthy seller is available, then a seller from the set of non-untrustworthy sellers is chosen. The seller's trustworthiness estimation is updated based on whether the seller meets the expected value for the demanded product with proper quality. A decentralized extension to the model used in [9] is describe in [11], [12], to enable indirect trustworthiness where advising agents are partitioned into trustworthy, untrustworthy and neutral sets to address buyers' subjectivity in opinions. However, the authors did not present any experimental results to justify their theoretical approach [13].

Recent survey such as [3][14] provide more insight on existing work in the field of MAS trust modeling.

III. Basic Concepts

A. Fuzzy Logic System (FLS)

FLSs have been extensively applied with success in many diverse application areas due to their similarity to human reasoning, and their simplicity [15]. An FLS provides a nonlinear mapping of input data vector into a scalar output. Such system maps crisp inputs into crisp outputs. It has four components: fuzzy logic rules, fuzzifier , an inference engine, and defuzzifier [16].

The main idea is that, the sets are based on the concept of a membership function (MFs), that defines the level to which a fuzzy variable is a member of a set. One represents full membership, whereas zero represents no membership; in other words, sets used for expressing input and output parameters are fuzzy [6]. An MF provides a measure of the level of similarity of an ingredient to the fuzzy subset. It is necessary to note that in fuzzy logic an ingredient can reside in more than one set to varying levels of association, which can't happen in crisp set theory. Triangular, trapezoidal, piecewise linear and Gaussian, are commonly used shapes for MFs [16].

Rules may be implemented by experts or can be derived from numerical data. In either case, fuzzy rules are represented as a collection of IF- THEN statements. MFs map input values into the interval [0,1] by the process known as "fuzzification" [6]. The fuzzifier maps crisp inputs into fuzzy sets, to stimulate rules which are in terms of linguistic variables. Fuzzy logic rules define the relationship between inputs and output. The inference engine, handles the way in which rules are combined. The conclusion membership levels are aggregated by superimposing the resultant membership curves. In many applications, crisp numbers must be collected at the output of an FLS. The defuzzifier maps output sets into crisp numbers[16]. Figure 1 presents the general architecture of an FLS.

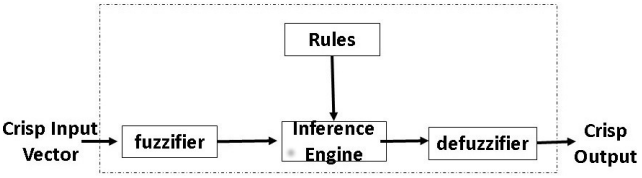

Fig. 1. Fuzzy Logic System [16]

During fuzzy inference, for each fuzzy rule, the inference engine determines the membership level for each input. Then measures the degree of relevance for each rule based on membership levels of inputs and the connectives (such as AND, OR) used with inputs in the rule. After that, the engine drives the output based on the calculated degree of relevance and the defined fuzzy set for the output variable in the rule[17].

Mamdani min-max method [18] is a well known direct inference method. where the degree of membership of rule conclusions is clipped at a level determined by the minimum of the maximum membership values of the intersections of the fuzzy value antecedent and input pairs. This ensures that the degree of membership in the inputs is reflected in the output [6]. In this work, Mamdani's method is used.

The centroid defuzzification method is an appealing defuzzification method [17]. The centroid method takes the center of gravity of the final fuzzy space in order to produce an output sensitive to all rules. In this work, the centroid defuzzification method is used.

B. Reinforcement learning

The reinforcement learning problem is the problem of learning from interaction to achieve a goal. In this problem, an agent observes a current state s of the environment, performs an action an on the environment, and receives a feedback r from the environment (reward, or reinforcement). The goal of the agent is to maximize the cumulative reward it receives in the end [10].

Temporal-difference (TD) learning algorithms can learn directly from experience without a model of the environment. TD algorithms do not require an accurate model of the environment and are incremental in a systematic sense [10]. One of the most widely used TD algorithms is known as the Q-learning algorithm. Q-learning works by learning an action-value function based on the interactions of an agent with the environment and the instantaneous reward it receives. For a state s, the Q-learning algorithm chooses an action a to perform such that the state-action value $Q(s, a)$ is maximized. If performing action a in state s produces a reward r and a transition to state s', then the corresponding state-action value $Q(s, a)$ is updated accordingly. State s is now replaced by s' and the process is repeated until reaching the terminal state [10]. The detailed mathematical foundation and formulation, as well as the core algorithm of Q-learning, can be found in [19] therefore it is not repeated here.

Q-learning is an attractive method of learning because of the simplicity of the computational demands per step and also

because of proof of convergence to a global optimum, avoiding all local optima, as long as the Markov Decision Process (MDP) requirement is met; that is the next state depends only on the current state and the taken action (it is worth noting that the MDP requirement applies to all RL methods) [15].

IV. Using Fuzzy Logic and Q-Learning for Trust Modeling in Multi-agent Systems

In this section, we propose the use of Fuzzy Logic and Q-Learning for Trust Modeling in Multi-agent Systems (FQT) as an improvement over RL based trust estimation by incorporating fuzzy subsystems to perform human-like decisions.

A. Overview

According to the proposed model, TRs classify TEs into three non-overlapping sets. The first set includes trustworthy TEs, the second set contains untrustworthy TEs and the third set includes neutral (neither trustworthy nor untrustworthy) TEs. Additionally, TRs classify witnesses in a similar way. If a TR is not satisfied by the interaction with a TE, the TR suspends the use of that TE for incoming transactions for a while. TRs suspend witnesses in a similar way.

TRs use Q-Learning to estimate the trustworthiness for TEs based on direct experience (DT). For those TEs that are not categorized as untrustworthy, the calculated DT is used as an input to the direct trust fuzzy subsystem, together with suspension period and the average of time-decayed utility gain within the last G interaction with the TE. The defuzzified output of this fuzzy subsystem is the fuzzy direct experience (FDT) of trustworthiness estimation.

For those TEs that are not categorized as untrustworthy, TRs consult witnesses for their testimonials about TEs. This is known as indirect trust (IT). Then information from both sources (direct experience and testimony of witnesses) are combined to compute total trust estimation (TT).

TRs request TEs to bid for coming transactions. The calculated TT is used as an input to the TE selection fuzzy subsystem (TSF). The second input is the difference between the bid value of the TE and the average bidding of all TEs for the same transaction. The third input is the difference between the average of time-decayed utility gain within the last H interaction with the TE and the average of time-decayed utility gain within the last H interaction with all TEs. The TR selects the TE that maximizes the outcome of TSF.

Figure 2 present the general architecture of the proposed model.

B. Fuzzy Direct Trustworthiness Estimation FDT (TR,TE):

In the proposed model, TRs use Q-learning to estimate the direct trust of TEs in a way similar to the process in [10]. If the TR is satisfied by the interaction with the TE, Eq. (1) is used to update the credibility of the TE as viewed by the TR.

$$DT_i(TR, TE) = DT_{i-1}(TR, TE)+\alpha(1-|DT_{i-1}(TR, TE)|) \quad (1)$$

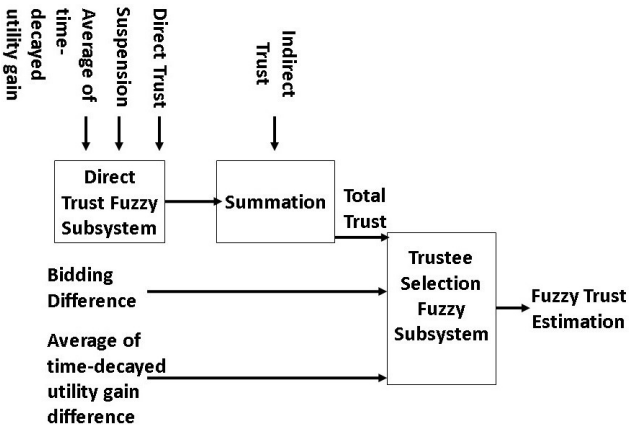

Fig. 2. Architecture of FQT

Here DT_i (TR, TE) is the direct trust estimation of the TE by the TR at time i. The value of DT (TR, TE) varies from -1 to 1. A TE is considered trustworthy if the trustworthiness estimation is above an honesty threshold (HT). The TE is considered untrustworthy if the trustworthiness estimation value falls below a fraudulent threshold (FT). TEs with trustworthiness estimation values between the two thresholds are considered neutral. The cooperation factor α is positive ($1>\alpha>0$) and the initial value of the direct trustworthy estimation is set to zero. TR will consider TE as being cooperative if the resulting UG of the transaction is greater than or equal the TR's satisfactory threshold.

If the TR is not satisfied by the interaction with the TE, Eq. (2) is used to update the credibility of the TE as viewed by TR.

$$DT_i(TR, TE) = DT_{i-1}(TR, TE)+\beta(1-|DT_{i-1}(TR, TE)|) \quad (2)$$

Here β is a negative factor called the non-cooperation factor ($0> \beta > -1$). TR will consider TE as being non-cooperative if the resulting UG of the transaction is less than the TR's satisfactory threshold. [10] described mathematical formulas to calculate the cooperation and non-cooperation factors in the context of an e-marketplace; however, we believe that those factors are application dependent and should be set by each agent independently. In general, we agree with [10] that the factors should be related to the value gain of the transaction.

Furthermore, the TR suspends the use of the TE for a period of time determined by equation (3)

$$SUS_i(TE) = SUS_{i-1}(TE) + BSI * IV \quad (3)$$

Where SUS_i(TE) is the suspension penalty associated with TE at time instant i. Basic Suspension Interval (BSI) is application dependent, it could be days in e-marketplace or seconds in a robotics system that has a short life time and Interaction Value (IV) indicates how much the TR values the interaction, not the actual utility gain of the interaction.

The value $SUS_i(TE)$ decreases with time if ther is no dissatisfactory transaction. That is $SUS_i(TE) = SUS_{i-1}(TE) - 1$, but can't be less than 0.Therefore, a large value of $SUS_i(TE)$ for a TE means a recently misbehaved TE

In the proposed model, each trust evaluation agent uses a direct trust fuzzy subsystem to find the Fuzzy Direct Trustworthiness Estimation (FDT). We define three input parameters for the fuzzy engine of the trust model and one output parameter; the input parameters are:

- The calculated DT using Q-Learning, calculated in equations 1 and 2. This parameter represents the long term relationship between the TR and the TE. A TE with a large value of DT means a TE that used to be cooperative for a relatively large number of transactions
- The suspension period of the TE, calculated in equation 3. This parameter is used to address the short term relationship between the TR and the TE. It helps the TR to address a recently malfunctioning TE that used to be honest for a relatively large number of transactions.
- AUG'$_t$The average of time-decayed utility gain within the last G interactions with the TE, calculated in equation 4. UG is the net benefit that the TR achieves from the transaction. Time decaying is used to to emphasize that UG from recent transaction weigh more compared to UG from old transactions if they have the same absolute value.

$$AUG'_t = \frac{\sum_{j=1}^{G} e^{-\lambda \Delta T_j} UG_j}{G} \quad (4)$$

Here ΔT_j = Current Time - Time of transaction j, λ is the decaying factor, $UG_j$is the utility gain for transaction j with the TE being evaluated, and G is the size of the historical window considered for calculating AUG'$_t$

The input parameters should be fuzzified before being used in the engine. We define the FDT as the defuzzified output. The individual "if…then" rules for driving the FDT is of the kind "if DT is HIGH and the SUS is LOW, and the AUG'$_t$ is HIGH then the FDT is VERY HIGH". This rule intuitively states that if the estimated direct trust is high and the suspension period is low, and the average utility gained by interacting with this TE is HIGH then the TE is expected to be honest and the transaction result is expected to be very high based on local experience of TR.

In the proposed model, we use the rules presented in Table I. Since each of the input parameters can be categorized as being Low (L), Medium (M), and High (H) and the output parameter can be categorized as being Very Low (VL), Low (L), Medium (M), Very High (VH), and High (H). We use a Mamdani min-max approach of inference and the centroid technique for the defuzzification

In table I, we insisted that a recently suspended TE will have a low direct trust value. The idea is that a TR will stop interacting with a misbehaving TE immediately, and wait utile it is clear whether this misbehaviour is accidental or it is a behavioural change. Because suspension is temporary, and because TR uses information from witnesses, the effect of accidental misbehavior will phase out, but the effect of a behaviour change will be magnified

C. Indirect Trustworthiness Estimation IT(TR, TE):

To estimate indirect trust, a TR consults other witnesses who interacted previously with the TE. To reduce the effect of fraudulent witnesses, a TR excludes reports from any witness where the mean of the differences between the witness's trustworthiness estimation and the TR's trustworthiness estimation of TEs other than the one under consideration is above the witnesses differences threshold (WDT). An honest witness (WT) reports its testimony (RT) about a TE as

$$RT(WT,\, TE) = FDT(WT,\, TE) \quad (5)$$

where FDT (WT, TE) is the WT fuzzy direct experience of trustworthiness estimation of the TE.

A TR will calculate the indirect trust (IT) component as

$$IT(TR,\, TE) = \frac{\sum_{k=1}^{N} weight_k * RT(WT_k,\, TE)}{N} \quad (6)$$

where N is the number of consulted witnesses. RT (WT_k, TE) is the testimony of witness k about TE, and $weight_k$ is the weight assigned by the TR to testimony of WT_k. The calculation of the weight factor, or the adaptation of a calculation technique from the literature, is considered a future work.

TRs track the credibility of their witnesses. Each TR updates its rating for the witnesses after each interaction as follows

- If the transaction was satisfactory for the TR and the witness WT had recommended TE or

- If the transaction was NOT satisfactory and WT's opinion was "not recommend".

Then the trustworthiness estimation of WT is incremented as in equation 7

$$DT(TR, WT) = DT(TR, WT) + \gamma(1 - |DT(TR, WT)|) \quad (7)$$

- Otherwise, the trustworthiness estimation of WT is decremented as in equation 7

$$DT(TR, WT) = DT(TR, WT) + \zeta(1 - |DT(TR, WT)|) \quad (8)$$

where γ and ζ are positive and negative factors respectively and chosen by the TR as cooperation and noncooperation factors. The value of DT (TR, WT) varies from -1 to 1. A witness is considered trustworthy if the trustworthiness estimation is above the witnesses' honesty threshold (WHT). A witness is considered untrustworthy if the trustworthiness estimation falls below the witnesses' fraudulence threshold (WFT). Witnesses with trustworthiness estimation values in between the two thresholds are considered neutral.

When a TR wants to interact with a TE at instant i, the TR avoids any WT that is untrustworthy.

D. Total Trustworthiness Estimation TT(TR,TE):

The proposed trust model takes into consideration TRs' direct trust of TE(s), testimonials of witnesses, and credibility of witnesses. Therefore, the total trust estimate can be calculated using Eq. (9)

$$TT(TR, TE) = x*FDT(TR, TE)+(1-x)*IT(TR, TE) \quad (9)$$

Here FDT(TR,TE) is the fuzzy direct experience estimation component of the TR for the TE, IT(TR,TE) is the indirect trust estimation component of the TR for the TE and x is a positive factor, chosen by the TR, which determines the weight of each component in the model.

E. Trustee Selection

In the proposed model, TRs request TEs to bid for the coming interactioneach. Each TR uses a fuzzy engine to select a profitable TE. We define three input parameters for the fuzzy engine of the trust model and one output parameter; the input parameters are

- The total trust estimation (TT), as calculated by combining information from direct experience and testimony of witnesses, detail calculations described later in this section.
- Bidding Difference (BD): The difference between the promised UG, i.e. bidding value, of the TE (B_t) and the average bidding values of all TEs bidding for the same transaction.This parameter is used to differentiate a TE that promises high UG while the average promise is relatively low, from one that promises high UG while almost every TE promises high UG. In both cases, the TE promises high UG. but this value in more important in the first case compared to the second case

$$BD = B_t - \frac{\sum_{l=1}^{M} B_l}{M} \quad (10)$$

- Average UG Difference (DAUG'$_t$): The difference between the average of time-decayed UG within the last H interactions with the TE and the average of time-decayed utility gain within the last H interactions with all TEs. Time decaying is used to emphasize that recent transaction weighs more compared to old transactions if they have the same value of UG.

$$DAUG'_t = \frac{\sum_{p=1}^{H} e^{-\lambda\Delta T} UG_p}{H} - \frac{\sum_{q=1}^{H} e^{-\lambda\Delta T} \bar{UG}_q}{H} \quad (11)$$

Here ΔT = Current Time - Time of the transaction. UG$_p$is the utility gain for transaction p with the TE being evaluated, $\bar{UG}_q$ is the utility gain for transaction q, regardless of the TE, and H is the size of the historical window considered for calculating AUG'$_t$

The input parameters should be fuzzified before being used in the engine. We define the fuzzy estimated utility gain (FUG) as the defuzzified output parameter. The individual "if... then" rules for driving the fuzzy estimated utility gain FUG is of the kind "if the estimated total trust is HIGH and the DAUG'$_t$ is HIGH and the BD is HIGH then the Fuzzy UG is VERY HIGH". This rule intuitively states that if the estimated trust is high and utility gained by interacting with this TE is higher than the overall average utility gain, and the TE is promising higher utility gain compared to other bidding TEs, then the TE is expected to be honest and the transaction result is expected to be very high.

In the proposed model, we use the rules presented in Table II for TSF. Since each of the input parameters can be categorized as being Low (L), Medium (M), and High (H) and the output parameter can be categorized as being Very Low (VL), Low (L), Medium (M), Very High (VH), and High (H). Here, again, we use a Mamdani min-max approach to inference and the centroid technique for the defuzzification.

TR evaluates the trustworthiness of TEs that are not untrustworthy. TEs whose trustworthiness cannot be determined (due to no available rating) are placed in the Unknown Trust (UT) set. Those, whose trustworthiness has been determined, are placed in the Known Trust (KT) set. On one side, selecting a TE from the set KT is likely to give a more predictable value for the expected UG. However, the TR has not learnt enough about the TE population, therefore, it may get a non-optimal performance. On the other side, selecting a TE from the set UT allows TR to explore more about the TE population, although it may risk losing utility if it encounters a bad TE [2]. To encourage honest bidding when selecting a TE from UT set, a random TE with the second highest bidding value is selected.

Obviously, if one of the two sets is empty, TR can only select from the other set. Otherwise, it needs to determine

which action it should take. The exploit-vs explore dilemma can be addressed by using the Boltzmann exploration strategy [20]. Using this strategy, an agent tends to explore its environment first and then gradually move towards exploitation when it learns more about the environment. When exploiting, TR selects the TE with the highest FUG.

V. PERFORMANCE EVALUATION

It is often difficult to find suitable real world data set for comprehensive evaluation of trust models, since the effectiveness of various trust models needs to be assessed under different environmental conditions and misbehaviors [3]. Therefore, in trust modeling for MASs research field, most of the existing trust models are assessed using simulation or synthetic data [3]. One of the most popular simulation test-beds for trust models is the agent reputation and trust (ART) test-bed proposed in [21]. However, even this test-bed does not claim to be able to simulate all experimental conditions of interest. For this reason, many researchers design their own simulation environments when assessing the performance of their proposed trust models [3].

A. Simulation Environment

We use simulation to evaluate the performance of the proposed model for distributed, multi-agent environment using the discrete-event multi-agent simulation toolkit MASON [22] with TEs, that provide services, and TRs, that consume services. For the Fuzzy subsystems, we used the jFuzzyLogic Java package [23]. As with [2], we assume that the performance of a TE in a particular service is independent from that in another service. Therefore, without loss of generality, and in order to reduce the complexity of the simulation environment, it is assumed that there is only one type of service in the system simulated and all TEs offer the same service with, possibly, different performance. In order to study the performance of the proposed trust model for TE selection, we compare the proposed model with the well known FIRE trust model [2]. Each simulation experiment is repeated 10 times with different seed values for the random number generators, and the average of the 10 experiments is presented as the simulation result. Network communication effects are not considered in this simulation. Each agent can reach each other agent. The simulation step is used as the time value for interactions. Transactions that take place in the same simulation step are considered simultaneous. Locating TEs and witnesses are not part of the proposed model; therefore, TRs locate TEs and witnesses through the system. TRs evaluate the trustworthiness of the TE(s), and then selects one to interact with.

Having selected a TE, the TR then interact with the selected TE and gains some utility from the transaction (UG). The value of UG is in [−10, 10] and depends on the level of performance of the TE in that transaction. A TE can serve many users at a time. A TR does not always use the service in every round. The probability it needs and requests the service, called its activity level, is selected randomly when the agent is created.

After each transaction, the TR updates the credibility of the TE participated in the transaction. It is assumed that TEs may be selfish, liars, non cooperative or simply malfunctioning. In order to compare our work with FIRE [HuynhJS2006], honest witnesses assumed.

TEs can be in one of four types: good, ordinary, bad, and intermittent. Each of them, except the last, has a mean level of performance. The actual performance follows a normal distribution around this mean which is in the reange of (5,10] for good TEs, [0, 5] for ordinary TEs and [-10,0) for bad

TEs. Intermittent trstees, on the other hand, yield (random) performance levels in the range [-10, 10] and they can result in positive UG some times and negative UG other times.

Since agents are owned and controlled by various stake-holders, the performance of an agent may not be consistent over time. A TE may change its behavior. In this simulation study, the performance of a TE can be changed by a randomly selected amount with a probability selected randomly when the agent is created. When bidding, an honest (good or ordinary) TE bids its utility gain value, this value is considered the value of the transaction with the corresponding TR. A bad (unhonest) TE bids a positive value for its utility gain, but the utility gain that the corresponding TR can get is the true utility gain that the bad TE can afford (negative value).

Table III presents the number of agents, and other parameters used in the proposed model and those used in the environment.

The membership functions for the input, output parameters used for direct trust fuzzy subsystem in our evaluation are summarized in Table IV, the membership functions for the input, and output parameters used for the TE selection fuzzy subsystem in our evaluation are summarized in Table V.

B. Experimental results

1) Performance in a static environment: The first thing to test is whether the proposed model helps TRs select profitable TEs (i.e. those yielding positive UG) from the population and, by so doing, helps them gain better utility than when using FIRE trust model. In this section, we use a static environment, which means that each TR attempt to make a transaction each step, and witnesses and TEs do not change their honesty levels.

Figure 3 describes the average UG per transaction as the number of transactions increases from 5 to 50 in the static environment. The charted UG is calculated as the averaged value for 10 different runs of the experiment. For each run, the summation of UG that all TRs accumulated at the end of each fifth simulation step is divided by the number of TRs (note that in the static environment, each TR interact in each simulation step.). The figure shows that selecting providers using the proposed model perform closely to FIRE despite the fact that FIRE make use of rule-based trust that can't be assumed to be available all the time. Moreover, the performance of both

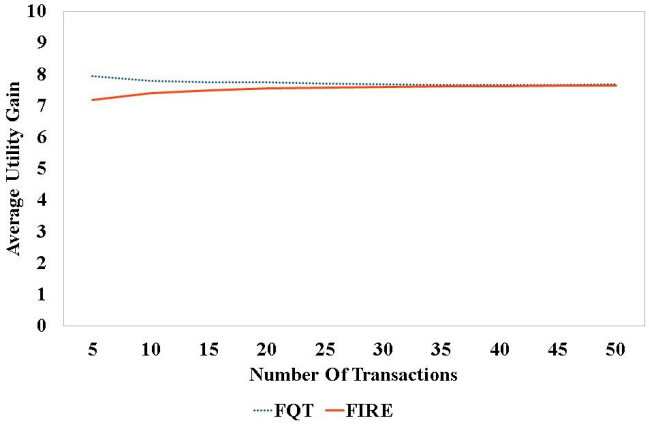

Fig. 3. Performance in Static Environment

models stabilize after a while. For FIRE, this is consistent with the results obtained in [2]. This stabilization in the performance of the two models indicates that they both learned to interact with the most beneficial TEs in the system

2) Performance in a dynamic environment: A trust model designed for MAS should be able to function properly in a dynamic environment. In this section we test the performance of the proposed model in a changing environment, as described below. As with static environment, we compare the performance of the proposed model with the case of using FIRE.

Specifically, the same experiments will be run, but with each of the following conditions: each TE may alter its average level of performance at maximum 1.0 UG unit with a probability of 0.10 each simulation step. A TR uses the service with probability in the range [0.25 - 1.0], intermittent TEs flip their honesty randomly and TEs may leave the system and new TEs may join the system with probability 0.5

Figure 4 describes the average UG per transaction as the number of transactions increases from 5 to 50 in the dynamic environment. The charted average UG is calculated as the averaged value for 10 different runs of the experiment. For each run, the summation of UG that all TRs accumulated when the total number of transaction in the system equals a multiple of five of the number of TRs is divided by the number of TRs. This value is averaged for 10 different runs of the experiment.

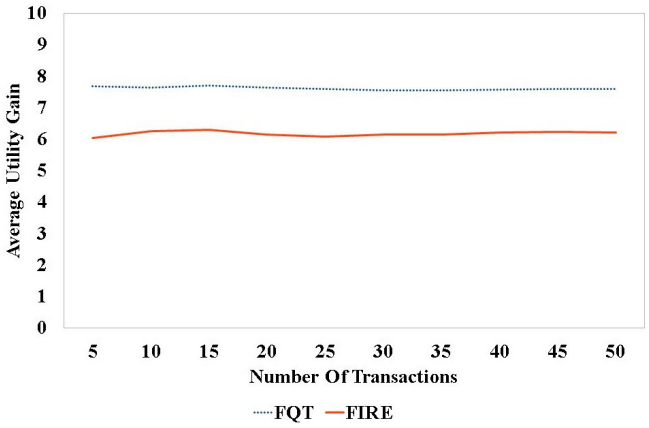

Fig. 4. Performance in Dynamic Environment

The figure shows that selecting TEs using the proposed model performs consistently better than using FIRE in terms of UG in a dynamic environment, which indicates that the proposed model responds better to dynamic changes compared to FIRE. Moreover, the performance of both models stabilize after a while. For FIRE, this is consistent with the results obtained in [2]. However, FIRE is not able to respond to the dynamics of the system as fast as the proposed model. This is due to the use of the fuzzy subsystems and due to picking the TE with the second highest bid.

VI. Conclusion and Future Work

In this paper, we presented a trust model for MASs that combines the use of Q-learning to estimate trustworthiness and incorporate two fuzzy subsystems for TE selection to enhance the utility gain estimation. The presented model allows direct and indirect sources of trust information to be integrated to provide a collective trust estimation. In addition, the proposed model incorporates fuzzy subsystems to account for suspension periods, average utility gain, bidding differences, and the relative average utility gain of a TE compared to the overall utility gain. The proposed model has been simulated using MASON with the use of the jFuzzyLogic package. The results indicate that the model can help TRs enhance their utility gain and that the proposed model can respond better to dynamic changes in the environment. In short, we believe the proposed model can provide a trust measure that is sufficiently useful to be used in MASs

Dynamically determining parameter values for the fuzzy subsystems, enabling TEs to actively promote their honesty, bootstrapping trust for new TEs and using Q-learning to dynamically select the proper action in each rule of the fuzzy subsystem are considered as future work.

***Abstract*—We used decision tree as a model to discover the knowledge from multi-label decision tables where each row has a set of decisions attached to it and our goal is to find out one arbitrary decision from the set of decisions attached to a row. The size of the decision tree can be small as well as very large. We study here different greedy as well as dynamic programming algorithms to minimize the size of the decision trees. When we compare the optimal result from dynamic programming algorithm, we found some greedy algorithms produce results which are close to the optimal result for the minimization of number of nodes (at most 18.92% difference), number of nonterminal nodes (at most 20.76% difference), and number of terminal nodes (at most 18.71% difference).**

I. Introduction

NOW a days, multi-label decision tables have gained attention in problem of semantic annotation of images [1], music categorization into emotions [2], functional genomics [3], and text categorization [4]. Furthermore, it is natural to have such data sets in optimization problems such as finding a Hamiltonian circuit with the minimum length in the traveling salesman problem [5], finding nearest post office in the post office problem [5]; in this case we give input with more than one optimal solutions.

In multi-label decision tables, each row is labeled with a set of decisions. It is common to have such tables in our real life because we do not have enough number of attributes of the domain to separate rows. Thus we have objects with equal values of conditional attributes but with different decisions. In literature, often, decision trees and other classifiers for multi-label data are considered for prediction (multi-label classification problem) [6], [7], [8], [9]. However, in this paper our aim is to study decision trees for multi-label decision tables for knowledge representation, and as algorithms for problem solving.

In [10] we studied a greedy algorithm for construction of decision trees for multi-label decision tables using the heuristic based on the number of boundary subtables. Besides, in [11] we have studied this algorithm in the cases of most common decision, and generalized decision approaches (in that paper, we considered decision tables with one-valued decisions as multi-label decision tables where sets of decisions attached to rows have one element).

This paper is a continuation of the conference publication [11]. We have introduced new greedy heuristics 'misclassification error', 'absent', 'combined' whose performances are as good as the previous one. Also we adapt, 'multi-label entropy', 'sorted entropy' heuristics from literature. We compared the performance among themselves for the cost function of number of nodes, number of nonterminal nodes and number of terminal nodes. We have done experiments using modified data sets from UCI Machine Learning Repository [12]. Based on the results of the experiments, we have presented rankings among the algorithms in the form of critical difference diagram [13]. Furthermore, we have shown the average relative difference between greedy and optimal results to describe how close they are. Hence, our goal is to choose some of the greedy heuristics which are close to the optimal results.

This paper consists of six sections. Section II contains the related background study of this problem. Section III contains the important definitions related to our study. After that, in Sect. IV, we presented the dynamic and greedy algorithms for construction of decision trees, then in Sect. V we gave comparison among algorithms using Friedman test. Section VI contains results of experiments and Sect. VII concludes the paper.

II. Related Work

In literature, often, problems that are connected with multi-label data are considered for classification: multi-label learning [14], multi-instance learning [9] etc. In multi-label learning, the output for each instances can be a set of decisions, whereas in our framework, we chose only one decision as output for each instance. In multi-instance learning, bag of instances are labeled rather than individual example which is far away from our problem. There is also semi-supervised learning [15] where some examples are labeled but some are not labeled, but we deal with examples that are labeled with multiple decisions.

Furthermore, some learning problems deal with many-valued data sets in different ways such as partial learning [16], ambiguous learning [17], and multiple label learning [18]. These problems consider only one label as correct and others as incorrect, but we consider all labels that are attached to an object as correct labels for that object. In [16], [18], the authors showed probabilistic methods to solve the learning problem whereas in [17], the author used standard heuristic approach to exploit inductive bias to disambiguate label information.

978-83-60810-58-3/$25.00

Additionally, these papers only focus on classification results rather than optimization of data model.

In this paper, we consider the problem of knowledge representation and optimization of data model. Therefore, our goal is to choose a data model which will be optimized and will give us one arbitrary decision from the set of decision attached with each row.

III. Main Definitions

A. Multi-label Decision Tables

A *multi-label decision table* T is a rectangular table filled by nonnegative integers. Columns of this table are labeled with conditional attributes $f_1, \ldots, f_n$. If we have strings as values of attributes, we have to encode the values as nonnegative integers. We do not have any duplicate rows, and each row is labeled with a nonempty finite set of natural numbers (set of decisions). We denote the number of rows in the table T by $N(T)$. We denote row i by r_i where $i = 1, \ldots, N(T)$. For example, r_1 means the first row, r_2 means the second row and so on.

TABLE I
A multi-label decision table T^0

	f_1	f_2	f_3	
r_1	0	0	0	{1}
r_2	0	1	1	{1,2}
r_3	1	0	1	{1,3}
r_4	1	1	0	{2,3}
r_5	0	0	1	{2}

If there is a decision which belongs to the set of decisions attached to each row of T, then we call it a *common decision* for T. We will say that T is a *degenerate* table if T does not have rows or it has a common decision. For example, T' is a degenerate table as shown in Table II, where the common decision is 1.

TABLE II
A degenerate multi-label decision table, T'

	f_1	f_2	f_3	
r_1	0	0	0	{1}
r_2	0	1	1	{1,2}
r_3	1	0	1	{1,3}

A table obtained from T by removing some rows is called a subtable of T. There is a special type of subtable called *boundary subtable*. The subtable T' of T is a *boundary subtable* of T if and only if T' is not degenerate but each of its proper subtable is degenerate. We denote the number of boundary subtables of the table T by $nBS(T)$. Below are examples of all boundary subtables of T_0:

T_1:

	f_1	f_2	f_3	d
r_2	0	1	1	$\{1,2\}$
r_3	1	0	1	$\{1,3\}$
r_4	1	1	0	$\{2,3\}$

T_2:

	f_1	f_2	f_3	d
r_1	0	0	0	$\{1\}$
r_4	1	1	0	$\{2,3\}$

T_3:

	f_1	f_2	f_3	d
r_3	1	0	1	$\{1,3\}$
r_5	0	0	1	$\{2\}$

T_4:

	f_1	f_2	f_3	d
r_1	0	0	0	$\{1\}$
r_5	0	0	1	$\{2\}$

The subtable of T which consists of rows that have values $a_1, \ldots, a_m$ at the intersection with columns $f_{i_1}, \ldots, f_{i_m}$ is denoted by $T(f_{i_1}, a_1), \ldots, (f_{i_m}, a_m)$. Such nonempty subtables (including the table T) are called separable subtables of T. For example, if we consider subtable $T^0(f_1, 0)$ for table T^0 (see Table I), it will consist of rows $1, 2$, and 5. Similarly, $T^0(f_1, 0)(f_2, 0)$ subtable will consist of rows 1, and 5 (see Table III).

TABLE III
Example of subtables of multi-label decision table T^0

$T^0(f_1, 0)$ =

	f_1	f_2	f_3	
r_1	0	0	0	{1}
r_2	0	1	1	{1,2}
r_5	0	0	1	{2}

$T^0(f_1, 0)(f_2, 0)$ =

	f_1	f_2	f_3	
r_1	0	0	0	{1}
r_5	0	0	1	{2}

The set of attributes (columns of table T), such that each of them has different values is denoted by $E(T)$. For example, if we consider table T^0, $E(T^0) = \{f_1, f_2, f_3\}$. Similarly, $E(T^0(f_1, 0)) = \{f_2, f_3\}$ for the subtable $T^0(f_1, 0)$, because the value for the attribute f_1 is constant (=0) in subtable $T^0(f_1, 0)$. For $f_i \in E(T)$, we denote the set of values from the column f_i by $E(T, f_i)$. As an example, if we consider table T^0 and attribute f_1, then $E(T^0, f_1) = \{0, 1\}$.

The minimum decision which belongs to the maximum number of sets of decisions attached to rows of the table T is called the *most common decision* for T. For example, the most common decision for table T^0 is 1. Even though both 1 and 2 appears 3 times in the sets of decisions, but 1 is the minimum decision, so we choose 1 as the most common decision. We denote the number of rows for which the set of decisions contains the most common decision for T by $N_{mcd}(T)$. For the table T^0, $N_{mcd}(T^0) = 3$.

B. Decision Tree

A *decision tree over* T is a finite tree with root in which each terminal node is labeled with a decision (a natural number), and each nonterminal node is labeled with an attribute from the set $\{f_1, \ldots, f_n\}$. A number of edges start from each nonterminal node which are labeled with different non-negative integers (e.g. two edges labeled with 0 and 1 if the nonterminal node is labeled with binary attribute).

Let Γ be a decision tree over T and v be a node of Γ. There is one to one mapping between node v and subtable of T i.e. for each node v, we have a unique subtable of T. We define a subtable $T(v)$ of T corresponding to the node v. If node v is the root of Γ then $T(v) = T$ i.e. the subtable $T(v)$ is the same as T. Otherwise, $T(v)$ is the subtable $T(f_{i_1}, \delta_1) \dots (f_{i_m}, \delta_m)$ of the table T where attributes $f_{i_1}, \dots, f_{i_m}$ and numbers $\delta_1, \dots, \delta_m$ are respectively node and edge labels in the path from the root to node v.

We will say that Γ is a decision tree for T, if for any node v of Γ:

- if $T(v)$ is degenerate then v is labeled with the common decision for $T(v)$,
- if $T(v)$ is not degenerate then v is labeled with an attribute $f_i \in E(T(v))$, and if $E(T(v), f_i) = \{a_1, \dots, a_k\}$, then k outgoing edges from node v are labeled with $a_1, \dots, a_k$.

An example of a decision tree for the table T can be found in Fig. 1. If v is the node labeled with the attribute f_3, then subtable $T(v)$ corresponding to the node v will be the subtable $T(f_1, 0)$ of table T. Similarly, the subtable corresponding to the node labeled with 2 will be $T(f_1, 0)(f_3, 0)$.

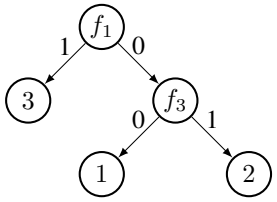

Fig. 1. A decision tree for the multi-label decision table, T^0

The number of nodes in the decision tree Γ is denoted by $N(\Gamma)$. The number of terminal and nonterminal nodes in the decision tree Γ are denoted by $N^t(\Gamma)$, and $N^n(\Gamma)$ respectively.

C. Impurity Functions and Uncertainty Measures

In greedy algorithm, we need to choose attributes to divide the decision table into smaller subtables until we get degenerate table which then be used to label the terminal node. To choose which partition to consider for tree construction, we need to evaluate the quality of partition. Impurity function is the criterion for the evaluation of quality of partition. We assume that, the smaller the impurity function value, the better is the quality of partition. We can calculate impurity function based on uncertainty measure value for the considered subtables corresponding to the partitioning. The uncertainty measure evaluates the uncertainty of the considered subtable. If we have a common decision, then there is no uncertainty in the data, hence we get uncertainty measure as zero, otherwise we will get positive values for it. We have used six different uncertainty measures, and four different impurity function types for our experiments.

1) Uncertainty Measures: Uncertainty measure U is a function from the set of nonempty multi-label decision tables to the set of real numbers such that $U(T) \geq 0$ for any decision table T, and $U(T) = 0$ if and only if T is degenerate.

Let T be a multi-label decision table having n conditional attributes, $N = N(T)$ rows and its rows be labeled with sets containing m different decisions $d_1, \dots, d_m$. For $i = 1, \dots, m$, let N_i be the number of rows in T that has been attached with sets of decisions containing the decision d_i, and $p_i = \frac{N_i}{N}$. Let $d_1, \dots, d_m$ be ordered such that $p_1 \geq \dots \geq p_m$, then for $i = 1, \dots, m$, we denote the number of rows in T such that the set of decisions attached to row contains d_i, and if $i > 1$ then this set does not contain $d_1, \dots, d_{i-1}$ by $N_i^{'}$, and $p_i^{'} = \frac{N_i^{'}}{N}$. We have the following six uncertainty measures (we assume $0 \log_2 0 = 0$):

- Misclassification error: $me(T) = N(T) - N_{mcd}(T)$. It measures the difference between total number of rows and number of rows with the most common decision.
- Sorted entropy: $entSort(T) = -\sum_{i=1}^{m} p_i^{'} \log_2 p_i^{'}$ (see [17]). First we sort the probability for each decision. Then, for each row, we keep the decision having maximum probability and discard others. After that, we calculate entropy for this modified decision table.
- Multi-label entropy: $entML(T) = 0$, if and only if T is degenerate, otherwise, it is equal to $-\sum_{i=1}^{m}(p_i \log_2 p_i + q_i \log_2 q_i)$, where, $q_i = 1 - p_i$. (see [19]). It measures entropy for multi-label decision table.
- $nBS(T)$: number of boundary subtables in T. We calculate number of boundary subtables using brute force approach by checking all possible subtables of T (see [10]).
- Absent: $abs(T) = q_1 \cdots q_m$, where $q_i = 1 - p_i$. It measures the absent probability q_i, and multiplies all of q_i's.
- Combined: $comb(T) = me(T) + B_2 + B_3$, where B_2 and B_3 are the number of boundary subtables with two rows and three rows, respectively. It is the combination of uncertainty measures.

2) Impurity Functions: Let $f_i \in E(T)$, and $E(T, f_i) = \{a_1, \dots, a_t\}$. The attribute f_i divides the table T into t subtables: $T_1 = T(f_i, a_1), \dots, T_t = T(f_i, a_t)$. We now define an impurity function I which gives us the impurity $I(T, f_i)$ of this partition. Let us fix an uncertainty measure U from the set $\{me, entSort, entML, nBS, abs, comb\}$, and type of impurity function from {weighted sum (ws), weighted max (wm), divided weighted sum (Div_ws), multiplied weighted sum ($Mult\_ws$)}. Then:

- wm: $I(T, f_i) = \max_{1 \leq j \leq t} U(T_j) N(T_j)$. For this type, we take the maximum among all the uncertainties of tables $T_1, \dots, T_t$ multiplied by the weights of its number of rows.
- ws: $I(T, f_i) = \sum_{j=1}^{t} U(T_j) N(T_j)$. For this type, we take the sum over all the uncertainties of tables $T_1, \dots, T_t$ multiplied by the weights of its number of rows.
- Div_ws: $I(T, f_i) = (\sum_{j=1}^{t} U(T_j) N(T_j)) / \log_2 t$. For this type, we divide the weighted sum impurity type (wt_sum) by the logarithmic function of number of branches ($\log_2 t$).

- *Mult_ws*: $I(T, f_i) = (\sum_{j=1}^{t} U(T_j)N(T_j)) \cdot \log_2 t$. For this type, we multiply the weighted sum impurity type (wt_sum) by the logarithmic function of number of branches ($\log_2 t$)

As a result, we have 24 (4 types multiplied by 6 uncertainty measures) impurity functions.

IV. Algorithms for Decision Tree Construction

In this section, we consider dynamic programming algorithm and greedy algorithms. Dynamic programming algorithm gives us optimal solution whereas greedy algorithms give us suboptimal solutions. As dynamic programming is highly time consuming, we need to choose some greedy algorithms which will be fast enough as well as their performances will be comparable to the optimal one.

A. Dynamic Programming Algorithm

We now describe an algorithm A_d which, for a given multi-label decision table constructs a decision tree with minimum size (number of nodes, or number of nonterminal nodes, or number of terminal nodes). This algorithm is based on dynamic programming approach [20], [5], and the complexity of this algorithm in the worst case is exponential.

Let T contains n conditional attribute $f_1, \ldots, f_n$. The set of all separable subtables of the table T including the table T is denoted by $S(T)$. The first part of the algorithm A_d constructs the set $S(T)$ (see Algorithm 1). For each subtable from $S(T)$, the second part of the algorithm A_d constructs a decision tree with minimum size (see Algorithm 2). Note that here size refers to either the number of nodes in the tree, or the number of nonterminal nodes in the tree, or the number of terminal nodes in the tree.

Algorithm 1 Construction of the set of separable subtables $S(T)$

Require: A multi-label decision table T with conditional attributes $f_1, \ldots, f_n$.
Ensure: The set $S(T)$
Assign $S(T) = \{T\}$, and mark T as not treated;
while (true) **do**
  if No untreated tables in $S(T)$ **then**
    Return $S(T)$;
  else
    Choose a table T_s in $S(T)$ which is not treated;
    if $E(T_s) = \phi$ **then**
      Mark the table T_s as treated;
    else
      Add to the set $S(T)$ all subtables of the form $T_s(f_i, \delta)$, where $f_i \in E(T_s)$, and $\delta \in E(T_s, f_i)$ which were not in $S(T)$, mark the table T_s as treated, and new subtables $T_s(f_i, \delta)$ as untreated.
    end if
  end if
end while

After that, A_d returns the minimum size of the optimal tree which corresponds to the table T.

Algorithm 2 Construction of a decision tree with minimum size for each table from $S(T)$

Require: A multi-label decision table T, with conditional attributes $f_1, \ldots, f_n$, and the set $S(T)$.
Ensure: Decision tree $A_d(T)$ for T.
while (true) **do**
  if T has been assigned a decision tree **then**
    Return this tree as $A_d(T)$;
  else
    Choose a table T_s in the set $S(T)$ which has not been assigned a tree yet and which is either degenerate or all separable subtables of the table T_s already have been assigned decision trees.
    if T_s is degenerate **then**
      Assign to the table T_s the decision tree consisting of one node. Mark this node with the common decision for T_s;
    else
      For each $f_i \in E(T_s)$ and each $\delta \in E(T_s, f_i)$, we denote the decision tree assigned to the table $T_s(f_i, \delta)$ by $\Gamma(f_i, \delta)$. We now define a decision tree Γ_{f_i} with a root labeled by the attribute f_i where $f_i \in E(T_s)$, and $E(T_s, f_i) = \{\delta_1, \ldots, \delta_r\}$. The root has exactly r edges $d_1, \ldots, d_r$ which are labeled by the numbers $\delta_1, \ldots, \delta_r$, respectively. The roots of the decision trees $\Gamma(f_i, \delta_1), \ldots, \Gamma(f_i, \delta_r)$ are ending points of the edges $d_1, \ldots, d_r$, respectively. Assign to the table T_s one of the trees $\Gamma_{f_i}, f_i \in E(T_s)$, having minimum size.
    end if
  end if
end while

B. Greedy Algorithms

Let I be an impurity function. For a given multi-label decision table T, the greedy algorithm A_I constructs a decision tree $A_I(T)$ for T (see Algorithm 3).

It constructs decision tree sequentially in a top-down fashion. It greedily chooses one attribute at each step based on uncertainty measure and type of the impurity function. We have total 24 algorithms. The complexities of these algorithms are polynomially bounded above by the size of the table. In case of 'number of boundary subtables' uncertainty measure, we will only consider those tables where the maximum number of decisions are bounded.

V. Comparison of Algorithms

To compare the algorithms statistically, we use Friedman test with the corresponding Nemenyi post-hoc test as suggested in [13]. Let we have k greedy algorithms $A_1, \ldots, A_k$ for constructing trees and M decision tables $T_1, \ldots, T_M$. For each decision table T_i, $i = 1, \ldots, M$, we rank the algorithms $A_1, \ldots, A_k$ on T_i based on their performance scores (from the point of view of cost functions: number of nodes, or number of nonterminal nodes, or number of terminal nodes of constructed

Algorithm 3 Greedy algorithm A_I

Require: A multi-label decision table T with conditional attributes $f_1, \ldots, f_n$.
Ensure: Decision tree $A_I(T)$ for T.
Construct the tree G consisting of a single node labeled with the table T;
while (true) **do**
if No node of the tree G is labeled with a table **then**
Denote the tree G by $A_I(T)$;
else
Choose a node v in G which is labeled with a subtable T' of the table T;
if $U(T') = 0$ **then**
Instead of T', mark the node v with the common decision for T';
else
For each $f_i \in E(T')$, we compute the value of the impurity function $I(T', f_i)$;
Choose the attribute $f_{i_0} \in E(T')$, where i_0 is the minimum i for which $I(T', f_i)$ has the minimum value; Instead of T', mark the node v with the attribute f_{i_0};
For each $\delta \in E(T', f_i)$, add to the tree G the node v_δ and mark this node with the subtable $T'(f_{i_0}, \delta)$;
Draw an edge from v to v_δ and mark this edge with δ.
end if
end if
end while

trees), where we assign the best performing algorithm as the rank 1, the second best as the rank 2, and so on. We break ties by computing the average of ranks. Let r_i^j be the rank of the j-th of k algorithms on the decision table T_i. For $j = 1, \ldots, k$, we correspond to the algorithm A_j the average rank

$$R_j = \frac{1}{M} \cdot \sum_{i=1}^{M} r_i^j.$$

For a fixed significant level α (in our work $\alpha = 0.05$), the performance of two algorithms is significantly different if the corresponding average ranks differ by at least the critical difference

$$CD = q_\alpha \sqrt{\frac{k\,(k+1)}{6M}}$$

where q_α is a critical value for the two-tailed Nemenyi test depending on α and k (see [13]).

We can also compare performance scores of algorithms $A_1, \ldots, A_k$ with optimal results obtained by dynamic programming algorithm. For $j = 1, \ldots, k$ and $i = 1, \ldots, M$, we denote, by N_{ij} the number of nodes of the decision tree constructed by the algorithm A_j on the decision table T_i. For $i = 1, \ldots, M$, we denote the minimum possible number of nodes of a decision tree for T_i by N_i^{opt}. Thus, we can compute the average relative difference in percentage for number of nodes as

$$ARD_j^N = \frac{1}{M} \sum_{i=1}^{M} \frac{N_{ij} - N_i^{opt}}{N_i^{opt}} \times 100\%.$$

Similarly, for number of nonterminal nodes ($N_n(\Gamma)$), we have

$$ARD_j^{N^n} = \frac{1}{M} \sum_{i=1}^{M} \frac{N_{ij}^n - N^{n\,opt}_i}{N^{n\,opt}_i} \times 100\%.$$

Similarly, for number of terminal nodes ($N_t(\Gamma)$), we have

$$ARD_j^{N^t} = \frac{1}{M} \sum_{i=1}^{M} \frac{N_{ij}^t - N^{t\,opt}_i}{N^{t\,opt}_i} \times 100\%.$$

VI. Experimental Results

We consider 16 decision tables from UCI Machine Learning Repository [12]. There were missing values for some attributes which were replaced with the most common values of the corresponding attributes. Some conditional attributes have been removed that take unique value for each row. To convert such tables into multi-label decision table format, we removed the more conditional attributes from these tables. As a result we obtained inconsistent decision tables which contained equal rows with different decisions. Each group of identical rows was replaced with a single row from the group which is labeled with the set of decisions attached to rows from the group. The information about obtained multi-label decision table can be found in Table IV. Modified decision table has been renamed in Table IV by the name of initial table plus an index equal to the number of removed conditional attributes. Table IV also contains the number of rows (column "Rows"), the number of attributes (column "Attr"), and the spectrum of the corresponding decision table (column "Spectrum"). Spectrum of a multi-label decision table is a sequence $\#1$, $\#2$,..., where $\#i$, $i = 1, 2, \ldots$, is the number of rows labeled with sets of decisions with the cardinality equal to i.

TABLE IV
Characteristics of multi-label decision tables

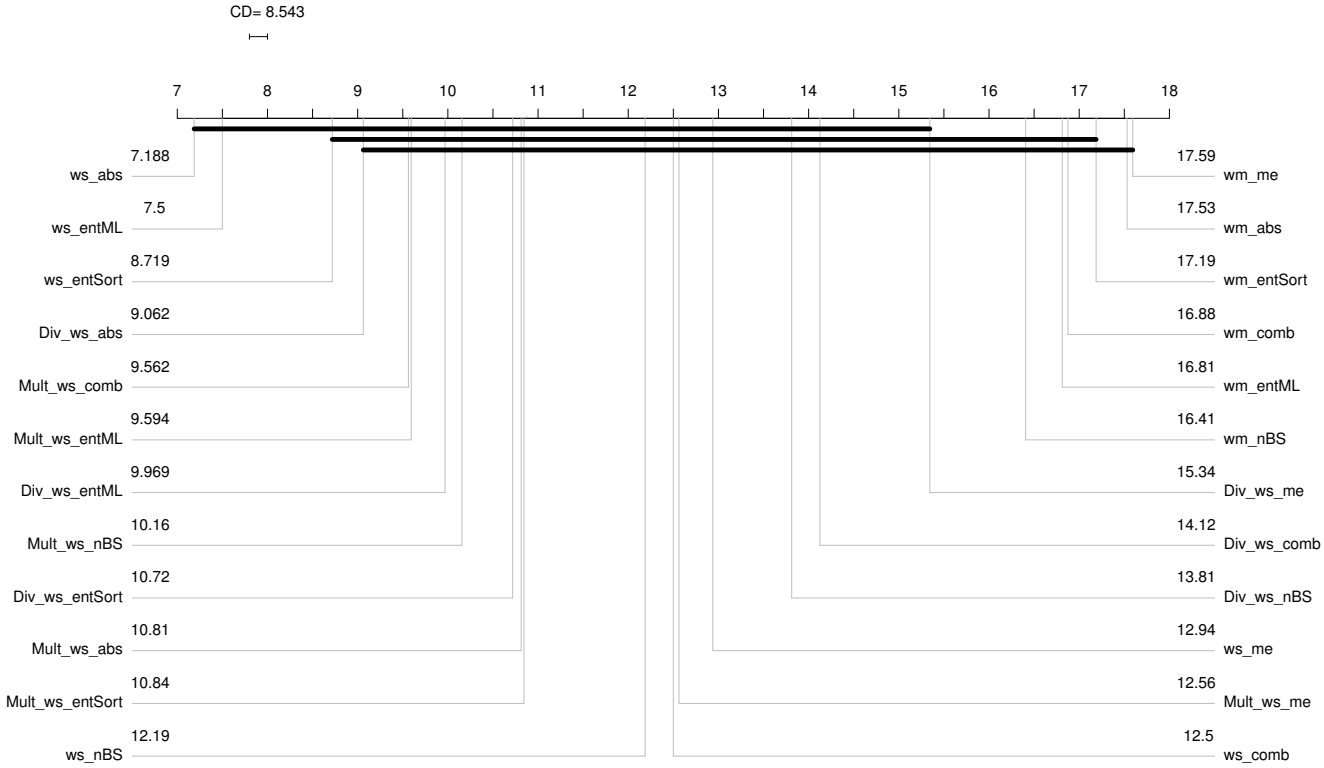

Fig. 2. CDD for number of nodes of decision trees constructed by greedy algorithms

We have six uncertainty measures (me, nBS, abs, $comb$, $entSort$, $entML$) and four types of impurity functions (ws, wm, Div_ws, $Mult\_ws$), so total 24 greedy algorithms have been compared. In the critical difference diagram (CDD), we showed the names of the algorithms as combined name of heuristic and impurity function types separated by '_'. For example, if the algorithm name is wm_nBS, this means it uses wm as a type of impurity function and nBS as uncertainty measure.

Figure 2 shows the CDD containing average (mean) rank for each algorithms on the x-axis for significant level of $\alpha = 0.1$. When Nemenyi test cannot identify significant difference between some algorithms, the algorithms are clustered (connected). It is clear from Figure 2 that, 18 algorithms from the 24 algorithms are clustered in the first group (left most algorithms is the best ranked algorithm) which are the leaders among all greedy algorithms for minimization of number of nodes in decision trees, and the best ranked algorithm is ws_abs. We have shown the best three algorithms having minimum ARD in Table V. If we look at the ARD table, we can see the best algorithm that is closer to the optimal results is ws_abs, and the average relative difference is only 18.92%.

Also, we can see from Figure 3 that, 17 algorithms among 24 algorithms are leaders for minimization of number of nonterminal nodes in decision trees, and the best ranked algorithm is ws_abs. We have shown the best three algorithms having minimum ARD for minimization of number of nonterminal nodes in Table VI, and the ARD for ws_abs is only 20.76% relative to the optimal results.

Now, for the minimization of number of terminal nodes, we can see from Figure 4 that 19 algorithms from 24 algorithms are in the best group, and the best ranked algorithm is $Mult\_ws\_entML$. Also from ARD Table VII, we can see that $Mult\_ws\_entML$ is closer to the optimal results by only 18.71%.

TABLE V
ARD IN PERCENTAGE BETWEEN RESULTS OF GREEDY AND DYNAMIC ALGORITHMS FOR TOTAL NUMBER OF NODES

Algorithm	ARD
ws_abs	18.92%
$Mult\_ws\_entML$	19.73%
ws_entML	20.58%

TABLE VI
ARD IN PERCENTAGE BETWEEN RESULTS OF GREEDY AND DYNAMIC ALGORITHMS FOR NUMBER OF NONTERMINAL NODES

Algorithm	ARD
ws_abs	20.76%
ws_entML	22.6%
$ws\_entSort$	23.7%

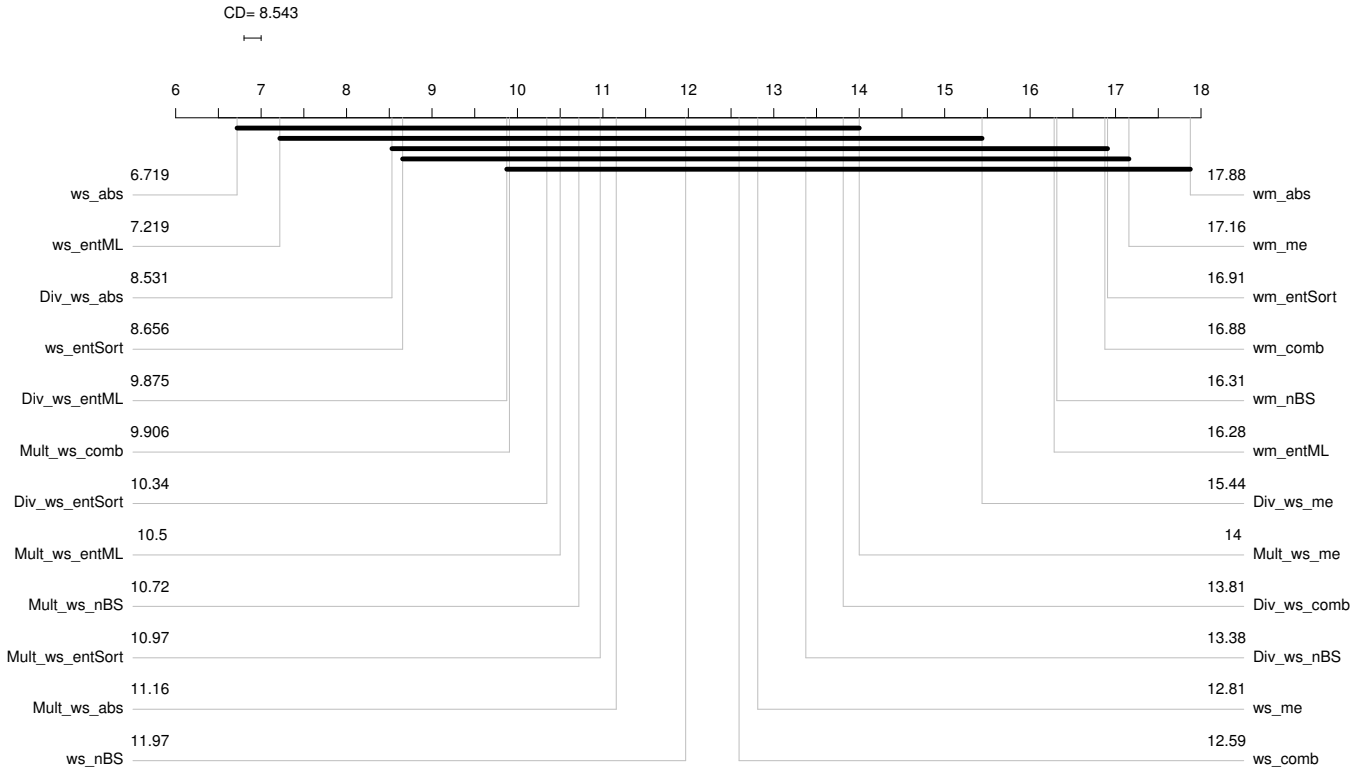

Fig. 3. CDD for nonterminal nodes of decision trees constructed by greedy algorithms

TABLE VII
ARD IN PERCENTAGE BETWEEN RESULTS OF GREEDY AND DYNAMIC ALGORITHMS FOR NUMBER OF TERMINAL NODES

Algorithm	ARD
$Mult\_ws\_entML$	18.71%
ws_abs	21%
$ws\_entSort$	22.49%

VII. CONCLUSION

In this paper, we studied greedy algorithms for decision tree construction which are based on various impurity functions. We compared these algorithms to find out which algorithm gives us minimum number of nodes, minimum number of nonterminal nodes and minimum number of terminal nodes. We also considered the average relative difference between optimal results and results obtained by the greedy algorithms. We found that, for the best greedy algorithm, it is at most 18.92% ARD for the minimization of number of nodes, at most 20.76% ARD for the minimization of number of nonterminal nodes, and 18.71% ARD for the minimization of terminal nodes, which are promising results. In future, our goal is to compare the above best greedy algorithm for the problem of prediction i.e. to minimize the prediction error.

***Abstract*—The applications of infection models like the Linear Threshold or the Domingos-Richardson model requires a graph weighted with infection probabilities. In many real-life applications these probabilities are unknown; therefore a systematic method for the estimation of these probabilities is required. One of the methods proposed to solve this problem, the Inverse Infection Model, was originally formulated for estimating credit default in banking applications. In this paper we are going to test the capabilities of the Inverse Infection Model in a more controlled environment. We are going to use artificially created graphs to evaluate the speed and the accuracy of estimations. We are also going to examine how approximations and heuristics can be used to improve the speed of the calculations. Finally, we will experiment with the amount of a priori information available in the model and evaluate how well this method performs if only partial information is available.**

I. Introduction

THE STUDY of infection processes has roots in two seemingly different fields of research: sociology and the medical sciences. In the latter, it was used to model the spread of epidemics [9]. Applications focused on prevention, and the identification of the “choke points" during an epidemic. In the former, the spreading of information or opinions came into focus. One of the earliest models in sociometry, Granovetter’s Linear Threshold [12] model is still considered to be a viable description of information diffusion.

In economics, Domingos and Richardson developed the Independent Cascade model (IC) [10] for the purpose of viral marketing. They proposed the influence maximization problem, that is to find the set of k initial infectors for any k that results in the largest expected infection. Kempe et al. [15], [16] proved the influence maximization problem was NP-hard, proposed a greedy algorithm for it, and also showed that the generalization of the IC model is in fact an equivalent of the Linear Threshold model. They also used random simulations to approximate the vertex infection probabilities, and they choose an arbitrary constant for edge infection probabilities. This result stresses the importance of the exact computation of vertex infection probabilities. This problem was proven to be #P-complete by Cao [4].

Computing the maximal infection or the exact probabilities of infection with any kind of model requires a weighted network, that is the edge infection probabilities must be available. This information is usually not known beforehand. In most real-life applications, the edges are considered to be some constant, or estimated using intuition guided trial-and-error method based on known edge or vertex attributes. Recently, a few papers were published in this topic discussing systematic approaches for the estimation of edge infection probabilities. In some of them [11], [17], the steps or iterations of the infection process are assumed to be known, which is realistic in the case of twitter or blog-based networks.

The Inverse Infection Problem, an application-driven approach was proposed recently by the authors [1] for the prediction of credit default in bank transaction networks. Unlike the above mentioned methods, this does not require information on the individual steps of the infection process. Instead it builds on other available data, such as estimations of the probabilities of default for individual companies and additional information characterizing the connection between the companies.

Based on the good results of this method in applications, our goal in this paper is to provide a solid foundation to the Inverse Infection Problem in a more controlled environment. Our method is based on the Generalized Cascade (GC) model [3], a generalization of the Independent Cascade model. To compute the edge infection probabilities themselves we will use a meta-heuristic: the Particle Swarm Algorithm of Kennedy and Mendes [14].

The paper is constructed as follows. In the next section we will give a short introduction into infection mechanisms, define the GC model, and the Inverse Infection Problem. In Section III we will describe several ways to accurately estimate the infection probabilities, including gradient-based methods and Particle Swarm Optimization. Then we will discuss various options to customize the estimations including heuristics of the GC model, choices for attribute functions and the number of patterns required to accurately estimate the infection probabilities.

II. Problem definition

The process of infection takes place on a graph G, where $V(G)$ denotes the set of vertices, and $E(G)$ denotes the set of edges. While most traditional models require directed edges, depending on the application, they can be easily modified to handle undirected ones. We also need to know the edge

978-83-60810-58-3/$25.00

infection probabilities, that is a weight $w_e \in [0,1]$ for each edge e.

The notion of states is important. Each vertex of the network has a state of infection. The number of states and the transitions between them are governed by the specific model. One of the most basic approaches, the SIR model, [9] has three states: Susceptible, Infected and Recovered. Infected nodes infect susceptible ones, but after a certain period, which is usually a parameter of the model, they may recover, no longer infectious. Models in epidemics have a variety of states and the transitions between them are often more complicated. Models in economics or models describing information diffusion can be considered simpler. In the case of the Independent Cascade model, there are three states loosely corresponding to the ones in the SIR model and the infection period only lasts for one iteration. These three states are: susceptible, just infected (and still infectious), infected (but no longer infectious).

Most infection processes are also iterative, that is the process takes place in discrete time steps. Those models, that allow nodes to become susceptible again some time after becoming infected, may not terminate. It is easy to see, that the IC model terminates in finite steps.

A. Infection Models

Any infection model can be described as a process, that has two inputs: the first one is a weighted graph, where the edge weights are probabilities. The second input is the set of initial infectors $A_0 \subset V(G)$. These nodes are considered as infected at the beginning of the process. The process terminates at iteration t, and results in the set of infected nodes $A = \bigcup_{i=0}^{t} A_i$.

The specific way one vertex infects another varies depending on the model. In the case of the IC model [10], let $A_i \subseteq V(G)$ be the set of nodes newly activated in iteration i. In the next iteration $i+1$, each node $u \in A_i$ tries to activate its inactive neighbors $v \in V \setminus \cup_{0 \leq j \leq i} A_j$ according to the edge infection probability $w_{u,v}$, and v becomes active in iteration $i+1$, if the attempt is successful. If more than one node is trying to activate v in the same iteration, the attempts are made independently of each other in an arbitrary order within iteration $i+1$. If $A_t = \emptyset$, the process terminates in iteration t. It is easy to see, that the process always terminates in a finite number of iterations.

B. Generalized Cascade Model

Following the works of Bóta et al. [3], we can generalize this model in the following way. Instead of using vertex sets for representing the initial infectors, we work with two probability distributions. The *a priori* distribution defines the probability, that a vertex becomes infected on its own, independently of other vertices at the beginning of the process. The *a posteriori* defines the probability, that a vertex becomes infected at the end of the process. For all vertices $v \in V(G)$, we will denote the a priori probability of infection as p_v, the a posteriori as p'_v.

In some applications, an estimate of one or both of the above described probability distributions is available. For example, in the case of the banking application [1], [7] an accurate estimation of the probability of default for each company was given by standard models used by the bank[1]. Another application in telecommunications uses estimations for the probability of churn using similar methods. If such estimations are not available we can resort to a crude but effective method. Suppose we can observe the beginning and the end of the infection process k times. By counting the frequencies of infection, for all vertices v, how many times did v belong to A_0 or A we can construct the respective probability distributions. The accuracy of the estimation obviously depends on k, but k does not have to be a large number. We will show in section IV.D, that 6-8 observations are enough to produce outputs with acceptable quality.

Based on these remarks and formulations, we can define the Generalized Cascade model [2]:

The Generalized Cascade Model: *Given an appropriately weighted graph G and the a priori infection distribution p_v, the model computes the a posteriori distribution p'_v for all $v \in V(G)$.*

The infection process itself is the IC model, although other models might also be used for different applications. We have chosen the Independent Cascade model as the basis of our method, because it performs well in modeling infection-like processes in business applications [7]. Alternatively, this model can be considered as a general framework of infection.

Unfortunately, the computation of the a posteriori distribution in the IC model is #P-complete. There are several existing heuristics to provide estimations of p'_v [5], [6], including the ones the authors proposed in [2]. Two of these are Monte Carlo based simulations. *Complete Simulation* is a direct adaptation of the idea of Kempe et al. to the framework of the GC model. The basis of the idea is the notion of reachability. By selecting the edges $(u,v) \in E(G)$ independently of each other according to their infection probabilities $w_{u,v}$, they construct an unweighted graph which is a realization of the infection process. Any vertex, that can be reached from any initially infector is considered to be infected. We can adapt this process into the GC model by computing a large number of individual runs of the model and counting the frequencies of infections (both a priori and a posteriori). The process has an unfortunate property: the frequency (or sample size) must be high enough to reduce the standard deviation characteristic of Monte Carlo based methods.

The *Edge Simulation* method decreases the standard deviation of the previous method. In each run, a subgraph containing all of the vertices able to infect the individual vertex v is constructed for all vertices $v \in V(G)$. This way the a posteriori infection of v can be computed directly in each run. The results of individual runs are averaged. The authors have proposed two additional heuristics: In the *Neighborhood Bound Heuristic* a tree is constructed from the 2-neighborhood

[1]The BASEL II default probabilities were computed using vertex attributes.

of a given vertex v representing all possible routes of infection. Both the tree and the a posteriori infection of v can be computed in a short time, resulting in a very fast heuristic. The *Aggregated Linear Effect* model is a linear approximation of the mechanism of the IC model. A more detailed description of these methods can be found in [2].

C. Inverse Infection Problem

Based on the framework of the Generalized Cascade model, we can define the Inverse Infection Problem.

Inverse Infection Problem: *Given an unweighted graph G, the a priori and the a posteriori probability distributions p_v and p'_v, compute the edge infection probabilities w_e for all $e \in E(G)$.*

Directly estimating each individual edge in a graph is computationally infeasible even in small graphs. However, in real-life applications the probability of infection between vertices is a combination of other properties of the edges, vertices and the graph itself. We are going to take advantage of this fact to simplify computations and make the problem solvable in reasonable time. We are going to assume, that on each edge there are several *attributes*[2], and the infection probability of the edge is a parametrized*function* of these attributes[3]. This way, only the *coefficients* of this function have to be estimated, which is a small number compared to the number of edges.

There are multiple ways to define these functions. In this paper, we are going to consider, that there is a polynomial function f_i on each individual attribute $a_i, i = 1, \ldots, \ell$, where ℓ is the number of attributes. Then, a normalized sum or product is calculated from each $f_i(a_i)$ resulting in the infection probability w_e. The degree of these polynomials should be low, but we allow different polynomials on different edges, with possibly different degrees. If the maximum degree of these polynomials is f_{max}, then there are at most $(f_{max}+1)\ell$ coefficients to estimate.

III. Estimation with learning methods

To provide a solution for the Inverse Infection Problem, we have developed the following learning algorithm. The problem definition states, that the a posteriori distribution is required as an input of any algorithm. In the case of a learning algorithm, it is considered as a test or reference dataset. By taking the a priori distribution we compute an estimation of the a posteriori distribution with some initially random starting coefficients. Then, an error function calculates the difference between the reference set and the newly calculated infection values. Our goal is finding the global minimum of this error function: the difference between the a posteriori vertex infections. Using an optimization algorithms, we can efficiently estimate the coefficients of the attribute-functions and thus the edge weights.

[2]Vertex attributes can be easily converted into edge attributes.

[3]It is possible, that some of these attributes have no influence on the infection probability, but we expect the method to ignore the effect of these.

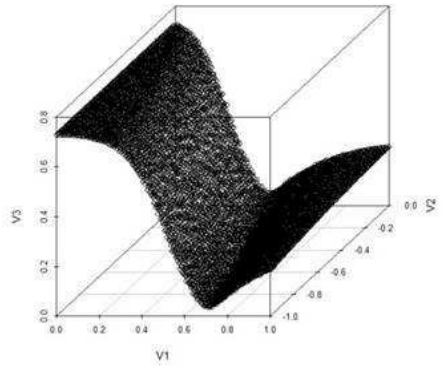

Fig. 1. The error surface of an IIP with one edge attribute and $f_1(a_1) = c_0 * a_1 + c_1$ as the attribute function. Root mean squared error was used for the evaluation.

A. Previous approaches and experiences

We have tried several optimization algorithms, including more simple ones, like grid search, gradient-based methods and meta-heuristics. Our first analysis was performed on banking data where we used grid search for optimization. While this early approach provided promising results [7], it was clear that further refinement of the optimization algorithm was required. Later, we have implemented a multi agent gradient based method, and compared the performance of it with our previous results [3]. The gradient method provided more accurate estimations, but highlighted several unfortunate properties of the problem itself.

Our first observation was that the error function was noisy. This comes from using Monte Carlo methods to approximate the IC model, since the deviation of these simulations makes different runs with the same coefficient values have different results. The noise can be reduced by increasing the frequency parameter of the simulation, but this also increases the time complexity of the method [3].

The second observation was that the problem is underdetermined. Different edge weight configurations can result in the same infection pattern, the same a posteriori distribution. This results in alleys and plateaus on the error surface. In the case of the example on Figure 1, the global minimum is in the middle of the alley. Even in this simple example neither algorithms are able to reliably find the best solution.

Grid search had serious performance issues both in finding the global minimum and in time complexity. Due to its search pattern, its precision is simply not enough to tackle with this surface, and it also scales exponentially with the number of coefficients. The gradient method also performs poorly: it easily gets lost on the alleys and plateaus especially if they are noisy as well. As a consequence, it rarely finds a solution close to the global minimum, and the number of steps it takes to find a solution at all can be quite high.

We have tried several error functions, mainly vector distance

measurements, and ROC evaluation. One of our first experiences was, that the latter is not enough to properly guide the optimization method to the global minimum, so we have shifted our attention to other measurements, and finally settled on the root mean squared error. In this work we are going to use the RMSE as an error measurement, that is we are looking for the minimum of

$$\sqrt{\frac{1}{|V(G)|}\sum_{v\in V(G)}(\vec{p}'_v - \vec{p}_v)^2}, \tag{1}$$

where $\vec{p}'_v$ denotes the estimated a posteriori infection of vertex v.

B. Particle-Swarm Optimization

In order to handle the above mentioned problems, we have decided to implement the particle swarm optimization algorithm of Kennedy [13]. This is an iterative method based on the interaction of multiple agents or "particles". Each agent corresponds to a different coefficient configuration, representing a coordinate in the parameter space of the problem[4].

Apart from the coordinates themselves, the agents also have a velocity. In each iteration the position of an agent is updated by adding its velocity. The velocity of the agent is computed using the best solution the agent has found and the best solutions of the neighboring agents; the goodness of the solution is measured by evaluating the error function on the coordinates visited by the particles. Agents are connected to each other according some topology describing the neighborhood of each agent.

The specific way the velocities of the agents are updated and the topology itself is not fixed: there are various approaches in the literature for specific applications and for more general problem solving. In our work we have followed the recommendations of Kennedy and Mendes [14], and found, that it performs well in finding coefficient configurations close to the global minimum.

We have used the Fully Informed Particle Swarm published in [14] with 9 agents in a von Neumann neighborhood[5]. The position and the velocity of the agents are updated according to the following equations:

$$\vec{v}_i \leftarrow \chi\left(\vec{v}_i + \sum_{n=1}^{N_i}\frac{U(0,\varphi)(\vec{b}_{nbr(n)} - \vec{x}_i)}{N_i}\right), \tag{2}$$

$$\vec{x}_i \leftarrow \vec{x}_i + \vec{v}_i, \tag{3}$$

where $\vec{x}_i$ and $\vec{v}_i$ denotes the coordinate and velocity of particle i, $U(min, max)$ is a uniform random number generator, $\vec{b}_i$ is the best location found so far by particle i, N_i is the number of neighbors i has and $nbr(n)$ is the nth neighbor of i. The formula has two parameters: χ is the constriction coefficient and φ is the acceleration constant. Again, we have used the recommendations of Kennedy et al., and set $\chi = 0.7298$ and $\varphi = 4.1$.

Algorithm 1 Particle Swarm Optimization

```
for all a_i do
    Initialize x_i for agent a_i within the boundaries of the search space
    Initialize v_i for agent a_i
    Set b_i ← x_i
    Select the neighbors of a_i according to the topology
end for
repeat
    for all a_i do
        Update v_i according to equation 2
        Update x_i according to equation 3
        Calculate the error function e(x_i) in position x_i
        if e(x_i) < e(b_i) then
            b_i ← x_i
        end if
    end for
until termination criterium is met
```

At the beginning of the search, the agents are initialized with zero velocities and random starting coordinates within some reasonable bounds of them. Then in each iteration these two vectors are updated according to equations 2 and 3 in a synchronized manner. The search is completed if the global minimum found considering all agents does not change for five consecutive iterations. We have experimented with other values and found, that increasing it does not improve the quality of the results, and decreasing it does not reduce the running time considerably.

IV. Evaluation

The most natural way to evaluate the stability of the optimization method is by counting the average and maximum number of iterations the method takes before it finishes. However, the quality of the solution of the Inverse Infection Problem depends on additional factors; we will discuss three of these. The first one is the choice of the attribute functions. Choosing an appropriate function is important, since depending on the available attributes this function either maps into the $[0, 1]$ interval directly or some additional form of normalization is required. The second one is the choice of heuristics applied for the GC model. These have a serious impact on both the accuracy and the running time of the learning method. The third factor is the number of learning patterns available. In case the exact a priori and a posteriori infection probabilities are not available, the only thing to do is to rely on counting the frequencies of infections. In real life we cannot hope to witness an infection process on any network in more than a handful of times. It is therefore necessary to investigate the sensitivity of our method to low-quality inputs.

As a basis of our analysis we have used graphs generated with the forest fire method of Leskovec et al. [18]. We have

[4]Again, the subject of the optimization is the coefficient values of the attribute function(s)

[5]Each agent has four neighbors in a grid, connected to the upper, lower, left and right, while wrapping around the edges.

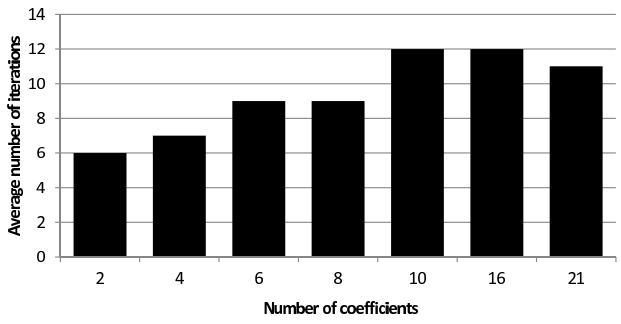

Fig. 2. The average number of iterations with different function configurations.

created a series of graphs of sizes $n = 1000, \ldots, 100000$, with parameters $p = 0.37$ and $p_b = 0.32$, for forward and backward burning probabilities, respectively. We have assigned a number of edge attributes $a_i, i = 2, \ldots, 10$ to these networks. These attributes are randomly generated: they were drawn independently from a uniform distribution between $[0, 0.5]$. We have also used randomly generated a priori infections. The expected size of the set of initial infectors is $0.3{*}n$. If v is selected, then an a priori infection probability was drawn from an uniform distribution between $[0, 0.5]$, otherwise $p_v = 0$. We have used various attribute functions, description of these will be given in section IV.B. Finally for each network and each attribute function we have created an a posteriori infection distribution as the reference dataset. For this purpose we have used Compete Simulation with sample size $k = 10000$, because this method gives the best approximation of the original IC model.

A. Stability of the optimization

The performance of the optimization method itself can be measured in two ways. The distance between the solution found by the method and the global minimum is conveniently measured by the error function itself. However, the precision of the algorithm also depends on the heuristics used to approximate the Generalized Cascade model. Consequently, we will discuss this in the following sections.

The time complexity of the method is the sum of two distinct parts of the algorithm: evaluating points on the error surface and the search method itself. The latter consists of the repeated evaluation of the formula above, after initializing the neighborhood and the starting coordinates. Since the number of agents is small, this part of the algorithm is very fast, and has negligible impact on the running time of the overall method.

In each iteration every agent evaluates the error function. This evaluation is the computation of the GC model using the coordinates - coefficients of the given agent. The time complexity of this step heavily depends on the used heuristic. Altogether, we can say, that the time complexity of a single run is $s * a * h$, where s is the number of iterations, a is the number of agents (a constant) and h is the time complexity of the infection heuristic. This also means, that we can describe the time complexity of the algorithm by measuring the average or maximum number of iterations and multiplying it with the time complexity of the infection method and the number of agents. Breaking the time complexity of the method into two different factors makes sense because of another reason: the individual runs of the GC heuristics may be run on multiple threads simultaneously, significantly improving the speed of the method.

On Figure 2 we can see the average number of iterations for different numbers of coefficients. We have used a small network with $|V(G)| = 1000$. The point of interest here is, starting from a simple problem with only two coefficients to more complex ones, the expected number of iterations grows slowly, and stabilizes around 12. The maximum number of iterations remains bounded as well, even in the experiment with 21 coefficients, it does not go beyond 30. The results shown on Figure 2 were computed with 9 agents. We have tried this problem with 16 agents as well and got similar results. If we compare the different infection heuristics, they perform similarly, with the non-Monte Carlo methods finishing slightly sooner, usually by 4-5 iterations.

We can conclude, that the Particle-Swarm Optimization method described in this section is able to solve the Inverse Infection Problem with satisfying results. The algorithm is very stable, and even in the worst case, it finishes within 30 iterations. We will evaluate the precision and running times of this method considering different heuristics of the Generalized Cascade model in section IV.C. We will also discuss choices for attribute functions, and the number of patterns required to get good estimations of the edge infection probabilities.

B. Choice of attribute functions

We have seen, that in our model, the edge infection probabilities are computed from some additional information on the edges in the form of edge attributes by so-called attribute functions. The choice of these attribute functions is an important part of our method. A natural requirement of this choice is, that it must result in infection probabilities: it must map into the $[0, 1]$ interval.

There are two approaches to this problem: the first one is to construct problem-specific functions, taking into account the structure of the network, the nature of the infection model and the number and domain of the attributes. This way it is possible to calculate the infection probabilities directly, without any form of additional normalization. This is the obvious choice if the above mentioned information is available.

If we do not have this information, we can try a more user-friendly approach. We can apply functions to the individual attributes, summarize them and finally normalize them. A variety of functions might be considered for this purpose. In our work, we have used low-degree polynomials for the individual attributes and simple addition or multiplication to join them. We have normalized the resulting edge infection probabilities according to

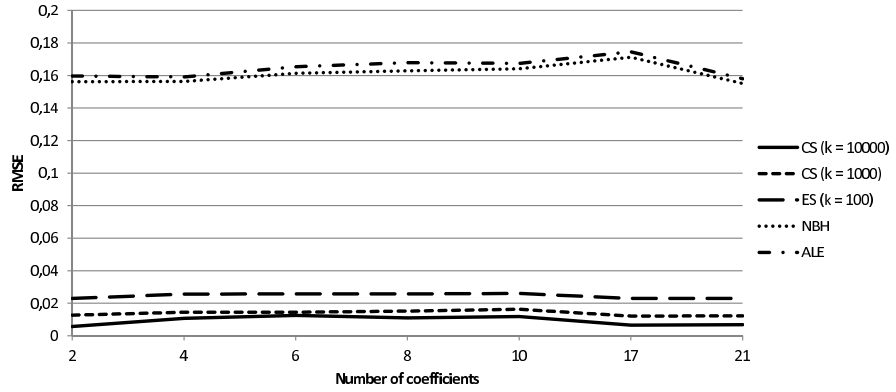

Fig. 3. The RMSE with different function configurations on a small network with $n = 1000$.

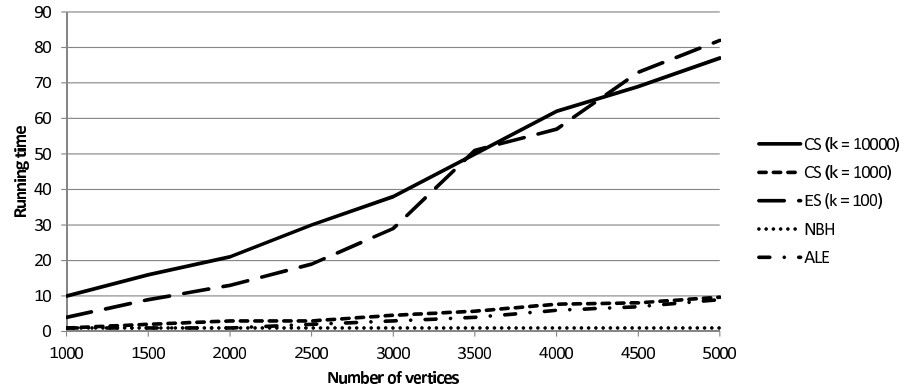

Fig. 4. The running time of the infection heuristics with different network sizes measured in seconds. Figure used with the permission of the authors [2].

$$\text{norm}(\vec{e}) = \frac{\vec{e} - \min(\vec{e})}{3(\max(\vec{e}) - \min(\vec{e}))}, \tag{4}$$

where $\vec{e}$ is a vector containing the infection probabilities for each individual edge. The reason why we have used the multiplier 3 in the denominator is, that according to our findings in the prediction of default events on banking data, the edge infection probabilities are low [7]. The normalizer function obviously distorts the shape of the individual attribute functions, but in real-life problems a simple weighted, normalized sum of attributes is sufficient to produce acceptable results.

In this paper, we have used seven attribute function configurations, a_i denotes attribute i and c_j denotes coefficient j:

- Weighted sum of two attributes: $c_1a_1 + c_2a_2$, two coefficients in total.
- Weighted sum of four attributes: $\sum_i c_ia_i, i = 1, 2, 3, 4$, four coefficients in total.
- Weighted sum of six attributes: $\sum_i c_ia_i, i = 1, \ldots, 6$, six coefficients in total.
- Weighted sum of eight attributes: $\sum_i c_ia_i, i = 1, \ldots, 8$, eight coefficients in total.
- Weighted sum of ten attributes: $\sum_i c_ia_i, i = 1, \ldots, 10$, ten coefficients in total.
- Sum of quadratic polynomials with eight attributes $c_1 + \sum_i (c_{2i}a_i^2 + c_{2i+1}a_i), i = 1, \ldots, 8$, 17 coefficients in total.
- Sum of quadratic polynomials with ten attributes $c_1 + \sum_i (c_{2i}a_i^2 + c_{2i+1}a_i),\ i = 1, \ldots, 10$, 21 coefficients in total.

In section IV, we have tested the effect of these function configurations on the stability and accuracy of the optimization method. Details of these can be found in the appropriate subsections.

C. Accuracy and the choice of heuristics

Previously, in section II.B, we have given short descriptions of some heuristics of the GC model [2]. In this section we will evaluate the performance of them in relation with the learning method described above. Complete Simulation is a direct adaptation of the idea of Kempe et al. [15], it can be considered as the best approximation of the original IC model. Therefore, we will use CS with sample size $k = 10000$ to create an a posteriori distribution as a reference set. Then, we

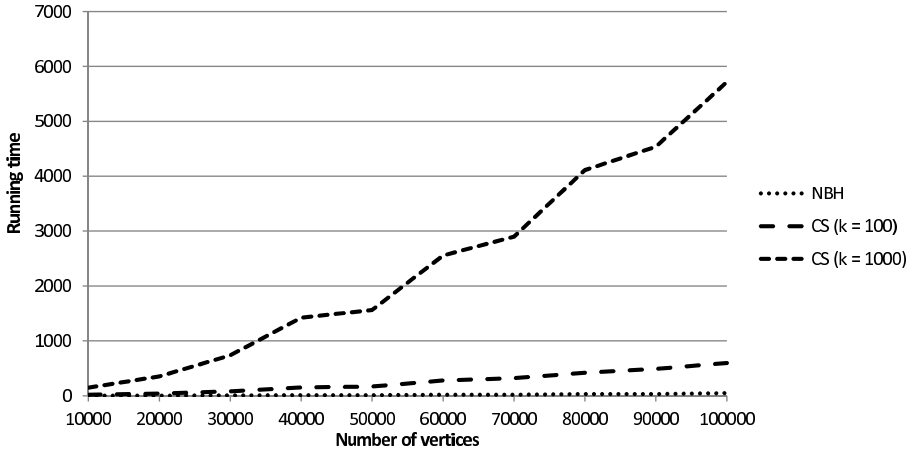

Fig. 5. The running time of the infection heuristics on large networks measured in seconds.

will use each heuristic together with the learning method to compute the edge infection probabilities:

- Complete Simulation (CS) with sample size $k = 10000$, a very accurate simulation.
- Complete Simulation (CS) with sample size $k = 1000$, a very fast simulation.
- Edge Simulation (ES) with sample size $k = 100$, a simulation based heuristic.
- Neighborhood Bound Heuristic (NBH), an extremely fast lower approximation.
- Aggregated Linear Effect (ALE) model, a de Groot [8] based simplification of the infection process.

Since the running time and the accuracy of the heuristics are different, we are going to use two different datasets to evaluate their performance. First, small networks with $|V(G)| \leq 5000$ will be used to make general observations, then we will test the more robust heuristics on large networks with $|V(G)| = 10000, \ldots, 100000$. Our largest network has 100000 vertices and 2.3 million edges.

As we can see on Figure 3, the Monte Carlo based simulations of the GC model (CS and ES) are able to estimate the reference distribution well, with the measured error between $0.01 - 0.03$. The other two heuristics (NBH and ALE) are tailored to small edge infection probabilities with rare infections, hence they do not perform so well on this dataset. Note, that in some cases even an error of this magnitude is acceptable, and the time complexity of these methods allows them to handle larger networks. If we compare the results computed by using different attribute functions, we can see that they have minimal effect on the accuracy of the methods.

Our results on the running times[6] of these heuristics on small networks correspond with our previous findings [2]. The speed of the simulations are governed by the sample size. Complete Simulation is considerably faster than ES[7] because the latter focuses on the fast computation of smaller infections. By decreasing the sample size CS can tackle larger networks as well. The Neighborhood Bound Heuristic is able to compute the a posteriori infections of the largest networks within a minute, enabling our method to scale upwards and handle real-life datasets and networks with possibly millions of nodes and edges.

We can conclude, that in general, the use of Complete Simulation is recommended. Both its precision and accuracy are good on large graphs. If the infection probabilities are lower than our current dataset, the use of Edge Simulation is also advisable. The Neighborhood Bound Heuristic and the Aggregated Linear Effect model are able to handle even larger networks, yet this comes at the cost of a significantly lower precision.

D. Number of patterns

In many real-life applications the a priori or a posteriori probabilities of infections are unavailable. In this section we are going to assume, that the initial infection probabilities are given, but we only have a small number of observations on the a posteriori infections. We are going to simulate this on a small network by generating an a posteriori distribution using CS with $k = 1, \ldots, 10$, corresponding to $1, \ldots, 10$ observations.

We can see, that the proposed method gives a rough estimate of the vertex infection probabilities in only a few iterations. If we consider a threshold of 0.15 as an acceptable estimation, our method only requires 6 observations to reach it. However, it is important to keep in mind, that the method tries to create a posteriori infections close to the reference. The problem is underdetermined even with exact possibilities of vertex infection, with only a handful number of observations many attribute function configurations (and edge weights) may result in the same infection. The results in this section only imply, that our method is able to give one of these.

Different infection heuristics are shown on Figure 6, one can see, that the simulations have identical performance regardless

[6]We have implemented the methods in JAVA, and we have used a computer with an Intel i7-2630QM processor, and 8 gigabytes of memory.

[7]Note the sample sizes.

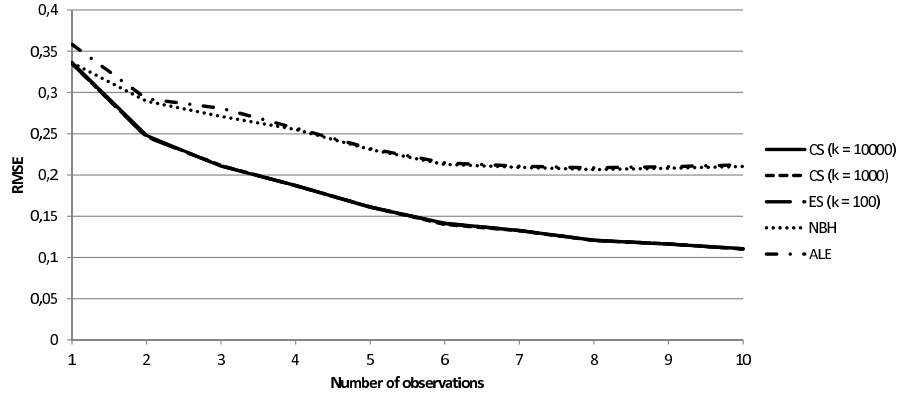

Fig. 6. The precision of the infection heuristics with a limited number of observations of the reference distribution.

of the sample size. As before, the non-Monte Carlo based methods perform poorly, their use is not recommended with low-quality inputs.

V. Conclusions

Our goal on this paper was to extend the previous results of the Inverse Infection Problem and its solution. We have given a detailed description and analysis of the Generalized Cascade Model, the Inverse Infection Problem and a Particle-Swarm Optimization algorithm capable of giving a good estimation of the latter. Several aspects of the method were investigated: We have tested the stability and accuracy of the optimization method, we have given a general approach to choose the correct attribute functions, we have examined the implications of choosing between the heuristics of the GC model and we have tested our method in low-quality inputs as well.

The given method is able to accurately predict the edge infection probabilities in a small number of iterations while the number of attributes and the shape of the attribute functions have only a small effect on this. Our method also handles low-quality inputs well. Of the infection heuristics we recommend the use of Complete Simulation, because it gives accurate results with acceptable standard deviation in reasonable time.

In our previous paper we have also given an application of this method in the prediction of credit default [7]. Our method was able to predict the default of the worst 5% of clients accurately.

***Abstract*—Recent developments in imaging cameras has opened a new way of analyzing facial expression. We would like to take advantage from this new technology and present a method of imaging and processing images of human face as a response to the particular stimuli. The response in this case is represented by the facial expressions and the stimuli are still images representing six basic emotions according to Eckmann. Working hypothesis of presented research, states that the new method of tracking facial expressions is more precise and distinctive enough to give characteristic description of the analyzed human face. The biggest advantage of the presented method, in the opinion of research team, is the fact that it uses remote sensing techniques and presents dynamics of the changes happening on the human face. Therefore, FMRI might not be required, which decreases the costs of experiments, additionally, method is less stressful for the examined persons and provides more natural reactions.**

I. Introduction

SCIENTISTS all over the world are looking for new methods of tracking facial expressions to use in the field of psychology, neuroscience and affective computing. Emotion influence all modes of human activity, communication, interpersonal relations, family and business life. There are lots of empirical models of affect. Basically they are focused on analysis of speech, visual and biophysiological signals (see for example [1], [2], [3], [4], [5]. In this paper we would like to focus attention on visual methods. Typically, these methods are based on comprehensive description of the changes in facial expressions, discernment of action units for all visually distinguishable facial movements and mapping them with basic emotion (based on Facial Action Coding Systems [6], [7]). Characteristic points, located in specific segments of the human face (mouth, eyebrow, eyes etc.) are tracked and their movement is identified as a certain type of emotion [8], [9], [10]. However in our opinion, emotions represents extremely complicated states of the human's brain and they have rather fuzzy nature, thus tracking changes in the position of only few characteristic points might not be effective. Due to the nature of the observed phenomenon there is no simple method of distinguishing certain type of emotion among diversity of emotional states. Fig. 1 shows how complicated are representations of emotional states when they are expressed by human beings. Taking into account the movement of the lips or eyebrows we are not able to distinguish in what emotional state the tested person is. In addition, presenting on Fig. 1 images are taken when the emotion is the most intensive (for example the moment when the smile is the widest and brightest). We have decided to create our own database of facial expressions because we would like to investigate the process of creation facial expression from the beginning to the end (when the face comes to neutral state). Data gathered in the new database let us track changes on the face throughout the period of observation.

The caption of the Fig. 1 is a starting point for the further investigations. Humans ability to recognize different emotions is very difficult and complicated process to implement in the machine like computer. Recognizing emotional states is important for human-computer interaction or other form of coexisting in an artificial environment. In the opinion of the research team., dynamics of the facial expressions is the key to find the efficient way of recognizing emotional states. The main goal of presented experiment was to develop a new method of tracking changes in facial expressions, because, in the opinion of research group, it might be a promising direction to develop fully automatic method of recognition emotional states. Proposed method opens a long way to find the solution of the problem how emotions are expressed and how they arise.

Recent developments in imaging cameras has opened a new way of analyzing facial expression of emotions [11]. We would like to present a new method of imaging and processing images of human face in order to quantify the response to the particular stimuli [12]. This article presents a method of processing images of human face recorded by a fast camera Phantom MIRO 310. Method was applied on a collection of 65 persons (30 female students and 35 male students) expressing happiness, sadness, anger, fear and disgust, as well as surprise.

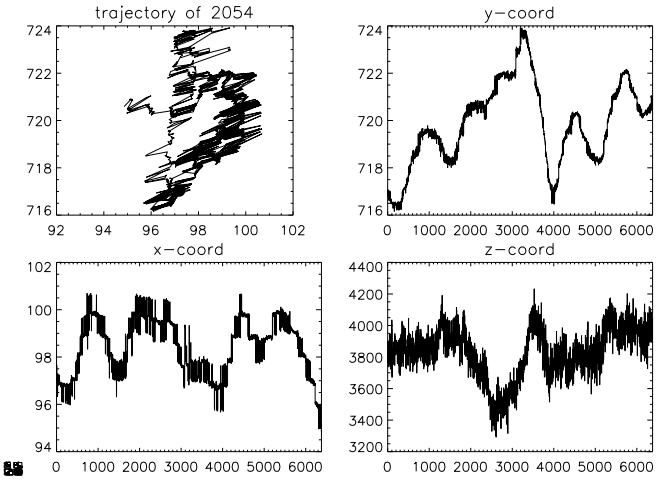

Fig. 2. Single object trajectory, $Z - coord$ - represents brightness

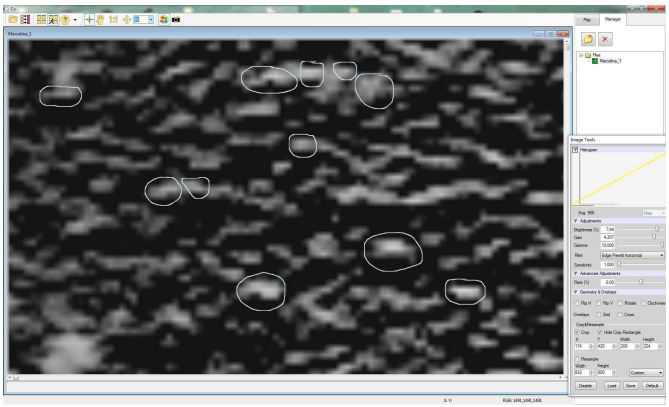

Fig. 3. Objects on the human face, characteristic for the certain structure of the skin

Each emotion was expressed be the students for about 2 seconds. Resulting images represent series of frames recorded at the speed of 1000 frames per second. Presented method is based on the assumptions coming from Particle Image Velocimetry (PIV) [13], [14]. The most important one is that there are some objects on the human face, characteristic to the certain type of skin (see Fig. 4) (as well as certain mechanical and chemical properties of the skin), that are determined and identified while processing series of images. Those objects are of non-spherical shape (as it is presented on the Fig. 3). Working hypothesis of presented research states that the facial expressions are determined by the mechanical and chemical properties of the human's skin and the tension of the muscles, however all those properties might influenced the motion of the identified objects only in very limited range, as it is presented on the Fig. 2.

The following sections are the attempt to the answer the question whether the working hypothesis is true or false.

The main idea of proposed research comes from the methods of studies colloidal particle's trajectories and particle image velocimetry. While both image processing, photographic, study of colloidal suspensions and particle image velocimetry are well developed fields, applying them to the field of affective computing and psychology gives new view on the problem of facial expressions what in consequence might constitute new approach to the problem of automatic recognition of human emotions [15], [2]. The methods described below are generalized to the objects or areas of non-spherical shape that can be identified on human face (see Fig. 3). Shape and position of non-spherical objects located on the face plays very important role in this method. Thanks to the speed of the recording (1000/frames per second) collected positions of the identified objects create trajectories of their movement.

In the following, section typical instrumentation required for collecting digital video images of human face has been described, and some details of the steps required to convert a digital movie into an ensemble of single-object trajectories. We stress those aspects of the analysis which allow us to track particular objects on the human face. High-resolution trajectory data makes possible a wide range of quantitative measurements of the changes occurring on human face.

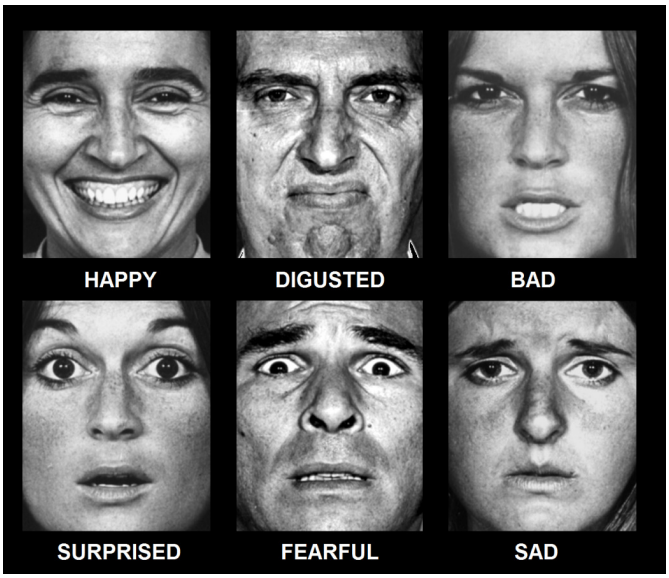

Fig. 5. Standard representations of the basic emotions

II. METHODS

Research was conducted in the Gdansk University of Technology, Remote Sensing Lab on 30 female and 35 male, students of the Psychology at the Gdansk University. The study was based on the assumption that students have to reproduce emotion which was showed them on the laptop's screen. Our team has prepared PowerPoint presentation based on the set of facial expression images proposed by Professor Eckman (see Fig. 5). Each emotion was earlier presented to the examined person and then on the mark he or she should reproduced it straight to the camera. It seems necessary to stress that the stimuli - picture of certain emotion wasn't active when examined person was asked to reproduced the image, because the eyes of the research participant were directed straight at the camera, not on the computer screen with the image of emotion pattern. In fact, only the imagination of the image is used to render the emotion.

Standard commercial video cameras produce 30 complete images per second but in order to track changes on the human face we need speed camera with ability to record at least 1000 complete images per second. Monochrome CCD cameras may be preferable to color models not only because they are less expensive but also because they tend to have superior noise figures and greater sensitivity to subtle brightness variations. Color information, furthermore, is not used in the techniques we describe below. We use an Phantom Miro 310 camera connected to the Dell m4700 mobile workstation. To apply Particle Images Velocimetry method we have to transform an image of human face in to map of small objects like it is presented on Fig. 6

map of small objects

Fig. 6. Zoom of the ROI from Fig. 4

At this stage of the processing the filtering methods are very helpful, in this particular case Prewitt filter has been used, which was implemented in the Phantom Miro 310 camera software. The following parameters has been used in this experiment:

- brightness of the image set to 7.44,
- gain factor set to 4.207,
- gamma factor set to 10.00.

By using camera software it was possible to collect series of frames from the recorded movie already transformed into a map of small objects, and represents them as a series of tiff images directly from the camera without loosing the time for additional computations and transformations, an example is presented on the Fig. 6. After this operation a series of images, about 2000 frames for each of 6 basic emotions, have been created. Every image represents face as a map of small objects that move while facial expression (typical for the certain type of emotion) come out on the face (see Fig. 6).

Digital video analysis and methods of tracking and identifying objects, enables extracting trajectories of individual micro-objects from a series of images. The time evolution of the distribution of interested objects (or areas) can be calculated according to the following equation

$$\theta(r,t) = \sum_{i=1}^{N} \delta(r - r_i(t)), \tag{1}$$

where:

- $r_i(t)$ is the location of the i-th object in a field of N objects at time t,
- δ - distance.

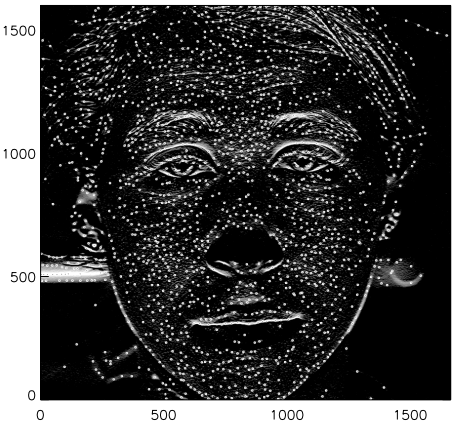
III. Results.

The process of extracting useful information from a sequence of digital images consists of five logical steps:

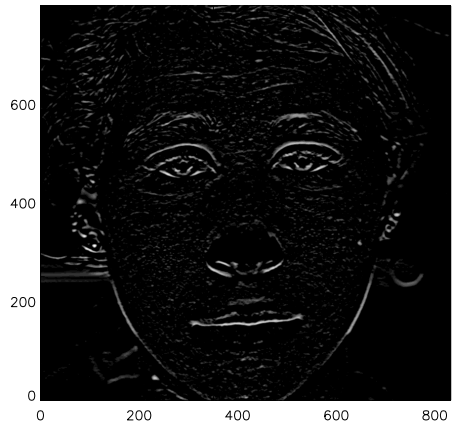
1) correcting imperfections in the individual images,
2) locating candidate particle positions,
3) refining these positions,
4) discriminating „false" objects,
5) and finally linking the time-resolved object locations into trajectories.

In this case, the tracking algorithm has to deal with the changing appearance of the interested areas as they move. Furthermore, it has to distinguish marginally focused particles from noise. In practice, the image $A(x, y)$ must be cast from an array of bytes to a higher precision data format, such as a floating point array, before convolution. We have used an object oriented method for identifying candidate object within an image as a local brightness maxima's. The pixel is assigned as a candidate if no other pixel within a certain distance w is brighter. Because only the brightest pixels correspond to the location of interested us objects on the human face, we further require candidates to be in the upper 50th percentile of brightness for the entire image, see Fig. 7.

This operation is called, the gray-scale dilation [16], [17] and provides an implementation of the regional maximum



Identified objects



Objects of the same brightness

Fig. 7. Non-spherical areas (objects or particles) on the human face after processing. Objects represents the same spectral feature - brightness

selection criterion. Gray-scale dilation is an elementary morphological operation which sets the value of pixel $A(x, y)$ to the maximum value within a distance w of coordinates (x, y). A pixel in the original image which has the same value in the dilated image is then a candidate particle location. We use the same value of w as was used in the filtering step.

Having already found a locally brightest pixel at (x, y), which presumably is near the geometric center of an interested us object's at the coordinates x_0, y_0 , we calculate the offset from (x, y) to the brightness-weighted centroid of the pixels in a region around (x, y) according to following equation:

$$\begin{pmatrix} \epsilon_x \\ \epsilon_y \end{pmatrix} = \frac{1}{m_0} \sum_{i^2+j^2 \le w^2} \begin{pmatrix} i \\ j \end{pmatrix} A(x+i, y+j), \tag{2}$$

where:

- moment $m_0 = \sum_{i^2+j^2 \le w^2} \binom{i}{j} A(x+i, y+j)$ is the integrated brightness of the sphere's image.

Having located objects or particles in a sequence of images, the next step is to match up locations in each image with corresponding locations in later images to produce the trajectories. This requires determining which particle in a given image most likely corresponds to one in the next image. Tracking more than one object is very difficult. Thus, it is necessary to seek the most probable set of N identifications between N locations in two consecutive images. Linking particle distributions into trajectories is only feasible if the typical single particle displacement in one time step is sufficiently smaller than the typical inter-particle spacing, otherwise, particle positions will become inextricably confused between snapshots. In this case the speed of recording (1000/frames per second) let us discriminate very small displacement between objects, and thus the trajectories are more accurate and precise. This process is repeated for the particle locations in each frame until is completely determined. The examples of calculated trajectories are presented on Fig. 8.

One of the most important aspects of particle dynamics in the fluid flow, which underlies the proposed method, is the mean squared particle displacement while the time of observation evolve. This quantity can be calculated according to the Eq. 3. On the Fig. 9 we would like to present results of calculating msd for the few members of the research group. The $Panel\ \ A$ represents $MSD\ \ curves$ calculated for 6 basic emotions reproduced by participant according to the images showing on the laptop's screen.

$$MSD(\tau) =< \triangle r(t)^2 >=< [r(t+\tau) - r(t)]^2 > \qquad (3)$$

where:

- $r(t)$ particle position at time t,
- τ lag time between two positions,
- operator $<>$ designates a time-average over t and/or an ensemble-average over several trajectories.

Figure 9 $Panel\ \ B$ presents the examples of calculating $MSD\ \ curves$ for selected number of representatives of the research group. Each curve for each person, is an average of 6 basic emotion presenting on the $Panel\ \ A$. In order to keep the figure as readable as possible only 3 MSD-curves are drawn. The most important conclusion from this figure states, that it is possible to see differences between particular curves (Fig. 9 $Panel\ \ B$). The second conclusion - shape of the MSD is similar for examined persons. However, in our opinion, it depends on the individual features of human skin. As it was mentioned in the Introduction in our opinion, mechanical and chemical properties of the skin plays an important role in this phenomenon. The next conclusion is, that noticeable differences between different emotional states or different person starts from about $t = 100$ of time of observation. While watching video of recorded persons it is noticeable that the facial expression appears after a few moments of inactivity. This behavior has its own mark in the results of calculating MSD. And the last conclusion which in opinion of the research group seems to be very important, especially in the field of neural science and psychology, there is some activity on the human face even before the facial expression appears (at the Fig. 9 segment from $t = 0$ till $t = 100$). We believe that human brain express the certain emotion before the face is able to showed it. This conclusion may acknowledge recent discoveries of Professor Laeng in the field of imagination and perception.

IV. Conclusion

The preceding sections describes image analysis methods we have developed to perform quantitative time-resolved imaging studies of non-spherical objects (or areas) on the human face which we have found useful in the process of tracking facial expressions.

We have shown that the trajectories of the identified areas on the human face are distinctive enough to find differences between persons taking part in the research.

The measurable effect of the presented in the article transformations of the collected series of images is the collection containing the identification number of the identified areas (same size and brightness) on the face and the trajectories of their movement throughout the observation period.

The study of that phenomenon is based on the assumption that there are objects on the human face and they movement depend on the muscles tension, mechanical and chemical properties of the skin. Presented method may open the way to a much larger and broader question of the automatic identification of emotional states. It gives the possibility to find quantitative description of the observed changes of emotional states happening on human face [18], [19] what may have big value for the security systems.

Recent research on the connections between imagination and perception suggest that unconditional reflex narrowing of the pupil and caused by changes in the amount of light reaching them, can be elicit also by only imagining the appropriate situation. Usually people treat ideas as private and subjective experience, which is not accompanied by significant physiological changes. The results achieved by the Professor Laeng team and presented in [20] challenge this view. They suggest that imagination and perception are based on similar sets of neural processes. Presented in this article experiment on tracking facial expressions also confirms their thesis.

***Abstract*—Spatial data structures, for vector or metric spaces, are a well-known means to speed-up proximity queries. One of the common uses of the found neighbors of the query object is in classification methods, e.g., the famous *k*-nearest neighbor algorithm. Still, most experimental works focus on providing attractive tradeoffs between neighbor search times and the neighborhood quality, but they ignore the impact of such tradeoffs on the classification accuracy.**

In this paper, we explore a few simple approximate and probabilistic variants of two popular spatial data structures, the k-d tree and the ball tree, with *k*-NN results on real data sets. The main difference between these two structures is the location of input data — in all nodes (k-d tree), or in the leaves (ball tree) — and for this reason they act as good representatives of other spatial structures. We show that in several cases significant speedups compared to the use of such structures in the exact *k*-NN classification are possible, with a moderate penalty in accuracy. We conclude that the usage of the k-d tree is a more promising approach.

I. Introduction

FINDING objects similar to a given one in a large database is a classic research topic, with applications in pattern recognition, multimedia processing, genomic analyses, and other fields. There exist many particular variants of the problem, but one of the most popular is: given object x, we wish to find its k nearest neighbors in a given database D of size n, according to the specified similarity measure. The parameter $k \geq 1$ is usually selected at query time. A naïve solution to this problem is to calculate the distances between the query x and all objects in the database and choose k nearest ones, but this approach requires computation of n distances. If database preprocessing is allowed, we can usually reduce the query time. One of major applications of the proximity search is *classification*, when the query sample is assigned a class label according to the known class labels of its neighbors, and the rest of this paper is focused on this application.

We assume a vector space, in which objects are identified with d real-valued vectors (tuples). The distance function in this space is usually a metric (i.e. it satisfies non-negativity, identity of indiscernibles, symmetry, and the triangle inequality), and the most common particular metrics used are the Euclidean or Manhattan (city-block) one. In vector spaces, the popular search structures include the k-d tree, R-tree, quadtree, X-tree, and their numerous variants. Their common trait is to cluster objects in space, to allow pruning the dataset during most queries. For example, the popular k-d trees partition the space along different coordinates while R-trees group objects in hyperrectangles.

As the (in)famous curse of dimensionality subdues the performance of practically any (however sophisticated) nearest-neighbor finding data structure in high dimensions, it is interesting to investigate how approximate or probabilistic variations of the true nearest neighborhood of the given query affect the classification accuracy. This question has met significant interest from both theoreticians and practitioners, see for instance Arya et al. [1], Indyk and Motwani [2], or Jones et al. [3].

In this work we introduce simple modifications to well-known spatial data structures: the k-d tree and the ball tree, in order to explore how approximate or probabilistic speedup idea (e.g., via more aggressive pruning than in the original method) affect the time-accuracy tradeoff. While our conclusions are hardly definite, we believe that experimentations with popular (and relatively easy to implement) data structures have their own, practice-oriented, value.

II. K-d tree

One of the oldest spatial data structures, the *k-d tree*, was introduced by Jon Louis Bentley in 1975 [4], and the name refers to k dimensions it operates on. To avoid confusion with the number of neighbors in the k-NN rule, from now on we will use the symbol d for the number of dimensions.

The k-d tree is a binary tree, where every instance of the indexed data corresponds to one node. The left child together with its descendants contain points whose values of the feature (coordinate) f are smaller than the f value of the splitting hyperplane H — analogously, the right child together with its descendants contain points with higher f values. As regards the selection of H, the most popular approach is to choose the point whose f is the median, and divide the points into

978-83-60810-58-3/$25.00

two parts of equal size (assuming that the number of points to divide is even).

A. Construction of the tree

During the construction, the current feature space is recursively divided into two subspaces, with half of the points lying in each subspace. This division is based on the current dimension, and the algorithm switches to the next dimension with each step as the recursion progresses. After all dimensions have been processed, it goes back to the first dimension in a circular manner. The recursion stops when there is only a single point left, and this point is stored in a leaf. The result is a binary tree, where inner nodes represent points situated on the splitting hyperplanes, and leaves represent the rest of the given data.

B. K-nearest neighbor search

When the *k*-NN search is performed, the tree is traversed from the root to the leaf. The algorithm goes left or right depending on feature values, and this can be represented by following relations, where Q is the queried point, N is the point corresponding to the current node, and d is this node's split dimension: $Q_d \leq N_d \rightarrow left$, $Q_d > N_d \rightarrow right$. Dimensions are switched in the same way as during the construction, so that the dimension which is checked at each level is always the one on which the space was split in halves.

After a leaf has been found, the search goes back towards the root, following the same path which was traversed downwards. From this moment, the algorithm maintains the list of k points with smallest distances to the queried point Q, and tries to update it every time a new node is visited.

At each step upwards, there is a possibility of inspecting a subtree whose root is the sibling of the current node N_{cur}. Such a subtree can be pruned if and only if k points have already been found, and all distances from Q to these k points are smaller than or equal to the distance between Q and the point P_{spl}. P_{spl} represents the point located on the splitting hyperplane, and it is associated with the node which is the parent of N_{cur}. This is demonstrated by the relation in Figure 1, where P represents the set of points found so far, and D refers to the distance.

$$prune \leftrightarrow |P| = k \wedge \bigvee_{p \in P} D(p, Q) \leq D(Q, P_{spl})$$

Fig. 1. Pruning condition in an exact k-d tree.

If the subtree S could not be pruned and it has been checked, the list of best points from S must be merged with the current list of best points. This is rather straightforward, because we simply select k points with lower distances from both lists, or if the size of the combined list would be smaller than k, all points are retained.

The whole *k*-NN search procedure can be summarized as follows:

1) Find the leaf.
2) Go to the parent and try to update the list of k best points.
3) Recursively check the subtree whose root is the sibling of a current node, unless the relation in Figure 1 is satisfied.
4) If checked the subtree, merge the lists of best points.
5) Repeat 2. until found the root of the whole tree.

C. Complexity

As regards search time complexity, the average case for the nearest neighbor lookup (1-NN), under favorable assumptions (discussed in the next sentences), is equal to $O(\log n)$ [4], and the worst case, where all points are checked, is clearly equal to $O(n)$. Performance degrades to linear time when, roughly speaking, the number of dimensions is large, and for this reason the number of visited nodes also tends to be large. In general, for optimal performance the relation $2^d \ll n$ should hold [5]. When it comes to *k*-NN, the average case expands into $O(\log n \cdot \log k)$, and the worst case expands into $O(n \log k)$, assuming a heap is used to maintain the list of best points. In practice, a k-d tree might turn out to be slower than a naïve method, due to the search procedure overhead.

The construction takes $O(n \log n)$ time, assuming the median required to split points in halves is found with a linear worst-case time algorithm [6, Ch. 9]. Since the number of nodes is proportional to the number of points, the space complexity is equal to $O(n)$.

III. Ball tree

The aim of the *ball tree* is akin to the one of the k-d tree, as it attempts to reduce time spent on a nearest-neighbor query by partitioning the feature space. Just as the name suggests, this is achieved by constructing closed balls, that is geometric objects containing a sphere S and the space inside S.

The ball tree is a binary tree, where each internal node N_I is associated with one ball, and this ball contains all balls of the descendants of N_I. Hence, the biggest ball is stored as a root and it contains all other balls in the tree. The training data are stored in the leaves, with one leaf corresponding to one training instance, and internal nodes act only as guidance during the search. Subspaces resulting from the partitioning are clearly overlapping, unlike in the case of other structures, such as the aforementioned k-d tree.

A. Construction of the tree

We opt for the bottom-up construction algorithm, which is the most efficient one with respect to the search time of *k*-NN queries performed on the resulting tree [7]. This efficiency results from the fact that we try to reduce the volume (the radius) of the balls.

At the beginning of the construction, we create a set of balls from the training data, with one ball corresponding to one instance. At each step, we search for a pair of balls, whose resulting ball R_B (one that contains the selected pair of balls) is the smallest. Subsequently, two selected balls are set as children of R_B, and R_B is inserted back into the set of

available balls. Thus, at each step we reduce the size of the set by one. When we are left with only one ball, this ball is associated with the root node and the algorithm terminates.

For more details on other construction algorithms, we refer the reader to the original article by Omohundro [7].

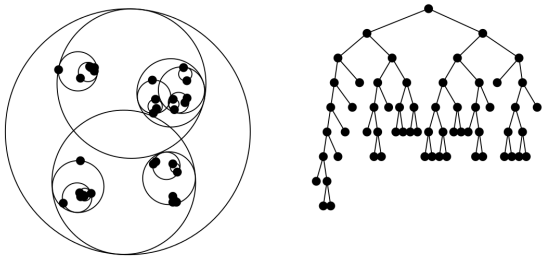

Fig. 2. Space partitioning with balls and the resulting binary tree using the bottom-up construction algorithm; reproduced from Omohundro [7].

B. K-nearest neighbor search

When the *k*-NN search is performed, the tree is traversed in the depth-first manner. At each step, there is a possibility of recursively inspecting two children of the current node, and each child can be pruned together with all of its descendants, if and only if the following condition is satisfied. For safe pruning, it is required that we have already found k points, and the ball that is centered at the query point and that contains all k points found so far does not intersect the ball of the child in question. This is demonstrated by the relation in Figure 3, where *P* represents the set of points found so far, and B_Q and B_C refer to the ball centered on the query and the ball centered on the child, respectively.

$$prune \leftrightarrow |P| = k \wedge intersects(B_Q, B_C) == false$$

Fig. 3. Pruning condition in an exact ball tree.

Whole *k*-NN search procedure can be summarized as follows:

1) If we are at the leaf, try to update the list of k nearest neighbors and terminate.
2) If k nearest neighbors have already been found, compute the ball that is centered at the query point and contains these k points.
3) Recursively inspect the left child, unless the relation in Figure 3 is satisfied.
4) If *k* nearest neighbors have already been found, recompute the ball from step 2).
5) Recursively inspect the right child, unless the relation in Figure 3 is satisfied.

C. Complexity

We construct a binary tree, whose bottom level contains n nodes, because all training data are stored as leaves. For this reason, the space complexity of the ball tree is equal to $O(n)$.

As regards the search time complexity, the worst case where all nodes are checked is clearly proportional to the size of the tree, that is $O(n)$. Because of the time overhead resulting from tree traversal, the ball tree can turn out to be slower than a brute-force algorithm. Assuming optimal space partition, where branches can be pruned, for a *k*-NN search it is possible to achieve the best case bound of $O(\log n + k)$.

Since our focus is solely on finding nearest neighbors, we ignore the preprocessing time complexity, however, it is worth noticing that it can be fairly expensive. For instance, a naïve bottom-up construction algorithm requires $O(n^3)$ time.

IV. Approximate algorithms

The objective of approximate search algorithms based on tree data structures introduced in previous sections is to decrease the time spent on classification, at the cost of an increase in the error rate. This is accomplished by limiting the visited area of a tree.

We utilize the notion of *bounds*, where after the specified bound has been crossed, current list of nearest neighbors is returned. This means that the bound should be chosen with care, since the list can actually contain less than k points when the algorithm terminates. For probabilistic pruning (Subsection IV-D), we ensure that branches are pruned only after k points have been found.

It is to be noted that time and space overheads presented in this section are relevant only to described modifications, and for a complete analysis, complexities of exact algorithms should be added.

A. CPU time bound

CPU time refers to the time spent by the processing unit on executing actual instructions, which means that it is not affected by context switches or time changes. The bound is checked for the first time after the leaf has been found, which is required for the ball tree, and allows us to concentrate the search in the bottom part of the k-d tree. Bounds checking introduces a small time overhead $O(v)$, where v refers to the number of nodes visited by the algorithm after the first leaf has been reached. The space overhead is constant.

B. Depth bound

The depth bound specifies a maximum depth of the tree that can be reached by the search algorithm. This is relevant only for the k-d tree, since in the ball tree all training data are situated in the leaf nodes. The depth is checked every time a new node is visited, and for this reason the time overhead is equal to $O(v_t)$, where v_t refers to the total number of nodes visited by the algorithm. The space overhead is equal to $O(n)$, because every node stores its depth.

C. Node bound

The idea of the node bound is simply to set a hard threshold t on the number of nodes, which can be checked by the algorithm. Analogically to the CPU time bound, this bound is checked for the first time after the leaf has been found, which

is required for the ball tree, and allows us to concentrate the search in the bottom part of the k-d tree. For this reason, the total number of nodes which have been traversed might turn out to be greater than t. Again, bounds checking introduces a small time overhead $O(v)$, where v refers to the number of nodes visited by the algorithm after the first leaf has been reached.

D. Probabilistic pruning

Similarly to approximate variants introduced in previous subsections, the aim of this algorithm is to limit the space that is inspected during the search procedure. This is achieved by introducing the pruning factor σ, which describes the probability that the subtree is pruned, even if the pruning condition presented in Figure 1 for the k-d tree or in Figure 3 for the ball tree is not satisfied. For instance, if $\sigma = 25\%$, every time a subtree should be inspected, there is a $1/4$ chance that it will be ignored instead. It should hold that $\sigma > 0 \wedge \sigma \leq 1$. It is worth noticing that in the case of $\sigma = 1$, the algorithm's behavior is in fact deterministic, as all possible branches are pruned.

Since pseudorandom number generation can be done in constant time, the time overhead is proportional to the number of pruning decisions which have to be taken. These decisions are made only when the subtree cannot be safely pruned, and the complexity is equal to $O(1)$ in the best case, since then all subtrees can be safely pruned. As regards the worst case, a decision has to be made every time a new subtree is encountered, and for this reason the time overhead expands into $O(n)$. The space overhead is constant.

E. Best bin first (BBF)

The *best bin first* (BBF) algorithm [8] is relevant only to the k-d tree and it aims to increase the accuracy of an approximate search. Since an inexact algorithm does not visit all nodes which would be required to provide an exact answer, the order in which the nodes are visited is crucial to the performance in terms of an error rate. After the leaf has been found, instead of following the path to the root from the bottom, going up one level per step, the algorithm selects an optimal node lying on this path. Subsequently, it continues to choose an optimal node from the remaining ones, until the path is exhausted, or some limit (such as the node bound) is exceeded. We choose a straightforward method to determine node's optimality, which selects the node whose splitting hyperplane is closest to the queried point [8].

The time overhead depends on the kind of priority queue that is used for selecting the smallest distance. We have $O(V_T)$ inserts and $O(t)$ delete-min operations, where V_T represents the total number of nodes traversed by the search procedure, and t is the number of nodes visited after the first leaf has been found. For instance, if the Fibonacci heap [9] were used, the complexity would be equal to $O(V_T + t \log V_T)$ amortized time. As regards the space overhead, it is possible to achieve a bound of $O(V_T)$. These complexities refer only to maintaining a priority queue and not to bounds checking.

V. Experimental results

The error rates presented in this section were calculated using the *leave-one-out* method for the k-d tree, and 5-fold *cross validation* for the ball tree, the reason for the second method being computational demands. We used the *Manhattan* metric for the similarity measure. Classification times presented in the diagrams refer to CPU time in milliseconds spent on classifying one sample, and the preprocessing time is not taken into account. CPU time values are arithmetic mean values obtained in the course of three runs, in order to minimize an influence of external factors such as cache utilization. Error rates presented for probabilistic variants are arithmetic mean values obtained in the course of five runs. The value $k = 5$ was selected arbitrarily. The machine used for experiments was equipped with Intel e2160 processor running at 2.9 GHz and 4 GB DDR2 memory. The code was compiled using the GCC suite and run on Ubuntu 12.04 64-bit operating system.

Only selected results are presented due to space constraints, nevertheless, results reported for different data sets (for a short description of the sets, see Appendix A) were consistent to a satisfactory degree. Unexpected or particularly unusual behavior was rare, and it was most probably caused by a unique structure of specific data set in question.

Selected diagrams were published in the Bachelor's Thesis of the first author [10].

A. CPU time bound

CPU time bound values are significantly smaller than the times spent on classification shown in other diagrams. This results from the fact that the execution time spent on classifying one sample is calculated as the total time used by all procedures in the *k*-NN algorithm, such as allocating the memory or comparing class counts. On the other hand, the CPU time bound refers only to the internal approximate search procedure.

Just as expected, we observed a growth in the error rate as the time bound decreased. Above certain higher bound value there was no change with respect to exact algorithms, and as the bound approached zero, there was a dramatic increase in the error rate. For the k-d tree with Ferrites data set, there was only a marginal increase in the error rate until the bound value of about 0.35 ms, as demonstrated in Figure 4. Other data sets and the ball tree behaved similarly, although relative increases in the error rate were more significant.

B. Depth bound

The depth bound introduced a rather moderate increase in the error rate, although associated time decreases were lower than in the case of other bounds. For instance, for Banknotes data set, there was almost no increase in the error rate up to the bound value of 7, with a roughly 3-fold decrease in classification time (see Figure 5). At the other extreme was the Isolet data set, for which both time decrease and error rate increase were more substantial than for other sets (see Figure 6).

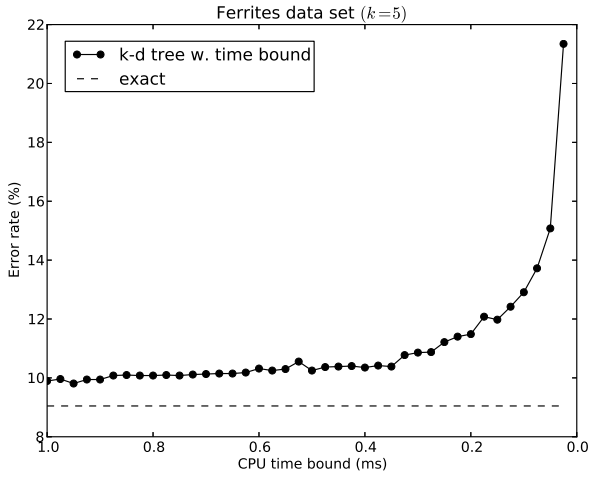

Fig. 4. Error rate vs CPU time bound for the k-d tree with Ferrites data set.

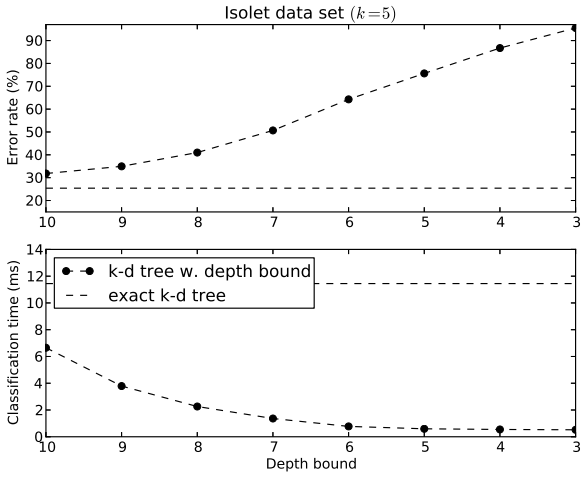

Fig. 6. Error rate and classification time vs depth bound for the k-d tree with Isolet data set.

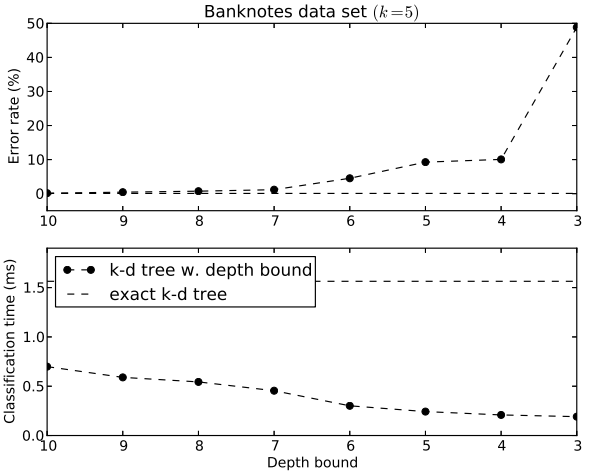

Fig. 5. Error rate and classification time vs depth bound for the k-d tree with Banknotes data set.

C. Node bound

Similarly to other algorithms with bounds, as the node bound value decreased, expected increase in the error rate and a decrease in classification time were observed. Lower limit for the node bound t was set so that the relation $t \geq k$ was satisfied, and above higher limits there was no change in the error rate with respect to an exact result.

For the k-d tree, all data sets demonstrated roughly similar behavior, showing that the node bound is indeed a promising approach. For instance, in the case of Ferrites data set, for $t = 9$ the time was reduced approximately 5-fold, with the absolute increase in the error rate of around 1.2% (see Figure 7).

The *best bin first* algorithm achieved mostly a slight improvement over the regular search procedure (e.g., for Banknotes data set demonstrated in Figure 8), and it turned out to be most effective for the Isolet data set with 617 dimensions (see Figure 9). Nonetheless, very optimistic results reported by Lowe [11] were not reproduced for data sets used in this article. The difference between classification time for BBF and the regular node bound approach was negligible, and thus the former is omitted.

As regards the ball tree, the error rate behaved rather strangely. For Banknotes and Iris data sets (presented in Figure 10 and Figure 11, respectively), we can see unexpected spikes in the error rate, although there remained a steady decrease in classification time.

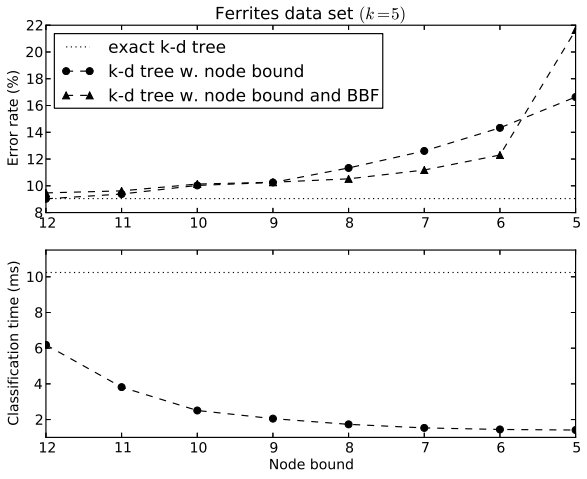

Fig. 7. Error rate and classification time vs node bound for the k-d tree with Ferrites data set, with and without BBF.

D. Probabilistic pruning

Since the pruning probability (σ) is equal for all subtrees, it might be the case that the pruned subtree contains one node, just as well as it might be the half of the entire tree. For this

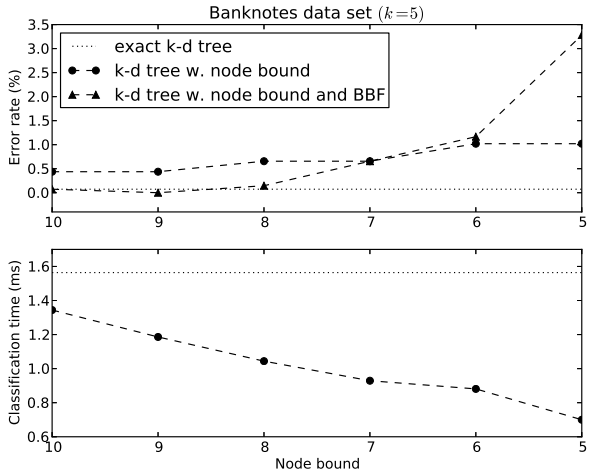

Fig. 8. Error rate and classification time vs node bound for the k-d tree with Banknotes data set, with and without BBF.

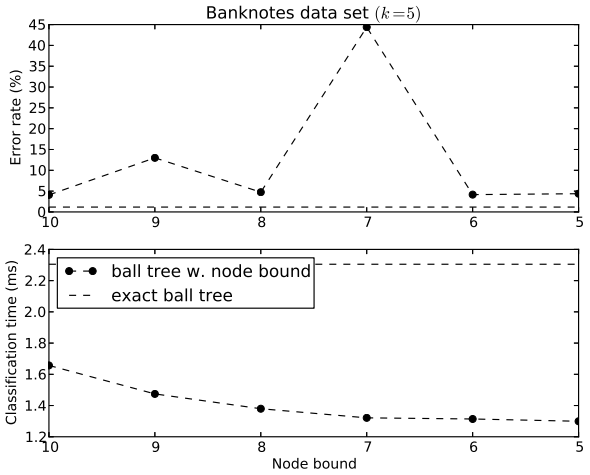

Fig. 10. Error rate and classification time vs node bound for the ball tree with Banknotes data set.

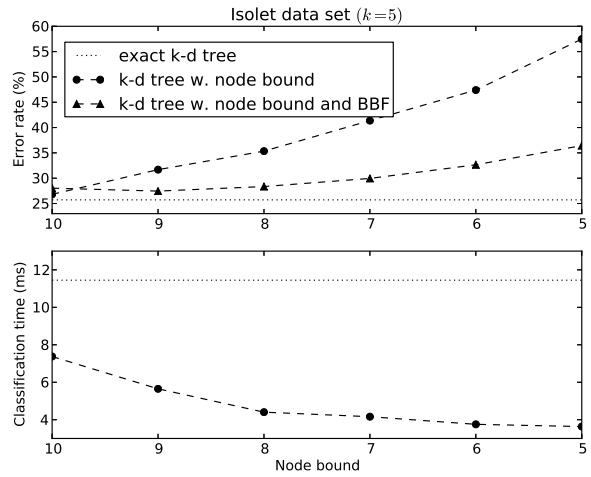

Fig. 9. Error rate and classification time vs node bound for the k-d tree with Isolet data set, with and without BBF.

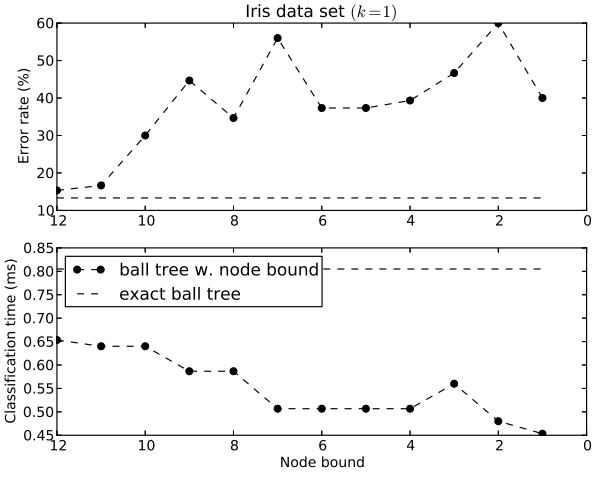

Fig. 11. Error rate and classification time vs node bound for the ball tree with Iris data set.

reason, effectiveness of this approach is clearly subject to a substantial amount of chance. Nevertheless, similar tendencies were observed for all data sets.

For the k-d tree, the ratio of error rate increase to classification time decrease tended to be less favorable than in the case of bounds presented in previous subsections — compare Figure 5 with Figure 13 to see how depth bound performed better for Banknotes data set. Still, for the Isolet data set (Figure 12), there was only a marginal increase in the error rate for $\sigma \leq 0.4$, and for these values the time was reduced by up to 35%.

Error rate increases for the ball tree were sharp (e.g., see Figure 14), and we observed once again unexpected results when the error rate for Banknotes data set actually decreased as more branches were pruned (see Figure 15). This can be most probably ascribed to simple luck resulting from the particular structure of this data set. Influence of the probabilistic nature of this algorithm was minimized by the fact that it was run five times.

VI. Conclusion

We have investigated two spatial data structures with identical applications, but different mechanics. The main difference between the k-d tree and the ball tree is the location of nodes associated with training data. The k-d tree does not consist of any redundant nodes, and each node corresponds to one instance from the training data. On the other hand, all training data in the ball tree are stored in the leaves, and internal nodes are utilized only in order to speed up the search procedure.

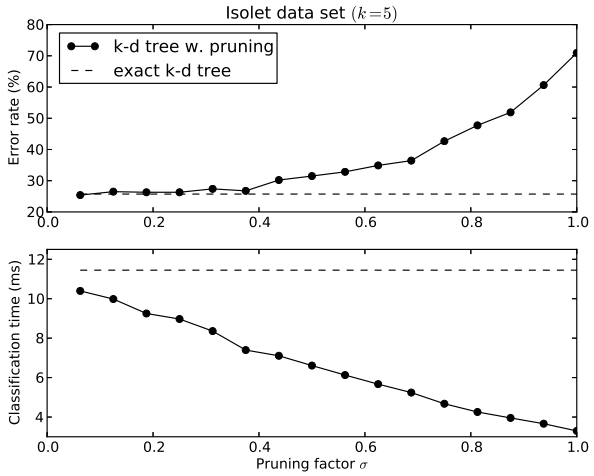

Fig. 12. Error rate and classification time vs pruning factor σ for the k-d tree with Isolet data set.

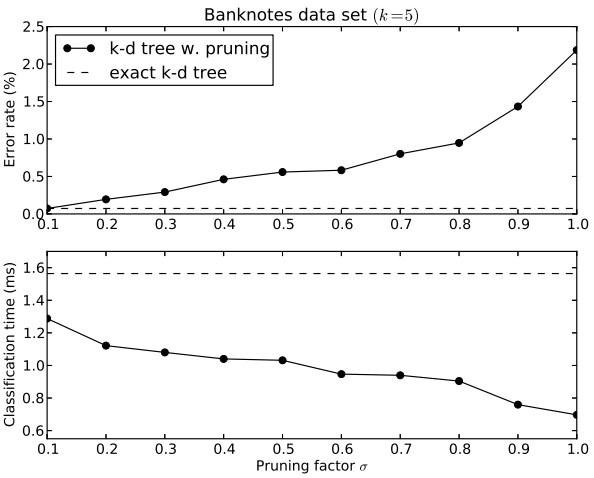

Fig. 13. Error rate and classification time vs pruning factor σ for the k-d tree with Banknotes data set.

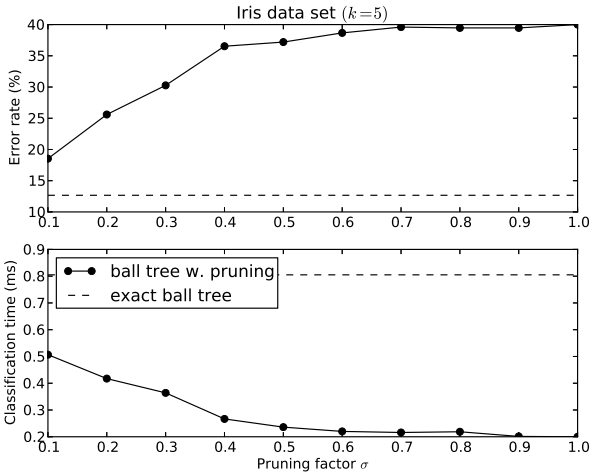

Fig. 14. Error rate and classification time vs pruning factor σ for the ball tree with Iris data set.

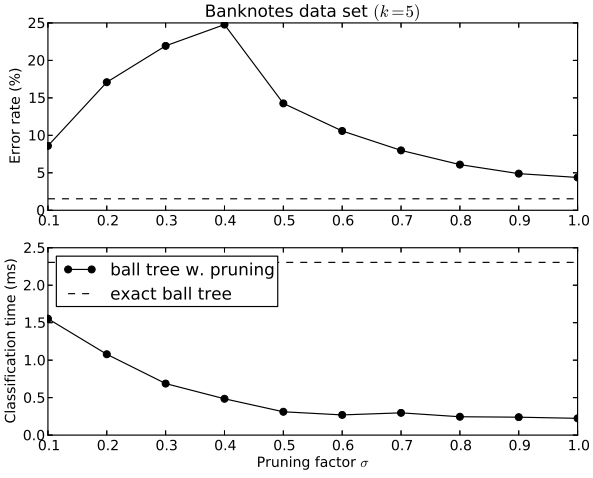

Fig. 15. Error rate and classification time vs pruning factor σ for the ball tree with Banknotes data set.

Approximate algorithms based on both trees turned out to perform rather well. The ratio of the increase in the error rate to the decrease in classification time was favorable, and the best results were reported for the k-d tree with node bound and best bin first (BBF) priority search. In the case of the ball tree, increases in the error rate were more rapid and unpredictable, however, this can be partially explained by the use of 5-fold cross validation instead of the leave-one-out method. Overall, the k-d tree was faster than the ball tree for both exact and approximate variants, which is consistent with exact performance measures presented by Munaga and Jarugumalli [12], and Kibriya and Frank [13].

Results depended chiefly on the data set that was used. No particular relation between the structure or size of the input data and results was observed, and it can be concluded that empirical findings remain the most valuable indicator, in spite of general tendencies.

We conclude that approximate variants of the *k*-nearest neighbor classification rule are indeed a very promising approach, and they are often indispensable when it comes to real-world massive data sets. Other data structures, which are based on the notion of partitioning the feature space, could also be adapted to use aforementioned bounds (CPU time, depth, node) and probabilistic pruning.

APPENDIX A

We list the data sets that were used for obtaining experimental results, along with their properties: class count, attribute count, and instance count.

- Banknotes — 2, 4, 1372
- Ferrites — 8, 30, 5903
- Iris — 3, 4, 150
- Isolet — 26, 617, 1559

***Abstract*—The article describes the method of malware activities identification using ontology and rules. The method supports detection of malware at host level by observing its behavior. It sifts through hundred thousands of regular events and allows to identify suspicious ones. They are then passed on to the second building block responsible for malware tracking and matching stored models with observed malicious actions. The presented method was implemented and verified in the infected computer environment. As opposed to signature-based antivirus mechanisms it allows to detect malware the code of which has been obfuscated.**

I. Introduction

OVERWHELMING number of computer systems are connected to each other by global network – Internet, which allows to produce results beyond those achievable by the individual systems alone. Outcomes of cooperative work and accessibility of information are perceived and appreciated probably by all its users.

The advantages of this technology are available, unfortunately, also for hostile goals. The number of cyber threats arises rapidly from 23 680 646 in 2008 [1] to 1 595 587 670 in 2012 [2], and this is nowadays one of the most vexing problems in computer system security [3]. At the end of 2012 Kaspersky Lab, the Russian producer of antivirus software, reported that [4] *it currently detects and blocks more than 200 000 new malicious programs every day, a significant increase from the first half of 2012, when 125 000 malicious programs were detected and blocked each day on average*.

Although awareness about necessary security appliances seems to be common and the tools used for that purpose are getting more and more advanced, the number of successful attacks targeted on computer systems is growing [5]. They are mostly related to denial of offered services, gaining access or stealing private data, financial fraud, etc. Moreover, the evolution towards cloud computing, increasing use of social networks, mobile and peer-to-peer networking technologies that are intrinsic part of our life today, carrying many conveniences within our personal life, business and government, gives the possibility to use them as tools for cyber criminals and potential path of malware propagation [6]. Computer systems are prone to cyber attacks even though a number of security controls are already deployed [7], [8]. Cyber criminals are focused on finding a way to bypass security controls and gain access into the protected network. For that reason organizations, companies, governments and institutions as well as ordinary citizens all over the world are interested in detection of all attempts of malicious actions targeted on their computer networks and single machines [9].

Malicious activity detection starts with application of various techniques, the success rate of which depends on the reliability of the malware model. Usually they are based on code signatures. Security controls (e.g. antivirus tools) might be maladjusted because signatures of new threats are not identified yet. Hackers often use existing parts of code in order to implement new types of malware. This allows, in return, to quickly develop signatures of new dangerous software. Therefore, the more signatures are deployed the more malicious codes are identified. On the other hand, one of the methods for misleading signature-based detection systems is code obfuscation, the aim of which is generating – from already existing code – a new application that cannot be assessed yet as risky by security controls [10]. This technique is simple to be used and potentially successful. One of the countermeasures in this case is to follow behaviors of malicious software in order to identify them and eliminate from the protected system.

According to the study conducted in 2012 by the Verizon RISK Team [11] with cooperation from many national federal organizations, including e.g. Australian Federal Police, Irish Reporting and Information Security Service, and United States Secret Service *new techniques that speed up the process of malware detection to hours* are necessary. Authors of the report [12] indicate that *antivirus products should be supported by malware behavioral analysis tools in order to detect those of attacks for which signatures were not established*. An existing example of appliance that uses behavioral analysis for advanced persistent threats detection is Digital DNA by HBGary that extends the capabilities of McAfee Total Protection antivirus [13]. Detailed technical specifications of this solution have not been released for public. The product brochure explains that *multiple low level behaviors are identified for every running program or binary*. This leads to conclusion that each application is observed from behavioral perspective. McAfee is proud that the solution allowed to detect last year more 0-day

Work has been partially financed byby the National Centre for Research and Development project no. PBS1/A3/14/2012 "Sensor data correlation module for detection of unauthorized actions and support of decision process" and the European Regional Development Fund the Innovative Economy Operational Programme, INSIGMA project no. 01.01.02-00-062/09.

attacks than during the previous five years combined. This indicates the scale of new malware development and efficacy of the behavioral approach.

II. State of the art in malware detection

Currently there are two major techniques seen as prospective for malicious threats detection. One of them is *machine learning* [14] which allows to detect anomalies in the use of host machines by malicious software. This approach is only applicable in systems, for which a model of normal behavior can be established. It is only possible in such an environment where patterns for host machine activity can be identified, e.g. in production environment, SCADA systems, etc. Current usage of computer systems, mobility of users, enormous number of executed applications and visited internet sites cause that setting up a normal behavior model for malware detection is almost impossible. Such a method may also generate too many *false positive* alarms.

Other methods used for identification of malicious actions are based on different forms of specially prepared behavioral patterns prepared in the process of static code analysis or various host-based honeypots and sandboxes. Those patterns can be then applied in detection tools, e.g. rule based engines and complex event processing (CEP) tools. This article presents the method that uses rules [15] in order to identify malicious actions of the host machine and filters out from the number of system activities only these that are typical for malware.

III. Idea of the solution

In our work we proposed and developed behavior-oriented malware hunting tool, so called `PRONTO`, that could be used in parallel to existing signature-based tools.

The main assumption for the introduced method is that the malware was not recognized yet by the signature mechanisms. The aim therefore is to track its suspicious activities in order to find it while running in the system.

`PRONTO` hunting tool performs its activity in two stages (Fig. 1):

- **Filtering of the system events** registered by the system monitors (sensors) to discover the main features of the hostile activity. These features are related to particular objects and actions triggered on that objects – e.g. registry (add entry, modify entry, delete registry entry, etc.), process (start, stop process, etc.), file (copy, delete, run, open, close file, etc.), domain (connect to, etc.), IP address (connect to, etc.);
- **Tracking suspicious activity** in order to discover malicious exploits running in the system. Filtered events are correlated in order to find similarities with the stored malware activities modeled in the form of Colored Petri nets [16]. The result of malware tracking is the alarm that contains information vector about malicious activity, similarity to the known attacks and list of incidents that affected the system.

This article presents only the first stage which is related to capturing events from sensors and analyzing them with an expert system that uses – defined for the purpose of the method – comprehensive ontology, so called `PRONTOlogy`. Registered events in the form of XML objects are sent to the PRONTOntology engine and lifted to add entries to the Knowledge Base. `PRONTOlogy` describes events registered by system monitors and is able, on the basis of rule engine and inference, with the use of specially defined rules [17], to classify an event as potentially suspicious, malicious or regular. As a result, markings of the modeled malware in the form of CP-nets [18][19] are delivered for further analysis.

The second element of the threats' tracking component of the solution is `PRONTOnet` [20]. It provides formal model of malware behavior and allows to track suspicious activities potentially assigning them to the class of known malware types or identifying unknown ones. Known exploits can be invisible to signature-based malware detecting tools after their code has been obfuscated, although their activities can be easily observed. It also happens often that a new malware piece of software is composed of known components from other ones. This results in another behavior pattern that can be tracked as a new exploit, not identified yet. The result of threats tracking stage is an alert informing about identification of suspicious or malicious events with a certain similarity rate to the known malware types.

IV. Identification of malicious actions

Static analysis of malicious code or intelligent algorithms for malware behavior recognition provide patterns that can be defined in low level programming language (e.g. Assembler) or can be represented on the level of operating system activities. In case of our solution the second approach was selected, which means that identification of malicious actions is performed while monitoring actions of the host machine. It was mainly due to availability of tools for operating system monitoring and easiness of processing.

The two-stage malware hunting process presented in this article starts with sifting through a great number of actions that are generated by the up and running operating system. This aimes for identification of those events that should be perceived as suspicious and processed further on. This process should enable automatic filtering of events on the basis of their characteristic features. However, it is not trivial to assume an action is suspicious since the mechanism must catch the context of its invocation in order to assess if it is a regular operating system or user activity, or anomaly that should be investigated further on. For this reason, it was necessary to use a method that could provide the possibility to deduce from the gathered data and analyze possible correlation among events. These requirements were met by the semantic techniques based on ontology and rules that enable to create knowledge base and infer additional facts automatically.

According to [21] *An ontology is an explicit and formal specification of a conceptualization*.

In general, ontology describes a domain of discourse formally. Typically, ontology consists of a finite list of terms, and relationships between those terms. This set describes so

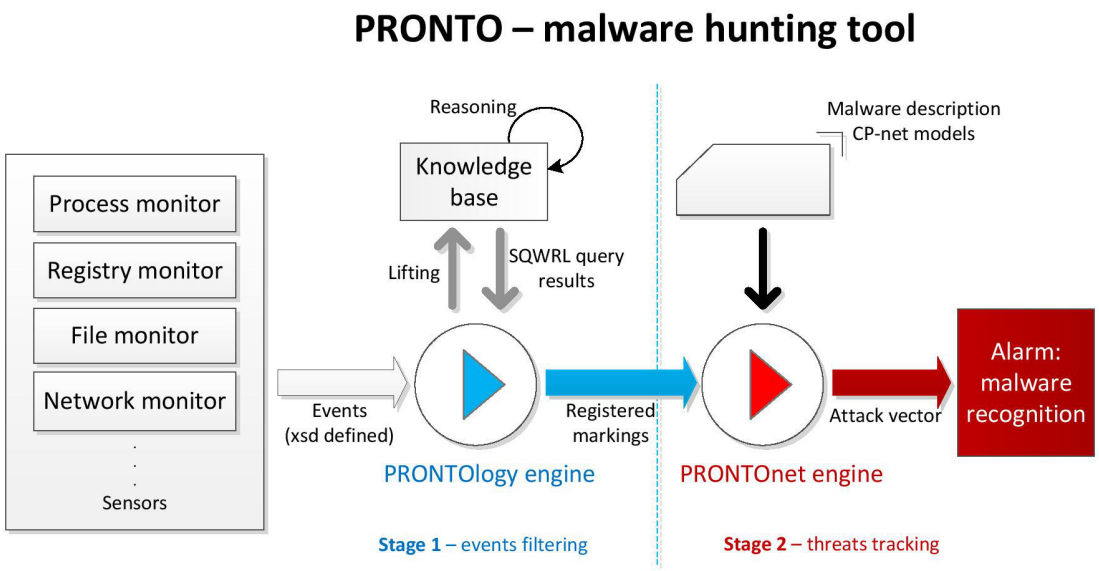

Fig. 1. PRONTO – malware hunting tool

called TBox statements, which are Terminological statements describing the domain in terms of controlled vocabularies. They describe important concepts (classes of objects) of the domain and their properties.

For the purpose of this solution there has been proposed an ontology modeled in the Web Ontology Language (OWL) titled `PRONTOlogy.owl` that describes basic classes and relationships among them. Since the investigated domain needs the description that would enable to reflect and represent facts that a resource executes an action on another resource particular object properties are used. They indicate actions executed on resources and enable to define appropriate triples (e.g. `run (x,y)`, where `x`, `y` are members of `Resource` class and `run` is *object property*, with *domain* and *range* equal to Resource).

Based on TBoxes there can be defined e.g. the following general statements:

```
Event(x)
Resource(y)
ResFile(z)
hasResource(x,y)
Resource(y) is a ResProcess
ResFile(z) is a Resource
run (y,z)
```

where:

- `Event, Resource, ResProcess, ResFile` – are classes,
- `hasResource, run` – are object properties,
- `is a` – is subclass relationship.

According to Fig. 2 the model ontology consists of the three main *classes*: `Event`, `Place`, `Resource`.

In order to differentiate types of resources that perform actions observed by system monitors, there have been defined

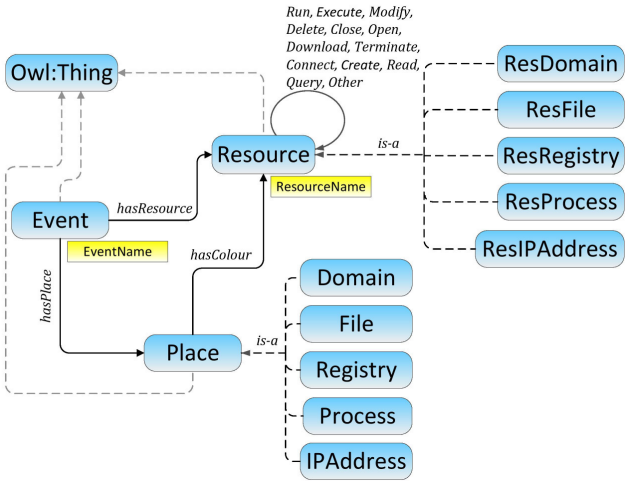

Fig. 2. PRONTOlogy model

the following *subclasses* of the `Resource` class:

- `ResFile` – where the resource is a file,
- `ResRegistry` – where the resource is a registry,
- `ResProcess` – where the resource is a process,
- `ResDomain` – where the resource is a domain the system is trying to connect to,
- `ResIPAddress` – where the resource is an IP address the system is trying to connect to.

In order to indicate particular registry entries, file names, etc. *datatype properties* have been proposed. They describe name of the Resource (`ResourceName`) and name of particular Event (`EventName`).

In order to reflect activities on system resources there have been modeled the following *object properties* that resemble

types of system activities:

- `run` – e.g. running a service, process;
- `open` – e.g. opening a file, registry;
- `close` – e.g. closing a file, application, process;
- `modify` – e.g. modification of registry entry, file, process;
- `execute` – e.g. executing an application;
- `terminate` – e.g. terminating a process;
- `connect` – e.g. connecting to the IP address or domain;
- `query` – e.g. querying the registry entry state;
- `download` – downloading data from remote location;
- `create` – creating a new object, e.g. registry entry, file;
- `delete` – deleting an object, e.g. file, registry entry.

For all *object properties* listed above `Domain` and `Range` are equal to `Resource`, which means that one resource can execute actions on other resources.

There are also additional *object properties* that can reflect the fact:

1) that particular event should be perceived as a `Place`: `hasPlace`, where `Domain = Event, Range = Place`,
2) that particular marking appears for particular `Place`: `hasColor`, where `Domain = Place, Range = Resource`, and
3) that particular event is related to a `Resource`: `hasResource`, where `Domain = Event, Range = Resource`.

The above defined types of *classes* and *object properties* enable to describe events that are registered by system monitors (sensors). Additionally, the model was constructed in such a way that it can reflect the fact that particular observed activity should be perceived as a token in the Petri net - used further on at the second stage of malware hunting tool operation. This process is performed automatically with the use of reasoning rules modelled with Semantic Web Rule Language (SWRL) [22], which offers appropriate expressiveness and tool support in order to use it for the assumed purpose [23].

A. PRONTOlogy engine

The ontology model presented above is used in the PRONTOlogy engine. System activities that are logged by different system sensors form a stream of hundreds to even hundred thousands of events per minute. They record activities of the user and related background activity of the system. In terms of presented solution sensors that cover the spectrum of incidents describing the behavior of different malware types are process, registry, file and network monitors, reflected in the ontology.

Sensors allow to log file system, registry and process/thread activities in real-time. After a proper configuration they enable sifting through incoming events and comprehensive event properties such as session ID numbers, user names, reliable process information, full thread stacks with integrated symbol support for each operation, simultaneous logging to a file, etc.

The first stage of the PRONTOlogy engine operation is devoted to the analysis of this events' stream and classification of single events as either suspicious or regular ones. This classification is assumed as a background activity for the monitoring of the system state realized by the second component of PRONTO, that is threats' tracking (PRONTOnet).

Particular types of malware perform distinctive activities. Each of them is different or, what is more, they can have their types. This entails various malware realization. If malware signature is unknown (the code has been obfuscated), identification of its activity can be done by analyzing system events. The first stage of this process is related to filtering of events and classifying them as neutral or suspicious. In the latter case information about the event is passed down to the next stage – threat tracking.

The stage of events filtering is based on the ontology engine that automatically, with the use of the knowledge base and a set of rules, defines if the registered event is suspicious and should be tracked further by the PRONTOnet module. Knowledge base is created with lifting the information about events registered by sensors to create assertions and facts (entering ABox statements into the knowledge base). Suspicious actions are modeled as instances of the `Place` class. As already mentioned, the rules will provide the possibility to infer facts that particular event indicates existence of a `Place` in the CP-net model (`hasPlace` object property) and therefore particular token (`hasColor` object property) exists and this fact should be passed further on to the PRONTOnet. For instance, the rules can infer that e.g. an event called *winlogon.exe_run_VRT7.tmp* which means that the `winlogon.exe` process has run `VRT7.tmp` file is suspicious and sends on this information to the threat tracing module for further investigation.

As events from sensors are delivered to PRONTOlogy engine, new facts are inserted into the knowledge base in the form of ABox statements. In order to provide additional facts to the knowledge base in terms of appearance of a new token in the CP-net model of particular attack, the rules are proposed. The following listing shows the rule which head defines a condition: an event where a process named *csrss* opens a file named *open.exe*, which in fact is an infected file. When this condition is met, it results in identification of a new `Place` in the CP-net model, which is a `File` with token `open.exe`.

```
Place(?c) ^ Resource(?y) ^ resourceName(?y,
"csrss.exe") ^ open(?y, ?z)   ^ ResFile(?z)
^ resourceName(?z, "open.exe") ->  File(?c)
^ hasColour(?c, ?z)
```

A new set of rules will be prepared whenever new threats appear in the process of system vulnerabilities analysis. For the purpose of the solution verification there has been shown an exemplary set that will provide the possibility to discover markings of places defined in the CP-net model and used in `PRONTOnet`.

V. PRONTOLOGY.OWL EVALUATION

This section is devoted to ontology evaluation which, according to [24], should consist in *validation and verification*

of an ontology in terms of its scope, consistency and expressiveness.

Semantic model defined in PRONTOlogy is devoted to reflect events that occur in the monitored system and enable to identify these suspicious ones. This model has direct relationship with the CP-net through the use of the `Place` class the instances of which are passed over to the PRONTOnet. PRONTOlogy defines:

- The event instance modeled with the use of `Event` class. Data about occurred events is received from the sensors, then lifted to the ontology model as instances of the `Event` class. Each instance has `eventName` (*data property*) defined by the sensor. The description of an event is modeled with the use of `hasResource` *object property* which indicates initiator of the event which is some system resource.
- System resources that are under monitoring by sensors – File, Registry, Process, Domain, IPaddress. They are modeled by the following classes: `ResFile`, `ResRegistry`, `ResProcess`, `ResDomain`, `ResIPAddress`, which are subclasses of the `Resource` class.
- The event description modeled with the use of *object properties* (`run`, `create`, `modify`, `delete`, `download`, `open`, `close`, `read`, `execute`, `terminate`, `connect`, `query`). These *object properties* `domain` and `range` is the `Resource` class, which means that resources perform actions on other resources.
- An abstract `Place` class that defines the fact that particular event is suspicious and should be handled over by the CP-net model for further investigation. This class has five subclasses that define the type of a Place, which in turn results from event originator and reflects Places in the CP-net model.

With the use of the proposed ontology it is possible to describe the event of running a file by particular process. For instance occurrence of `winlogon.exe_run_VRT7.tmp` event would cause inserting of the following instances into the knowledge base:

```
http://wil.waw.pl/secor/PRONTOlogy.owl#
Event_1
http://wil.waw.pl/secor/PRONTOlogy.owl#
eventName(http://wil.waw.pl/secor/
PRONTOlogy.owl#Event_1,
"winlogon.exe_run_VRT7.tmp")
http://wil.waw.pl/secor/PRONTOlogy.owl#
ResProcess_8
http://wil.waw.pl/secor/PRONTOlogy.owl#
resourceName(http://wil.waw.pl/secor/
PRONTOlogy.owl#ResProcess_8,
"winlogon.exe")
http://wil.waw.pl/secor/PRONTOlogy.owl#
ResFile_9
http://wil.waw.pl/secor/PRONTOlogy.owl#
resourceName(http://wil.waw.pl/secor/
PRONTOlogy.owl#ResFile_9, "vrt7.tmp")
http://wil.waw.pl/secor/PRONTOlogy.owl#
run(http://wil.waw.pl/secor/
PRONTOlogy.owl#ResProcess_8,
http://wil.waw.pl/secor/
PRONTOlogy.owl#ResFile_9)
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasResource(http://wil.waw.pl/secor
/PRONTOlogy.owl#Event_1,
http://wil.waw.pl/secor/PRONTOlogy.owl#
ResProcess_8)
```

The stage of events filtering is based on the ontology engine that automatically, with the use of the knowledge base and a set of rules defines if the registered event is suspicious and should be tracked further by the threat tracing module. As already mentioned knowledge base is created with lifting the information about events registered by sensors to create assertions and facts. Suspicious actions are modeled as instances of the `Place` class. The knowledge about the object which is also an instance of the `Place` class is derived by the set of rules proposed for the purpose of PRONTOlogy.

If the following rule is applied:

```
Place(?c)^Resource(?y)^resourceName
(?y, "winlogon.exe")^run(?y, ?z)
^ResFile(?z)^resourceName(?z,
"vrt7.tmp") -> File(?c)^hasColour(?c, ?z)
```

the following instances are added to the knowledge base:

```
http://wil.waw.pl/secor/PRONTOlogy.owl#
Place_1-is a member of File class
(inferred knowledge)
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasColour(http://wil.waw.pl/secor/
PRONTOlogy.owl#Place_1,
http://wil.waw.pl/secor/PRONTOlogy.owl#
ResFile_9).
```

If the following rule is applied:

```
Event(?e)^Place(?c)^hasResource(?e,?y)
^Resource(?y)^resourceName(?y,
"winlogon.exe")^run(?y, ?z)^ResFile(?z)
^resourceName(?z,  "vrt7.tmp")
-> hasPlace(?e,?c)^File(?c)^
hasColour(?c, ?z)
```

additionally the relation

```
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasPlace(http://wil.waw.pl/secor/
PRONTOlogy.owl# Event_1,
http://wil.waw.pl/secor/PRONTOlogy.owl#
Place_1).
```

is added.

If an event has `hasPlace` relation to any `Place` instance, it is a suspicious event.

The PRONTOlogy defines all entities that are necessary to describe events monitoring system behavior and identify suspicious events. Moreover, the direct relation between ontology and CP-nets has been modeled with the use of the `Place` class. That is why, they satisfy the required scope and expressiveness of ontology.

The second ontology evaluation step consists in checking the ontology consistency. According to [25] *ontology is consistent (also called satisfiable) when it does not contain a contradiction*. The lack of contradiction can be defined in either semantic or syntactic terms. The syntactic definition states that a theory is consistent if there is no such P formula that both P and its negation are provable from the axioms of the theory under its associated deductive system. The ontology model that contains formal definitions of classes, properties and individuals allows inferring new knowledge from knowledge that is already present. The fact that it is based on formal description logic makes it prone to logical reasoning and enables to infer knowledge from existing *facts* and *axioms* [26].

The consistency of `PRONTOlogy.owl` has been verified in the Protégé ontology editing tool (version 3.4.6) [27] using the Pellet 1.5.2 [28] reasoner on a machine with the following configuration:

- Processor: Intel Core i7 (2 cores 2,8 GHz each);
- RAM: 6 GB;
- Operating System: Windows 7 (64 bit).

The consistency check on this machine was successful and `PRONTOlogy.owl` has been proven consistent in 0,022 seconds.

To satisfy verification of events filtering with ontology and reasoning a web service `PRONTOlogyInterface` was implemented in Java programming environment. The service was developed with utilization of Protégé, Pellet, SWRL Jess bridge, and Jess71p2 programming libraries. Web Service was run on the GlassFish Server 3.1.2.

`PRONTOlogyInterface` consists of two programming packages:

- `wil.waw.pl.protegeclass.prontology`
- `wil.waw.pl.prontology`.

Java classes of `wil.waw.pl.protegclass.prontology` package were developed with *Generate Protégé-OWL Java Code* plug-in of Protégé editor. The generator allowed to define Java classes on the basis of `PRONTOlogy.owl` automatically.

Package `wil.waw.pl.prontology` consists of the following classes:

- `InferenceResult.java`,
- `OperationType.java`,
- `ResourceType.java`,
- `PRONTOlogy.java`.

`InferenceResult.java` class defines result code of `PRONTOlogyInterface` service. `OperationType.java` defines types of operations on resources:

```
public enum OperationType {RUN,EXECUTE,
CREATE,MODIFY,DELETE,CLOSE,OPEN,
DOWNLOAD,CONNECT ACCESS,TERMINATE,
QUERY,READ,OTHER}.
```

Enumerate class `ResourceType.java` defines types of resource:

```
public enum ResourceType{RESDOMAIN,
RESIPADDRES,RESUSER,RESREGISTRY,
RESFILE,RESPROCESS}.
```

`PRONTOlogy.java` is the main class of `PRONTOlogyInterface` and it implements the following web methods:

- `readOntologyFromFile()` that reads the ontology from the file;
- `inferKnowledge()` that realizes ontology reasoning;
- `queryForPetriPlace()` that identifies the *Place* in CP-net on the basis of defined knowledge base;
- `queryForPetriToken()` that identifies, on the basis of the knowledge base, a token assigned to a particular *Place*.

VI. Cyber attacks detection – an experiment

A. Data acquisition

The verification based on experimental data was made with the use of the most popular target of cyber infections – Microsoft Windows operating system. The authors do not claim that this is the most vulnerable system. In the authors' opinion the reason of cyber attacks on Windows operating system is the popularity of the system and potentially high gain from conducted attacks. Microsoft products are very popular which makes them attractive for cyber criminals.

For the observation of activities, applications, services and network connections in the native Microsoft Windows 7 operating system environment Sysinternals Suite utility package [29] was used. The Sysinternals Suite is a set of over 70 advanced diagnostic and troubleshooting programs for the Windows platform. These programs are available for free download from Microsoft's Technet web page [30].

Majority of events were observed with Process Monitor utility [31] – part of the Sysinternals Suite. Process Monitor is an advanced monitoring application for Windows that registers events which relate to file system, registry, and process activity in real-time. It enables monitoring event properties such as session IDs, user names, process information, thread stacks, simultaneous logging to a file, etc. It is a powerful utility that supports PRONTOlogy module with detailed information on activities in the protected system. An example of a single event acquired with Process Monitor is presented in following listing:

```
<event>
<ProcessIndex>14340</ProcessIndex>
<Time_of_Day>17:22:25,1104786</Time_of_Day>
<Process_Name>ThreatProc.exe</Process_Name>
<PID>2728</PID>
```

```
<Operation>RegQueryValue</Operation>
<Path>HKLMS\Microsoft\Windows NT\...\
SurrogateFallback\Plane2</Path>
<Result>SUCCESS</Result>
<Detail>Type: REG_SZ, Length: 24, Data:
SimSun-ExtB</Detail>
</event>
```

Process Monitor allows to report system events for further analysis and reasoning to the PRONTOlogy module. Detailed report on system activities includes, but is not limited to:

- **process name** – the name of the process performing the operation;
- **operation** – the name of the operation being logged;
- **path** (if applicable) – the path of the object that the operation is performed on (e.g. a registry path, a file system path);
- **result** – the result of the operation (e.g. Success, EoF, Buffer Overflow);
- **detail** – additional operation-specific information about the event.

For the purpose of data acquisition it is also possible to use API hooking tools [32], [33], however, they inject themselves (like viruses) to the processes, thus they can affect results of the verification. In case of utilization of PRONTO malware hunting tool for detection of network attacks various network utilities, e.g. SNORT [34], ARAKIS [35], iptables [36], should also be used [37], [38].

Having stored CP-net models of cyber attacks in the database, it is possible to go further with the experiment to malware detection phase. As mentioned above, the aim of the experiment is not only to identify existing malware that was obfuscated, but also 0-day attacks that have, to some degree, similar behavior to the already identified one.

B. Malware detection scenario

Within one minute operation of Windows 7 OS thousands or even hundreds of thousands single events may be observed. Report from the Process Monitor includes everything that took place in the system. It includes both regular and suspicious activities.

For the purpose of verification and, in particular, generation of these *unwanted* activities, three different machines were infected by Virut, VBMania@MM, and 0-day attack that was simulated with events typical to different parts of malicious codes.

At the same time, various programs were executed on these three machines in order to simulate legitimate user activity. This allowed us to generate background regular events.

In the article we show only the first example and provide the reader with information on steps of PRONTO operation in terms of malware detection with emphasis on events filtering phase.

Let us assume that data acquisition phase allowed to gather information about events collected by the Process Monitor. Obviously, the whole file with captured events will not be presented in this chapter although an exemplary excerpt from it is presented in following listing:

```
<event>
   <ProcessIndex>14340</ProcessIndex>
   <Time_of_Day>17:20:21,1001813
</Time_of_Day>
   <Process_Name>WINLOGON.EXE
</Process_Name>
   <PID>2728</PID>
   <Operation>ReadFile</Operation>
   <Path>C:\Windows\Temp\vrt7.tmp</Path>
   <Result>SUCCESS</Result>
   <Detail>Offset: 734 720, Length: 16 384,
 Priority: Normal</Detail>
</event>
<event>
   <ProcessIndex>14560</ProcessIndex>
   <Time_of_Day>17:22:25,1104786
</Time_of_Day>
   <Process_Name>ThreatProc.exe
</Process_Name>
   <PID>6043</PID>
   <Operation>RegSetValueEx</Operation>
   <Path>HKLMS\Microsoft\Windows\
CurrentVersion\Run\
   Windows System Monitor:
"C:\Windows\system\winrsc.exe"
   </Path>
   <Result>SUCCESS</Result>
   <Detail>Type: REG_SZ, Length: 24, Data:
SimSun-ExtB</Detail>
</event>
<event>
   <ProcessIndex>16640</ProcessIndex>
   <Time_of_Day>17:22:36,2548113
</Time_of_Day>
   <Process_Name>WINWORD.EXE
</Process_Name>
   <PID>6733</PID>
   <Operation>RegQueryKey</Operation>
   <Path>HKLM</Path>
   <Result>SUCCESS</Result>
   <Detail>Query: HandleTags, HandleTags:
0x0</Detail>
</event>
<event>
   <ProcessIndex>19240</ProcessIndex>
   <Time_of_Day>17:47:02,1294174
</Time_of_Day>
   <Process_Name>mmirc.exe
</Process_Name>
   <PID>12188</PID>
   <Operation>TCP Connect</Operation>
   <Path>MalwareTest1-VAIO:55052 ->
 irc.zief.pl:6667</Path>
```

```
   <Result>SUCCESS</Result>
   <Event_Class>Network</Event_Class>
   <Image_Path>C:\Windows\Temp\
mmirc.exe</Image_Path>
   <Session>1</Session>
</event>
```

The events presented in above listing are processed and XML data is lifted to the semantic metadata. Based on this example the following instances are inserted into the ontology model (as ABox entries):
for the first event:

```
http://wil.waw.pl/secor/PRONTOlogy.owl#
Event_1 - an instance of the  Event class

PRONTOlogy.owl#ResProcess_12188)
```

The rules that are valid in the presented scenario allow to infer that three of the above events are suspicious. These are the following rules:

```
Event(?e)^Place(?c) hasResource(?e,?y)^
resourceName(?y, "winlogon.exe")^
read(?y, ?z)^ ResFile(?z) ^
resourceName(?z,  "vrt7.tmp")->
hasPlace (?e,?c)^File(?c)^hasColour(?c, ?z)
```

```
Event(?e)^Place(?c)^hasResource(?e,?y)
^modify(?y, ?z)^ResRegistry(?z)^
resourceName(?z,"HKLMS\Microsoft\...\Run\
Windows System Monitor: C:\Windows\
system\winrsc.exe")->hasPlace(?e,?c)
^ Registry(?c)^hasColour(?c, ?z)
```

```
Event(?e)^Place(?c)^hasResource(?e,?y)
^connect(?y, ?z)^ResDomain(?z)
^resourceName(?z,  "irc.zief.pl")
-> hasPlace (?e,?c)^Domain(?c)^
hasColour(?c, ?z)
```

On the basis of these rules the following facts are inferred:

```
http://wil.waw.pl/secor/PRONTOlogy.owl#
Place_1 - member of the File class
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasPlace(http://wil.waw.pl/secor/
PRONTOlogy.owl#Event_1, http://wil.waw.pl/
secor/PRONTOlogy.owl#Place_1).
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasColour(http://wil.waw.pl/secor/
PRONTOlogy.owl#Place_1,
http://wil.waw.pl/secor/PRONTOlogy.owl#
ResFile_1).

http://wil.waw.pl/secor/PRONTOlogy.owl#
Place_2 - member of the Registry class
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasPlace(http://wil.waw.pl/secor/
PRONTOlogy.owl#Event_2,
http://wil.waw.pl/secor/
PRONTOlogy.owl#Place_2).
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasColour(http://wil.waw.pl/secor/
PRONTOlogy.owl#Place_2,
http://wil.waw.pl/secor/PRONTOlogy.owl#
ResRegistry_1).

http://wil.waw.pl/secor/PRONTOlogy.owl#
Place_3 - member of the Domain class
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasPlace(http://wil.waw.pl/secor/
PRONTOlogy.owl# Event_2,
http://wil.waw.pl/secor/
PRONTOlogy.owl#Place_2).
http://wil.waw.pl/secor/PRONTOlogy.owl#
hasColour(http://wil.waw.pl/secor/
PRONTOlogy.owl#Place_2,
http://wil.waw.pl/secor/PRONTOlogy.owl#
ResDomain_1).
```

Events 1, 2 and 4 have been identified as suspicious, whereas event 3 – as a regular system activity. The SQWRL query that allowed to select this knowledge from the ontology had the following structure:

```
tbox:isSubClassOf(?subClass, Place)^
abox:hasIndividual(?subClass, x)->
sqwrl:select(?subClass)
```

```
Place(?p)^hasColour(?p, ?c)^
resourceName(?c, ?n)->sqwrl:select(?n)
```

The rules applied in the PRONTOlogy module allowed to pass forward to the PRONTOnet module only information about suspicious events in the form of *Places* and appropriate *tokens* assigned to them (with the use of hasColour *object property*). It takes place in the *acquisition module* as presented in the architecture of solution. Then, in the PRONTOnet, these tokens are passed to *verification module* where marking M_a of *Places* is:

$M_a = M_{File} \cup M_{Domain} \cup M_{Registry}$, where:

- M_{File}={vrt7.tmp},
- M_{Domain}={irc.zief.pl},
- $M_{Registry}$ = {HKLMS\Microsoft\...\Run\Windows System Monitor:"C:\Windows\system\winrsc.exe"}.

At the machine described in this scenario the detection realized with the use of CPN MM and marking M_a allowed to identify Virut attack. The result vector is as follows:

```
1’ 1|Virut|vrt7.tmp,irc.zief.pl,
Windows System Monitor:
"C:\Windows\system\winrsc.exe"
```

VII. Summary

Realization of this scenario allowed to prove that the proposed ontology model as well as applied reasoning rules were successfully adapted to detection of single malicious incidents. Then, these incidents were collected and compared with the CP-net models. As a result, Virut malware has been detected.

Ontology presented for malware activities identification together with rules allows to filter out suspicious system activities and strongly supports malware detection mechanism implemented in PRONTO. The effectivenes of signature-based antivirus software is rapidly decreasing. Behavior based methods give promissing effects and should be investigated further on in modern security controls such as one presented here.

***Abstract*—The paper describes a new method of combining Artificial Neural Networks (ANN), technical analysis and fractal analysis for predicting share prices on the Warsaw Stock Exchange. The proposed hybrid model consists of two consecutive modules. In the first step share prices are preprocessed and calculated into moving averages and oscillators. Then, in the next step, they are given to the ANN inputs, which provides the closing values of the asset for the next day. ANN of Multi-Layer Perceptron (MLP) type, and fractal analysis are applied. The hybrid model combining ANN with technical and fractal analysis is compared with hybrid model combining ANN with technical analysis. The obtained results indicate that hybrid model combined with fractal analysis is more accurate and stable in the long run than the hybrid model.**

I. Introduction

AS TRADING systems are becoming more complex, there is also a growing interest in applying artificial intelligence methods, i.e. artificial neural networks [28; 24; 27], fuzzy logic [31] or increasingly popular fractal analysis to support stockbrokers and investors in their decisions aimed at maximizing profits. The financial market, which uses the most advanced IT solutions, provides a variety of products to meet this goal. From all of them, the most popular are financial instruments offered by the Stock Exchange, which may be very profitable, but with a big profit there is also a risk of losing all assets [5]. Recently, artificial neural network (ANN) are gaining in importance for stock quotes time series prediction. The most commonly used artificial neural networks to predict trading signals are the feed-forward neural networks (FNN) [10, 24, 28, 32] of Multi-Layer Perceptron (MLP) type, but also new approaches and ANN structures, like for e.g.: dynamic artificial neural network [11], Probabilistic Neural Networks (PNN) [27], State Space Wavelet Network (SSWN) [3] or a neural-wavelet analysis [14] are still subject of scientific studies. The most common use of ANN on Stock Exchange is: prediction of future stock market indices [3, 24, 26], exchange rates [27], share prices, etc.

Nowadays, hybrid modelling approach is used more often by many researchers. The aim of using hybrid models for Stock Exchange shares forecasting is to reduce risk of failure and obtain the results which are more accurate. Typically, this is done because the underlying process cannot easily be determined. The motivation for combining models comes from the assumption that either one cannot identify the true data generating process or that a single model may not be sufficient to identify all the characteristics of the time series. Different hybrid models were used for this purpose. Khashei and Bijari [18] proposed a new combination of ARIMA and ANN approaches, in which a time series predicted by ANN is considered as nonlinear function of several past observations and random errors. This model was more accurate than ARIMA, ANN and Zhang models [33].

Güresen and Kayakutlu [13] investigated hybrid neural networks which used generalized autoregressive conditional heteroscedasticity (GARCH) and exponential generalized autoregressive conditional heteroscedasticity (EGARCH) to extract new ANN input variables. They also tested combinations of statistical GARCH and EGARCH models with different neural networks [12], i.e. MLP and DAN2 dynamic artificial neural network developed by Ghiassi and Saidane [11]. The lowest error for the testing data in prediction of NASDAQ index was achieved by the use of DAN2 network and next by MLP network. Hybrid GARCH-ANN and EGARCH-ANN models ensured worse results, contrary to expectations.

Majhi, Panda, and Sahoo [19] compared functional link artificial neural network (FLANN), cascaded functional link artificial neural network (CFLANN), and LMS model and also observed that the CFLANN model performs the best prediction of exchange rates followed by the FLANN and the LMS models. Interesting hybrid approach combining technical analysis and ANN for trading systems development was proposed by Witkowska and Marcinkiewicz [29]. 15 trading systems were designed for the Warsaw Stock Exchange future contracts and compared. Five strategies of investment decisions were investigated, including four based on

978-83-60810-58-3/$25.00

technical analysis indicators, which were combined with three methods of the WIG20 index future closing prices forecasting. The final conclusion was that the combination of the technical analysis and artificial intelligence in order to gain profit from trading on the Stock Exchange can bring much better investment results than trade in the traditional way. The best results for the WIG20 index time series forecasting were obtained by the use of ANN of MLP type with a set of about 30 input variables, which were divided in 3 subsets: variables related to the WIG20 index Close prices, variables related to the technical analysis indicators, variables related to the external factors.

In this paper, a new hybrid analytical and ANN model is proposed, which combines ANN with technical and fractal analysis. Previously, the hybrid models combining technical analysis with ANN without fractal analysis were compared with purely ANN based approach [22].

It will be shown that hybrid ANN model which uses technical and fractal analysis is more stable in the long run than hybrid ANN model using only technical analysis and that fractal analysis reduces the error of shares forecasting.

II. TECHNICAL ANALYSIS INDICATORS

Technical analysis indicators are used to determine trend of the market, the strength of the market, and the direction of the market. Some technical analysis indicators can be quantified in the form of an equation or algorithm. Others can show up as patterns (e.g., head and shoulders, trend lines, support, and resistance levels). At some point, the technical analyst will receive a signal. This signal is the result of one technical analysis indicator or a combination of two or more indicators. The signal indicates to the technical analyst a course of action whether to buy, sell, or hold [29].

The most commonly used technical analysis indicators are moving averages and oscillators [20], which were selected for the proposed approach. These include the following:

- Moving averages:

a. Expotential (5-, 10-, 20-days) – EMA (Expotential Moving Average)

$$EMA_{N,C}(k) = \frac{C(k) + aC(k-1) + a^2C(k-2) + ... + a^{N-1}C(k-N+1)}{1 + a + a^2 + ... + a^{N-1}} \quad (1)$$

where:

a- coefficient

b. Envelopes (3% error with 20-days average)

- Oscillators

a. ROC - Rate of Change (5-, 10-, 20-days) – determines the rate of price changes in a given period (usually 10 days)

$$ROC_N(k) = C(k) / C(k-N) \quad (4)$$

b. RSI - Relative Strength Index – i.e. the measure of overbought / oversold market. It assumes values in the range of 0-100. For values greater than 70 it is considered that the market is buyout. When oscillator values are below 30, it signifies that market is sold out. In the case of periods of strong trends it is assumed that the market is buyout when RSI> 80 (at the time of a bull market) and sold out for RSI <20 (during a bear market).

For:

C(k) > C(k-1), U(k) = C(k) – C(k-1)

C(k) < C(k-1), D(k) = |C(k) – C(k-1)|

$$RSI(k) = 100 - \left[\frac{100}{1 + \frac{EMA_{N,U}(k)}{EMA_{N,D}(k)}} \right] \quad (5)$$

where

U(k) – average increase in the k-th day

D(k) – average decrease in the k-th day

c. Stochastic oscillator (K%D) – determines the relation between the last closing price and the range of price fluctuations in the given period. The result belongs to the range of 0-100. K% D> 70 is interpreted as the closing price near the top of the range of its fluctuations, and K% D <30 points to the fact that prices are shaping near the lower limit of that range.

$$K\%D(k) = 100 * \left[\frac{C(k) - L(14)}{H(14) - L(14)} \right] \quad (6)$$

where:

L(14) – the lowest price from last fourteen days

H(14) - the highest price from last fourteen days

d. Moving Average Convergence/Divergence (MACD) is the difference between two moving averages. On the graphs, it usually occurs with 10- day, exponential moving average (called the signal line). The intersection of the signal line (SL) with the MACD line

coming from the bottom is a buying signal, while with the line from the top - a selling signal.

$$MACD(k) = EMA_{12,C}(k) - EMA_{26,C}(k) \quad (7)$$

$$SL(k) = EMA_{9,MACD}(k) \quad (8)$$

e. Accumulation/Distribution (AD) indicator presents whether price changes are accompanied by increased accumulation and distribution movements.

$$AD(k) = V(k) * \frac{C(k) - L(k) - [H(k) - C(k)]}{H(k) - L(k)} \quad (9)$$

where:

V(k) - total number of shares which were rotated on k day

f. Bollinger Oscillator

Its construction is based on Bollinger bands. Bollinger oscillator informs when market is overbought or oversold.

$$BOS_k = \frac{C_{k+(N-1)} - SMA_N(C(k))}{StandardDev(k)} \quad (10)$$

For the purpose of counting highest errors between predicted value and real CLOSE value, the following formulas have been used:

a. The highest prediction error per month

E_{max} = Highest difference between real CLOSE value and predicted by ANN value per month (11)

b. Arithmetical mean of E_{max} value per tested period of time

$$\overline{E_{max}} = \frac{1}{N}\sum_{i=1}^{N} E_{max_i} \quad (12)$$

III. FRACTAL ANALYSIS

Recently it can be seen that fractal market hypothesis is constantly expanding. It was presented for the first time by Peters [7] in 1994, and is based on chaos theory [8]. Fractal shapes can be formed in many ways. The simplest is a multiple iteration of generating rule (e.g. the Koch curve or Sierpinski triangle). They are generated in deterministic way and all have fractal dimension. There are also random fractals, like stock prices, which are generated with the use of probability rules.

Performing a fractal analysis is based on identification of fractal dimension. To do this, chart has to be divided into N small elements with S surface. The relationship between the number of objects N_1 and N_2, which are used to cover the first and second graph with objects of surface size, respectively S_1 and S_2, describes the relationship [9]:

$$\frac{N_2}{N_1} = \left(\frac{S_1}{S_2}\right)^D \quad (13)$$

$$D = \frac{\log\left(\frac{N_1}{N_2}\right)}{\log\left(\frac{S_1}{S_2}\right)} \quad (14)$$

where:

D – fractal dimension

In order to measure fractal dimension on stock exchange, we need to divide the given period of time by two. For each period, share prices curve have to be divided into N pieces. It can be done by dividing the subtraction result of highest and lowest value on graph in given period of time, by this period:

$$N_{1T}(k) = \frac{H_T(k) - L_T(k)}{T} \quad (15)$$

$$N_{2T}(k) = \frac{H_{2T}(k) - L_{2T}(k)}{T} \quad (16)$$

$$N_{0-2T}(k) = \frac{H_{0-2T}(k) - L_{0-2T}(k)}{2T} \quad (17)$$

$$D = \frac{\log\left(\frac{N_{1T} + N_{2T}}{N_{(0-2)T}}\right)}{\log\left(\frac{2T}{T}\right)} = \frac{\log(N_{1T} + N_{2T}) - \log(N_{(0-2)T})}{\log(2)} \quad (18)$$

where:

$H_T(k)$ – the highest share price in the first period T

$H_{2T}(k)$ – the highest share price in the second period (from T till 2T)

$H_{0\text{-}2T}(k)$ – the highest share price in 2T period

$L_T(k)$ – the lowest share price in the first period T

$L_{2T}(k)$ – the lowest share price in the period from T till 2T

$L_{0\text{-}2T}(k)$ – the lowest share price in 2T period

Fractal dimension is used in this paper in Fractal Moving Average (FRAMA). This moving average is based on Expotential Moving Average (eq. 1) where a coefficient is constructed with the use of fractal dimension:

$$a = \exp(-4.6*(D-1)) \quad (19)$$

IV. APPLICATION OF TECHNICAL ANALYSIS AND ANN FOR PREDICTION OF CLOSING PRICES

Closing price of the asset for the next day is one of the most important parameters for investors, who plan to make transactions at the Stock Exchange. In this work a hybrid approach combining technical analysis with ANN and a hybrid approach combining technical and fractal analysis with ANN is being compared. The main idea of the proposed method is shown in Fig. 1. Technical analysis methods are used to calculate moving averages and oscillators, which are important market indicators. These are the inputs of ANN, which predicts the CLOSE value of the next day. The aim of this paper was to investigate if the proposed data pre-processing with market indicators calculation connected with the use of fractal dimension would improve the ANN effectiveness in the CLOSE value prediction.

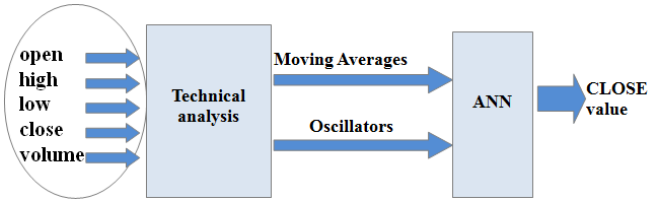

Fig. 1. Processing scheme for predicting course of a CLOSE value for the next day [19]

The programming application was designed and implemented for the data collecting and pre-processing. The calculated moving averages and oscillators were used for neural network training and testing. Feedforward networks of Multi-Layer Perceptron (MLP) type [25] trained with the Levenberg-Marquardt algorithm were used for the CLOSE value prediction. The choice of the ANN input variables presented in this paper was made based on the experience and knowledge of a stock market expert.

The model structure was overtaken from the Authors' previous experience with hybrid analytical-neural approach in engineering applications, which ensured better modelling results as pure ANN solutions [16, 17]. Thanks to the data preprocessing the designed model is efficient and ANN has a simple structure.

V. EXPERIMENTAL RESEARCH

Research was conducted for 2 exemplary companies (Vistula SA and Budimex SA) appearing on the Warsaw stock market since 2.01.1996 until 14.04.2014. The aim of the research was to compare the results of short-term prediction of two hybrid models. Their hybridity differs in terms of the technical analysis indicators and fractal moving averages used as ANN inputs (Table II). The research was performed with the use of Java and Encog 3.2 library, creating ANN of MLP type. Each network consists of an input, hidden and output layer. A common feature of all of the tested network architectures is a small number of input nodes and neurons in the hidden layer, and only one neuron in the output layer. Too many neurons would increase the network training error and could cause learning time extension [5]. The relations between the number of input nodes and the number of neurons in the hidden layer were tested for the combinations shown in Table 1.

Table I

COMBINATIONS OF THE TESTED MLP ARCHITECTURES

Input layer	Hidden layer	Output layer
n	n+1	1
	1.5n	
	2n-1	
	2n+1	

where n – number of neurons (n = 4, 5, 6 neurons)

Market indicators for the input data were selected based on the literature [1, 4, 10, 20, 32] and an advice of a stock market expert. ANN training was performed according to the following rules:

1. All entered data were normalized using the following heuristic formula:
$$(\text{Value}/\text{Value}_{max})*0.8 + 0.1 \quad (10)$$
2. The results of each company were divided into two groups: learning data and testing data in the proportion 70:30 [19]
3. Neural networks were taught with the Levenberg-Marquardt algorithm [16, 23].
4. For each ANN architecture and each set of input data, eight neural networks were trained, and the ANN with the smallest medium square error (MSE) for the testing data has been selected as the best one.

The hybrid model structures combining MLP with technical analysis with or without using the fractal dimension, and also the obtained results are gathered in Table II. Technical analysis indicators, which are ANN inputs are listed in the second column. The MLP (7-15-1) structure means, that it consists of seven input nodes, fifteen neurons in a hidden layer and one neuron in an output layer.

The results of short-term forecast of CLOSE value of Vistula SA shares predicted with the use of Hybrid MLP (7-15-1) model (no. 1 in Table 2) and Hybrid MLP (7-15-1) model with fractal dimension (no. 2 in Table 2) are shown in

figures 2 and 3. In the first case (Fig. 2) share prices of Vistula SA are in horizontal trend and in the second period of time (Fig. 3) in downward trend.

Table II

HYBRID MODELS WITH SELECTED ANN STUCTURES, FOR WHICH THE BEST RESULTS WERE ACHIEVED

No.	ANN inputs	Model structure	Transfer function	Periods	Training error	Testing error
1.	RSI MACD AD BO EMA_{k-4} EMA_{k-9} ROC	Hybrid MLP(7-15-1)	sigmoidal	7000	0.0327	0.023
2.	RSI MACD AD BO $FRAMA_{k-4}$ $FRAMA_{k-9}$ ROC	Hybrid MLP(7-15-1)	sigmoidal	7000	0.0312	0.021

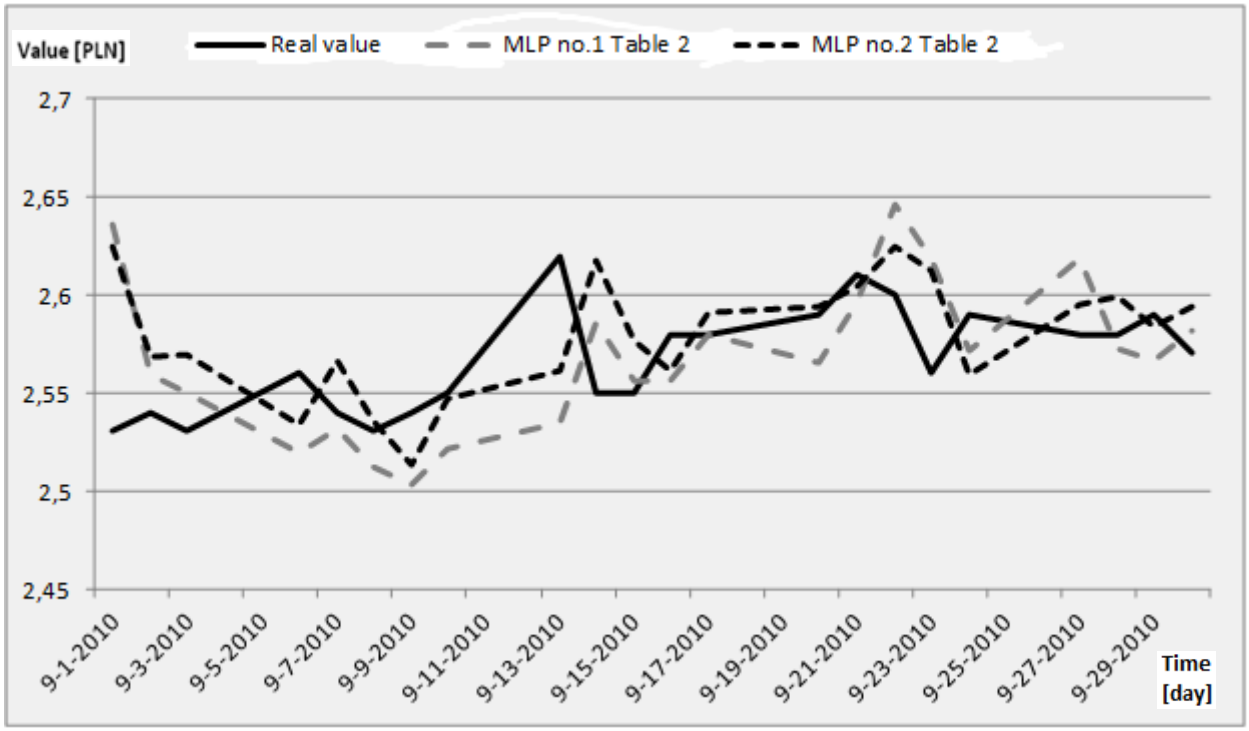

Fig. 2. Short-term forecast of two hybrid models with MLP (7-15-1) network: no. 1 in Table 2 and no. 2 in Table 2 (with fractal dimension) and real CLOSE value of Vistula SA shares in September 2010.

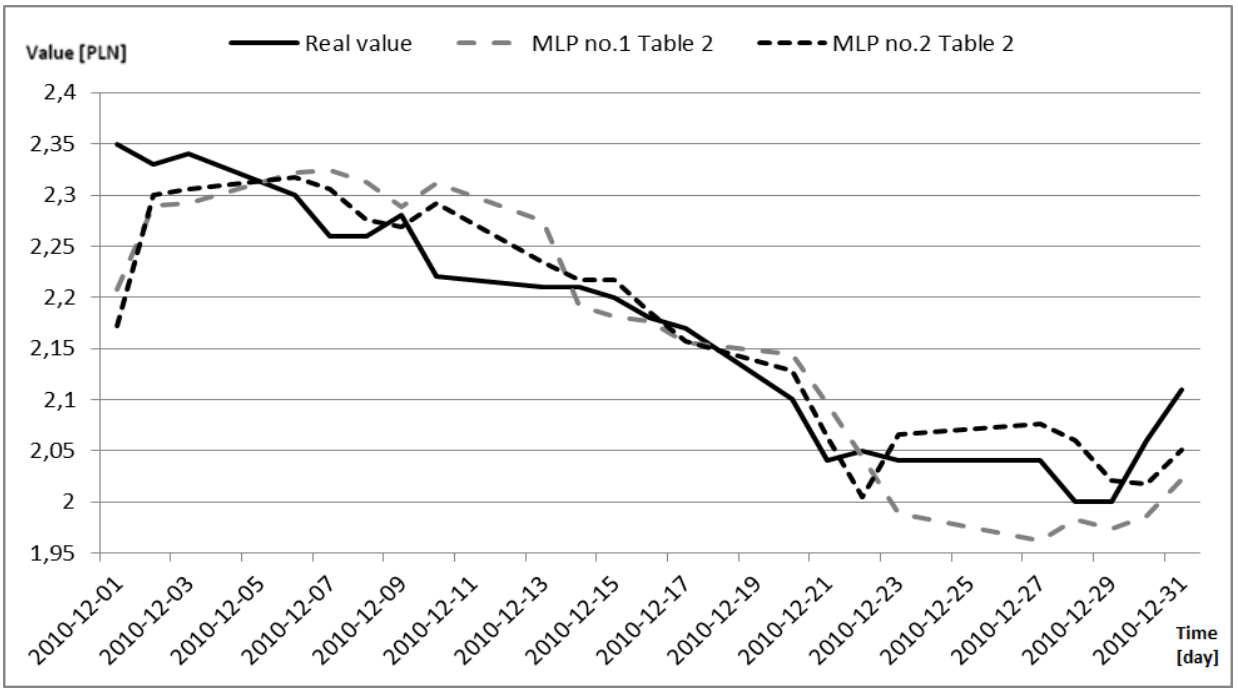

Fig. 3 Short-term forecast of two hybrid models with MLP (7-15-1) network: no. 1 in Table 2 and no. 2 in Table 2 (with fractal dimension) and real CLOSE value of Vistula SA shares in December 2010.

Comparison of the obtained results shows that prediction of hybrid model with FRAMA (no. 2 in Table 2) was more accurate while share prices were in distinct trend. Example is being shown in figure 3, where Vistula SA shares have been in downward trend on December 2010. On the other hand, both hybrid models provide similar results when share prices are in horizontal trend, which can be seen in figure 2.

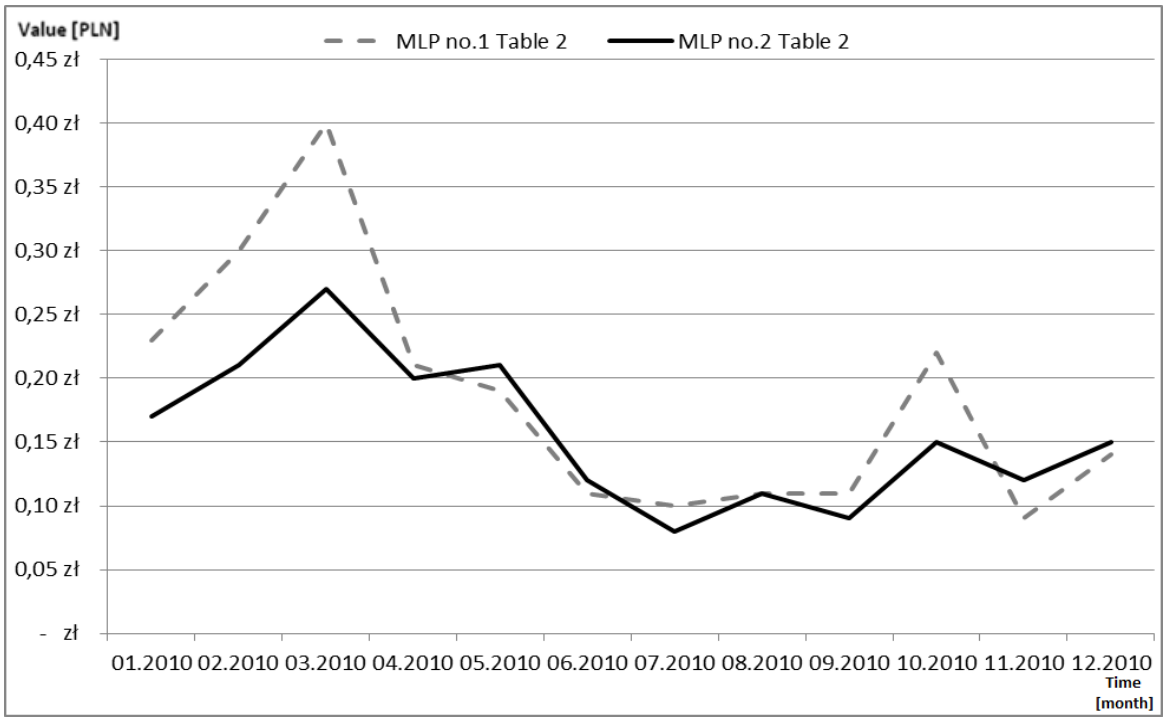

Fig. 4. Comparison of E_{max} values between hybrid model with hybrid MLP (7-15-1) (no. 1 in Table 2) and hybrid MLP (7-15-1) (no. 2 in Table 2) for Vistula SA

To assess which model is more accurate and stable, the maximum absolute errors E_{max} of prediction in the period of one year were compared. Maximum absolute error was calculated as the maximum absolute difference between true CLOSE value and the model prediction for each month. Summary of the results for hybrid models with and without FRAMA are presented in figures 4 and 5. Similar results have been achieved for Vistula SA (Fig. 4) and for Budimex SA (Fig. 5). For a comparison results are shown for the same period of time.

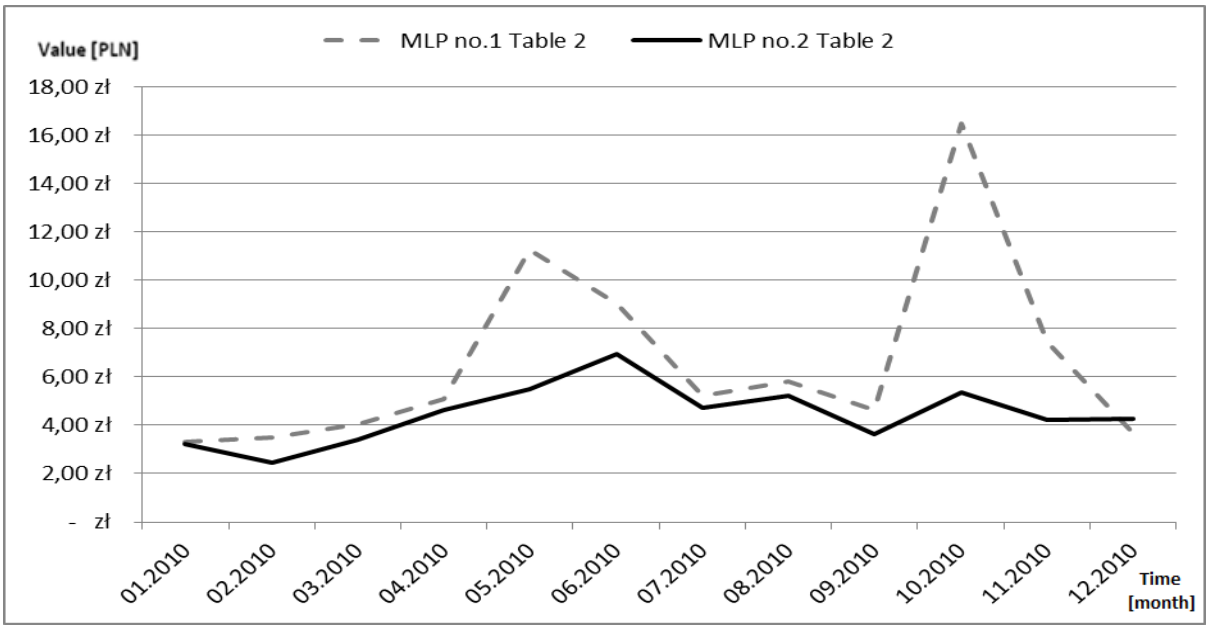

Fig. 5. Comparison of E_{max} values between hybrid model with hybrid MLP (7-15-1) (no. 1 in Table 2) and hybrid MLP (7-15-1) (no. 2 in Table 2) for Budimex SA

VI. CONCLUSIONS

The obtained experimental results for Vistula SA and for Budimex SA suggest that the hybrid analytical-neural model combined with the fractal analysis yields better approximation of the real shares values than the hybrid model without fractal analysis. Comparison of maximum error E_{max} values for two hybrid models: with and without fractal analysis (no. 2 and 1 in table 2), during the audited period from January 2010 to December 2010, allows to conclude that the proposed prediction hybrid model of hybrid ANN with fractal moving average is more stable and accurate. Thus, the more stable hybrid model reduces the probability of influence of false signals coming from the market in decision-making process, simultaneously increasing potential profits.

Finally, the results lead also to the conclusion that the proposed hybrid models forecast correct direction of CLOSE price changes. Therefore, they can be used as a basis for the decision-making system, which would be used to support investor decisions on the Warsaw Stock Exchange.

Fuzzy Logic Rules Modeling Similarity-based Strict Equality

Ginés Moreno, Jaime Penabad and Carlos Vázquez

***Abstract*—A classical, but even nowadays challenging research topic in declarative programming, consists in the design of powerful notions of "equality", as occurs with the flexible (fuzzy) and efficient (lazy) model that we have recently proposed for hybrid declarative languages amalgamating functional-fuzzy-logic features. The crucial idea is that, by extending at a very low cost the notion of "strict equality" typically used in lazy functional (HASKELL) and functional-logic (CURRY) languages, and by relaxing it to the more flexible one of similarity-based equality used in modern fuzzy-logic programming languages (such as LIKELOG and BOUSI~PROLOG), similarity relations can be successfully treated while mathematical functions are lazily evaluated at execution time. Now, we are concerned with the so-called *Multi-Adjoint Logic Programming approach*, MALP in brief, which can be seen as an enrichment of PROLOG based on *weighted rules* with a wide range of fuzzy connectives. In this work, we revisit our initial notion of SSE (*Similarity-based Strict Equality*) in order to re-model it at a very high abstraction level by means of a simple set of MALP rules. The resulting technique (which can be tested on-line in `dectau.uclm.es/sse`) not only simulates, but also surpass in our target framework, the effects obtained in other fuzzy logic languages based on similarity relations (with much more complex/reinforced unification algorithms in the core of their procedural principles), even when the current operational semantics of MALP relies on the simpler, purely syntactic unification method of PROLOG.**

***Index Terms*—Equality, Similarity, Fuzzy Logic Programming**

I. INTRODUCTION

THANKS to the high expressive power and the rule-based nature of declarative languages, their influences are growing in the design of intelligent systems and techniques related with artificial/computational intelligence, expert systems, soft-computing and so on. In particular, *Logic Programming* (LP) [1] has been widely used for problem solving and knowledge representation in the past. Nevertheless, traditional logic programming languages are not able to treat with partial truth. *Fuzzy Logic Programming* is an interesting and still growing research area that agglutinates the efforts for introducing Fuzzy Logic into Logic Programming, in order to provide these traditional languages with techniques or constructs (coming up from the mathematical background of fuzzy logic [2]) to deal with uncertainty in a natural way. In the last two decades, several fuzzy logic programming languages have been developed where, in essence, the classical SLD resolution principle of PROLOG [3] (based on syntactic unification) has been replaced by a fuzzy variant of itself, with the aim of dealing with partial truth and reasoning with uncertainty in a natural way. Most of these languages implement (extended versions of) the resolution principle introduced by Lee [4], such as Elf-Prolog [5], Fril [6], F-Prolog [7] and MALP [8]. There exists also a family of fuzzy languages based on sophisticated unification methods [9] to cope with similarity/proximity relations, as occurs with LIKELOG [10], SQLP [11] and BOUSI~PROLOG [12], [13] (some related approaches based on *probabilistic logic programming* can be found in [14], [15]).

On the other hand, during the last three decades of investigation in the field of the integration of declarative programming paradigms (functional, fuzzy and logic), the scientific community of the area has produced important and advanced contributions related to both theoretical and practical aspects. However, whereas the functional and logic programming styles have been successfully integrated in the past and, as said before, more recently fuzzy logic has also been introduced into the logic programming paradigm, there is not precedent for a total integration of all these frameworks, apart from our preliminary approach presented in [16].

In [17], we gave a new step in this last sense, by proposing a method combining different equality models traditionally supported by each one of these declarative paradigms. It is important to take into account that an appropriate notion of equality has a crucial importance when designing the repertoire of expressive resources for a particular declarative language. In general, when we use the term "equality" in declarative programming, there are several different meanings depending of the concrete paradigm being considered. A representative (not exhaustive) list of some cases could be:

- **Syntactic equality.** It is the simplest equality model used in the context of classical pure logic programming (as occurs with PROLOG, but also in the fuzzy logic language MALP) which is simply concerned with syntactic identity. In this sense, two element are considered "equal" if they have exactly the same syntax. For instance, $f(a)$ is equal to $f(a)$ but not to $g(b)$.

This work was supported by the EU (FEDER), and the Spanish MINECO Ministry (Ministerio de Economía y Competitividad) under grant TIN2013-45732-C4-2-P.

- **Strict equality.** When considering lazy languages, both pure functional (HASKELL [18]) and integrated functional-logic (CURRY [19]) languages, this new equality notion is the only applicable one in a lazy setting, mainly due to the possible presence of non terminating functions. For instance, if the evaluation of $f(a)$ does not finish then we can not say that $f(a)$ is strictly equal to itself. And, on the contrary, two terms with different syntax, such as $g(b)$ and $h(c)$, could be proved equal if they produce the same final value (for example 0) after being evaluated by rewriting or narrowing.
- **Similarity-based equality.** As we will see in Section II, this model emerges as a direct consequence of several attempts for fuzzifying the original notion of syntactic equality, which are appreciable in the design of fuzzy logic languages such as LIKELOG, SQLP and BOUSI~PROLOG. In this case, the idea is to allow the presence of a set of the so-called "similarity/proximity equations" between symbols of a given program. So, if we have a program with the equations $eq(a, b) = 0.5$ and $eq(f, g) = 0.3$ then, it could be proved that expressions $f(a)$ and $g(b)$ are similar with a concrete truth degree.

Here, we recall from [17] our original definition of SSE (*Similarity-based Strict Equality*), initially modeled by means of a set of rewriting rules and which fuses the last two equality versions above. The crucial idea of our method is to simply add to a given functional-logic program (written in CURRY, for instance) a set of rewriting rules defining the new symbol $\approx$:$\approx$ which captures similarities and thus, is implemented at a very low cost by simply performing a syntactic pre-process on programs.

The main goal of this paper is to adapt such definition to the MALP framework. In Section III we will see that SSE admits a much more natural formulation by means of a set of MALP rules instead of using rewriting rules. Moreover, although this fuzzy programming style is based on pure syntactic unification, our method introduces a similarity-based equality model without altering its core, which is useful not only for testing if two ground data terms are comparable (as occurs too with more complex languages -LIKELOG, BOUSI~PROLOG- with extended unification algorithms), but also for producing complete lists of similar terms (not achievable by LIKELOG and BOUSI~PROLOG). Although the technique is recasted from [20], the main contribution of the present paper consists in proving some interesting formal properties for it. Moreover, before concluding in Section V, we describe in Section IV some implementation details regarding the two main processes needed for effectively embedding SSE into MALP: after performing the reflexive-symmetric-transitive closure of a set of similarity equations for obtaining a similarity relation, then it is easily translated into a set of MALP rules modeling SSE.

II. SIMILARITY RELATIONS AND FUZZY LOGIC PROGRAMMING

As we have just said, although in principle it is not the case of MALP (whose operational semantics uses syntactic unification on its core), some fuzzy languages such as LIKELOG, SQLP and BOUSI~PROLOG are able to treat with the mathematical notions of similarity (and proximity), by incorporating a flexible variant of unification -beyond the simpler case of PROLOG- on their procedural principles.

A similarity relation is a mathematical notion able to manipulate alternative instances of a given entity that can be considered equals with concrete truth degrees. Similarity relations are closely related with equivalence relations (and, then, to closure operators) [21]. Let us recall that a T-norm $\wedge$ in $[0, 1]$ is a binary operation $\wedge : [0, 1] \times [0, 1] \to [0, 1]$ associative, commutative, non-decreasing in both the variables, and such that $x \wedge 1 = 1 \wedge x = x$ for any $x \in [0, 1]$. Formally, a *similarity relation* $\Re$ on a domain $\mathcal{U}$ is a fuzzy subset $\Re : \mathcal{U} \times \mathcal{U} \to [0, 1]$ of $\mathcal{U} \times \mathcal{U}$ such that, $\forall x, y, z \in \mathcal{U}$, the following properties hold: reflexivity $\Re(x, x) = 1$, symmetry $\Re(x, y) = \Re(y, x)$ and transitivity $\Re(x, z) \geq \Re(x, y) \wedge \Re(y, z)$. It is important to note that this last property is not required when considering *proximity relations*. In order to simplify our developments, as in [9], we assume that $x \wedge y$ is the minimum between the two elements $x, y \in [0, 1]$.

A very simple, but effective way, to introduce similarity relations into pure logic programming, generating one of the most promising ways for the integrated paradigm of fuzzy logic programming, consists of modeling them by a set of the so-called *similarity equations* of the form $eq(s1, s2) = \alpha$, with the intended meaning that $s1$ and $s2$ are predicate/function symbols of the same arity with a similarity degree α. As in [16], we assume here that the intended similarity relation $\Re$ associated to a given program $\mathcal{P}$, is induced from the (safe) set of similarity equations of $\mathcal{P}$, verifying that the similarity degree of two symbols s_1 and s_2 is 1 if $s_1 = s_2$ or, otherwise, it is recursively defined as the transitive closure of the similarity equations.

This approach is followed, for instance, in the fuzzy logic languages LIKELOG [10] and BOUSI~PROLOG [12], where a set of usual PROLOG clauses are accompanied by a set of similarity equations playing an important role at (fuzzy) unification time. Instead of classical *syntactic unification*, we speak now about *weak unification* [12]. Of course, the set of similarity equations is assumed to be safe in the sense that each equation connects two symbols of the same arity and nature (both predicates or both functions) and the properties of the definition of similarity relation are not violated, as occurs, for instance, with the wrong set $\{eq(a, b) = 0.5,\ eq(b, a) = 0.9\}$ which, in particular, it does not satisfy the symmetric property.

Example 2.1: Following [10], if we consider a database of books containing the fact "`book(horror,drakula)`", then goal "`?-book(adventures,Title)`" should not have classical solution in the case that there were no rule in the database unifying with atom "`book(adventures,Title)`". Nevertheless, it seems reasonable that the user considers the words "`adventures`" and "`horror`" to be *similar* with a certain degree. More precisely, if the user introduces a similarity equation like "`eq(adventures, horror) = 0.9`" into a

LIKELOG or BOUSI~PROLOG interpreter, the system should successfully respond with a computed answer incorporating the corresponding truth degree "`0.9`" (i.e, something like the 90 % of credibility) to substitution "`Title/ drakula`", as obviously expected.

III. SSE FOR/WITH MULTI-ADJOINT LOGIC PROGRAMMING

In this section we firstly summarize the main features of the MALP language[1], next we introduce the "*Fuzzy LOgic Programming Environment for Research*", $\mathcal{FLOPER}$ in brief, developed in our research group (see [26], [27] and visit `http://dectau.uclm.es/floper/`) and finally, we illustrate and formally prove the properties of our new MALP-based model of SSE according to Figure 2.

A. MALP

We work with a first order language containing variables, function symbols, predicate symbols, constants, quantifiers ($\forall$ and $\exists$), and several arbitrary connectives such as implications ($\leftarrow_1, \leftarrow_2, \ldots, \leftarrow_m$), conjunctions ($\&_1, \&_2, \ldots, \&_k$), disjunctions ($\vee_1, \vee_2, \ldots, \vee_l$), and general hybrid operators ("aggregators" $@_1, @_2, \ldots, @_n$), used for combining/propagating truth values through the rules, and thus increasing the language expressiveness. Additionally, our language contains the values of a multi-adjoint lattice $\mathcal{L} = \langle L, \preceq, \leftarrow_1, \&_1, \ldots, \leftarrow_n, \&_n \rangle$, equipped with a collection of adjoint pairs $\langle \leftarrow_i, \&_i \rangle$ (where each $\&_i$ is a conjunctor intended to the evaluation of *modus ponens*) verifying the so-called *adjoint property*: $\forall x, y, z \in L, \quad x \preceq (y \leftarrow_i z)$ if and only if $(x \,\&_i\, z) \preceq y$. The set of truth values L may be the carrier of any complete bounded lattice, as for instance occurs with the set of real numbers in the interval $[0, 1]$ with their corresponding ordering $\leq$. A *rule* is a formula $[A \leftarrow_i \mathcal{B}\ with\ \alpha]$, where A is an atomic formula (usually called the *head*), $\mathcal{B}$ (which is called the *body*) is a formula built from atomic formulas $B_1, \ldots, B_n$ ($n \geq 0$), truth values of L and conjunctions, disjunctions and aggregators, and finally $\alpha \in L$ is the "weight" or *truth degree* of the rule. A rule with empty body, written $[A\ with\ \alpha]$, is called *fact*. Consider, for instance, the following program $\mathcal{P}$ composed by three rules with associated multi-adjoint lattice $\langle [0,1], \leq, \leftarrow_{\mathtt{P}}, \&_{\mathtt{P}}, \leftarrow_{\mathtt{G}}, \&_{\mathtt{G}} \rangle$ (where labels `P` and `G` mean for *Product logic* and *Gödel intuitionistic logic*, respectively, with the following connective definitions: "$\leftarrow_{\mathtt{P}} \ (x, y) = \min(1, x/y)$", "$\&_{\mathtt{P}}(x, y) = x * y$", "$\leftarrow_{\mathtt{G}} \ (x, y) = 1$ if $y \leq x$ or x otherwise" and "$\&_{\mathtt{G}}(x, y) = min(x, y)$"):

$$\begin{array}{lllll} \mathcal{R}_1: & p(X) & \leftarrow_{\mathtt{P}} \quad q(X,Y) \ \&_{\mathtt{G}}\ r(Y) & with & 0.8 \\ \mathcal{R}_2: & q(a,Y) & & with & 0.9 \\ \mathcal{R}_3: & r(b) & & with & 0.7 \end{array}$$

[1]As said before, this fuzzy language uses a syntax near to PROLOG and enjoys high level of flexibility, for which we give some theoretical/practical reinforcements in our precedent works [22], [23], [24], [25].

In order to describe the procedural semantics of the multi–adjoint logic language, in the following we denote by $\mathcal{C}[A]$ a formula where A is a sub-expression (usually an atom) which occurs in the –possibly empty– one hole context $\mathcal{C}[]$ whereas $\mathcal{C}[A/A']$ means the replacement of A by A' in context $\mathcal{C}[]$, and $mgu(E)$ is the *most general unifier* of an equation set E. The pair $\langle \mathcal{Q}; \sigma \rangle$ composed by a goal and a substitution is called a *state*. So, given a program $\mathcal{P}$, an *admissible computation* is formalized as a state transition system, whose transition relation $\overset{\text{AS}}{\rightsquigarrow}$ is the smallest relation satisfying the following *admissible rules*:

1) $\langle \mathcal{Q}[A]; \sigma \rangle \overset{\text{AS}}{\rightsquigarrow} \langle (\mathcal{Q}[A/v \&_i \mathcal{B}])\theta; \sigma\theta \rangle$ if A is the selected atom in goal $\mathcal{Q}$, $[A' \leftarrow_i \mathcal{B}\ with\ v] \in \mathcal{P}$, where $\mathcal{B}$ is not empty, and $\theta = mgu(\{A' = A\})$.

2) $\langle \mathcal{Q}[A]; \sigma \rangle \overset{\text{AS}}{\rightsquigarrow} \langle (\mathcal{Q}[A/v])\theta; \sigma\theta \rangle$ if $[A'\ with\ v] \in \mathcal{P}$ and $\theta = mgu(\{A' = A\})$.

The following derivation illustrates our definition (note that the exact program rule used -after being renamed- in the corresponding step is annotated as a super–index of the $\overset{\text{AS}}{\rightsquigarrow}$ symbol, whereas exploited atoms appear underlined and id represents the empty substitution):

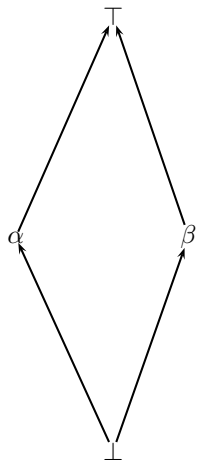
$$\begin{array}{ll} \langle \underline{p(X)}; id \rangle & \overset{\text{AS}}{\rightsquigarrow}{}^{\mathcal{R}_1} \\ \langle 0.8 \ \&_{\mathtt{P}}\ (\underline{q(X_1, Y_1)} \ \&_{\mathtt{G}}\ r(Y_1)); \{X/X_1\} \rangle & \overset{\text{AS}}{\rightsquigarrow}{}^{\mathcal{R}_2} \\ \langle 0.8 \ \&_{\mathtt{P}}\ (0.9 \ \&_{\mathtt{G}}\ \underline{r(Y_2)}); \{X/a, X_1/a, Y_1/Y_2\} \rangle & \overset{\text{AS}}{\rightsquigarrow}{}^{\mathcal{R}_3} \\ \langle 0.8 \ \&_{\mathtt{P}}\ (0.9 \ \&_{\mathtt{G}}\ \overline{0.7}); \{X/a, X_1/a, Y_1/b, Y_2/b\} \rangle & \end{array}$$

The final formula without atoms can be directly interpreted in lattice $\mathcal{L}$ to obtain the desired *fuzzy computed answer* (or *f.c.a.*, in brief), where the substitution only contains bindings associated to variables of the initial goal. So, since $0.8 \ \&_{\mathtt{P}}\ (0.9 \ \&_{\mathtt{G}}\ 0.7) = 0.8 * \min(0.9, 0.7) = 0.56$, in our case the fuzzy computed answer is $\langle 0.56, \{X/a\} \rangle$ indicating that goal $p(X)$ is true at 56 % when X is a.

B. $\mathcal{FLOPER}$

As detailed in [28], [26], our parser has been implemented by using the classical DCG's (*Definite Clause Grammars*) resource of the PROLOG language, since it is a convenient notation for expressing grammar rules. Once the application is loaded inside a PROLOG interpreter (such as Sicstus or SWI), it shows a menu which includes options for loading/compiling, parsing, listing and saving fuzzy programs, as well as for executing/debugging goals and managing multi-adjoint lattices.

All these actions are based in the compilation of the fuzzy code into standard PROLOG code. The key point is to extend each atom with an extra argument, called *truth variable* of the form "`_TV`$_i$", which is intended to contain the truth degree obtained after the subsequent evaluation of the atom. For instance, the first rule in our target program is translated into



```
member(bottom).   member(alpha).
member(beta).     member(top).

bot(bottom).      top(top).

leq(bottom,X).     leq(alpha,alpha).
leq(alpha,top).   leq(beta,beta).
leq(beta,top).    leq(X,top).

and_godel(X,Y,Z) :- pri_inf(X,Y,Z).

pri_inf(bottom,X,bottom) :- !.
pri_inf(alpha,X,alpha) :- leq(alpha,X),!.
pri_inf(beta,X,beta) :- leq(beta,X),!.
pri_inf(top,X,X) :- !.
pri_inf(X,Y,bottom).
```

Figure 1. A finite, partially ordered multi-adjoint lattice modeled in PROLOG

$$\texttt{sse}(c,d) \qquad\qquad \texttt{with}\ \ \Re(c,d)$$
$$\texttt{sse}(c(x_1,..,x_n),d(y_1,..,y_n)) \leftarrow_G \texttt{sse}(x_1,y_1)\ \&_G \ldots \&_G\ \texttt{sse}(x_n,y_n) \qquad \texttt{with}\ \ \Re(c,d)$$

Figure 2. MALP Rules defining "Similarity-based Strict Equality"

the clause:

```
p(X,_TV0) :- q(X,Y,_TV1), r(Y,_TV2),
             and_godel(_TV1,_TV2,_TV3),
             and_prod(0.8,_TV3, _TV0).
```

Moreover, the remaining rules in our fuzzy program, becomes the pure PROLOG facts "`q(a,Y,0.9)`" and "`r(b,0.7)`", whereas the corresponding lattice is expressed by these clauses (the meaning of the mandatory predicates `member`, `top`, `bot` and `leq` is obvious):

```
member(X) :- number(X),0=<X,X=<1.
bot(0).                    top(1).
leq(X,Y) :- X=<Y.
and_godel(X,Y,Z):- pri_min(X,Y,Z).
pri_min(X,Y,Z) :- (X=<Y,Z=X;X>Y,Z=Y).
and_prod(X,Y,Z) :- pri_prod(X,Y,Z).
pri_prod(X,Y,Z) :- Z is X * Y
```

Finally, a fuzzy goal like "`p(X)`", is obviously translated into the pure PROLOG goal: "`p(X, Truth_degree)`" (note that the last truth degree variable is not anonymous now) for which, after choosing option "`run`", the PROLOG interpreter returns the desired fuzzy computed answer $[\texttt{Truth\_degree} = 0.56, \texttt{X} = \texttt{a}]$. Note that all internal computations (including compiling and executing) are pure PROLOG derivations, whereas inputs (fuzzy programs and goals) and outputs (fuzzy computed answers) have always a fuzzy taste, thus producing the illusion on the final user of being working with a purely fuzzy logic programming tool.

Moreover, it is also possible to select into the menu of $\mathcal{FLOPER}$, options "`tree`" and "`depth`", which are useful for tracing execution trees and fixing the maximum length allowed for their branches (initially 3), respectively. To finish this block, in Figure 1 we show the PROLOG clauses modeling a lattice which will be used afterwards in Section IV. Here, apart for dealing with a partially ordered lattice, we use the conjunction of the *Gödel* logic described in this non numeric case as: $\&_{\texttt{G}}(x,y) \triangleq inf(x,y)$. From `http://dectau.uclm.es/floper/` it is possible can download our last version of the $\mathcal{FLOPER}$ tool, which incorporates a graphical interface as shown in Figures 3 and 4.

C. SSE, MALP *and* $\mathcal{FLOPER}$

Now, we are ready to illustrate and prove the properties of our MALP-based model of SSE which is defined according to [20] in Figure 2, where we assume that both c and d are constants (i.e., constructor symbols with arity 0) in the first rule, or both are functions with the same arity n in the second rule and then, $\Re(c,d)$ represents the similarity degree between such pair of symbols with the same arity. In order to illustrate our technique, assume that we plan to compare data terms built with constants "mary" and "maria", which have a similarity degree of 80% and function symbols (with arity one) "brother" and "sibling" which are similar at 90%. According to our

MALP-based definition of SSE we generate a set of MALP rules using the "min" operator (based on *Gödel logic*, as usual in LIKELOG and BOUSI~PROLOG) to propagate similarity degrees. Instead, in the following MALP program loaded into $\mathcal{FLOPER}$ we have used a version inspired on "product logic' (in the following section we describe an application which allows to select the desired conjunction operator or t-norm for composing similarity degrees):

```
sse(maria,maria)                    with 1.
sse(mary,mary)                      with 1.
sse(mary,maria)                     with 0.8.
sse(maria,mary)                     with 0.8.
sse(sibling(X),sibling(Y)) <prod
                        sse(X,Y) with 1.
sse(brother(X),brother(Y)) <prod
                        sse(X,Y) with 1.
sse(sibling(X),brother(Y)) <prod
                        sse(X,Y) with 0.9.
sse(brother(X),sibling(Y)) <prod
                        sse(X,Y) with 0.9.
```

Now, for a goal like "`sse(brother(mary), sibling(maria))`", our technique tests that both parameters are similar terms (with degree $0.9 * 0.8 = 0.72$) in the same way than LIKELOG and BOUSI~PROLOG. Anyway, these last languages only would report just one solution for goals "`sse(brother(mary),X)`" and "`sse(X,Y)`" (the answers computed by LIKELOG and BOUSI~PROLOG for those queries would include the bindings "`{X/ brother(mary)}`" and "`{ X/ Y }`", respectively, both ones with similarity degree 1), whereas our system is able to provide the corresponding four answer for the first query shown in Figure 3, as well as infinite solutions for the second goal (some of them displayed in Figure 4), including the following ones:

```
[Truth_degree=1,X=mary,Y=mary]
[Truth_degree=0.8,X=mary,Y=maria]
[Truth_degree=0.9, X=brother(maria),
                   Y=sibling(maria)]
[Truth_degree=0.72,X=brother(mary),
                   Y=sibling(maria)]
```

In order to formally prove the properties we have just illustrated, it is mandatory to introduce the following auxiliary definition:

Definition 3.1 (Similar terms): Let t and t' be two ground terms, $\Re$ a similarity relation and $\mathcal{L} = \langle L, \preceq, \leftarrow, \& \rangle$ a multi-adjoint lattice. We say that t and t' are similar terms according $\Re$ and $\&$ with similarity degree $s \in L$, if the evaluation of function $\Phi(t, t')$ returns $s \neq \bot$, where function Φ is recursively defined as follows:

$$\Phi(t,t') = \begin{cases} \Re(t,t'), & \text{if } t \text{ and } t' \text{ are constants} \\ \Re(c,c')\&\Phi(t_1,t'_1)\& \ldots \&\Phi(t_n,t'_n) & \text{if } t = c(t_1,\ldots,t_n) \text{ and } t' = c'(t'_1,\ldots,t'_n) \end{cases}$$

The following result reveals the ability of our technique for testing similar terms.

Theorem 3.2: Let t and t' be two ground terms, $\mathcal{L} = \langle L, \preceq, \leftarrow, \& \rangle$ a multi-adjoint lattice, $\Re$ a similarity relation and $\mathcal{P}^{\Re}_{sse}$ the set of MALP rules defining predicate sse w.r.t. $\Re$. Then, t and t' are similar terms according $\Re$ and $\&$ with similarity degree $s \in L$, iff $\langle s, id \rangle$ is a fuzzy computed answer for goal $sse(t, t')$ in $\mathcal{P}^{\Re}_{sse}$.

Proof: We prove this claim by structural induction on the shape of t and t'.

• Base case. We assume here that t and t' are similar constants, and then, $\Re(t, t') = s \neq \bot$ whereas rule $[\mathcal{R} : sse(t, t')\ with\ s]$ belongs to $\mathcal{P}^{\Re}_{sse}$. Then, it is easy to see that $\Phi(t, t') = \Re(t, t') = s$ as well as to perform with rule $\mathcal{R}$ the following admissible step $\langle sse(t, t'), id \rangle \overset{\text{AS}}{\rightsquigarrow}^{\mathcal{R}} \langle s, id \rangle$.

• Induction step. Now we have that $t = c(t_1, \ldots, t_n)$ and $t' = c'(t'_1, \ldots, t'_n)$. Assuming that $\Re(c, c') = s_0 \neq \bot$ and $\Phi(t_i, t'_i) = s_i \neq \bot$, $1 \leq i \leq n$, then $\Phi(t, t') = s_0 \& s_1 \& \ldots \& s_n \neq \bot$. Moreover, since our technique generates the rule (which belongs to $\mathcal{P}^{\Re}_{sse}$):

$$\mathcal{R} : sse(c(x_1,\ldots,x_n), c(x'_1,\ldots,x'_n)) \leftarrow sse(x_1,x'_1)\& \ldots \& sse(x_n,x'_n)\ \ with\ s_0$$

and by the inductive hypothesis we can assume that $\langle s_i, id \rangle$ is a fuzzy computed answer for goal $sse(t_i, t'_i)$, $1 \leq i \leq n$, then it is possible to generate the following sequence of admissible steps (for readability reasons, we omit in the substitution component of each state the bindings associated to variables not belonging to the initial goal):

$$\begin{array}{ll} \langle sse(c(t_1,\ldots,t_n), c'(t'_1,\ldots,t'_n)); id \rangle & \overset{\text{AS}}{\rightsquigarrow}^{\mathcal{R}} \\ \langle s_0 \ \&\ sse(t_1,t'_1)\ \& \ldots \&\ sse(t_n,t'_n); id \rangle & \overset{\text{AS}}{\rightsquigarrow} \ldots \overset{\text{AS}}{\rightsquigarrow} \\ \langle s_0 \ \&\ s_1\ \& \ldots \&\ sse(t_n,t'_n); id \rangle & \overset{\text{AS}}{\rightsquigarrow} \ldots \overset{\text{AS}}{\rightsquigarrow} \\ \langle s_0 \ \&\ s_1\ \& \ldots \&\ s_n; id \rangle & \end{array}$$

which concludes our proof. ■

Next theorem reinforces the previous one by establishing the capability of our technique for generating (not only for testing) pairs of similar ground terms.

Theorem 3.3: Let t and t' be two ground terms, x a variable, $\mathcal{L} = \langle L, \preceq, \leftarrow, \& \rangle$ a multi-adjoint lattice, $\Re$ a similarity relation and $\mathcal{P}^{\Re}_{sse}$ the set of MALP rules defining predicate sse w.r.t. $\Re$. Then, t and t' are similar terms according $\Re$ and $\&$ with similarity degree $s \in L$, iff $\langle s, \{x/t'\} \rangle$ is a fuzzy computed answer for goal $sse(t, x)$ in $\mathcal{P}^{\Re}_{sse}$.

Proof: Our proof is based again on structural induction on the shape of t, and it clearly resembles the one built for Theorem 3.2 but pointing out now the effects on the variables of the original goal.

• Base case. We assume here that t and t' are similar constants, and then, $\Re(t, t') = s \neq \bot$ whereas rule $[\mathcal{R} : sse(t, t')\ with\ s]$ belongs to $\mathcal{P}^{\Re}_{sse}$. Then, obviously $\phi(t, t') = \Re(t, t') = s$ whereas it is possible too to perform with rule $\mathcal{R}$ the following admissible step $\langle sse(t, x), id \rangle \overset{\text{AS}}{\rightsquigarrow}^{\mathcal{R}} \langle s, \{x/t'\} \rangle$.

• Induction step. Now we have that $t = c(t_1, \ldots, t_n)$ and $t' = c'(t'_1, \ldots, t'_n)$. Assuming that $\Re(c, c') = s_0 \neq \bot$

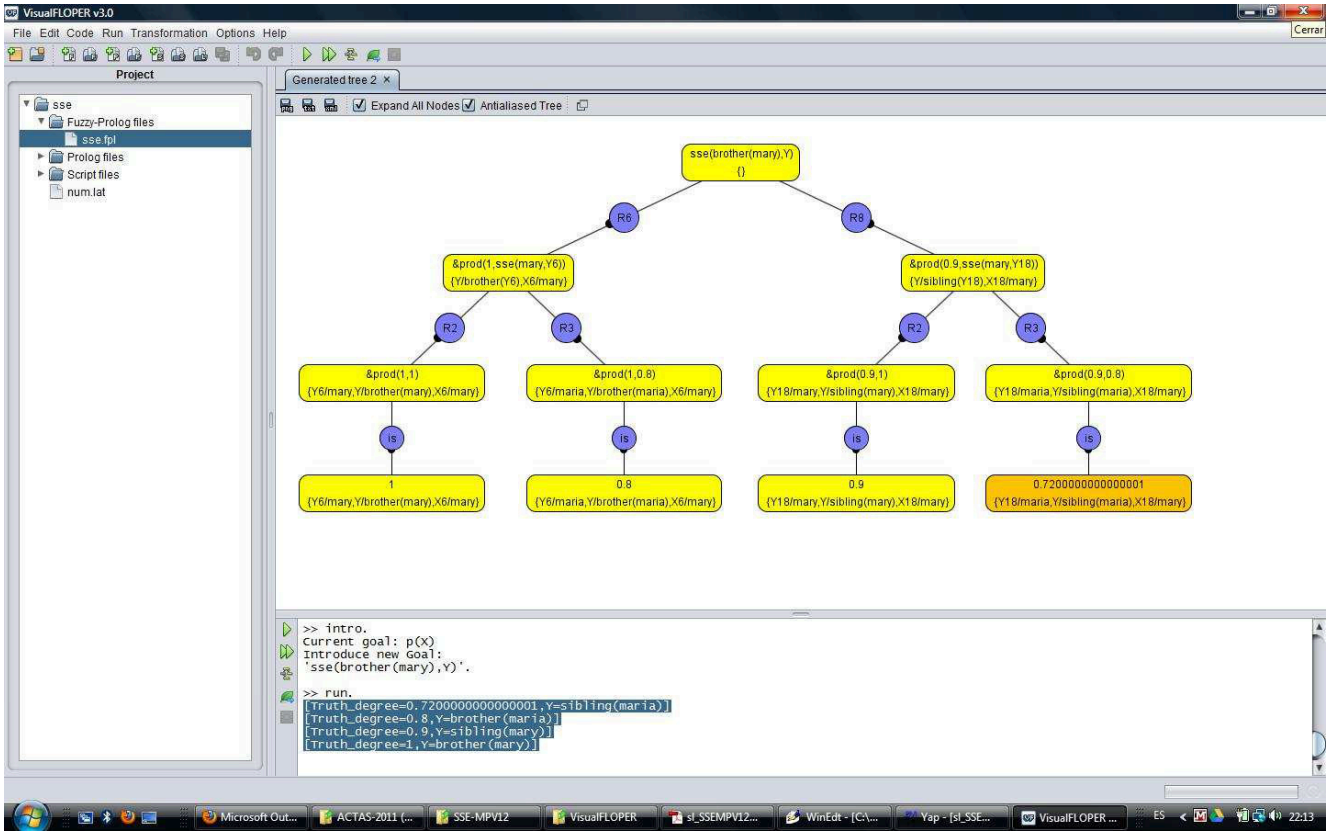


Figure 3. Screen-shot of a work session with $\mathcal{FLOPER}$

and $\Phi(t_i, t'_i) = s_i \neq \bot$, $1 \leq i \leq n$, then $\Phi(t, t') = s_0 \& s_1 \& \ldots \& s_n \neq \bot$. Moreover, since our technique generates the rule (which belongs to $\mathcal{P}^{\Re}_{sse}$):

$$\mathcal{R} : sse(c(x_1, \ldots, x_n), c(x'_1, \ldots, x'_n)) \leftarrow sse(x_1, x'_1) \& \ldots \& sse(x_n, x'_n) \quad with\ s_0$$

and by the inductive hypothesis we can assume that $\langle s_i, \{x'_i / t'_i\}\rangle$ is a fuzzy computed answer for goal $sse(t_i, x'_i)$, $1 \leq i \leq n$, then it is possible to generate the derivation shown in Figure 5 (for simplifying, we only include in the substitution component of each state those bindings which are relevant for our purposes) which concludes our proof. ■

The repeated application of the previous theorem implies the following result which, in essence, confirms the power of our method for producing all pairs of similar data terms.

Corollary 3.1: Let t and t' be two ground terms, x and x' two variables, $\mathcal{L} = \langle L, \preceq, \leftarrow, \& \rangle$ a multi-adjoint lattice, $\Re$ a similarity relation and $\mathcal{P}^{\Re}_{sse}$ the set of MALP rules defining predicate sse w.r.t. $\Re$. Then, t and t' are similar terms according $\Re$ and $\&$ with similarity degree $s \in L$, iff $\langle s, \{x/t, x'/t'\}\rangle$ is a fuzzy computed answer for goal $sse(x, x')$ in $\mathcal{P}^{\Re}_{sse}$.

IV. Implementation Issues

We start this section by firstly describing in sub-section IV-A how users can introduce into the new SSE tool (written in Prolog and freely accessible from `http://dectau.uclm.es/sse/`) a small set of similarity equations with a natural and very easy syntax. After that, the tool performs the reflexive-symmetric-transitive closure of that specification in order to obtain a similarity relation $\Re$ which is translated into a Prolog program, as explained in sub-section IV-B. Finally, the application uses $\Re$ to generate a MALP program defining SSE, as described in sub-section IV-C.

A. Syntax for Similarity Files

To specify a similarity relation, it is mandatory to load a file with extension '.sim' into the tool. This file is intended to contain a set of similarity equations, where each equation is expressed by separating two literals (the ones to be considered similar) with the '$\sim$' symbol, and adding a *truth value* to the similarity (usually, a number of the real interval [0,1], but our tool also admits an element from any multi-adjoint lattice, in contrast with other fuzzy languages such as Bousi~Prolog or Likelog) after the '=' symbol. So, for instance, `brother ~ sibling = 0.9`, is a valid similarity equation. Our syntax also allows to specify the arity of each symbol after a suffixed slash (i.e. '`brother/1`'). Thus, it is possible to discriminate between functors with the same name but different arities. When the user does not include arity information, it is simple assumed to be zero. To relate literals without arity specification (i.e., with no arity

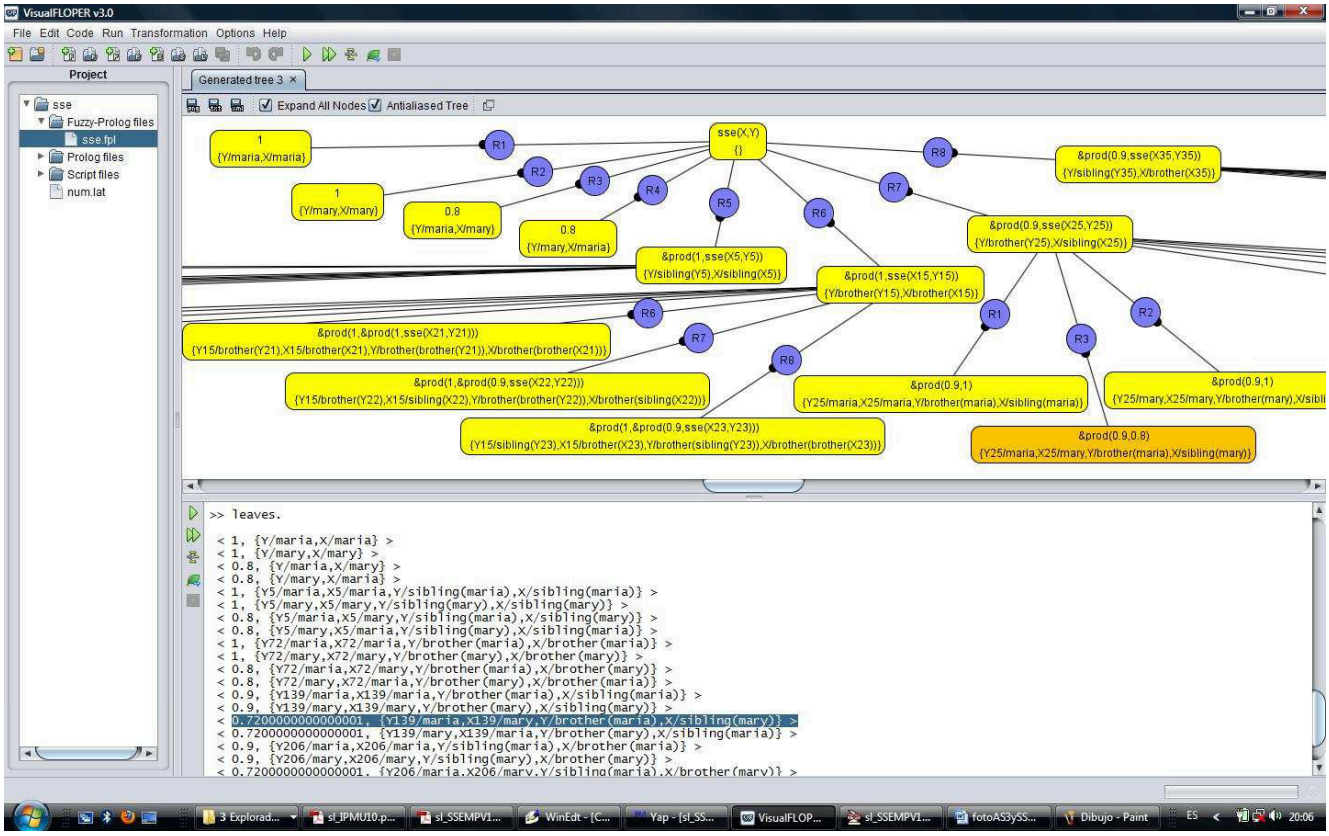

Figure 4. $\mathcal{FLOPER}$ showing three levels of an infinite evaluation tree

$$\langle sse(c(t_1,\ldots,t_n),x)); id\rangle \overset{\text{AS}}{\rightsquigarrow}^{\mathcal{R}}$$
$$\langle s_0 \;\&\; sse(t_1,x'_1) \;\&\ldots\&\; sse(t_n,x'_n); \{x/c'(x'_1,\ldots,x'_n), x_1/t_1,\ldots,x_n/t_n\}\rangle \overset{\text{AS}}{\rightsquigarrow}$$
$$\ldots \overset{\text{AS}}{\rightsquigarrow} \ldots \overset{\text{AS}}{\rightsquigarrow}$$
$$\langle s_0 \;\&\; s_1 \;\&\ldots\&\; sse(t_n,x'_n); \{x/c'(t'_1,\ldots,x'_n), x_1/t_1,\ldots,x_n/t_n, x'_1/t'_1\}\rangle \overset{\text{AS}}{\rightsquigarrow}$$
$$\ldots \overset{\text{AS}}{\rightsquigarrow} \ldots \overset{\text{AS}}{\rightsquigarrow}$$
$$\langle s_0 \;\&\; s_1 \;\&\ldots\&\; s_n); \{x/c'(t'_1,\ldots,t'_n), x_1/t_1,\ldots,x_n/t_n, x'_1/t'_1,\ldots,x'_n/t'_n\}\rangle$$

Figure 5. Proof of Theorem 3.3

discrimination), we need to write an underscore after the slash symbol (i.e., '`brother/_`').

Example 4.1: Consider now the following specification of a similarity relation:

```
mary ~ maria = 0.8.
sibling/1 ~ brother/1 = 0.9.
```

It is not necessary to add all similarity equations (for instance, the reflexive equation relating `mary` with `mary`), since the tool is able to "complete" the relation by performing the reflexive, symmetric and transitive closure of the given set of equations, as we will see in sub-section IV-B.

Note again that since our tool can work with different multi-adjoint lattices, similarity equations can be also described beyond the real interval $[0,1]$: the only required condition is that the similarity degrees of equations have to be members of the multi-adjoint lattice associated to the program or, in other words, with the lattice currently loaded into the system (see Figure IV-A).

B. Closure and Translation to PROLOG

Each similarity equation from the ".sim" file is translated into a PROLOG clause holding all its information. So, a similarity equation $\texttt{A/}n_A \sim \texttt{B/}n_B = \texttt{V}$ is coded as fact `r((A,`n_A`),(B,`n_B`),V)`, thus including the arity of each literal. The previous Example 4.1 (based on real numbers in the unit interval) should then be translated into:

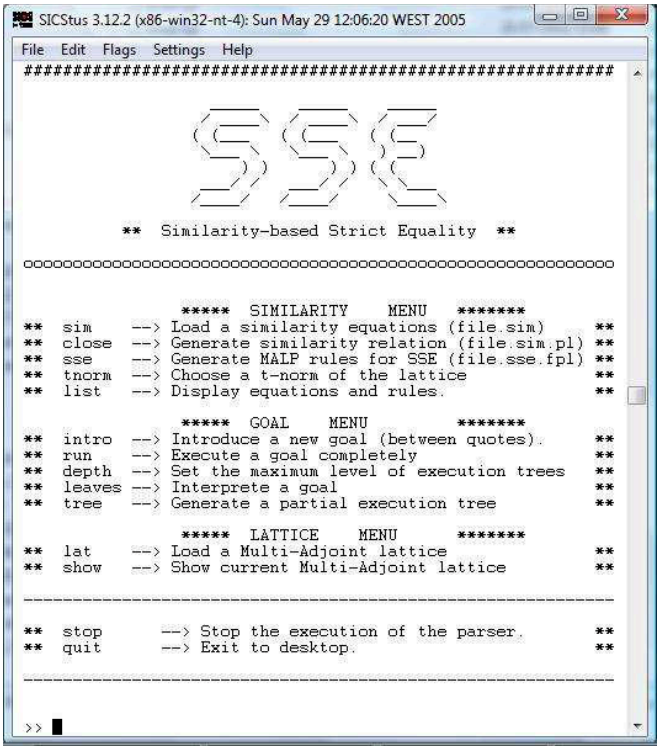

Figure 6. Main menu of the SSE application implemented with PROLOG

Algorithm 1

Require: An adjacency matrix $M = [m_{ij}]$, representing a fuzzy binary relation R on a set A, whose elements preserve transitivity and with all the elements of the superior triangular matrix set to $\bot$.

Ensure: The adjacency matrix $M^{\equiv}$ corresponding to the reflexive, symmetric, transitive closure of R.

for all $\langle i, i\rangle$ in M **do** {Build the reflexive closure}

2: $m_{ii} := \top$;

end for

4: **for all** $\langle i, j\rangle$ in M, such that $m_{ij} \neq \bot$ **do** {Build the symmetric closure}

$m_{ji} := m_{ij}$;

6: **end for**

for all column k and entry $\langle i, j\rangle$ in M **do** {Build the transitive closure}

8: $m_{ij} := m_{ij} \vee (m_{ik} \wedge m_{kj})$; where "$\vee$" and "$\wedge$" are, respectively, the supremum and infimum operators;

end for

10: $M^{\equiv} := M$

```
r((mary, 0), (maria, 0), 0.8).
r((sibling, 1), (brother, 1), 0.9).
```

All these facts are saved in their own PROLOG module "sim", in order to avoid collision of names. Also, the system saves the translated code into a file with the same name but extension "sim.pl".

Once this process has finished, the tool completes the intended similarity relation by performing the reflexive-symmetric-transitive closure according to Algorithm 1 (that we have just implemented in PROLOG) which is inspired by the one described in [29], [12], but generalizing it in order to deal with (multi-adjoint) lattices beyond the $[0, 1]$ case[2]:

As a result of performing this algorithm, the intended similarity relation is completed, and then, all similarity equations are successfully stored into module "sim" as PROLOG facts. The next step is to write these similarity equations into a file with the same name of that of the specification but extension "sim.pl", thus pointing out that the new file includes the same information, but using PROLOG syntax.

For instance, the closure of the similarity specification from Example 4.1 should return the relation of the following table, where a cell $\langle i, j\rangle$ gives the corresponding similarity degree between two symbols.

	maria	mary	brother	sibling
maria	1	0.8	0	0
mary	0.8	1	0	0
brother	0	0	1	0.9
sibling	0	0	0.9	1

This table is modeled by means of the following set of PROLOG facts resulting from the translation process previously described:

```
sim((maria,0),(maria,0),1).
sim((maria,0),(mary,0),0.8).
sim((mary,0),(maria,0),0.8).
sim((mary,0),(mary,0),1).
sim((brother,1),(brother,1),1).
sim((brother,1),(sibling,1),0.9).
sim((sibling,1),(brother,1),0.9).
sim((sibling,1),(sibling,1),1).
```

Example 4.2: For the following two similarity equations using degrees of the partially ordered lattice in Figure 1 (see again sub-section III-B), we show its corresponding table and associated PROLOG facts below (note that the 'top' element is the truth degree for all reflexive equations):

$$\mathrm{c} \sim \mathrm{d} = \mathrm{alpha}.$$
$$\mathrm{f}/2 \sim \mathrm{g}/2 = \mathrm{beta}.$$

	c	d	f	g
c	top	alpha	bot	bot
d	alpha	top	bot	bot
f	bot	bot	top	beta
g	bot	bot	beta	top

```
sim((c,0),(c,0),top).
sim((c,0),(d,0),alpha).
sim((d,0),(c,0),alpha).
sim((d,0),(d,0),top).
```

[2]Note that the algorithm can work with any particular multi-adjoint lattice: since any complete lattice (with supremum, infimum and a concrete ordering relation) is valid, then any multi-adjoint lattice is valid too.

Algorithm 2

Require: A set of similarity equations $S = \{S_i, i \in \{0,\ldots,N\}\}$ of the form $S_i = \{A/n_A \sim B/n_B = V\}$, where A and B are function symbols (possibly constants), n_A and n_B are their respective arities and V is the corresponding similarity degree.

Ensure: A set of MALP rules $R = \{R_i, i \in \{0,\ldots,N\}\}$.

for all $S_i = \{A/n_A \sim B/n_B = V\}$ in S **do**
  $body := \text{“}with\text{''} + V$;
  for all $j \in \{n_A,\ldots,1\}$ **do**
    $body := \text{“}, sse(X_j, Y_j)\text{''} + body$;
  end for
  if $n_A > 0$ **then**
    $body := \text{“} <- sse(X_1, Y_1)\text{''} + body$;
  end if
  $R_i := \text{“}sse(A(X_1,\ldots,X_{n_A}), B(Y_1,\ldots,Y_{n_B}))\text{''}$;
  $R_i := R_i + body$;
end for

```
sim((f,2),(f,2),top).
sim((f,2),(g,2),beta).
sim((g,2),(f,2),beta).
sim((g,2),(g,2),top).
```

C. *From similarities to* MALP *rules modeling* SSE

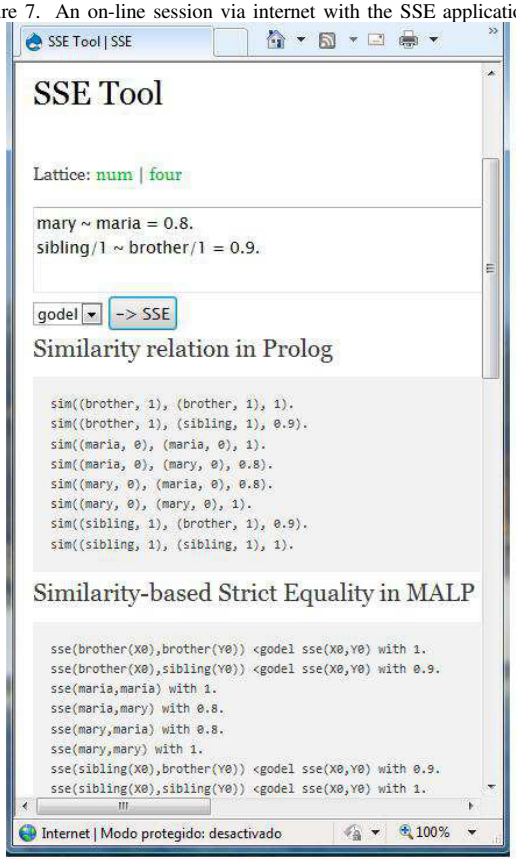
The last step consists on translating the similarity relation from its PROLOG syntax to the MALP syntax. Algorithm 2 performs such process, where the input is the set of PROLOG facts obtained after performing the closure, and the output is the intended MALP program:

Since $R = \{R_i, i \in \{0,\ldots,N\}\}$ is a set of MALP rules, it is also a valid fuzzy program, so it is located in a file with the same name of the original specification, and extension “sse.fpl”, thus implementing the notion of “Similarity-based Strict Equality SSE” as a MALP program. The resulting file can be naturally loaded into the $\mathcal{FLOPER}$ tool in order to run and debug goals, depicting evaluation trees, etc.

In order to illustrate this proccess, consider again the specification given in Example 4.1. Once we have the closure of the specification given in Section IV-A (expressed by means of PROLOG facts), the final MALP program has the following form:

```
sse(maria,maria)                    with 1.
sse(maria,mary)                     with 0.8.
sse(mary,maria)                     with 0.8.
sse(mary,mary)                      with 1.
sse(brother(X0),brother(Y0)) <- sse(X0,Y0)
                                    with 1.
sse(brother(X0),sibling(Y0)) <- sse(X0,Y0)
                                    with 0.9.
sse(sibling(X0),brother(Y0)) <- sse(X0,Y0)
                                    with 0.9.
sse(sibling(X0),sibling(Y0)) <- sse(X0,Y0)
                                    with 1.
```

Figure 7. An on-line session via internet with the SSE application



Moreover, regarding the similarity relation recasted from Example 4.2, we obtain the following set of MALP rules:

```
sse(c,c)                          with top.
sse(c,d)                          with alpha.
sse(d,c)                          with alpha.
sse(d,d)                          with top.
sse(f(X0,X1),f(Y0,Y1)) <- sse(X0,Y0) &
                          sse(X1,Y1) with top.
sse(f(X0,X1),g(Y0,Y1)) <- sse(X0,Y0) &
                          sse(X1,Y1) with beta.
sse(g(X0,X1),f(Y0,Y1)) <- sse(X0,Y0) &
                          sse(X1,Y1) with beta.
sse(g(X0,X1),g(Y0,Y1)) <- sse(X0,Y0) &
                          sse(X1,Y1) with top.
```

In addition to our desktop tool, we have developed too a comfortable on-line version of the application (so it is not necessary to download any file, but only work through the internet) which is located at the web page `dectau.uclm.es/sse`. We provide a link to download the PROLOG-based implementation of the tool but also, and more importantly, this URL enables the possibility of performing on-line work sessions, as illustrated in the screen-shot displayed in Figure 7.

V. CONCLUSIONS AND FUTURE WORK

In this paper we have recasted from [20] a static preprocess for improving the expressive power of a fuzzy declarative language in order to easily cope with similarity relations.

More exactly, we have adapted to the MALP framework our preliminary notion of SSE presented in [17], thus dealing with similarity relations by means of a simple but powerful method (somehow inspired by the -non fuzzy- functional paradigm) which surpass in some cases the effects obtained in other fuzzy languages which are not based on the simpler syntactic unification method of PROLOG. The main goal of this paper focused on proving some important formal properties of our technique for which we have shown some experimental results obtained by using our $\mathcal{FLOPER}$ platform as well as a preliminary PROLOG-based implementation of the technique (please, visit `http://dectau.uclm.es/sse/` for testing it on-line), which is nowadays being introduced inside the core of our system.

Dynamic Weighting

New method of weighting panels with large numbers of weighting parameters

Marcin Pery
Military University of Technology
Faculty of Cybernetics
Warsaw, Poland
marcin@pery.pl

Abstract - The algorithm for dynamic weighing presented in this paper is a method used in research studies based on samples when due to the large number of weighting parameters it is not possible to establish a fixed set of sample weights without non-acceptable dispersion of weights.

Keywords: weighting methods, internet audience research, dynamic weighting, machine learning, multiple classifier systems

I. Introduction

Research studies for traditional media have a solid theoretical basis and well-established research methods [1], [2] based on the construction of samples and estimating the number of subsets of the population with specific characteristics. The first step is creating samples - panels [3], [4]. The second step is using known methods of solving systems of equations with many unknowns, determining weights of every element of sample (panelist) in order to make sample "representative" for the entire population [5], [6]. The panel is considered to have better quality when the dispersion of weights is small [7], [8], [9]. The estimation of the number of individuals in the population with the desired attributes (e.g. reading a press title or watching a TV channel) is the sum of the weights of the panelists having these attributes. Internet research studies have their unique characteristics resulting from the number and the type of data, which do not have researchers of other media (e.g. through site-centric type research studies) [10]. Each user's contact with the internet service leaves a trace in servers sending content to the user. Therefore, in the case of internet research studies, we have a vast number of hard data from the measurement of a large number of websites [11]. In practice, the estimation results for the samples (constructed the same way as for the other media) turned out to be unacceptable due to significant discrepancies between the results estimated by using a panel and hard data obtained from the measurement. If the number of weighting parameters is large it is very difficult to correctly determine the weights for a sample. Systems of equations are then unsolvable, or results are unacceptable because the dispersion of weights is too large.

The dynamic weighting algorithm was created in order to estimate coherent and useful results for the whole population (e.g. for audience research studies) even when it is not possible to determine one fixed set of weights of a sample. The algorithm can be used in machine learning and multiple classifier systems where there is a need to draw conclusions on the basis of samples [12], [13], [14], [15].

The very simple example of standard task for computing weights is as follow:

Let us assume that we have a population P of 100 objects which is a set of individuals with two attributes: $\{"is\ men", "is\ woman"\}$. Each of the individuals has exactly one of these two attributes. Let us assume that there are 40 individuals who have attribute "$is\ men$" and 60 with attribute "$is\ woman$". In a sample we have 4 objects, two of which have the attribute "is men" and the other two have the attribute "is woman". To compute weights of objects in the data sample we have to compute systems of equations with many unknowns: $\begin{cases} w_1 + w_2 \approx 40 \\ w_3 + w_4 \approx 60 \end{cases}$

There are infinitely many solutions to this system of equations. We need to find such a solution where weights of objects in a sample are as similar as it is possible. The simplest solution is: $w_1 = 20, w_2 = 20, w_3 = 30, w_4 = 30$. It means that the first object in the sample represents 20 objects in the population, the third object in the sample represents 30 objects in the population, etc.

Let us assume now that there are more attributes (not only sex but also a place of living, age, etc.) and the number of equations is much bigger. There could be no possibility to compute one set of weights which are similar. In a great number of cases some weights have to be set on zero (or close to zero). It means that the sample has very poor quality and as such is of no use. In such cases there is a need to take another approach to determine weights of objects in the sample - this new approach is presented in this very paper.

II. Model

A. Population

Let us define a population of objects P as follows:

$$P = \{p_1, p_2, \ldots, p_N\} \quad (1)$$

Let us define a set of objects' attributes A as follows:

$$A = \{a_0, a_1, a_2, \ldots, a_M\} \quad (2)$$

978-83-60810-58-3/$25.00

Let us define a function which assigns subsets of attributes from set A to objects from set P :

$$a: P \to 2^A \quad (3)$$

Values of function a are known only for some objects from set P. For most of the objects from set P values of function a are unknown.

Attributes are questions about some features of objects. There are only two possible answers: "yes" or "no". If $a_j \in a(o_i)$ it means that the answer is "yes" and the object o_i has the attribute a_j.

The attribute a_0 is special and it is the question: "Does the object belong to the population?". The attribute a_0 meets the following condition:

$$\forall_{o \in P}\left(a_0 \in a(o)\right) \quad (4)$$

Attributes are organized in the *Attributes tree*.

Let us define a function $parent$ which assigns to attribute a_i direct parent node in the *Attributes tree*:

$$parent: A \to A \quad (5)$$

Let us define a function $children$ which assigns a set of direct children nodes in the *Attributes tree* to attribute a_i :

$$children: A \to 2^A \quad (6)$$

Attributes tree meets the following conditions:

- The attribute a_0 is a root of the *Attributes tree*.
- For every pair of p_i and a_j object p_i has no more than one attribute which is the direct child of a_j:

$$\forall_{\mathrm{p_i \in P}} \forall_{\mathrm{a_j \in A}} \overline{\left(\mathrm{a(p_i) \cap children(a_j)}\right)} \leq 1 \quad (7)$$

If object p_i has attribute a_j then object p_i has attribute which is a direct parent of a_j (it does not apply to $\mathrm{a_0}$ as a root of the *Attributes tree*):

$$\forall_{\mathrm{p_i \in P}} \forall_{\mathrm{a_j \in A \setminus \{a_0\}}} \left(\mathrm{a_j \in a(p_i) \Rightarrow parent(a_j) \in a(p_i)}\right) \quad (8)$$

There is non-empty subset of attributes $A^{universe} \subset A$, $\mathrm{A} \neq \emptyset$ that contains only such attributes that we know how many objects from set P have them. Let us define a function $universe$ which assigns number of objects which have the following attribute to the attribute a_i :

$$univers: A^{universe} \to \langle 0, N \rangle \quad (9)$$

$A^{universe}$ meets the following conditions:

$$a_0 \in A^{universe} \quad (10)$$

$$\mathrm{universe(a_0) = N} \quad (11)$$

Let us define a function p which assigns subsets of objects from set P to attributes from set A:

$$p: A \to 2^P \quad (12)$$

$$\forall_{a_j \in A} \forall_{p_i \in p(a_j)} \left(a_j \in a(p_i)\right) \wedge \forall_{p_i \in P} \forall_{a_j \in a(p_i)} \left(p_i \in p(a_j)\right) \quad (13)$$

B. Sample

There is a non-empty subset $S \subset P$ (called *Sample*) that contains only such objects that we know values of function a for these objects. Let us define such a subset as follows:

$$S = \{s_1, s_2, \ldots, s_n\}, S \neq \emptyset \quad (14)$$

Let us define a function w (called *Weighing function*) which assigns the size of part of population which these objects "represent" (called *Weight*) to objects from set S:

$$\mathrm{w: S \to \langle 1, N \rangle} \quad (15)$$

Weighting function meets the following conditions:

- The sum of *Weights* of every element from set S is N:

$$\sum_{i=1}^{n} w(s_i) = N \quad (16)$$

- The sum of Weights of objects which have some attributes must be equal to values of function $universe$ for this attributes:

$$\forall_{a_j \in A^{universe}} \left(\sum_{s_i \in s(a_j)} w(s_i) = universe\left(a_j\right)\right) \quad (17)$$

Let us define *dispersion* e as a quality measure of *Weighting function* for *Sample*:

$$e = \frac{\sum_{i=1}^{n} \left(w(s_i) - \frac{N}{n}\right)^2}{n} \quad (18)$$

If e is big, the quality of sample data is bad and *Sample* cannot be used as a reliable source of information for the whole population P.

C. Task

Let us define *Question* as a subset $\mathrm{Q \subseteq A}$:

$$Q = \{q_1, q_2, \ldots, q_m\} \quad (19)$$

Having given:

- *Question* Q,
- Attributtes tree,
- function a,

- function p,
- *Sample* S,
- function $universe$,
- *Weighting function* w

find number R which is a size of a subset of objects from set P which have at least one attribute from set Q.

D. The trivial solution

If the model satisfies all the above assumptions, including the assumption (17), the number R is computing as follows:

$$R = \sum_{s_i \in \left(\cup_{j=1}^{m} p(q_j) \cap S\right)} w(s_i) \tag{20}$$

III. PROBLEM

If the number of attributes in set $A^{universe}$ is as big that it is almost impossible to satisfy all the above assumptions, including the assumption (17) with acceptable level of *dispersion* e. The set of equations needed to solve this case has no solution or final *Weights* are so different that it is not possible to draw conclusions on the basis of *Sample*.

To be able to compute any reliable results, the assumption (17) is satisfied only for some subset $\mathrm{A^{universe'}} \subset \mathrm{A^{universe}}$. In the internet research studies number of attributes in set $A^{universe'}$ is even tens of times greater than size of $A^{universe}$. Because of that, there is a need to use a different method of constructing *Weighting function* and computing number R than the trivial solution presented above.

IV. DYNAMIC WEIGHTING

A. Assumptions

The basic property of the algorithm is that the *Weights* are calculated based on the questions Q. Depending on what attributes belong to Q, the *Weighting function* will assign different values to objects from *Sample*. Dynamic *Weighting function* meets the following conditions:

1. Monotonicity:

$$\forall_{a_j \in A} R(Q,\ldots) \leq R\left(Q \cup \{a_j\},\ldots\right) \tag{21}$$

2. Additivity:

$$\forall_{a_j \in A} R(Q,\ldots) = R\left(Q \setminus \{a_j\} \cup children(a_j),\ldots\right) \tag{22}$$

3. Completeness:

$$\forall_{a_j \in A^{universe'}} \left(\sum_{s_i \in s(a_j)} w(s_i) = universe\left(a_j\right)\right) \tag{23}$$

B. Algorithm

Input: *Question* Q, *Attributes tree*, function a, function p, *Sample* S, function $universe$.

Task: determine the *Weighting function* w'.

The algorithm is an iterative algorithm providing the ultimate form of the function w' in the steps going from the bottom of the *Attributes tree* to its root.

Step 1. Calculate initial value of the *Weights* w' using classical methods based on the completeness condition (23).

Step 2. If set Q is empty it ends the algorithm.

Step 3. Determine the attribute a^{parent} from set A which is the parent of all the attributes from set Q with the longest path from the root. If Q contains only one element q_j, then $a^{parent} = q_j$.

Step 4. Create the set Q' including:

- all elements from Q ,
- attribute a^{parent},
- all children of attribute a^{parent} which are parents of any attribute from set Q .

Step 5. Each attribute q_j from a set Q' assigns a temporary *Weighting function* w', as follows:

- if $q_j \in A^{universe'}$:

$$\forall_{p_i \in p(q_j)} w'_j(p_i) = w'(p_i) * \frac{universe(q_j)}{\sum_{p_k \in p(q_j)} w'(p_k)} \tag{24}$$

- otherwise:

$$\forall_{p_i \in p(q_j)} w'_j(p_i) = w'(p_i) \tag{25}$$

Step 6. If the set Q' contains only one element q_j, $it\ w'$ assigns to w'_j and it stops the algorithm.

Step 7. Determine from a set Q' such attribute q' for which the distance from the root is the largest (in the case where there is more than one attribute of the longest path, select any of them by any means).

Step 8. Determine the attribute $\mathrm{a'}$ which is the direct parent of q':

$$\mathrm{a'} = \mathrm{parent(q')} \tag{26}$$

Step 9. Modify the temporary *Weighting function* w' for the attribute $\mathrm{a'}$ as follows:

a. create subsets $s'_{positive}$ i $s'_{negative}$ of *Sample* S as follows:

$$s'_{positive} = \cup_{a_j \in children(a') \cap Q'} p(a_j) \tag{27}$$

$$s'_{negative} = \left(\cup_{a_j \in children(a')} p(a_j)\right) \setminus s'_{positive} \tag{28}$$

b. create temporary *Weighting function* w'' as follows:

$$\forall_{p_i \in s'_{positive}} w''(p_i) = max_{\,a_j \in children(a')\cap Q'}\left(w'_j(p_i)\right) \quad (29)$$

$$\forall_{p_i \in s'_{negative}} w''(p_i) = min_{\,a_j \in children(a')\setminus Q'}\left(w'_j(p_i)\right) \quad (30)$$

c. Normalize the *Weighting function* w'' in the way that the sum of *Weights* w'' is $universe(a')$:

$$\forall_{p_i \in S}\, w''(p_i)^{new} = w''(p_i)^{old} * \frac{universe(a')}{\sum_{p_i \in S} w''(p_i)^{old}} \quad (31)$$

d. modify the temporary *Weighting function* w' for the attribute a' as follows:

$$corr = \frac{\sum_{p_i \in s'_{positive}} w''(p_i)}{\sum_{p_i \in s'_{positive}} w''(p_i) + \sum_{p_i \in s'_{negative}} w''(p_i)} \quad (32)$$

$$\forall_{p_i \in S}\, w'(p_i)^{new} = w''(p_i) + corr * (w'(p_i)^{old} - w''(p_i)) \quad (33)$$

Step 10. Delete from set Q' all children of node a' :

$$Q'^{new} = Q'^{old} \setminus children(a') \quad (34)$$

and back to step 6.

C. Solution

Having determined Weighting function w′for a given *Question* Q it is possible to answer the *Question* Q using analogous calculation as in the case of the classical selection of weights:

$$R = \sum_{s_i \in \left(\bigcup_{j=1}^{m} p(q_j) \cap s\right)} w'(s_i) \quad (35)$$

D. Known features of the algorithm

Where: *Sample* S is selected from the population P using the random function with known distribution, we know the size of the entire population N and the sample size M and the weight of the sample are selected by the classical method satisfying the assumption (17), we are able to calculate statistical errors of estimates of the function R. In the case of Dynamic weighting calculating statistical errors it is difficult due to the complexity and nonlinearity of the algorithm for determining *Weighting function* w'.

Due to the condition of monotonicity (21) the algorithm tends to overestimate the weights of objects that have more than one attribute and whose weights differ in the temporary weights significantly. The better the quality of the *Sample*, the less noticeable the phenomenon is.

E. Example

Input:

Size of population is:

$$\mathrm{N} = 1000 \quad (36)$$

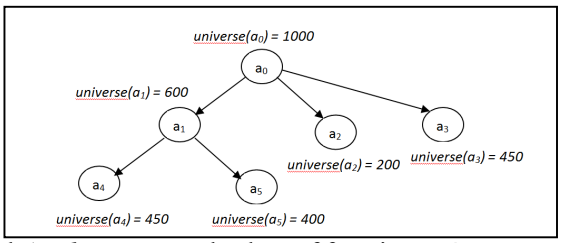
Set of attributes is:

$$\mathrm{A} = \{\mathrm{a}_0, \mathrm{a}_1, \mathrm{a}_2, \mathrm{a}_3, \mathrm{a}_4, \mathrm{a}_5\} \quad (37)$$

where:

$$\mathrm{A}^{\mathrm{universe}} = \{\mathrm{a}_0, \mathrm{a}_1, \mathrm{a}_2, \mathrm{a}_3, \mathrm{a}_4, \mathrm{a}_5\} \quad (38)$$

$$\mathrm{A}^{\mathrm{universe}'} = \{\mathrm{a}_0\} \quad (39)$$



and *Attributes tree* and values of function $universe$ are:

Fig. 1. Example: Atrributes tree and values of function universe

Sample is:

$$\mathrm{S} = \{\mathrm{s}_1, \mathrm{s}_2, \mathrm{s}_3, \mathrm{s}_4, \mathrm{s}_5, \mathrm{s}_6, \mathrm{s}_7, \mathrm{s}_8\} \quad (40)$$

Values of function a are described by the following table:

TABLE I. EXAMPLE: VALUES OF FUNCTION A FOR SAMPLE OBJECTS

Sample	***Attributes***					
	a_0	**a_1**	**a_2**	**a_3**	**a_4**	**a_5**
s_1	▪	▪			▪	
s_2	▪	▪			▪	
s_3	▪	▪	▪		▪	▪
s_4	▪	▪	▪			▪
s_5	▪		▪			
s_6	▪		▪	▪		
s_7	▪			▪		
s_8	▪			▪		

Question:

How many objects having the attribute a_3 or a_4 are in the population *P*?

$$\mathrm{Q} = \{\mathrm{a}_3, \mathrm{a}_4\} \quad (41)$$

Solution:

Step 1: Based on (32) initial values of the *Weights* w' were calculated as follows:

TABLE II. EXAMPLE: INITIAL VALUES OF WEIGHTS

	w'
s_1	125
s_2	125
s_3	125
s_4	125
s_5	125
s_6	125
s_7	125
s_8	125

Step 3: a^{parent} is determined as follows:

$$\mathrm{a}^{\mathrm{parent}} = \mathrm{a}_0 \tag{42}$$

Step 4: Set Q' was determined as follows:

$$\mathrm{Q}' = \{\mathrm{a}_0, \mathrm{a}_1, \mathrm{a}_3, \mathrm{a}_4, \mathrm{a}_5\} \tag{43}$$

Step 5: The temporary *Weighting function* w' was determined as follows:

TABLE III. EXAMPLE: INITIAL TEMPORARY WEIGHTS

Sample	Weights					
	w'_0	w'_1	w'_2	w'_3	w'_4	w'_5
s_1	125	150			150	
s_2	125	150			150	
s_3	125	150	50		150	200
s_4	125	150	50			200
s_5	125		50			
s_6	125		50	150		
s_7	125			150		
s_8	125			150		

Step 7: Attribute a_4 was determined as the node which has the longest path from the root in the *Attributes tree*.

Step 8: Attribute a_1 was determined as the direct parent of a_4:

$$\mathrm{parent}(\mathrm{a}_4) = \mathrm{a}_1 \tag{44}$$

Step 9: The temporary *Weights* w'_1 was modified as follows:

b.

TABLE IV. EXAMPLE: CREATING W''_1

	w''_1	w'_4	w'_5
s_1	150	150	
s_2	150	150	
s_3	150	150	100
s_4	100		100

c.

TABLE V. EXAMPLE: NORMALIZING W''_1

TABLE VI. EXAMPLE: MODIFYING W'_1

	w'^{old}_1	w'^{new}_1	w''_1
s_1	150	146	138
s_2	150	146	138
s_3	150	146	138
s_4	150	162	186

Step 10: Set Q' was modified as follows:

$$\mathrm{Q}' = \{\mathrm{a}_0, \mathrm{a}_1, \mathrm{a}_3\} \tag{45}$$

and went back to step 6.

Step 7^2: Attribute a_4 was determined as the node which has the longest path from the root in the *Attributes tree*.

Step 8^2: Attribute a_0 was determined as the direct parent of a_3:

$$parent(a_3) = a_0 \tag{46}$$

Step 9^2: The *Temporary weights* w'_0 was modified as follows:

b.

TABLE VII. EXAMPLE: CREATING W''_0

	w''_0	w'_1	w'_2	w'_3
s_1	146	146		
s_2	146	146

s_6	125	128	152
s_7	125	128	152
s_8	125	128	152

Step 10^2: Set Q' was modified as follows:

$$Q' = \{a_0\} \tag{47}$$

and went back to step 6.

Step 6: Since there is only one element in set Q' T*emporary weights* w'_0 are the final weights for *Sample*:

TABLE X. EXAMPLE: FINAL WEIGHTS FOR SAMPLE

	w'
s_1	127
s_2	127
s_3	127
s_4	117
s_5	117
s_6	128
s_7	128
s_8	128

Answer:

There are 765 objects in population P which have attributes a_3 or a_4.

$$R \cong 765 \tag{48}$$

V. CONCLUSIONS

There are cases where it is not possible to determine one constant *Weights* for *Sample* with acceptable *dispersion* e (and not only in internet research studies). In these cases Dynamic weighting algorithm may determine an individual set of *Weights* for each *Question*. The algorithm satisfies conditions (21) and (22) and (23), which makes the results reliable and useful for applied studies.

The presented algorithm is not protected against possible specific cases and possible incorrect input. Its practical implementation must take into account such cases like inconsistency of information ($e.g. universe(a_j) < \sum_{a_k \in children(a_j)} universe(a_k)$) or even contradictory information ($universe(a_j) > universe\left(parent(a_j)\right)$ at different levels of the *Attributes tree*.

The algorithm is presented in the simplest possible form. In the practice of its implementation in many places it can be optimized in terms of speed as well as memory resource consumption (e.g., through the use of temporary variables that store the temporary results) .

In order to simplify the algorithm, the questions Q are created as the sum of sets of attributes (corresponding to the logical operators OR). Practical implementations can also use the intersections (corresponding to the logical operators AND).

The assumptions of the presented algorithm are used by Gemius SA (research company) in the commercial online research studies in Poland, where the size of the population of internet users is several million people, the sample (panel of internet users) counts several thousand panelists and there are thousands of websites, internet services and web applications presented in final results of the audience research study.

In further work on the algorithm there seems to be a promising direction for estimating the statistical error of the results.

***Abstract*—The paper shows the application of election algorithms in networks of comparators. We have described and adopted six election methods which have been used as an aggregator of partial results. We have performed experiments on the data gathered at the fire ground. All of them have been well described and results have been compared. The paper includes a discussion and interpretation of results obtained. It indicates the algorithm with the greatest potential to adapt and to obtain the best results.**

***Index Terms*—Networks of comparators, election algorithms, aggregation of partial results, similarity based reasoning, compound objects, fire rescue actions**

I. Introduction

SIMILARITY [1] is one of the fundamental aspects of reasoning methods used in AI. There are many techniques used by researchers to implement resemblance in practice. We can find many kinds of neural networks [2] which resolve pattern recognition problems, fuzzy sets [3] which are able to model complicated processes, rough sets [4] to perform knowledge discovery in data and many others. All of them are well-known and explored. There are many extensions of mentioned methods developed, e.g. neural networks with compound signals [5]. All these methods are specialized in resolving one of the defined problems.

In previous researches a common approach to similarity-based reasoning was developed. The same workflow is used to resolve various problems. The basic element of the authors' concept is a dedicated logical component called comparator [6]. It is responsible for examining the resemblance of a given feature between an input object and reference objects [7]. The comparator can be formally described as a function $C_B : A \rightarrow 2^{B\times[0,1]}$, where A is a set of input objects and B is a set of reference objects. Comparator outcome takes a form of weighted subsets of reference objects $C_B(a) = F(\{(b, g(\mu(a,b)) : b \in B\})$, where F is a function responsible for filtering partial results of a single comparator, e.g. min, max, top. Furthermore, $\mu(a,b)$ is a membership function of the fuzzy relation [3], which returns a similarity degree between $a \in A$ and $b \in B$, and $g(x)$ is an activation function which filters out results that are too weak. We put

$$g(x) = \begin{cases} 0 : x < p, \\ x : x \geq p \end{cases} \tag{1}$$

where p denotes the lowest acceptable similarity. One may also introduce some constraints which make $\mu(a,b) = 0$ based on the so-called exception rules [6].

The approach is based on a network of such comparators. This concept makes it possible to design a structure-driven solution as well as a flat one. The network consists of layers. They include comparators, aggregators and translators [8].

There are two types of aggregators: local and global. The functionality of a local aggregator comes down to selecting the best results for a given layer based on partial results. The functionality of the second one is focused on the synthesis of results of individual layers in order to calculate the final result.

The translator is an unit expressing the results of the one layer by objects existing in another layer. The general scheme of the type of network in question is shown in Figure 1. Complete information of the construction and operation of a network of comparators is not the subject of this article. It has been described well in the previous publication [8].

This article attempts to explore several different global aggregation methods and compare the results obtained by means of such methods. The authors also attempt to verify the importance of selection of the best results at the final stage of processing in this kind of networks. Quality level of this selection is expressed by the value of efficiency measures.

This research was motivated by authors' previous experiments. It was noticed that the final aggregation method may have a pronounced impact on results achieved. It can improve the efficiency of the model regardless of the way of evaluating

The research was supported by the Polish National Centre for Research and Development (NCBiR) - Grant No. O ROB/0010/03/001 in the frame of Defence and Security Programmes and Projects: "Modern engineering tools for decision support for commanders of the State Fire Service of Poland during Fire&Rescue operations in the buildings

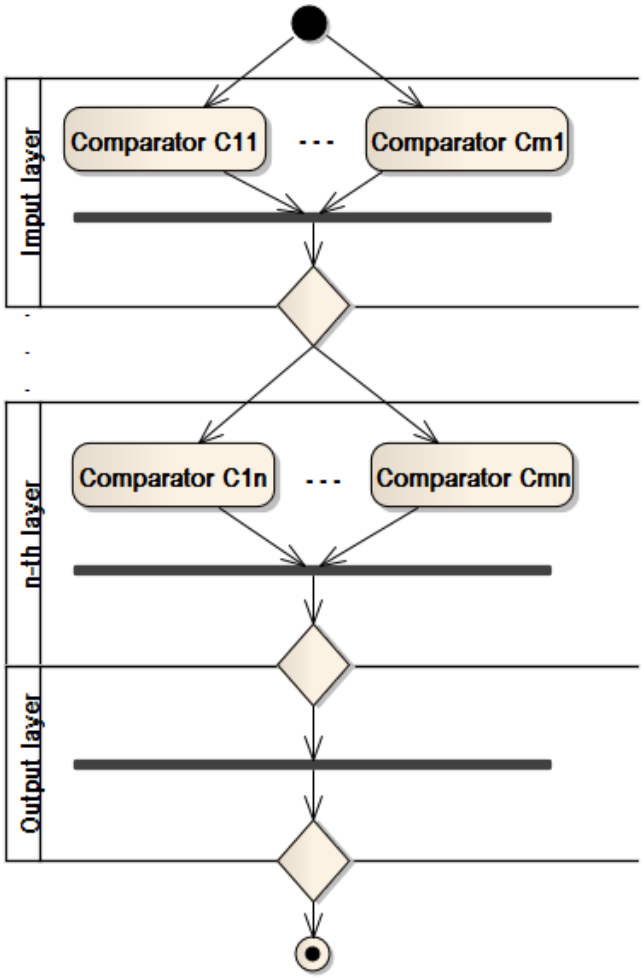

Fig. 1. General scheme of network of comparators. This is not an UML activity diagram. It only uses similar notation: oval boxes represent comparators, black horizontal lines are aggregators, the one in the output layer is a global aggregator. Diamonds between layers are translators.

similarity. Such comparison of voting algorithms has already been performed several times in the field of machine learning [9], [10]. The authors' work focuses strictly on the area of network comparators. Election algorithms were chosen as a group of methods which is well-known and described in literature. They are not the only methods which could be used, but they are easily accessible and implementable. Experiments use results obtained earlier [11] and take into account only the aspect of optimizing the process of global aggregation. This fact means that already calculated similarity results (from a previous research) are used and now attention is paid only to selecting a final set of objects. This is the main subject of this article called *global aggregation*.

The paper is organized as follows: the first section contains introductory information about context and a background of the problem presented. The second section presents the prime example used to perform the experiments, certain context required to be known to understand the results. The third section contains the description of methods used to conduct an experiment. It also contains a detailed description of elections algorithms used and their main properties. The fourth section presents data used in experiments performed and results obtained. The subsequent section discusses results and describes the best and the worst methods. It also introduces criticism of the methods used. The final part contains a brief summary.

II. Context and motivation example

The main example concerns the Fire&Rescue (F&R) actions and emerging risks during the rescue activity. Threats defined in the risk matrix [12] and objects that have vulnerabilities to these threats are taken into account. This matrix is used by fire brigades in certain countries to determine the prevalence of potential risks at the fire ground based on information collected (observation, interview, etc.).

TABLE I
Risk matrix used for evaluating the quality of fit between resembled actions. LEGEND: A1 - fear, A2 - toxic smoke, A3 - radiation, A4 - fire spreading, C - chemical substances, E1 - collapse, E2 - electricity, E3 - disease or injury, E4 - explosion

Risk/object	A1	A2	A3	A4	C	E1	E2	E3	E4
People (ME)									
Animals (T)									
Environment (U)	-								
Property (S)	-	-				-	-	-	
Rescuers (MA)								-	
Equipment (G)	-	-						-	

The previous research concerned the automation of acquiring potential risks using text descriptions and repository of historical F&R actions. The solution is based on the similarity of actions and assumption that the most resembled ones have a similar list of risks occurring. The resemblance takes into account domain knowledge acquired from experts and injected in a form of measures. In order to perform such reasoning a model of F&R action represented by a set of attributes is necessary. Data from the EWID[1] system are used to create it as well as domain knowledge from experts (e.g. division of F&R action into phases).

On this basis, the following division into stages can be distinguished: notification, disposal, recognition and activities. It is quite a rare division due to the limited number of available attributes.

Notification refers to the act of transfer of information about threat. This phase collects attributes related to time, place and approximate description of event. It contains basic information necessary to make a decision about what forces and resources should be disposed.

Disposals contain quantitative data of already disposed forces and resources. There is information on the number of rescuers, cars and equipment used for the event in question. In addition, there is a number of units of other services (medical, police, etc.) that took part in the F&R action.

[1]Polish Incident Data Reporting System used by Polish State Fire Service

Recognition is the stage at which rescuers carry out inspection, search and identification of the situation at the scene after arrival at the place of event. There are attributes describing dimensions of the place of event, building, size of event and also information about the existence of internal hydrants, smoke detectors, etc.

Actions form the actual start of firefighting operations. After collecting the required information at previous stages, firefighters start activities related to the neutralization of threats. They prepare an action strategy, assign tasks for rescuers and decide whether to use the specialized equipment.

These four stages are not independent. They are ordered in a sequence. If the notification materialized the disposal cannot be realized.

The solution mentioned earlier designates subsets of the most similar actions from the perspective of individual parts. The similarity ranking of each part may comprise a different list of preferred objects in order of significance. At this point s method has to be implemented, consisting in the combination of partial results into one coherent answer of the system which is a final result in form of subset of F&R objects with assigned risk labels.

This method is a decision problem of selecting the object that best meets the preferences of individual parts of F&R (based on similarity). In other words, it is analogous to the election case, where support for a candidate is expressed by voting. This analogy was the motivation for carrying out research on the application of elections algorithms to final selection of the results set (global aggregation). It was also an impulse to examining the importance of the choice of method. The authors were interested in the type of impact of the choice of election methods on final results achieved at the fire ground.

III. Methods

The global aggregation method is a part of a bigger solution mentioned in Section II. Therefore, the full path which must be passed in order to obtain the results described furtherwill be presented here.

The first step of the proposed solution is to design a network of comparators. The network is based on expert knowledge which should be part of the F&R ontology. It consists of concepts and their relations. It describes different aspects of action using evidenced concepts [13].

At the beginning division of an F&R action provided by expert is taken into account and described in Section II. The authors seek a possibility of comparing single parts and having partial results from each of them. This division consists of four parts: notification, disposal, recognition, actions. Each of them is represented by a composite comparator [14]. It means that each of them is independent sub-net. *Notification* consists of nine comparators responsible for examining different features associated with notification of fire. The complete list of these comparators is shown in Table II. The next phase is disposal. The sub-net of *disposal* consists of thirteen comparators. All these features are connected with a group of activities assigned to a disposal part. Other parts are constructed in an analogous manner. *Recognition* includes eleven comparators and *actions* consists of ten of them. Tables III, IV and V show respectively the detailed list of comparators for particular part of action. These tables also contain similarity measures applied in a particular comparator. This information is required for complete implementation.

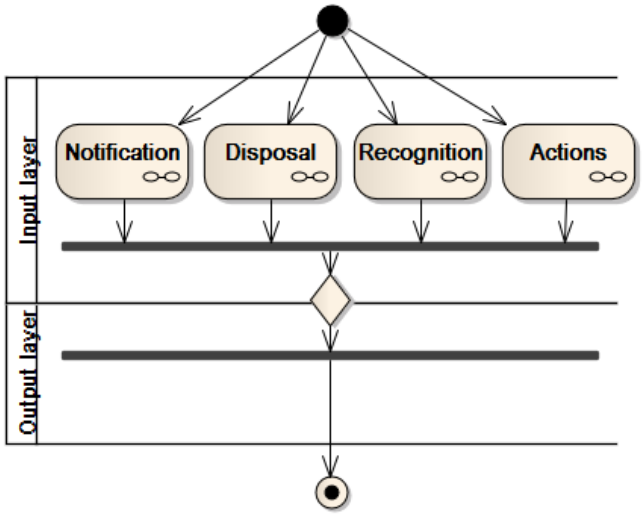

Fig. 2. The scheme of the network of comparators used for the designation of the most similar set of F&R actions. The oval boxes represent composite comparators. The translator in the output layer was skipped because there translation objects are not necessary in this case.

A particular comparator has a function to evaluate similarity between a given pair of objects. The pairs are created in combination of the input object and the reference object (taken from the F&R repository one by one). Each pair has assigned value of similarity determined by a given comparator. The calculation for a single input object implies a number of local results sets in the form of $\{(b_i, \mu(a, b_i) : b_i \in B\}$, where B is a set of reference objects.

Our solution consists of two parts. The first one is responsible for building a similarity model and computing partial results of resemblance. The second one is dedicated to optimization and aggregation of results. These two methods are classified as lazy [15] and eager types [16] respectively. The similarity model evaluates a given pair after calculating similarity for each comparator and it is a lazy one. On the other hand, aggregation of partial results requires learning certain parameters (in certain cases) or making certain decisions earlier. This part is classified as eager methods, e.g. learning weights for weighted average aggregator using genetic algorithm.

A *leave one out* [17] method is used to obtain four matrices with partial results. Each object is treated once as input objects against the remaining objects of the reference set. Such processing is performed for every single object one by one.

Our method can evaluate partial similarities and aggregate them to a higher level of resemblance and finally to a global one. The aggregator is a dedicated unit to handle such processes.

TABLE II
COMPARATORS OF FEATURES FOR NOTIFICATION PHASE

Comparator	Description	Comparison function
Time	F&R time. t_{a1}, t_{a2} - action time in compared objects, t_{e1}, t_{e2} - extinguish time in compared objects.	$\frac{t_1+t_2}{2}$, where $t_1 = \begin{cases} 1.0: & t_{d1}=0 \\ 1-\frac{t_{d1}}{\max(t_{a1},t_{a2})}: & t_{d1}\neq 0 \end{cases}$ $t_2 = \begin{cases} 1.0: & t_{d2}=0 \\ 1-\frac{t_{d2}}{\max(t_{e1},t_{e2})}: & t_{d2}\neq 0 \end{cases}$ where $t_{d1} = \lvert t_{a1} - t_{a2}\rvert$, $t_{d2} = \lvert t_{e1} - t_{e2}\rvert$.
Event place	F&R place. Places divided into a three level hierarchy. The first level is the most general.	$\mu(a,b) = \begin{cases} 1.0: & a_3 = b_3, \\ 0.8: & a_2 = b_2, a_3 \neq b_3, \\ 0.55: & a_1 = b_1, a_2 \neq b_2 \end{cases}$ where a_n, b_n, $n \in 1..3$ - level hierarchy.
Access	Access to F&R place. The Access is divided into a two level hierarchy. The first level is the most general.	$\mu(a,b) = \begin{cases} 1.0: & a_2 = b_2 \\ 0.55: & a_1 = b_1, a_2 \neq b_2 \end{cases}$ where a_n, b_n, $n \in 1..2$ - level hierarchy.
Building height	Building height for F&R place. Building heights are divided into clusters.	$\mu(a,b) = ms[C_a][C_b]$ where ms - matrix of similarity between clusters, C_a, C_b - cluster values for building height in compared objects.
Building type	Building type for F&R like a building low, a building medium, a building hight.	$\mu(a,b) = \begin{cases} 1.0: & a = b \\ 0.0: & a \neq b \end{cases}$ where a, b - building types in compared objects.
Notification channel	Notification channel about fire, e.g. by phone, by radio.	The same as above.
Entity notifier	Entity notifier about fire, e.g. an employees.	The same as above.
ZL category	Building category risk to humans.	$\mu(a,b) = ms[a][b]$ where ms - matrix of similarity, a, b - building category risk to humans.
Distance	Distance between the first units and the F&R.	$\mu(a,b) = \begin{cases} 1.0: & a = b \\ 1-\frac{\lvert a-b\rvert}{6}: & a \neq b \end{cases}$ where a, b - distance in compared objects.

TABLE III
COMPARATORS OF FEATURES FOR DISPOSAL PHASE

Comparator	Description	Comparison function
Firefighters	How many firefighters were sent to F&R.	$\mu(a,b) = \begin{cases} 1.0: & a = b \\ 1-\frac{\lvert a-b\rvert}{\max(a,b)}: & a \neq b \end{cases}$ where a, b - number of firefighters in compared objects.
Vehicles	How many vehicles were sent to F&R.	The same as above.
Firefighting cars	How many firefighting cars were sent to F&R.	The same as above.
Special cars	How many special cars were sent to F&R.	The same as above.
Additional vehicles	How many additional vehicles were sent to F&R.	The same as above.
Ambulances	How many ambulances were sent to F&R.	The same as above.
Power emergencies	How many power emergencies were sent to F&R.	The same as above.
Gas emergencies	How many gas emergencies were sent to F&R action.	The same as above.
Forest services	How many forest services were sent to F&R.	The same as above.
Police	How many police services were sent to F&R.	The same as above.
City guards	How many city guards were sent to F&R.	The same as above.
Other services	How many other services were sent to F&R.	The same as above.
Other region vehicles	How many vehicles from other regions were sent to F&R.	The same as above.

It has been noted in the research that the elections algorithms theory [18] is one of the approaches available, dealing with methods of selection of the best candidate for a group of voters. In this case, similarity results can be treated as voting results, comparators as voters and reference objects as candidates. The optimization task is to select the best candidate who will became a winner acceptable for the majority of voters.

There are a lot of known and available election algorithms. Six of them have been shosen, those which are the most popular, well-known or fulfil important criteria (e.g. majority, condorcet winner, condorcet looser, etc.) [19].

A. Plurality voting system

This is a single winner voting system. Each voter votes for one candidate only [20]. The winner is the one who receives the highest number of votes. This voting system is very easy for voters and it is easy to implement. However, it fails to provide information about preferences and support for individual candidates only for the most supported one. This is quite a popular method in real elections.

Implementation performs voting for each input object iteratively. For a given input object the candidate with the highest score is selected. The score is calculated from results of comparators. The winner for given comparator is the first candidate with the maximum similarity value. After this selection there are four votes. The global winner is the one with the highest global score. In the case of a tie, the first candidate is obtained.

TABLE IV
COMPARATORS OF FEATURES FOR RECOGNITION PHASE

Comparator	Description	Comparison function
Dust explosion	During F&R there was the dust explosion.	$\mu(a,b) = \begin{cases} 1.0: & a = b \\ 0.0: & a \neq b \end{cases}$ where a, b - the dust explosion in compared objects.
Gas explosion	During F&R there was the gas explosion.	The same as above.
Object dimensions	Object dimensions for F&R place. The object dimension was divided into clusters.	$\mu(a,b) = \begin{cases} 0,8 + (0,2 * f): & diff = 0 \\ 0,5 + (0,3 * f): & diff = 1 \\ 0: & diff > 1 \end{cases}$ where $f = (1 - \frac{\lvert a-b \rvert}{\max(a,b)})$, $diff$ - difference between clusters, a, b - dimensions in compared objects.
Event size	Event size for F&R.	$\mu(a,b) = \begin{cases} 1.0: & a = b \\ 1 - \frac{\lvert a-b \rvert}{\max(a,b)}: & a \neq b \end{cases}$ where a, b - event size of compared objects.
Without PSP	The fire was extinguished without PSP.	$\mu(a,b) = \begin{cases} 1.0: & a = b \\ 0.0: & a \neq b \end{cases}$ where a, b - fire was extinguished without PSP in compared objects.
Fire cause	Fire cause. Fire causes are divided into clusters.	$\mu(a,b) = ms[C_a][C_b]$ where ms - matrix of similarity between clusters, C_a, C_b - cluster values for fire cause in compared objects.
Internal hydrants	Status internal hydrants in a building during F&R.	$\mu(a,b) = ms[a][b]$ where ms - matrix of similarity, a, b - statuses of internal hydrants.
Smoke devices	Status smoke devices in a building during F&R.	The same as above.
Fire extinguishing	Status fire extinguishing in a building during F&R.	The same as above.
Auto transmission	Status auto transmission system in a building during F&R.	The same as above.
Fire detection	Status fire detection system in building during F&R.	The same as above.

TABLE V
COMPARATORS OF FEATURES FOR ACTIONS PHASE

Comparator	Description	Comparison function
Extinguishing on offensive	Flag indicates than during F&R extinguishing was used in offensive activities.	$\mu(a,b) = \begin{cases} 1.0: & a = b \\ 0.0: & a \neq b \end{cases}$ where a, b - extinguishing in offensive activities in compared objects.
Extinguishing in defense	Flag indicates than during F&R extinguishing was used in defensive activities.	The same as above.
Fire extinguisher	Fire extinguishers used during F&R with values.	$\mu(a,b) = \begin{cases} 1.0: & a = b \\ 1 - \frac{\lvert a-b \rvert}{\max(a,b)}: & a \neq b \end{cases}$ where a, b - number of fire extinguishers in compared objects.
Extinguishing media	Used extinguishing media during F&R.	The same as above.
Medical	Medical assistance provided during F&R.	The same as above.
Actions taken	Set of activities taken during F&R. Matrix of similarity defined by an expert.	$\mu(A,B) = \forall r \in R, r \in A, r \in B, \frac{\sum ms[a][b]}{n}$ where ms - matrix of similarity, A, B - sets of activities in compared objects, R - a reference set, n - size the reference set.
Medical actions	Set of medical activities taken during F&R.	The same as above.
Activities place	Place of activities taken during F&R.	The same as above.
Equipment used	Equipment used during F&R.	The same as above.
Water supply	Water supply methods during F&R.	The same as above.

This method has a computational complexity estimated at $O(N)$. This provides for good computational properties in terms of time and computational power consumption.

B. Borda count

This is also a single winner voting method where voters produce a ranking of candidates in order of preferences [21]. The candidate receives a number of points connected with a position in ranking. The higher position in the ranking the more points candidate gets. There are various scoring methods: promoting higher place more than the lower, linear or specific one (e.g. only first three places are scored). The winner is the candidate with the highest point result.

Implementation treats comparators as four voters. Each voter gives a ranking for all candidates. Rankings are created on the basis of similarity value for a given input object and particular candidates. Candidates are reference objects. Each candidate receives points. Linear scale is used. The candidate of the first place takes maximum number of points (in this case 406). The score function is given by the following formula:

$$score(a) = n(C) + 1 - RankPos(a), \tag{2}$$

where $n(C)$-quantity of candidates, $RankPos(a)$ - position in ranking of candidate a. After that all points from particular rankings are summed up for each candidate. The last part is selecting a candidate with a maximum number of points. In the case of a tie, the first candidate with the maximum score is obtained.

This method is characterized by a very good computational complexity estimated at $O(N)$. One of the variable parameter

is a method of allocating points. It is an important procedure because it favors higher ranking position.

C. Copeland's method

This is a condorset [19] method which returns results in form of a ranking. The score for setting a ranking position is calculated from the number of wins in pairs minus the number of defeats [22]. This is a round-robin tournament methods which is easy understandable and easy implementable in software solutions. The winner is a candidate with the highest score. Implementation performs this method for each input object independently. For a given input object it starts with creating the cartesian product of candidates (F&R objects). The winner is calculated for each pair. Every winner is computed with data from four comparators (voters). Each of them specifies which similarity value (between input object and given candidate) is bigger. The local winner gets one point, the local looser gets minus one point. In the case of a tie, both take a zero point. After resolving this problem for all comparators, points for both candidates are summed up. The winner of a single duel is the one who scores more points. This procedure is repeated for each pair of candidates to create full tournament table with score for each candidate. The global winner for the current input object is the candidate with the maximum global score calculated in a following way:

$$score(a) = wins(a) + defeats(a) \tag{3}$$

where $wins(a)$ is a number of points for wins (positive value) for candidate a, $defeats(a)$ is a number of points for defeats (negative value).

This method has a computational complexity estimated at $O(N^2)$. It does not provide any parameters to set.

D. Approval voting

This is a single winner voting method where each voter may approve or disapprove of any candidate from a ballot. It means that the voter has to specify approval or disapproval as regards each candidate. Consequently, the ballot designates the accepted set of candidates for a particular voter. The winner is the candidate who has the highest number of votes of approval [23].

This algorithm has been implemented by means of four comparators as voters and 405 reference objects as candidates. Approval voting is performed for each input object (406 times). This method has been adapted to the requirements in the following way: the approval factor is found, starting from the biggest one (1.0); then it is reduced by 0.01 in the case of failure to obtain majority in voting. Then, the approval factor is the threshold for similarity value of pair of objects. If the resemblance value is greater than or equal to the threshold, the vote is interpreted as approved or as disapproved for a candidate who is the reference object in given pair. In the case of a tie, first candidate with the highest number of *approved* votes is obtained. For each input object the winner is calculated in the same way.

This method is characterized by a very good computational complexity estimated at $O(N)$. This allows for very efficient calculation of the final results. Implementation presented could have various values of the reduction factor. It has impact on the quality of results and the speed of calculation.

E. Range voting

This is a single winner voting system. The voting is realized by rating ballots. A rate scale is specified, e.g. $[0, 1]$ or $[0, 100]$. Voters rate each candidate with own score matched with a fixed scale [24]. All candidates scores are summarized. The winner is a candidate with the highest sum of points. If certain candidates are not scored, the zero value is assigned. In general, all candidates should be rated.

Implementation takes on the form of calculating the mean value for each pair (input object and reference object). There are four comparators. Each of them provides similarity value for a given pair. The mean value is calculated from these four similarities for each pair.

This method has a computational complexity estimated at $O(N)$. It does not provide any parameters.

F. Weighted voting

This is a voting system which makes it possible to favour certain voters. In real life, one can find this kind of voting on boards of companies, where there are different shares or stocks [25]. The weight connected with a vote makes it stronger or weaker depending on the value of the weight. In this particular case, if all weights are equal, the system is identical to *range voting*.

In this case, voting is implemented in a similar way to *range voting*. This method works only if weights are given. Weights are indicated as a w_i where i is a number of comparator.

The solution has been expanded by adding the sub-optimal learning procedure determining weights for voting. A genetic algorithm [26] is used in order to find weights which give the highest evaluation score for this kind of voting. There are four weights described by the following formulas:

$$w_1 = \frac{n}{n+d+r+a} : (n+d+r+a) \neq 0 \tag{4}$$

$$w_2 = \frac{d}{n+d+r+a} : (n+d+r+a) \neq 0 \tag{5}$$

$$w_3 = \frac{r}{n+d+r+a} : (n+d+r+a) \neq 0 \tag{6}$$

$$w_4 = \frac{a}{n+d+r+a} : (n+d+r+a) \neq 0 \tag{7}$$

where n - factor responsible for *notification*, d - factor responsible for *disposal*, r - factor responsible for *recognition*, a-factor responsible for *actions*. Each of them is in the range of $[0, 63]$, but the sum cannot be zero. The chromosome in this representation contains four parts dedicated to each factor. Each of them is coded in six bits, i.e. there is a twenty four bits chromosome. As genetic operations tournament crossover with probability 0.5 and mutation with probability 0.065 is

TABLE VI
THE PERFORMANCE COMPARISON FOR THE NETWORK OF COMPARATORS (NOC) WITH DIFFERENT METHODS OF AGGREGATION

Algorithm	Precision	Recall	F1-score
NoC with Approval voting	0.73	0.68	0.65
NoC with Borda count	0.77	0.73	0.69
NoC with Copeland's method	0.77	0.73	**0.70**
NoC with Plurality voting	0.68	0.63	0.61
NoC with Range voting	0.76	0.73	0.69
NoC with Weighted voting	**0.78**	**0.74**	**0.70**

used. As fitting function the measure in the following form is implemented:

$$f(ch) = \frac{3 * RQ + sum(F1score)}{4 * ARQ} : ARQ \neq 0. \quad (8)$$

where ch is a chromosome, *RQ* is a number of identified risks, *ARQ* is a total quantity of all considered risks and *sum(F1score)* is a sum of all F1score values.

Parameters for genetic algorithm were chosen in an experimental way. Population stands at one hundred individuals. Weights have been learnt by means of a training set consisting of 136 out of 406 F&R actions (33%). The procedure was repeated ten times. Every time the population was initialized with random values. Termination condition was reached for a one hundred generation. The final weights are the ones with maximum evaluations. The evaluation function (8) took into account the number of recognized risks, as well as the overall prediction quality.

This method allows to use many different types of crossover operations, mutations and successions of a population. A number of combinations of particular parts of procedures in question may be considered.

IV. RESULTS

This research is based on data available in the EWID system. The data describe F&R after it had already finished. This is one of the disadvantages of this set of data. There is no information about the point in time when something has happened for a given F&R. The only information is whether it had happened over the duration of the whole action. The full set of data consists of 291 683 F&Rs. A subset of 406 F&Rs is used in these experiments. These actions have been labeled with risks from Table I by experts. The data consist of 506 binary, numeric, multi-value attributes and descriptive attributes. This research does not take into account the descriptive ones. This set has been divided into four subsets according to four stages of action (mentioned in the previous section). Partial results data set is obtained and it contains 164430 pairs of objects after calculating the similarity by composite comparators. The pair consists of two objects representing F&R actions. This is not a complete Cartesian product. Some pairs have been eliminated by activation functions.

Partial results were achieved by means of default parameters of the network. Activation functions parameters have the *0.5* value which limited the results to the ones with similarity value greater than or equal to that value. The aggregations method inside all composite comparators was implemented as a mean function.

The procedure of global aggregation using the Weighted Voting algorithm was performed for the following weights: $\frac{2}{70}, \frac{48}{70}, \frac{1}{70}, \frac{19}{70}$ for notification, disposals, recognition and actions comparators respectively. These values have been achieved in the learning process described above. The described partial results set is a data source for experiment in this particular paper.

The experiment consists of selecting the best reference object for each input object from leave-one-out method in such a way as to ensure the greatest similarity within each part of the F&R action (according to the adopted division). Here, six algorithms in question were applied (one by one) and efficiency of the overall solution was measured by the quality of final results.

In the experiment, measures dedicated for classifiers such as: *precision*, *recall* and *F1-score* are used. Two types of measurements were performed for each of the algorithms. The first was on the assessment of individual pairs as classification results while the other evaluated the efficacy from the perspective of individual risks.

In the first case, the relevant set is a collection of risks labels associated with the input object, and the retrieved set is the one assigned to the reference object identified as the most similar. *Precision*, *Recall* and *F1-score* are calculated for each best pair. Lastly, all these three factors are averaged. Final results of this measurement are presented in Table VI.

In the second case, classification effectiveness measures are

calculated for each individual risk from the threat matrix. The calculation uses a set of actions containing a given risk as a

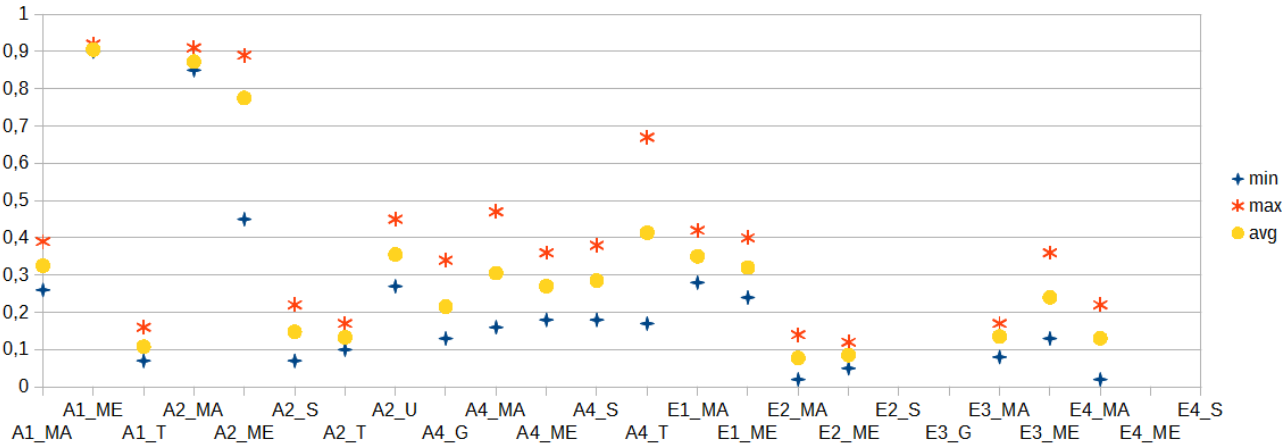

Fig. 4. Chart with the minimum, maximum and average results value for particular risks. It shows the range of values between the minimum and maximum followed by the mean value for all algorithms.

relevant set (on the basis of assignment of labels by an expert). The retrieved set consists of actions (reference objects) found by means of our solution. Table VII contains the performance comparison of all classification methods expressed by *F1-score*, *Precision* and *Recall*. Additionally, there are the *score* and *mean* rows at the bottom. They show the values of global scoring of algorithms. The first one is a normalized value of the number of recognized risks boosted tree times and summed with a total sum of *F1-score*. The second one is a mean value but calculated for all risks from the domain. It means that the zero value is taken for those risks which have not been identified. The *score* function is used to evaluate global efficiency of a particular algorithm in application in this experiment.

Table VIII contains statistical factors of the achieved results. They have been calculated on the basis of rows of Table VII limited to the *F1-score* measure. These are the most frequently used factors such as: min, max, mean, etc. The important one is the range factor which shows the difference between the best and the worst result for a given risk.

Versatility in identifying risks is a desired feature that should characterize the best solutions. Therefore, the function of evaluation algorithms (score) highly rewards those algorithms that identify the broadest spectrum of risks. Evaluation of a particular algorithm using only a number of identified risks is presented in Figure 5.

Results presented are extensions of results presented in the previous publication of the authors [11]. Three other methods are described in the publication: Naive Bayes, ESA, kNN Canberra. Authors' experiments are based on the same set of data. The results in relation to the previous ones show progress in terms of growth performance measures.

V. Discussion

It can be noted in Tables VI and VII that the best results for the whole described solution have been achieved by Weighted

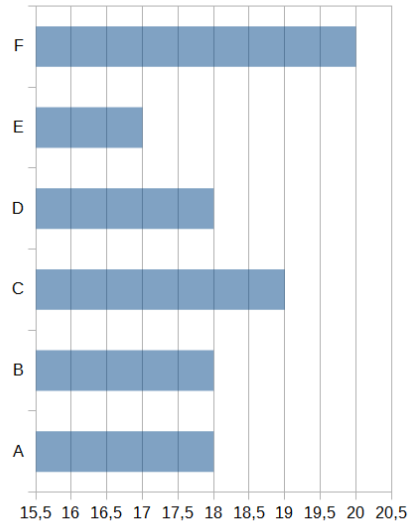

Fig. 5. The comparison of the number of identified risks by particular method. X-axis represents the number of different risks which were at least once properly assigned to an F&R action. The entire space consists of 24 risks. Abbreviations: A - Approval voting, B - Borda count, C - Copeland's method, D - Plurality voting system, E - Range voting, F - Weighted voting.

Voting algorithm. They have been obtained in terms of the largest number of identified risks as well as the highest values of effectiveness measures. Network of Comparators (NoC WA) with global aggregation implemented by means of this algorithm has identified 20 risks among all 24 existing in the threat matrix. All other algorithms obtained worse results. The second in this ranking is the result of the Copeland's method with a value of one less.

In terms of classification effectiveness from the risk point

of view it has achieved the highest value of score function calculated for all the three considered measures (0.7). Also, the mean value is the highest for both *F1-score* and *Recall* case and a little bit lower in the case of *Precision*. Similarly to the averaged measure for each best pair. The NoC WA has achieved 0.78, 0.74 and 0.70 for *Precision*, *Recall* and *F1-score* respectively.

Results presented prove that the problem of selecting the global aggregation method in a network of comparators is important and may have big impact on achieved results. They also show that election algorithms are a very good solution for optimization problems described. From the point of view of the arithmetic mean (range voting), all the methods used have obtained a higher value of the *score* function. Table VIII shows statistical factors for results generated from the risk perspective. Figure 4 demonstrates we can see exactly what the extreme values achieved by algorithms for individual risks are. This shows that in this range results can vary depending on the selection of an algorithm. It is clear that in certain cases it is the value of 0.5 which is a 50% of the scale. Additionally, it demonstrates how the average value fits the range.

Weak points of experiments are the tie solving methods. In experiments, the authors have used the method of getting the first candidate as a winner. This is quite a random method not showing real preferences.

VI. Conclusions

This paper shows similarity-based solution for recognition and identification purposes. This article in particular raises the problem of selecting the optimal results set. It presents theory and working solution on the example of recognition risks at the fire ground.

In order to investigate the problem of selecting the aggregation method for the network of comparators, six methods have been tested. The theory part for each of them is presented in detail as well as adaptation for our concrete problem. One of the strongest conclusions is that the election algorithms are a very powerful methods for implementation in such cases.

The results achieved are very promising. They are very good in comparison with different attempts to resolve risk recognition problem using the same set of data [12]. Based on these results we recommend a Weighted Average election algorithm to use as a global aggregator in the network of comparators. This method makes it possible to adapt to a specific problem by learning weights. For the purposes of the NoC solution, we have developed a learning method using a genetic algorithm.

The NoC is a very useful solution in the field of AI applications. It allows to build complex networks of comparators that can be used as ensemble classifiers [27]. In this way, very complex decision support problems can be solved as well as classification, recognition and identification problems.

The future work should concentrate on propagating the optimization method on the level of a single comparator and particular layer of the network (not only for output layer). Our research has showed that this might be a large field of improvement of performance for the whole solution.

***Abstract*—Urban traffic problems have become a quotidian problem that affects many cities in the world. This problem, caused by the exponential increase of vehicles, leads to the appearance of different complications such as environmental pollution, accidents and slow mobility. This work formulates MITC, a model of cooperation focused to conflict resolution for the traffic agents, considering explicit communication of their intentions, allowing them to adjust their decisions intelligently, so as to reduce the conflicts and mitigate traffic congestion.**

***Keywords*—Intelligent Traffic Systems; Conflict Resolution; Game Theory; Multiagent Systems**

I. Introduction

URBAN traffic problems have become an everyday problem that affects many cities in the world. The total amount of vehicles in the world is calculated to be about 600 million, with an annual increase of 50 million [18]. Different factors such as the inefficiency in the infrastructure and its planning or a weak public awareness of traffic have increased the complexity of the problem [18]. Traffic problems can be divided into three kinds [10][6]: 1) Mobility issues, related to traveling time, 2) Safety issues, specially focused in preventing accidents, and 3) Environmental issues, generally caused by CO2 emissions.

Intelligent Transportation Systems (ITS) have emerged as an answer to traffic problems becoming one of the most interesting and promising alternatives within the scientific community [4][5][6]. The ITS aim to apply different artificial intelligence techniques such as Fuzzy Logic [3][7], Neuronal Network [15][16], Evolutionary Computation [14] and, in a more general way, the Agent and Multiagent System paradigm [9][12]. The works on ITS based on Multiagent Systems have covered a great quantity of fronts, among which these can be found: road traffic [7][13], urban traffic control (UTC) [1][2] [4][6][8], and decision support systems [7][17]. In all these solutions, the agents make decisions in an intelligent and cooperative way based in their knowledge of their surroundings.

This paper describes the Intentional Model for Cooperative Traffic (MITC for its name in Spanish). This solution is a traffic model based on Multiagent Systems in which agents cooperate explicitly communicating their intentions in order to solve traffic conflicts. The communication of intentions allows agents to adjust their decisions in an intelligent way to reduce the conflicts generated by the scarcity of resources (highway network) and non-compatible goals (antagonism between vehicles). The conflict resolution is inspired in the *benevolence* concept, namely the traffic agents with best traffic culture are prioritized. The second section introduces the agent's model and the proposed interaction mechanisms between them. The third section exposes the cooperative model, specifically the conflict resolution protocol. The four section describes the decision making system game theory based, which aims to reduce the traffic conflicts. The experiments that were carried out to evaluate this model are detailed in the last section. Finally, the conclusions are exposed from the perspective of reduction of conflicts between the traffic agents.

II. Traffic Multiagent System

This section describes the architecture of the Multiagent System. Initially, the design precepts are presented to describe the general characteristics of architecture. Follow, the characterization of the agents is defined in terms of their main goal. The final part of this section characterizes the agents' interactions and the existing means of communication.

A. Multiagent System's Basic Characteristics

Urban Traffic systems are highly complex, inherently distributed and have to deal with limited infrastructural resources. Due to these restrictions, the proposed Multiagent model exhibits the following characteristics:

1. Focused in Congestion Problems: its components and its relations aim to lower the conflicts among the traffic agents.
2. Highly Concurrent: it supports the great number of interactions among the agents, which are usually simultaneous.
3. Robust: it controls the handling of exceptional situations such as the damaging of sensors and traffic lights, among others.
4. Scalable: it allows the deployment in cities of different size and complexity.

B. Agents

This work proposes a model with five agents is describing in the Table 1. Each of the agents of the system are characterized in terms of their main goal, namely their principal function

978-83-60810-58-3/$25.00

inside the system. Likewise, each agent has an alias for quickly reference in the document.

TABLE I. SYSTEM AGENTS

Name	*Main Goal*
Traffic Intersection Agent – TIA	Controls vehicles in crossing intersections; for instance traffic lights.
Traffic Sensor Agent – TSA	Provides traffic information and generates of metrics of vehicle flow performance in a vehicle segment. The vehicle segment refers to the structure proposed in a Linear Based System (LBS).
Driver Control Agent – DA	Controls the motion of a vehicle going from a origin point to a destination point in the shortest possible time.
Traffic Area Monitor Agent – TAMA	Delivers information concerning a determinate on very large traffic area.
Traffic Supervisor Agent – TSUA	Supervision, support and control of the decisions of human controllers.

Accordingly, Fig. 1 illustrates the agent interactions in the proposed model. These interactions involve the existence of last generation technologies such as the detection of pedestrian flow, the presence of sensors (such as GPS), among others. However, some of the mentioned technologies are optional (for example the sensor for pedestrian flow), if available it allows a higher efficiency for the proposed model.

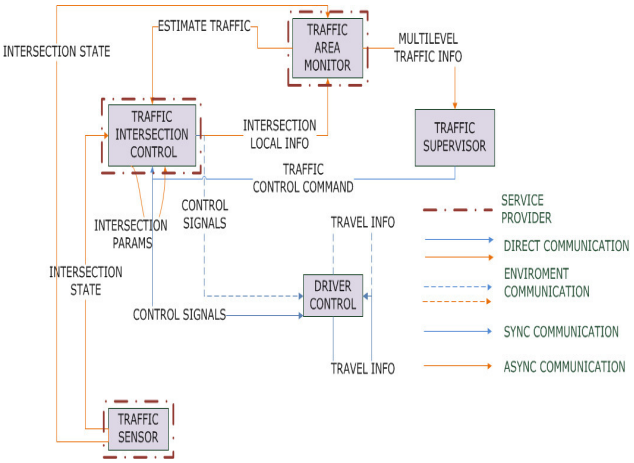

Fig. 1 Agent Interaction

Agent interactions can have different communication mechanisms, as follows:

1. Service Provider: It refers to an agent that provides an specific type of information to different agents. This information can be supplied in two ways:
   - Agents can subscribe to the Service Provider and receive the information asynchronously (Async Communication), whenever it is available.
   - Agents carry out demands to obtain information synchronously (Sync Communication).
2. Direct Communication: direct and explicit communication, usually through mechanisms like flashing headlights or other non-conventional ones, such as wireless networks.
3. Environmental Communication: Indirect communication across the environment. For instance, the horn or the turn signal lever.

III. CONFLICT RESOLUTION

In this section, the protocol of the MITC conflict resolution mechanism is described. Firstly, the concept and the categorization of the intentions that are used in this model are defined. Secondly, the intentions for each of the traffic agents are described. Finally, the characterizations of the traffic conflicts together with the proposed resolution protocol are introduced.

A. Definition of Intentions

This paper defines an intention as the goals that a traffic agent can have. These goals can follow a hierarchal and recursive classification, as follows:

1. Global Purpose Intentions: corresponds to the global aim of the agent.
2. Deliberative Intentions: refers to those intentions that are subject to the sequence of actions included in the plan of the agent. For example, the driver, according to his knowledge of traffic and exogenous information (news, weather forecast etc.), selects a path that includes several routes to go from his point of origin to his destination point.
3. Immediate Intentions: real-time actions carried out according to nearby traffic conditions. These intentions are motivated by the environment, the agent manage them in a reactive fashion; for instance, a traffic accident or a blockage due to adverse weather conditions.

Accordingly, consider a Multiagent System with N agents and $1 \le i \le N$.

- For every agent a_i one Global Intention G_i exists.
- G_i is achieved by a sequence of Deliberative Intentions included in a Plan $Pi = (P_{i1}, P_{i2}, \cdots P_{iP})$ of size p and $1 \le p \le P$.
- P_{ip} is carried out by a sequence of T Immediate Intentions $(I_{i1}, I_{i2,} \ldots It_{iT})$ and $1 \le t \le T$.

In this sense, the previous definition for the intentions can be to apply for the traffic agents´ model as shown in TABLE

II. These definitions let classify the traffic agents like: 1.) Expressive: agents can communicate the intentions for conflict resolution (TIA y DA are expressive agents) and 2.) Support Agents: agents provide information to use in conflict resolution.

TABLE I. TRAFFIC INTENTION AGENTS

Agent	*Global Purpose Intentions*	*Deliberative Intentions*	*Immediate Intentions*
TSA	Obtain traffic information and give rise to measures that can determine its performance.		
TIA	Mitigate vehicle time delay.	Control parameters adjustments according to historical acquisition.	High-beam switch
DA	Going from point A to point B in the least possible time.	Travel route selection.	Right or left turn.
			Move forward
			Brake
			Accelerate
			Change of lane
TAMA	Deliver multilevel information of a determined traffic area.		
TSUA	Support human controlers' decisions	Establish control rule per period.	

B.

C. Conflict Resolution Protocol

As previously mentioned, traffic conflicts are framed within road infrastructure shortages and agents' antagonist goals. Such conflicts happen in a defined geographic area (e.g. an intersection) and have a limited time duration. Accordingly, in order to solve conflicts the MITC model proposes the following:

1. A conflict has a scope CS denominated *conflict set*. The scope refers to the set of agents that intervene in the conflict, that is $CS=(a_1, a_2, a_k \cdots a_M)$ with $1 \leq k \leq M$.

2. Every agent a_k has a credit c_k. The credit represents the accumulated benefit that an agent has received when a conflict is solved to his favor.

3. There is an agent initiator of the a_i conflict protocol (an agent initiator is any agent traffic that can express its intentions), who communicates an immediate intention I_{it} of the set of available immediate intentions, that is $I_{it} \in (I_{i1}, I_{i2}, I_{i3} \cdots I_{iT})$ with $0 < t \leq T$ and $a_i \in CS$.

4. For every agent a_i, a possibility function $f_{pos}(I_{it})$ exists, which, given the I_{it} intention, evaluates the possibility of causing a conflict. The f_{pos} function complies with the following characteristics:

   - It is defined within the range [0,1]. Values close to 1 present a higher possibility of the intention causing a conflict.
   - If the value of the function f_{pos} exceeds a predefined threshold, the dialogue to prevent the conflict is initiated.

5. A CS *conflict set* has an a_m mediator agent associated to it, where $a_m \in CS$. The mediator agent is a virtual agent that emerges for to arbitrate the conflict resolution.

6. Each one of the a_k agents included in the conflict set generates an bid value b_k, calculated by a function f_{bid} such that $f_{bid}(I_{kt}) = b_k$.

7. For each a_k agent there is an associated unit value u_k obtained as the result in the conflict resolution process.

8. Every conflict has a unique identifier t_m. Every message that belongs to the conflict resolution dialogue has to include the identifier associated to it.

Taking into account these definitions and conditions, the proposed conflict resolution protocol is presented in the Fig. 2 and its formulation include the following steps or phases:

1. If the possibility function $f_{pos}(I_{it})$ of an agent a_i exceeds the *U* threshold, it creates a mediating agent a_m. The initiating agent sends a *conflict init* message to the mediating agent attaching the intention I_{it}, the offer b_i, the accumulated credit c_i, and the identifiers of the agents within the *conflict set* CS.

2. The mediating agent a_m forwards the message *conflict init* to all of the concerned agents a_k (with $k \neq i \ and \ k \neq m$) within the *conflict set* CS.

3. The agents a_k receive the request of a dialogue initiation for conflict resolution and answer with a message c*onflict response,* including their accumulated credit c_k, and their bid b_k. Notice that some agents may not respond to the petition of Conflict Resolution because of errors inherent to the communication channel.

4. The mediating agent a_m calculates the utility u_k for the agent a_i and for each agent a_k. Likewise, a_m sends the message *conflict result* announcing the utility u_i to agent a_i and the utility u_k for each agent a_k.

5. Finally, the initiating agent sends the message *conflict ACK* confirming the implementation of the intention.

In this sense, due to the fact that an agent can be involved in different conflicts simultaneously, the following considerations concerning the concurrency issues must be taken into account:

- When an agent a_i initiates a conflict dialogue, or an agent a_k receives a resolution request, he blocks his *availability* to participate in any other conflict resolution dialogue. This guarantees that an agent can only participate in one dialogue of conflict resolution at the same time.
- The participation of an agent a_i in a conflict is temporary and delimited in time. When time expires, the agent activates his *availability* in order to participate in any other resolution dialogue.
- For every agent a_i, $a_k \in CS$ two queues of handling messages exist:
  - One queue of incoming messages Qin, which stores the initial resolution messages. Each message received by the agent is stored in the queue using t_m as an identifier.
  - One queue to handle the events of a respective conflict $Qman$. This queue handles the messages for only one conflict simultaneously.
- When the conflict dialogue ends, the agents activate their *availability* to participate in any other resolution dialogue.

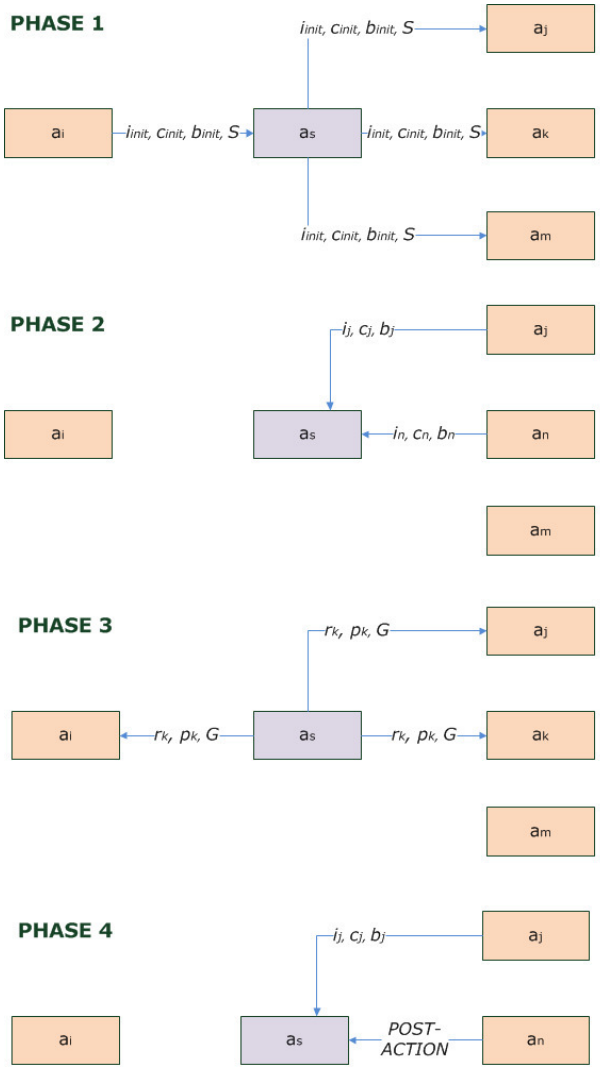

Fig. 2 Resolution Protocol Steps

IV. Decision Model by Game Theory

This section describes the model of decision making for traffic agents. First, the traffic conflicts are characterized as a game model. Then, the formalization of the game for a traffic conflict is carried out. Finally, the steps for the solution of the conflict are described in terms of the approach of a game in a normal-form.

A. General Assumptions for Traffic Conflict as a Non-Cooperative Model of Game Theory

MITC proposes a model based on Game Theory to find utility values u_k for agents a_k that are involved in a *conflict set* CS such that $CS = (a_1, a_2, a_k \cdots a_M)$ and $1 \leq k \leq M$.

Traffic conflicts can be described as a model of Game Theory according to the following considerations:

1. These are games of both complete information (the players know *completely* the strategy of the others, since they communicate their intentions) and perfect information (there is no uncertainty regarding the decisions of the agents).

2. These are games of simultaneous interaction. In other words, each conflict is independent of previous events that happen among the agents.

3. Players: every traffic agent $a_k \in CS$.

4. Actions: the vector $IC_k = (I_{kt}, -I_{kt})$, corresponds to one agent a_k where I_{kt} corresponds to the agent's immediate intention and $-I_{kt}$ corresponds to the non-carrying out of such intention. Be noted that this chapter refers to the terms of action and immediate intention indistinctively.

5. Utility Value: corresponds to the utility value u_k obtained by agent a_k.

B. Traffic Conflict as a Normal-form Game

One traffic conflict can be characterized as a Normal-form Game, as a tuple (CS, IC, u) where:

1. CS (*conflict set*) is the finite set of agents a_k that take part in the game.

2. $IC = (IC_1, IC_2, IC_3 \cdots IC_M)$ is a vector such that $IC_{kt} = (I_{kt}, -I_{kt}), \quad with \quad 0 < k \leq M$. The intentions IC_{kt} correspond to the set of available actions for agent a_k and is denominated *action profile* for agent a_k.

3. $u = u_1, u_2 \ldots\ldots\ldots\ldots u_M$, where the utility u_k is defined in terms of accumulated credit c_k and bid value b_k.

A more intuitive way to represent a game in a normal-form is the bimatrix mechanism. In the bimatrix, the cells contain the utility of each agent for the possible combinations of strategies. Each cell contains two numbers (and therefore the origin of its name), which represent the utility of the agents in such strategy. The figure 3 illustrates the bimatrix for a conflict of change of lanes between two vehicle agents (DA – Driver Agents) $a_1 and\ a_2$.

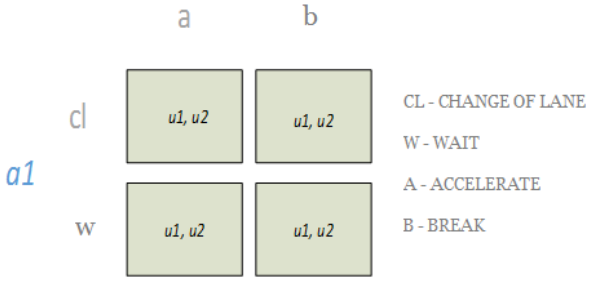

Fig. 3 Bimatrix of a Traffic Game

In general terms, for a traffic conflict with *M* agents, the actions $I^*_{1t}, I^*_{2t} \cdots I^*_{Mt}$ form a Nash Equilibrium if for each agent a_k, the immediate action I^*_{kt} is the best action that can be taken by agent a_k for the actions of the other $k-1$ players $I^*_{1t}, I^*_{2t}, I^*_{|k-1|t}, I^*_{|k+1|t} \cdots I^*_{Mt}$. That is:

$$u(I^*_{1t}, I^*_{2t}, I^*_{|k-1|t}, I^*_{kt}, I^*_{|k+1|t} \cdots I^*_{Mt}) > u(I^*_{1t}, I^*_{2t}, I^*_{|k-1|t}, I_{kt} I^*_{|k+1|t} \cdots I^*_{Mt})$$

For each possible action I_{kt} in IC_{kt}, I_{kt} is a solution for:

$$\max(I^*_{1t}, I^*_{2t}, I^*_{|k-1|t}, I^*_{kt}, I^*_{|k+1|t} \cdots I^*_{Mt})$$

C. Strategy of Nash Equilibrium Calculation

During steps 3 and 4 of the Conflict Resolution Protocol the mediating agent receives the offers of the agents in the *conflict set* and must solve the conflict calculating the corresponding Nash equilibrium. The strategy for this calculation given an immediate intention, consists of the following steps:

1. The bids $b_1, b_2, b_3, b_4 \cdots b_M$ are obtained. The bid function $f_{bid}(I_{kt}) = b_k$ for an agent a_k follows these criteria:

   a. Each intention I_{kt} has one base bid value associated w_{kt} with $w_{kt} \in Z$. The base bid value can be seen as the importance of the intention within the system's context (e.g. an ambulance can have a greater importance in its intentions than private cars).

   b. Each agent a_k has a benevolence coefficient v_k with $v_k \in Z$. For more

information about the benevolence calculation see section 5.3.

c. Each bid is attenuated by the accumulated credit c_k. The higher the accumulated credit value, the lesser the bid value b_k is. This approach allows controlling those agents that intend to abuse of their benevolence to accumulate excessive credit.

Accordingly, the function for the bid is calculated as:

$$b_k = f_{bid}(I_{kt}) = (w_{kt} * v_k)\left(\frac{1}{c_k}\right) \quad para \quad c_k > 0$$

2. The mediating agent a_m calculates the game bimatrix T_{ik} for every couple of agents a_i (initiating agent) and a_k with $i \neq k$. The calculation of the utilities for the bimax is based on the following conditions:

- If the intention I_{il} is chosen and not I_{kl}, then $u_i = b_i - b_k, \; u_k = b_k + b_i$
- If the intention I_{kl} is chosen and not I_{il}, then $u_k = b_k - b_i, \quad u_i = b_i + b_k$
- If I_{il} and I_{kl} are chosen, then $u_i = -b_i, \quad u_k = -b_k$
- If I_{il} and I_{kl} are not chosen, then $u_i = 0, \; u_k = 0$

1. For each matrix T_{ik} the corresponding Nash equilibrium is calculated as Eq_{ik}.

2. All equilibriums Eq_{ik} are obtained, where the intention I_{it} of the initiating agent a_i is selected. Afterwards, the equilibrium Eq_{ik} is selected as the one that produces the maximum utility u_i.

3. The agents a_i and a_k modify their accumulated credit as follows:

$$c_i = c_i + u_i, \quad c_k = c_k + u_k$$

The calculation of Nash equilibrium includes certain characteristics to be taken into account:

- There can be situations in which there is no equilibrium, in which case there is no conflict resolution.
- The state for $u_i = -b_i \; and \; u_k = -b_k$ can never correspond to an equilibrium; namely, the state in which both agents comply with their intention simultaneously is omitted.

V. RESULTS

This chapter describes the experiments carried out to validate the proposed MITC model. First the scenario design for the simulation is presented in order to, later on, present the results of the conducted experiments.

A. Simulation Scenario

The validation experiments use the scenario of Crossing on a Slow Lane, which is described in terms of figure 4 as follows:

- From point **1** to point **2** there is a distance of 1400 meters.
- From point **1** to point **3** there is a distance of 1408.93 meters.
- The scenario is comprised of six roads R1, R2, R3, R4, R5, y R6.
- R1 and R5 have a length of 800 meters with two lanes in each one of them.

- R2 has a length of 200 meters and 5 lanes.
- R4 has a length of 408.1 meters and 1 lane. It has a connection at the final point of R2.
- R3 and R6 have a length of 400 meters.

B. Results

During the first part of the protocol, 5 of the experiments were carried out using the native behavior included in the simulator and 5 experiments were carried out using the cooperative model with the following characteristics:

- 10 repetitions were carried out for each experiment.
- The flow of vehicles was varied (HIGH, MEDIUM-HIGH, MEDIUM-LOW, LOW) with a duration of the experiment of 3600 seconds and a 0.2 time step for the simulation[1].
- The variables Resolution Activation and Benevolence were established in HIGH.

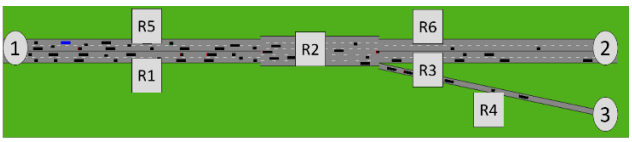

Fig. 4 Simulation Scenario

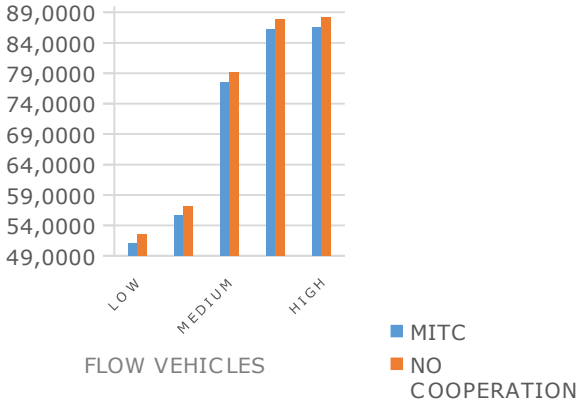

Fig. 5 Time Comparison

[1] The duration constitutes the time that the simulation lasts until it reaches 3600 (it represents one hour in MovSim) with an increasing value by cycle of 0.2. That is to say, in this case 18000 cycles of simulation would be carried out.

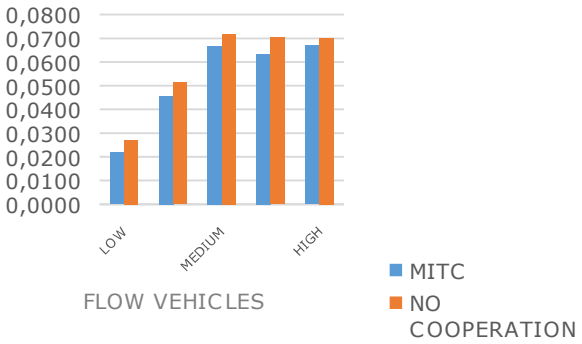

Fig. 6 Consumption Comparison

According to figures 5 and 6, the MITC model provides an improvement of travel time of 2.17% per vehicle and of 8.8% for energy consumption. At first glance these indicators pose an improvement in a local scenario of 1400 meters and, taking it to a scenario with higher dimensions (e.g. a metropolitan area), it may represent great benefits.

The second part of the experiments was focused in the analysis of the Activation Resolution and Benevolence variables. These variables determine the behavior of the model towards exceptional situations, such as infrastructure communication errors and traffic agents with lack of collaborative culture.

As can be observed in Fig. 7 and Fig. 8, the MITC model has a similar behavior in comparison with the results observed in the basic behavior (the simulation without the cooperative model included), when the Activation of the Resolution has values LOW and MEDIUM. This means that the model can cohabit, without negatively affecting the performance of the system, in mixed scenarios that not only include cooperation but also indifference.

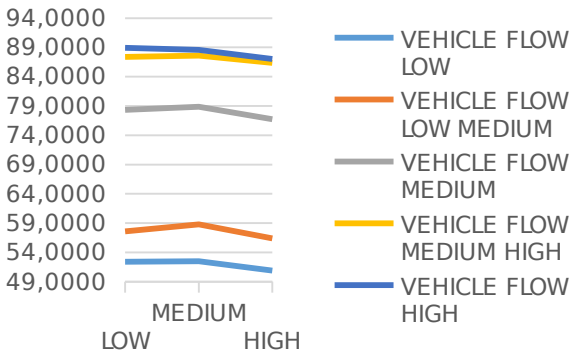

Fig. 7 Results Comparison Activation Resolution – Travel Time

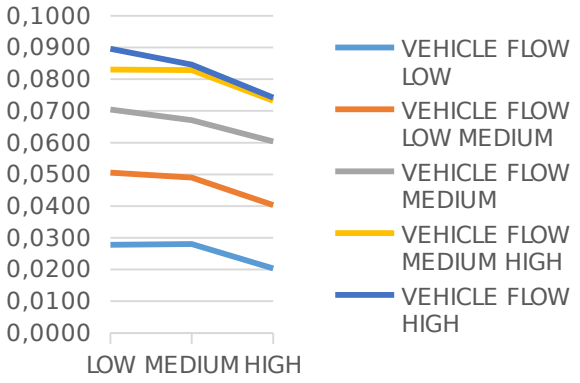

Fig. 8 Results Comparison Activation Resolution – Consumption

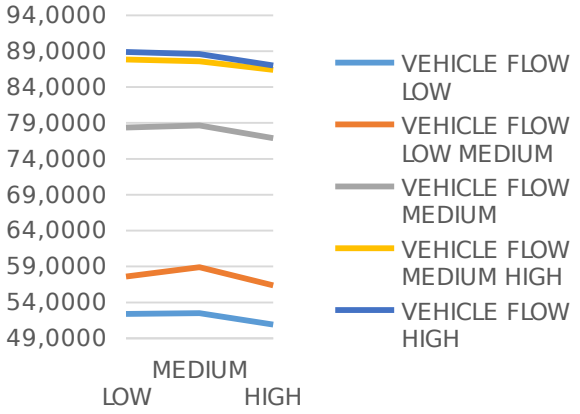

Fig. 9 Comparison Results Benevolence – Travel Time

Likewise, the results for the Benevolence variable can be observed in Fig. 9 and 10. Only when there is higher benevolence (specifically, for HIGH values), traffic conditions improve significantly. This highlights the importance of traffic culture in a city.

VI. Conclusions

The design and construction of an Intention-Based Model for Cooperative Resolution of Traffic Conflicts offers a different approach in order to solve congestion problems. MITC allows explicitly expressing the cooperative mechanisms between traffic agents in scenarios where conflicts are presented, according to shared resources and according to conflicting goals. In this sense, MITC provides a set of advantages:

1. The Multiagent Model is designed to tolerate different requirements given by an Urban Traffic System, such as concurrency, scalability and its complexity. In computational terms, MITC allows approaching traffic problems in a distributed way, which brings important advantages in terms of availability and fault tolerance.
2. The Multiagent Model poses a Conflict Resolution Protocol that supports the essential characteristics such as concurrency and its temporality.
3. The Multiagent Model covers transversally every aspect of a Traffic System, including control areas, administration and supervision.
4. The definition of the concept of Intention and its three level hierarchies allows modeling the characteristics of traffic agents in a manner that is natural and closer to reality.
5. The Decision Making Model based in Game Theory guarantees the solution of conflict in a rational and balanced way. Additionally, its inspiration in the concept of benevolence allows analyzing essential aspects such as public traffic conscience.

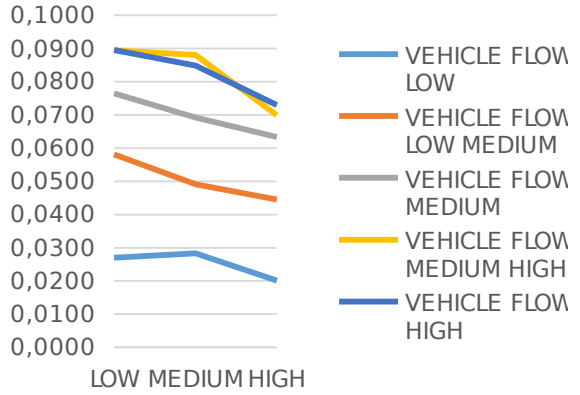

Fig. 10 Comparison Results Benevolence – Consumption

This work opens the door to a great number of applications. For instance, in the development of campaigns for intelligent traffic and traffic culture, it provides formal and measurable elements in terms of travelling time. Likewise, it would be very helpful to include experiments that determine the decrease of accidental rates through MITC on behalf of incorporated elements of road safety that give as a result a pedagogic frame for urban traffic. In this sense and although in Latin American cities traffic networks are far from implementing technologies such as inter-vehicular nets or smart vehicles, MITC is an adaptable model that can be implemented partially. Therefore, designing a System of Urban Traffic Control becomes interesting, posing options for intentional traffic lights and its respective strategies for conflict solving. In a similar way, it is possible to generate a system of traffic recommendations in real time that can

assist users while they drive their vehicles. Likewise, the model can be extended with a realistic Deliberative Intentions implementation, where the model express a coherent traceability across of intention hierarchy.

MITC is a model with a significant impact when implemented in real traffic scenarios, since it can mitigate some of the factors that have negative effects in the quality of life of people. For example, it can decrease atmospheric pollution, given that vehicles would spend less time on the streets, and it can decrease environmental noise, as it prevents the emission of sound signals of vehicles, as conflicts can be solved automatically.

***Abstract*—Particle swarm optimization constitutes currently one of the most important nature-inspired metaheuristics, used successfully for both combinatorial and continuous problems. Its popularity has stimulated the emergence of various variants of swarm-inspired techniques, based in part on the concept of pairwise communication of numerous swarm members solving optimization problem in hand. This paper overviews some examples of such techniques, namely Fully Informed Particle Swarm Optimization (FIPSO), Firefly Algorithm (FA) and Glowworm Swarm Optimization (GSO). It underlines similarities and differences among them and studies their practical features. Performance of those algorithms is also evaluated over a set of benchmark instances. Finally, some concluding remarks regarding the choice of suitable problem-oriented optimization technique along with areas of possible improvements are given as well.**

I. Introduction

PARTICLE Swarm Optimization introduced by Kennedy, Eberhart and Shi in 1995 [1] is at the moment one of the most noteworthy nature-inspired metaheuristics used for variety of tasks, both in science and engineering. It was induced by the observation of flocking and schooling patterns of birds and fish. An idea to represent each solution of the optimization problem at-hand as a member of the virtual swarm – communicating with others and modifying its position under the influence of best individuals – proved to be extremely successful. The degree of this success can be represented by the significant amount of contributions employing PSO in real-world problems e.g. in data analysis [2], resource allocation [3] etc. It can be also quantified through a number of related algorithms, based on the idea of intelligent swarms. One of recent examples of such include: Quantum-behaved Particle Swarm Optimization [4] and Multi-Swarm PSO [5].

The general goal of continuous optimization is to find x^* which satisfies:

$$f(x^*) = \min_{x \in S} f(x), \tag{1}$$

where $S \subset R^N$, and $f(x)$ constitutes solution's x cost function value. Therefore actual task of the optimizer is to find argument minimizing f.

Initial PSO algorithm's behavior was built on the assumption that each individual member of the swarm, i.e. solution of the optimization problem (1), changes its velocity vector in the consecutive algorithm's iteration as a result of the influence of two specific solutions: the best one found so far by the swarm and the top solution identified by this individual. Fully Informed Particle Swarm Optimization (FIPSO) presented first by Mendes, Kennedy and Neves [6] constitute a modification of this approach. In the most general variant of FIPSO velocity update is constructed using weighted average position of all swarm members. Creators of the algorithm considered however alternative communication topologies, e.g. ring or cluster, as well as different schemes of assigning weights to prioritize individuals' inputs. Firefly Algorithm (FA) created by Xin She Yang in 2008 is constructed on similar assumptions [7]. The position of swarm member x_m within feasible solution space S is determined by all other individuals' fitness – better solutions will attract those which are worse, in the sense of selected cost function f value [8]. Glowworm Swarm Optimization (GSO) developed by Krishnanand and Ghose [9] exhibits similar behavior however swarm member is attracted here by its better-performing neighbors found only within given radius. Considering those similarities FA and GSO like FIPSO can be perceived as most representative members of broader family of techniques named here Fully Informed Particle Swarm algorithms. It can be characterized by building solution space exploration process on exchanging information between swarm members regarding local fitness landscape and modifying their position accordingly. For other examples of such methods one can refer to [10], [11], [12].

The goal of this contribution is to provide synthetic comparative perspective on major Fully Informed Particle Swarm algorithms, introduced above, both on conceptual and performance-based grounds. It is organized as follows. First the description of all techniques studied here in their basic variants is provided, along with similarities between them. It also contains brief discussion of selected technical aspects, examples of applications and possible modifications. Then

978-83-60810-58-3/$25.00

the results of performed comparative experimental studies are given, both in the context of optimization performance, algorithms' convergence and computational demands. Finally general remarks concerning the choice of suitable problem-oriented optimization techniques and planned further studies are under consideration.

II. Fully-Informed Swarm Algorithms

First let us introduce the notation which will be used in the following subsections. To solve the optimization problem (1) the swarm, consisting of M members will be used. It will be represented by a set of N-dimensional vectors – equivalent to individuals' positions – within the iteration k denoted by:

$$x_1(k), x_2(k), ..., x_M(k). \tag{2}$$

Euclidean distance between two swarm members, indexed p and q is denoted here by $d(x_p, x_q)$. The best position found by given swarm member m prior to iteration k is given by $x_m(k)^*$ with cost function value $f(x_m(k)^*)$. At the same time:

$$x(k)^* = \arg \min_{m=1,...,M} f(x_m(k)), \tag{3}$$

corresponds to the best solution found by the algorithm in its k iterations, with $f(x(k)^*)$ representing its related cost function value. Swarm optimization algorithms, based in particular on PSO paradigm, employ frequently a concept of individual's m velocity, denoted here in iteration k as $v_m(k)$. It is used to update particles' positions and can be initialized randomly within given bounds.

The following part of the paper will provide comprehensive description of Fully Informed Particle Swarm algorithms, referring to the notation given above.

A. Fully-Informed Particle Swarm Optimization (FIPSO)

Fully Informed Particle Swarm Optimization constitutes one of heuristic algorithms derived from the basic PSO paradigm. The idea of using information from a group of particle's K_m neighbors, rather than just the best one – as in traditional canonical PSO – was first proposed by Suganthan in 1999 [13]. It was also included in complete Fully Informed PSO procedure suggested by Mendes, Kennedy and Neves. In each iteration of the algorithm particle's position $x_m(k)$ is updated by moving it iteratively along vector $v_m(k)$ with the coordinates $n = 1, ..., N$ adjusted as follows:

$$v_{mn}(k+1) = \chi \left[v_{mn}(k) + \frac{1}{K_m} \sum_{j=1}^{K_m} U(0,\varphi)(x_{N_m(j)_n}(k)^* - x_{mn}(k)) \right], \tag{4}$$

with χ known as a constriction factor, whereas $U(0,p)$ corresponds to the uniformly distributed random number in $(0,p)$, φ constitutes an acceleration coefficient, and finally, $N_m(j)$ is a function which returns the index of j-th nearest neighbor of particle m. Complete FIPSO procedure was provided below in the form of pseudocode (Algorithm 1).

Algorithm 1 Fully Informed Particle Swarm Optimization algorithm

```
k ← 1 {initialization}
for m = 1 to M do
    Generate_Solution(x_m(k))
    Initialize_Velocity(v_m(0))
    f(x_m(0)*) ← ∞
end for
{main loop}
repeat
    {evaluate and update best solutions}
    for m = 1 to M do
        f(x_m(k)) ← Evaluate_quality(x_m(k))
        if f(x_m(k)) < f(x_m(k−1)*) then
            x_m(k)* ← x_m(k)
        else
            x_m(k)* ← x_m(k−1)*
        end if
        if f(x_m(k)) < f(x(k)*) then
            x(k)* ← x_m(k)
        else
            x(k)* ← x(k−1)*
        end if
    end for
    for m = 1 to M do
        for n = 1 to N do
            c_mn(k) ← 0
            for all K_m nearest neighbors (index p) of m do
                c_mn(k) ← c_mn(k) + (U(0,φ)(x_pn(k)* − x_mn(k))
            end for
            v_mn(k) ← χ * [v_mn(k−1) + 1/K_m * c_mn(k)]
            x_mn(k+1) ← x_mn(k) + v_mn(k)
        end for
    end for
    stop_condition ← Check_stop_condition()
    k ← k + 1
until stop_condition = false
return f(x(k)*), x(k)*, k
```

One of the findings of initial study on FIPSO was that increasing the size of the "informing" neighborhood seems to deteriorate the performance of the swarm. FIPSO with a fully connected topology, i.e., when each particle has all the particles in the swarm as its neighbors, shows a particularly bad performance in comparison with the one attained with other topologies, e.g. ring or square. In addition to that FIPSO convergence was thoroughly studied in [14]. Authors observe there that for highly connected topologies, the particles explore a region close to the centroid of the swarm. It may bring positive results for some specific functions however the algorithm in that case is prone to becoming trapped in local minima. The algorithm in the form introduced above was successfully applied for engineering problems like power

systems optimization [15]. It was also used as a starting point for other similar approaches [16], [17] as well as a component of hybrid algorithms [18]. Here we consider most general FIPSO with fully-connected particles to study its performance when referencing it to two other more recent approaches.

B. Firefly Algorithm (FA)

Firefly Algorithm developed by Xin-She Yang [7] is inspired by mechanisms of firefly communication via luminescent flashes. This swarm intelligence optimization technique is based on the assumption that solution of an optimization problem can be perceived as agent (firefly) which "glows" proportionally to its quality in a considered problem setting. Consequently each brighter firefly attracts its partners (regardless of their sex), which makes the search space being explored more efficiently [8].

Each firefly has its distinctive attractiveness β which implies how strong it attracts other members of the swarm. For attractiveness in FA an exponential function of the distance $r_j = d(x_m, x_j)$ to the chosen firefly j is used:

$$\beta = \beta_0 e^{-\gamma r_j} \tag{5}$$

where β_0 and γ are predetermined algorithm parameters: maximum attractiveness value and absorption coefficient, respectively. Every member of the swarm is also characterized by its light intensity I_m which can be directly expressed as a inverse of a cost function $f(x_m)$.

To effectively explore considered search space S it is assumed that each firefly m is changing its position iteratively taking into account two factors: attractiveness of other swarm members with higher light intensity i.e. $I_j > I_m, \forall j = 1, ...M, j \neq m$ – which is varying across distance – and a fixed random step vector $U(min, max)$. It should be noted as well that if no brighter firefly can be found only such randomized step is being used [8].

Algorithm 2 presents generic Firefly Algorithm which includes all aforementioned elements. For a recent overview of FA modifications, variants and applications one can refer to [19]. We employ here standard FA algorithm with uniform random number generator and scaling factor related to search space size S [8].

Algorithm 2 Firefly Algorithm

$k \leftarrow 1$ {initialization}
for $m = 1$ to M **do**
  Generate_Solution($x_m(k)$)
end for
$f(x(0)^*) \leftarrow \infty$
{main loop}
repeat
  {evaluate and update best solution}
  for $m = 1$ to M **do**
    $f(x_m(k)) \leftarrow$ Evaluate_quality($x_m(k)$)
    if $f(x_m(k)) < f(x(k-1)^*)$ **then**
      $x(k)^* \leftarrow x_m(k)$
    else
      $x(k)^* \leftarrow x(k-1)^*$
    end if
  end for
  for $m = 1$ to M **do**
    for $p = 1$ to M **do**
      if $f(x_m(k)) < f(x_p(k))$ **then**
        $r_p \leftarrow Calculate\_Distance(x_m(k), x_p(k))$
        $\beta \leftarrow \beta_0 e^{-\gamma r_p}$
        for $n = 1$ to N **do**
          $x_{mn}(k) \leftarrow (1-\beta)x_{mn}(k) + \beta x_{pn}(k) + U_n(min, max)$
        end for
      end if
    end for
  end for
  {best moves randomly}
  for $m = 1$ to M **do**
    if $Was\_Moved(x_m(k))$ = **false then**
      for $n = 1$ to N **do**
        $x_{mn}(k) \leftarrow x_{mn}(k) + U_n(min, max)$
      end for
    end if
  end for
  $stop\_condition \leftarrow Check\_stop\_condition()$
  $k \leftarrow k + 1$
until $stop\_condition$ = **false**
return $f(x(k)^*)$, $x(k)^*$, k

C. Glowworm Swarm Optimization (GSO)

Glowworm Swarm Optimization is another optimization strategy which was stimulated by the observation of fireflies' social behavior. In contrast to Firefly Algorithm agents in GSO depend only on information available in their strict neighborhood to make decisions [9]. What is more GSO uses an adaptive neighborhood range in order to successfully deal with multimodal functions landscapes. Both luciferin quantity $\iota_m(k)$, which predetermines the probability of individual's movement, and neighborhood radius $r_m(k)$ are updated on per-iteration basis. It is realized using the following formulas:

$$\iota_m(k) = (1-\rho)\iota_m(k-1) + \gamma f(x_m(k))^{-1}, \tag{6}$$

$$r_m(k+1) = \min\{r_s, \max\{0, r_m(k) + \beta(N_{set} - |N_m(k)|)\}\}, \tag{7}$$

with ρ representing luciferin decay parameter, γ constituting luciferin enhancement constant, r_s - maximum sensor range, N_{set} - parameter controlling number of neighbors and finally, $N_m(k)$ denoting a set of neighbors of $x_m(k)$ located within radius $r_m(k)$:

$$N_m(k) = \{x_j(k) : d(x_m(k), x_j(k)) < r_m(k) : \iota_m(k) < \iota_j(k)\}. \tag{8}$$

Probability of glowworm movement towards one of other individuals in the neighborhood $N_m(k)$ is proportional to its

luciferin quantity, related to the sum of luciferin values for all neighbors found in $N_m(k)$. It is denoted for all neighbors by a vector $p_m(k)$. The Algorithm 3 presents plain description of GSO procedure including most important technical details.

Algorithm 3 Glowworm Swarm Optimization algorithm

$k \leftarrow 1$ {initialization}
$f(x(k)^*) \leftarrow \infty$
for $m = 1$ to M **do**
  Generate_Solution($x_m(k)$)
  $f(x_m(k)) \leftarrow$ Evaluate_quality($x_m(k)$)
  $\iota_m(0) \leftarrow \iota_0$
  $r_m(0) \leftarrow r_0$
end for
{main loop}
repeat
  {update luciferin quantity}
  for $m = 1$ to M **do**
    $\iota_m(k) \leftarrow (1-\rho)\iota_m(k-1) + \gamma f(x_m(k))^{-1}$
  end for
  {move glowworms}
  for $m = 1$ to M **do**
    $N_m(k) \leftarrow Find\_Neighborhood(x_m(k))$
    {sum selection probalities for all p neighbors in $N_m(k)$}
    $P_{sum} \leftarrow sum(\iota_p(k) - \iota_m(k))$
    for all $x_j(k)$ in $(N_m(k))$ **do**
      $p_{mj}(k) \leftarrow (\iota_j(k) - \iota_m(k))/P_{sum}$
    end for
    $q \leftarrow Select\_neighbor\_index(p_m(k))$
    {move towards selected}
    $x_m(k+1) \leftarrow x_m(k) + s(x_q(k) - x_m(k))$
      $/(\|x_q(k) - x_m(k)\|)$
    $r_m(k+1) \leftarrow \min\{$
    $r_s, \max\{0, r_m(k) + \beta(N_{set} - |N_m(k)|)\}\}$
  end for
  for $m = 1$ to M **do**
    if $Was\_Moved(x_m(k)$ = **false then**
      $x_m(k+1) \leftarrow x_m(k)$
    end if
    $f(x_m(k)) \leftarrow$ Evaluate_quality($x_m(k)$)
    if $f(x_m(k)) < f(x(k)^*)$ **then**
      $x(k)^* \leftarrow x_m(k)$
    else
      $x(k)^* \leftarrow x(k-1)^*$
    end if
  end for
  $stop\_condition \leftarrow Check\_stop\_condition()$
  $k \leftarrow k+1$
until $stop\_condition$ = **false**
return $f(x(k)^*)$, $x(k)^*$, k

GSO like FA attracted much attention resulting in several contributions improving the general scheme of the algorithm [20], studying theoretical properties [21] or employing GSO for real-life problems [22]. Here, for comparative studies we utilize standard GSO developed by Krishnanand and Ghose.

D. Summary

Techniques covered in this Section are employing mutual information exchange between all members of the swarm or its selected groups (depending on precise variant and parameter values). It is used for modifying swarm member position (GSO and FA) or its velocity vector (FIPSO).

In case of FIPSO individual's movement is influenced by a set of best solutions obtained by other swarm members. For GSO and FA latest position of other individuals can be used, however it must be better than the one of solution currently under consideration.

Algorithms studied here employ a randomization component, either in the form of implicit randomized movement (FA), by random selection of informing agent (GSO) or determining strength of each neighbor's influence (FIPSO). All mechanisms tend to improve algorithms' abilities to escape local minima. In this aspect additional dynamics contained within FIPSO technique could be extremely beneficial.

Every technique studied here possesses significant number of parameters, with GSO being most parameter-rich and FIPSO parameter-free one. All required parameters are listed in Table I. For most of them some guidelines have been already worked out in the related contributions - they are listed in the table as well.

TABLE I
ALGORITHMS' PARAMETERS AND THEIR SUGGESTED VALUES

Algorithm	Parameter	Suggested value/range	Source
FIPSO	M	[20,50]	[23]
	χ	0.72984	[24]
	φ	4.1	[24]
	K_m	[3,5]	[6]
FA	M	[20,50]	[25]
	α	[0.1,0.2]	[25]
	β_0	1	[8]
	γ	[1,30]	[8], [25]
GSO	M	[10,500]	[21]
	ρ	0.4	[21]
	γ	0.6	[21]
	β	0.08	[21]
	N_{set}	5	[21]
	s	0.03	[21]
	ι_0	5	[21]
	r_s	use pilot runs	[21]
	r_0	$r_0 = r_s$	[21]

As for computational complexity of algorithms studied here it is in all cases significant. With regards to swarm size M and iteration number K it can be expressed by notation $O(KM^2)$. The actual relative time needed for execution of all algorithms as other performance measures will be studied in the following Section.

III. EXPERIMENTAL STUDIES

One of the main goals of conducted experiments was to examine dynamics of swarm's performance for all considered techniques during the optimization process. Running times

TABLE II
BENCHMARK FUNCTIONS USED FOR EXPERIMENTAL STUDIES

f	Name	Expression	Feasible bounds	N	f^*
f_1	Sphere	$f_1(x) = \sum_{i=1}^{M} z_i^2 + f_1^*$ $z = x - o$	$[-100, 100]^N$	10	-1400
f_2	Different Powers	$f_2 = \sqrt{\sum_{i=1}^{N} \lvert z_i \rvert^{2+4\frac{i-1}{N-1}}} + f_2^*$ $z = x - o$	$[-100, 100]^N$	10	-1000
f_3	Rotated Rastrigin	$f_3(x) = \sum_{i=1}^{N} (z_i^2 - 10\cos(2\pi z_i) + 10) + f_3^*$ $z = M_1 \Lambda^{10} M_2 T_{asy}^{0.2}(T_{osz}(M_1 \frac{5.12(x-o)}{100}))$	$[-100, 100]^N$	10	-300
f_4	Schwefel	$f_4(x) = 418.9829N - \sum_{i=1}^{N} g(z_i) + f_4^*$ $z = \Lambda^{10}(\frac{1000(x-o)}{100}) + 4.209687462275036e + 002$ $g(z_i) = z_i \sin(\lvert z_i \rvert^{1/2})$	$[-100, 100]^N$	10	-100
f_5	Rotated Katsuura	$f_5(x) = \frac{10}{N^2} \prod_{i=1}^{N} (1 + i \sum_{j=1}^{32} \frac{\lvert 2^j z_i - round(2^j z_i) \rvert}{2^j})^{\frac{10}{N^{1.2}}} - \frac{10}{N^2} + f_5^*$ $z = M_2 \Lambda^{100}(M_1 \frac{5(x-o)}{100})$	$[-100, 100]^N$	10	200

Symbols:
$o = [o_1, o_2, ..., o_N]$ – shifted global optimum, randomly distributed in $[-80, 80]^N$,
M_1, M_2 – orthogonal (rotation) matrix generated from standard normally distributed entries by Gram-Schmidt orthonormalization.
Λ^α – diagonal matrix in N dimensions with the i^{th} diagonal element $\lambda_{ii} = \alpha^{\frac{i-1}{2(N-1)}}$ for $i = 1, 2, ..., N$.
T_{asy}^β – if $x_i > 0, x_i = x_i^{1+\beta\frac{i-1}{N-1}\sqrt{x_i}}$ for $i = 1, 2, ..., N$.
T_{osz} – for $x_i = sign(x_i)\exp(\hat{x}_i + 0.049(sin(c_1\hat{x}_i) + sin(c_2\hat{x}_i)))$ for $i = 1, 2, ..., N$.
where:
$\hat{x}_i = log(\lvert x_i \rvert)$ for $x_i \neq 0$, otherwise $\hat{x}_i = 0$,
$c_1 = 10$ if $x_i > 0$, otherwise $c_1 = 5.5$,
$c_2 = 7.9$ if $x_i > 0$, otherwise $c_2 = 3.1$.

were also carefully studied as well as final cost function values, which were additionally compared by means of statistical tests. The following subsections are covering the details of algorithms' numerical evaluation.

A. Problems and Experimental Setting

For computational experiments set of benchmark problems considered in CEC'13 competition was used [26]. Table II lists those functions along with their mathematical expressions, dimensionality and optimum values.

The experiments were conducted for fixed number of iterations $K = 10000$ $(1000 * N)$, and 30 trials for each function. Population size $M = 40$ was used for all algorithms. FIPSO was configured with fully-connected topology and parameter values as suggested in Table I. For FA we used $\alpha = 0.15$ and $\gamma = 10$ following the suggestions found in related literature. Random step size was also scaled to the size of search space S. GSO was configured with parameters given in Table I, with modified step size $s = 0.8$. For r_s we used half of maximum distance in S (that is $r_s = 315$) and for r_0 the value of 90 was selected. Both settings were established during a set of pilot runs to adopt neighborhood size properly to the domain of given optimization task.

As a performance measure mean optimization error $\overline{E}(k)$ was used (with $E(k) = |f(x(k)^*) - f^*|$) along with its standard deviation $\sigma_{E(k)}$. We have also studied mean execution time $\overline{t}$ in seconds needed for one algorithm's run.

B. Algorithms' Search Process Dynamics

First set of experiments was aimed at establishing dynamics of swarm performance in the function of execution time (iterations). For all algorithms mean optimization errors in 30 trials during 10000 iterations were reported. The results of this study for all investigated techniques are shown on Figures 1-5.

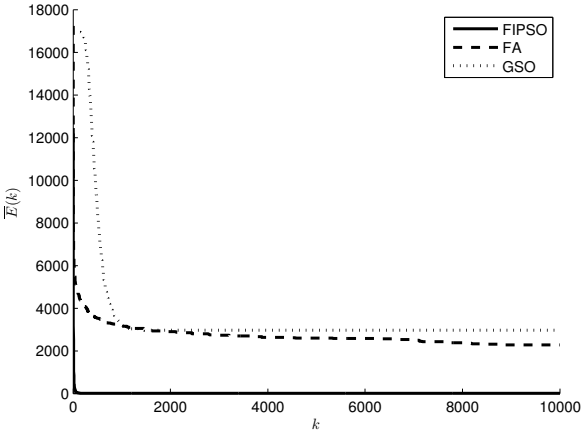

Fig. 1. Mean error values obtained within 10000 iteration of optimization process for f_1 (Sphere) function

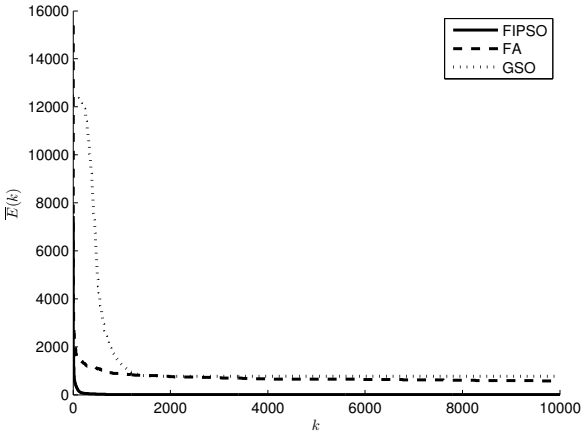

Fig. 2. Mean error values obtained within 10000 iteration of optimization process for f_2 (Different Powers) function

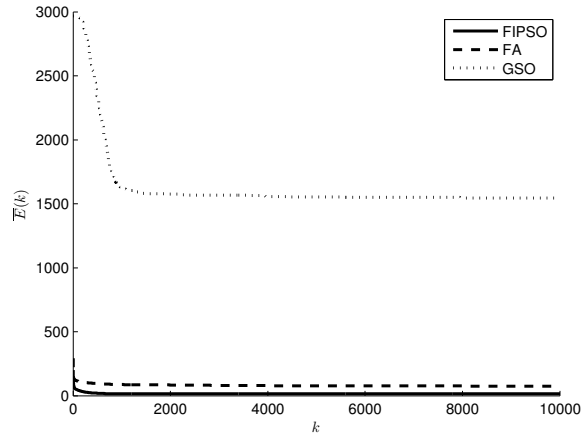

Fig. 3. Mean error values obtained within 10000 iteration of optimization process for f_3 (Rotated Rastrigin) function

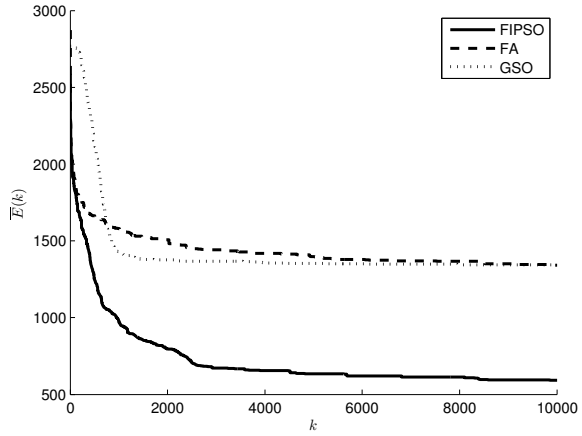

Fig. 4. Mean error values obtained within 10000 iteration of optimization process for f_4 (Schwefel) function

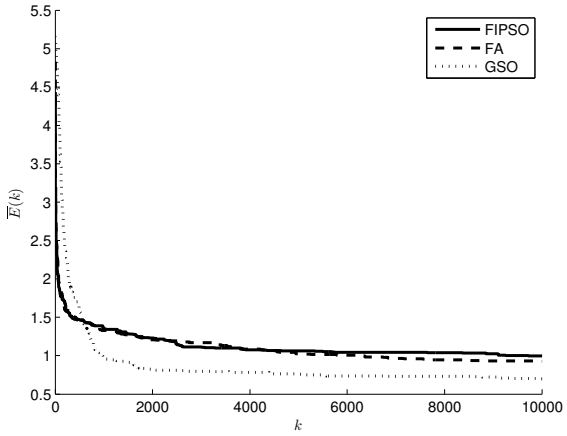

Fig. 5. Mean error values obtained within 10000 iteration of optimization process for f_5 (Rotated Katsuura) function

It can be seen that in the framework of GSO swarm members tend to find local minima and to stop exploring problem's search space afterwards. This tendency will demonstrate itself again in the next analysis. As for dynamics of FA it is also prone for being trapped in local minima. Most intense progress of error values' minimization during first optimization phase was observed for FIPSO, for all but one (f_5) function.

C. Algorithms' Performance

To compare performance of all considered algorithms we examined final cost function values obtained through a set of runs described above. In this quantitative comparison, both means, standard deviations and best obtained cost values were reported. Relation between algorithm's performance indicators was studied by means of pairwise T-tests. In most cases differences proved to be statistically meaningful at 0.95 significance level. We ranked all algorithms according to conclusive results of those tests.

Among studied algorithms FIPSO was found to be best-performing one. What is more its execution for fully-connected topology requires the least computational effort. Among two other algorithms FA was found to perform better than GSO, however here the difference – both in terms of final cost function values and required execution time – proved to be not very substantial. The most difficult problem for all the algorithms to tackle was minimization of Schwefel function. At the same time surprisingly Sphere function proved to be problematic for FA and GSO algorithms.

IV. Conclusion

The paper examined practical features of a set of important nature-inspired metaheuristics: Fully Informed Particle Swarm Optimization, Firefly Algorithm and Glowwworm Swarm Optimization. They were for the first time considered within the same methodological context, with their performance being examined on a set of benchmark functions.

We found that when using the most basic variants of aforementioned techniques Fully Informed Particle Swarm Optimization proved to be most effective and least-computationally expensive. At the same time Firefly Algorithm and Glowworm Swarm Optimization were found to be similar, both in terms of performance and computational resources' requirements. From our observations GSO is a very powerful technique for discovering local minima especially when it employs large swarm population. To use it as a tool of global optimization however one should complement it by randomized local search algorithm (e.g. Simulated Annealing [27]) or other procedure which would allow swarm members to escape from cost function valleys. In case of FA we see a suitable choice of random step generation method (e.g. Lévy Flight [28]) as a crucial element for successful applications in the field of continuous optimization.

Finally it should be noted that performed experiments do not include recent modifications of all analyzed optimization strategies, described briefly in Section 2, and more specific benchmarks. Their results however can be used as a baseline for enriching this study by including those aspects. It is planned within forthcoming follow-up contribution [29].

Ladder Tagger — Splitting Decision Space to Boost Tagging Quality

Mariusz Paradowski, Adam Radziszewski
Institute of Informatics, Wrocław University of Technology
Wybrzeże Stanisława Wyspiańskiego 27, 50-370 Wrocław
Poland

***Abstract*—This paper describes a part of speech tagger. The tagger is based on a set of probability mixture models. Each mixture model is responsible for tagging of a specific class of words, sharing similar context properties. Probability mixture models contain 25 various mixture components. The tagger is tested on Polish language and compared to other available taggers.**

I. Introduction

PART-OF-SPEECH (POS) tagging is a common and well-researched Natural Language Processing (NLP) task. It is the process of assigning POS tags to words and word-like units (*tokens*) in text. In languages with rich morphology the tags usually include significantly more information than just parts-of-speech, e.g. nouns may be specified for values of number, gender and case, adverbs may be specified for degree. In such a setting, the task is referred to as morphosyntactic tagging.

In this paper we present a novel approach to Part-of-Speech tagging (POS tagging), where the labelling is performed in a non-sequential manner using an array of simple probability mixture models. The models are derived directly from the training data. The approach has been developed for Polish, an inflective language that is typically described with a rich, positional tagset. However, very little language-dependent information is in fact employed and it is reasonable to expect that the approach will work equally well for other positional tagsets.

The presented version of the tagger deals only with disambiguation of the grammatical class (roughly corresponding to Part-of-Speech). In spite of that, it already makes use of the information available in the whole tags.

II. Tagging of inflective languages

Tagging of inflective languages is a not an easy task. One of the main difficulty is the relatively free word order, which makes sequences of n-grams much less frequent than in English [1]. The other major difficulty is related to the size and characteristics of tagsets. English tagsets usually define 40–200 different tags, while the 1-million-token manually annotated part of the National Corpus of Polish [2] contains about 1000 different tags. This is a frequently cited reason of low performance of taggers for inflective languages [3]–[5].

Tagging of inflective languages is usually performed in two stages: morphological analysis and morphological disambiguation [6]. The first stage is essentially dictionary look-up, resulting in attaching sets of tags attached to each token. The proper tagging happens during the disambiguation phase — tags that are recognised as contextually inappropriate are removed from the sets. The other technique that is commonly used is called *tiered tagging* (originating from a work by Tufiş [7]). This technique assumes splitting of positional tags according to some groups (tiers) of grammatical categories that the tags consist of. A sentence is disambiguated iteratively, one tier at a time.

Both techniques are used in three taggers made for Polish language during the last five years. PANTERA [8] is built upon an adaptation of the Brill's transformation-based learning algorithm. The tagger employs three tiers, but also makes uses of modified rule templates that operate on the level of particular tagset attributes (grammatical categories) instead of whole tags, which is an important enhancement when dealing with positional tagsets. Also, the sets of tags assigned in the course of morphological analysis are used to constrain possible transformations: if any transformation would result in generation of a tag not accounted for by the morphological dictionary, the transformation is cancelled.

WMBT [9] is a memory-based tagger that introduces morphological analysis and tiered tagging to the standard memory-based tagging framework, namely MBT [10]. The tagger uses as many tiers as there are attributes in the tagset (plus one for the grammatical class). The algorithm iterates over tiers; tagging of one tier involves classification of subsequent tokens with a k-Nearest Neighbour classifier. The classification process benefits from a rich feature set, including values of particular attribute (grammatical class, number, gender and case for tokens surrounding the token being tagged), but also tests for morphological agreement on number, gender and case. WMBT was later enhanced with a simple handling for unknown words [11]. The procedure assumes collecting separate case bases for known and unknown words.

WCRFT [11] is a modification of the WMBT tagger, where a linear-chain first-order Conditional Random Field (CRF) is used instead of the k-NN classifier. Also, instead of classifying independently each token, the CRF model is used to classify a whole sentence at a time. A separate model is trained for each tier and these models are run sequentially when performing disambiguation. The feature set is taken directly from WMBT. Also, similar unknown word handling procedure is employed.

Concraft [12] is based on a new mathematical model

978-83-60810-58-3/$25.00

devised for the purpose of morphosyntactic tagging, namely Constrained Conditional Random Fields (CCRF). CCRF is an extension of the CRF model where additional constraints are imposed on the set of labels that may be produced for each token in the output sequence. The constraints are used to enforce that each output tag belongs to the set of tags generated during morphological analysis. The model used for disambiguation is second-order. An interesting feature of the tagger is that disambiguation is performed on all layers simultaneously instead of using the standard tiered tagging scheme. Concraft also contains a separate model for handling of unknown words, which is based on first-order CCRF.

III. Ladder Tagger

In this paper we propose a new part-of-speech tagger called *Ladder Tagger*. Formally, part-of-speech tagging may be modelled as a sequence I of dependent multi-class decision problems $w \in I$. Decision problems w are statistically dependent because previously made decisions (tag assignments) influence further ones.

Natural language structure is highly complex, often very flexible, full of exceptions. The main idea of the proposed method is to divide the sequence of decision problems I into n subsets of problems with similar properties:

$$D_1 \subseteq I, D_2 \subseteq I, ..., D_n \subseteq I, \tag{1}$$

$$D_1 \cap D_2 \cap ... \cap D_n = \emptyset. \tag{2}$$

Each of these subsets $D_i : i \in \{1, ..., n\}$ should model a part of language complex structure. Statistical dependence of decision problems $w \in I$ makes the final tagging result dependent on the order in which they are solved. Our idea is to solve decision problems from the easiest to the most difficult ones (hence the name of the proposed tagger) in a non-sequential manner. The major advantage of this approach is that both **preceding** and **succeeding** tagging results may influence the current result.

The second contribution of the proposed tagger is highly intense usage of tagging context information. In probabilistic tagging smoothing plays a key role. Smoothing models may be more or less complex, but they should provide statistically significant information regarding token context. Of course smoothing parameters are highly dependent on the decision problem to solve. In the proposed tagger we use as much as 25 probability smoothing components, both taking into account preceding and succeeding tokens. Smoothing parameters are independently estimated for each set of decision problems.

The general outline of the tagging process is presented in Fig. 1. First, we assign each token (decision problem) to a set of decision problems according to its predefined properties. The first set D_1 contains the easiest, unambiguous tokens (they are trivial single-class cases). Remaining sets $D_2, ..., D_n$ contain difficult, multi-class decision problems. Sets of decision problems are now solved according the their difficulty.

Require: I – sequence of decision problems (tokens to be POS-tagged)
Ensure: t – part-of-speech tagging of I
1: $D_1 \leftarrow \emptyset$, $D_2 \leftarrow \emptyset$, ..., $D_n \leftarrow \emptyset$
2: **for all** $w \in I$ **do**
3: $m \leftarrow$get-problem-type(w)
4: $D_m \leftarrow D_m \cup \{w\}$
5: **end for**
6: **for all** $D \in \{D_1, D_2, ..., D_n\}$ **do**
7: **for all** $w \in D$ **do**
8: $t_w \leftarrow$solve-problem(w)
9: **end for**
10: **end for**
11: **return** t

Figure 1. Ladder Tagger algorithm

Our proposal follows the two-stage scheme described in the previous section: tagger's input must be first subjected to morphological analysis and the core algorithm is responsible for morphological disambiguation. In other words, it is assumed that each token is attached a set of *possible tags*[1] and each decision problem consists in selecting one of its elements. The information on *possible tags* is used during both training and normal tagger performance (disambiguation) to designate *ambiguity classes*.

A. Subsets of decision problems

The main goal of decision problems division is to build better, more specific classifiers. One of the key issues in case of POS tagging is proper usage of the available training information. Different type of information should be used in case of e.g. frequent known words, rare known words and unknown words. Thus, the following **classes of decision problems** are defined:

1) specific *known words* (SKN),
2) frequent *known words* (FKN),
3) possible *grammatical class (POS) ambiguity classes* of known words (GKN),
4) rare *known words* (RKN),
5) *word suffixes or prefixes* for unknown words (UNK).

Decision problem subsets are instances of the above classes. Specific known words (SKN) class contains very frequent words with lots of grammar exceptions. List of these words should be pre-specified by expert linguists. The list should not be too long, because classifiers for each specific known word are trained separately. Frequent known words (FKN) class contains frequently used words, generally following grammar rules. Due to their high frequency in the corpus they have a large training data available. *Ambiguity classes* class is much less specific, it often covers multiple known words. Number

[1]Possible according to the morphological analyser employed. Even if a word form is known to the analyser, the returned set of tags may be incomplete or erroneous. Given the evolving nature of language, it is impossible to create an exhaustive morphological dictionary that will be valid for any text.

of known instances of a given word is another important criterion. If a word has only one instance in the training set, any parameter estimation is not possible for such a word. Such words are considered rare and are tagged according to ambiguity classes.

The employed two-stage scheme is bound to face the problem of unknown words. Word forms of some tokens will be not recognised by the morphological analyser, hence no set of possible tags (ambiguity class) will be available. Such tokens are treated as a separate class (UNK). Tagging of such words is language-specific. For Polish (and also for many Slavic languages), word suffixes and, to some extent, prefixes, give useful inflectional information that helps make the correct decision.

During tagging process, a token is treated as an unknown word if the analyser failed to provide a set of possible tags. For our model to work, the UNK class must also be explicitly present in the training data. Fortunately, this information is easy to obtain. To make sure that the sets of possible tags present in the training corpus reflect the actual behaviour of the morphological analyser, we followed the procedure called *reanalysis of the training data* that was proposed in [11]. It assumes feeding the training data through the morphological analyser actually used to update the information on tags *possible* for each token. In case of word forms that were unknown to the analyser, the set of possible tags always consists of the proper tag (taken from the original training data) and the *unknown word tag* (`ign`). What results is consistent assignment of tokens to ambiguity classes, but also, explicit marking of unknown words.

B. Decision model

The proposed tagger applies Bayesian decision model. Maximum a posteriori decision rule is used:

$$t_w^* = \arg\max_{t \in g_w} p(t|w), \tag{3}$$

where: w – a word being currently tagged, t_w^* – chosen tag, g_w – set of possible POS tags for word w.

Class probability $p(t|w)$ is estimated from available training corpus data. Each decision problem subset has its own subset of corpus. Corpus subsets are built according to predefined rules. Rules of corpus subset generation for possible classes of decision problems are given in Tab. I.

Table I
RULES OF CORPUS SUBSET GENERATION FOR VARIOUS DECISION PROBLEM CLASSES.

problem class	word form	grammatical classes	prefix suffix
SKN	match	match	—
FKN	match	match	—
GKN	—	match	—
RKN	—	match	—
UNK	—	—	match

Exemplary, word *to* (eng. *it*) is belongs to the class of specific known word problems. The training set consists of all instances of word *to* with matching set of possible grammatical classes.

C. Probability smoothing

Probability smoothing is one of the key components in statistical approaches to tagging. There is no sufficient data to get well estimated probability distributions of word sequences. One of the most common approach to probability smoothing is Jelinek-Mercer smoothing [13]. The basic model is defined as follows:

$$p(w_0|w_1)_J = \lambda p(w_0|w_1)_D + (1-\lambda)p(w_0)_D, \tag{4}$$

where: $\lambda \in \langle 0;1 \rangle$ and $p(w_0|\cdot)_D$ is estimated directly from the data.

The Jelinek-Mercer model is further extended to Witten-Bell [13] smoothing and it takes a recurrent form:

$$p(w_0|s_i)_R = \lambda_i p(w_0|s_i)_D + (1-\lambda_i)p(w_0|s_{i-1})_R, \tag{5}$$

where: $\lambda_i \in \langle 0;1 \rangle$, s_i is the context of word w_0.

The above model $p(w_0|s_i)_R$ can be simply rewritten into non-recurrent equation and it takes the basic form of a well known probability mixture model. Thus, the probability smoothing used in the proposed approach is defined as follows:

$$p(w_0|s_i)_M = \sum_{j=0}^{i} \alpha_j p(w_0|s_j)_D, \tag{6}$$

where:

$$\alpha_i = \lambda_i \prod_{j=0}^{i-1}(1-\lambda_j), \quad \sum_{j=0}^{i} \alpha_j = 1. \tag{7}$$

Estimation of α_i parameters is not straightforward, and can be done in several different ways. In more complex language models (like the one proposed), the number of parameters may be high.

D. Mixture model probabilities

One of the key components to successful tagging is the definition of smoothing probabilities. As shown above, smoothing may be represented as a mixture probability. Component probabilities are estimated on four different types of data: word forms (w_i), grammatical class (POS) ambiguity classes (g_i), ambiguity classes of whole tags (c_i) and *tagging results* (grammatical classes assigned by the tagger) (t_i), where i stands for relative position of a word in the tagged corpus. In case the word in not yet tagged and a *tagging results* (t_i) is used, the probability is estimated as 0. Given the above events, various conditional probabilities can be defined. We use total 25 probability mixture model components, as shown in Tab. II. For instance, $p(t_0|x_0, g_{-1}, w_{+1})$ represents probability of tag t_0, given that:

1) decision class specific parameters x_0 on position 0 are matched,
2) grammatical class (POS) ambiguity classes g_{-1} on position -1 matches,
3) word form w_{+1} on position $+1$ matches.

Table II
PROBABILITY MIXTURE COMPONENTS USED FOR PROBABILITY SMOOTHING, x_0 REPRESENTS A DECISION CLASS SPECIFIC EVENT. FOR *SKN* AND *FKN* $x_0 = (w_0, g_0)$, FOR *GKN* AND *RKN* $x_0 = g_0$ AND FOR *UNK* x_0 IS DEFINED IN TERMS OF SUFFIXES AND PREFIXES.

$p(t_0\|\cdot)$	word forms (w)	g-class(g)	f-class(c)	tags(t)

$p(t_0\|x_0, g_{-1})$	–	first prec.	–	–
$p(t_0\|x_0)$	–	–	–	–

For the easiness of reading, mixture model components shown in Tab. II are sorted according to their assumed generality. More specific general estimates are shown at the top, more general ones are shown at the bottom of the table. The main idea of probability smoothing is preserved. Mixture components from the top of the table will have low recall, however high precision. Those from the bottom will have high recall and lower precision.

E. Tagger parameter estimation

The proposed tagger has a set of parameters, as described above, which need to be estimated before the tagging process. Parameter estimation is done at the training set. Given the smoothing model has n components and that there are m sets of decision problems, there are total nm parameters to be estimated. For each set of decision problems its smoothing model parameters are estimated independently.

Mixture parameters estimation is considered as a validation set tagging quality optimization problem. Validation sets are built on top of the training set using Leave-One-Out routine. Tagging quality is defined as a classic *recognition accuracy*. Training process is defined as maximization of recognition accuracy:

$$[\alpha]^* = \arg\max_{[\alpha]} \frac{1}{|I|} \sum_{w \in I} |\{t_w^*\} \cap \{r_w\}|, \tag{8}$$

where: r_w – reference tag for word w, t_w^* – tagging result of word w from the validation set.

Random-restart hill climbing method is used as the optimization tool. Exemplary estimates of smoothing parameters are given in Tab. III. Estimated mixture weights may provide an interesting insight into the language structure. They may show the importance of different contexts in various cases of language usage. Exemplary, word *to* (eng. *it*) has a very high importance of succeeding context, while in case of word *i* (eng. *and*) proceeding context is much more important. Thus, results of training may provide further information (and have done so in the past) how to extend available set of contexts.

F. Computational and memory complexity analysis

Proposed tagging approach is can be classified as a *lazy recognition method*, because it estimates probabilities directly from the data during the recognition phase. Thus, it requires memorization of the whole training data, i.e., the tagged corpus. Estimation of mixture probabilities requires iteration through the data, but can be limited only to its small subsets. The whole training set is organized as a *hash map*. Each element of the hash map represents a *decision class specific event* x_0. It contains a list of all indexes of event x_0 appearance in the training set. For example, to estimate $p(t_0|x_0, w_{+1})$ where: $x_0 = (w_0, g_0)$, w_0 is a specific word and g_0 a specific grammatical class, the tagger accesses the hash map with key (w_0, g_0) and extracts a list of relevant indexes. Given the list of indexes, it iterates through the training set and checks only for w_{+1} match condition. This results in a large speedup of tagging process, because size m of the relevant index is always much smaller than the size n of the whole training set.

As a result, memory complexity is equal to $T(kn)$ where n is the size of the corpus and $k = 5$ is the number of predefined decision problem classes (see Tab. I). The number of predefined classes is constant and practically should not

Table III
EXEMPLARY PROBABILITY MIXTURE MODEL PARAMETERS (WEIGHTS) FOR EACH SPACE SUBDIVISION.

$p(t_0\|x_0, w_{+1})$	0.072	0.003	0.004	0.037	0.072
$p(t_0\|x_0, w_{-1})$	0.115	0.016	0.022	0.086	0.088
$p(t_0\|x_0, t_{-1}, g_{+1})$	0.003	0.003	0.073	0.011	0.020
$p(t_0\|x_0, g_{-1}, g_{+1})$	0.023	0.026	0.022	0.037	0.010
$p(t_0\|x_0, c_{+1})$	0.069	0.016	0.004	0.052	0.119
$p(t_0\|x_0, c_{-1})$	0.029	0.006	0.027	0.011	0.020
$p(t_0\|x_0, t_{+1})$	0.003	0.040	0.004	0.030	0.005
$p(t_0\|x_0, t_{-1})$	0.003	0.020	0.009	0.007	0.005
$p(t_0\|x_0, g_{+1})$	0.006	0.026	0.009	0.003	0.005
$p(t_0\|x_0, g_{-1})$	0.006	0.026	0.018	0.015	0.010
$p(t_0\|x_0)$	0.003	0.010	0.018	0.003	0.005

grow any more ($k = const$), thus memory complexity is $T(kn) = O(n)$. Computational complexity for tagging a single word is equal to $O(im)$, where i is the number of mixture components and m is the size of x_0 relevant index, where $m \ll n$.

IV. EXPERIMENTAL VERIFICATION

In this section we describe our experiments aiming at evaluation of the proposed disambiguation method (Ladder Tagger). Its results are compared to the three Polish taggers described in Sec. II.

As noted earlier, the present variant of the tagger deals only with disambiguation of the grammatical class, hence the scope of evaluation is also limited to labelling with grammatical classes, while the ability to assign full morphosyntactic tags is not assessed.

The experiments described here are made using the manually annotated part of the National Corpus of Polish [2], version 1.0. This part consists of 86 thousand sentences and 1.2 million tokens and we call it NCP in short. Each token is labelled with exactly one tag, belonging to the NCP tagset [14]. The tagset defines 35 grammatical classes (besides one special class reserved for unrecognised forms — `ign`).

A. Experimental protocol

It has been argued [15] that taggers should be evaluated as whole systems that process plain text files into tagged corpora. Such an approach provides insight into tagging errors made at every possible stage, including tokenisation, morphological analysis and disambiguation. This is a close approximation of real-life scenario of tagger application where only text is available, possibly divided into paragraphs, but with no linguistic pre-processing such as manual division into tokens.

We employ this approach here. The taggers are assessed using a metric called *accuracy lower bound* [15] that is defined as the percentage of tokens from the reference corpus (manually divided into tokens and labelled with tags) that fulfil two conditions:

1) the token is present at the tagger output (no change in tokenisation took place),
2) the tagger classified the token with the same label as in the reference corpus.

In other words, every change in tokenisation is penalised as a tagging error and tags attached to tokens that are subjected to segmentation change are not even checked.

The second condition refers to "the same label". As our evaluation is limited to tagging with grammatical classes, the label is understood as grammatical class extracted from full morphosyntactic tag.

All the experiments described here were performed using ten-fold cross-validation. Each experiment is run against the same partitioning of the data. Each run n for a tagger T consists of the following steps:

1) Training data part n is used to train tagger model M_n^T. Before training proper, the training part is subjected to morphological reanalysis as described in Sec. III-A.
2) Testing data part n ($Test_n^T$) is converted to plain text. The division into paragraphs is preserved and marked with two newline characters.
3) Testing data in plain text part n is tagged with the trained model M_n^T and its output is saved to Out_n^T.
4) Out_n^T is compared to $Test_n^T$ and value of accuracy lower

Table IV
ACCURACY LOWER BOUND MEASURED FOR **ALL** TOKENS

Split	LT	WMBT	WCRFT s2	Concraft 5.0	Rank
1	97.22%	96.74%	97.16%	97.13%	1st

5	97.60%	97.39%	97.49%	97.39%	1st
6	97.47%	97.21%	97.33%	97.22%	1st
7	97.54%	97.38%	97.47%	97.34%	1st
8	97.63%	97.41%	97.53%	97.46%	1st
9	97.62%	97.41%	97.55%	97.39%	1st
10	97.55%	97.42%	97.52%	97.44%	1st
μ	97.57%	97.38%	97.50%	97.38%	1st

bound (for grammatical class) is calculated.

B. Tagging quality

Table IV presents the observed values of accuracy lower bound across ten runs. The average value (μ) is given in the last row. The experiment shows that Ladder Tagger consistently outperforms all other taggers with respect to grammatical class tagging. The improvement over the second best tagger (WCRFT) corresponds to 2.9% drop in error rate.

We also took the opportunity to measure separate values of accuracy lower bound for two classes of token: known and unknown words. Results for known words (Table V) present the same trends as the overall results: Ladder Tagger consistently outperforms other taggers.

Results observed for unknown words (Table VI) are different. It is evident that Concraft is achieving best results for unknown words. This may be attributed to the advantage given to Concraft by its sophisticated model to deal with unknown words (tag guessing module). Ladder Tagger is placed second or third in the ranking.

V. SUMMARY

This paper presented a part of speech (POS) tagger. Presented POS tagger is based on a set of simple probability mixture models. A list of 25 mixture components is defined. They describe various contexts of the tagged word. Parameters of mixture models are estimated using random-restart hill climbing method. Tagging accuracy of all and known tokens is highest among all tested taggers. Tagging accuracy of unknown tokens (not recognized by tag guessing module) is ranked either second or third.

Table VI
ACCURACY LOWER BOUND MEASURED FOR **UNKNOWN** TOKENS

Split	LT	WMBT	WCRFT s2	Concraft 5.0	Rank
1	85.13%	75.19%	85.13%	86.94%	3rd
2	86.09%	74.80%	85.37%	87.52%	2nd
3	85.48%	77.56%	85.45%	87.14%	2nd
4	86.27%	76.22%	85.40%	86.44%	2nd
5	86.09%	75.64%	84.95%	87.02%	2nd
6	87.02%	76.19%	86.23%	87.76%	2nd
7	86.21%	75.98%	85.63%	87.50%	2nd
8	86.35%	76.28%	86.96%	87.72%	3rd
9	86.58%	76.90%	86.50%	89.45%	2nd
10	86.93%	76.23%	86.63%	87.98%	2nd
μ	86.22%	76.10%	85.83%	87.55%	2nd

The results obtained are encouraging enough to extend the presented approach to cover full positional tagset — and this is a priority for us at the moment. The other worthy line of research is to improve handling of unknown words.

***Abstract*—In this paper, the use of Developmental Genetic Programming (DGP) for solving a new extension of the Resource-Constrained Project Scheduling Problem (RCPSP) is investigated. We consider a variant of the problem when resources are only partially available and a deadline is given but it is the cost of the project that should be minimized. RCPSP is a well-known NP-hard problem but in its original formulation it does not take into consideration initial resource workload and it minimises the makespan. Unlike other genetic approaches, where genotypes represent solutions, a genotype in DGP is a procedure that constructs a solution to the problem. Genotypes (the search space) and phenotypes (the solution space) are distinguished and a genotype-to-phenotype mapping (GPM) is used. Thus, genotypes are evolved without any restrictions and the whole search space is explored. The goal of the evolution is to find a procedure constructing the best solution of the problem for which the cost of the project is minimal. The paper presents genetic operators as well as GPM specified for the DGP. Experimental results showed that our approach gives significantly better results compared with methods presented in the literature.**

I. Introduction

THE Resource-Constrained Project Scheduling Problem (RCPSP), attempts to reschedule project tasks efficiently using limited renewable resources minimising the maximal completion time of all activities [Brucker et al., 1998], [Demeulemeester and Herroelen, 1997], [Demeulemeester and Herroelen, 2002]. A single project consists of m tasks which are precedence-related by finish-start relationships with zero time lags. The relationship means that all predecessors have to be finished before a task can be started. To be processed, each activity requires a limited resource R which is unique and therefore it has to perform different activities sequentially.

RCPSP is an NP-complete problem which is computationally very hard [Blazewicz et al., 1983]. The RCPSP occurs frequently, in high scale project management such as software development, power plant building, and military industry projects such as design, development and building of nuclear submarines [Pinedo and Chao, 1999]. The authors in [Möhring et al., 2003] state that it is one of the hardest problems of Operational Research. Results of the investigation in [Hartmann and Briskorn, 2010] showed that the best performing heuristics for solving the RCPSP were the Genetic algorithm (GA) of Hartmann [Hartmann, 1998] and the Tabu search (TS) procedure of Bouleimen and Lecocq [Bouleimen and Lecocq, 2003].

Various RCPSP extensions have been developed for solving practical problems [Hartmann and Briskorn, 2010]. However, there is still free room for research. In this paper we will attack the RCPSP where resources have already got their own schedule (like in a software house). Such tasks cannot be moved. Hence, the resources are available only in particular time periods. The goal is to allocate resources to the project tasks, taking into consideration the availability of resources, in order to minimise the total cost of the project and complete it before a deadline.

The resources can be used only in specified time periods what makes the problem computationally even more complex. To overcome this complexity Genetic programming (GP) [Koza, 1992] will be adopted. GP is a domain-independent method that genetically breeds a population of computer programs to solve a problem. It is an extension of the GA [Hartmann, 1998], [Goldberg, 1989], in which the structures in the population are not fixed-length character strings that encode candidate solutions to a problem, but programs that, when executed, produces the candidate solutions to the problem [Koza and Poli, 2005]. Most GP approaches do not distinguish between a genotype, i.e. a point in a search space, and its phenotype, i.e. a point in a solution space. Developmental genetic programming (DGP) [Koza et al., 2003] makes a distinction between the search space and the solution space. DGP evolves a schedule construction procedure instead of the schedule itself. Thus, genotypes are evolved without any restrictions and the whole search space is explored. The quality of the solution is evaluated on the phenotype after genotype-to-phenotype mapping (GPM). The mapping is critical to the performance of the search process [Keller and Banzhaf, 1999].

To summarize, the purpose of the paper is to introduce a new DGP approach for solving RCPSP when resources are

978-83-60810-58-3/$25.00

partially available. The next section of the paper contains a brief overview of related work. A motivation to the research is given in section 3. Section 4 presents an idea of the adaptation of developmental genetic programming for a solution of the RCPSP. In section 5, computational experiments to evaluate our approach and a comparison with other methods are given. The paper ends with conclusions.

II. Related work and preliminary remarks

Both exact and heuristic methods have been used for solving the RCPSP. Among the first ones, a depth-first branching scheme with dominance criteria and the bounding rules was proposed [Demeulemeester and Herroelen, 1997]. In [Brucker et al., 1998] a branching scheme which starts from a graph representing a set of conjunctions and disjunctions was used. Another method, a tree search algorithm was presented in [Mingozzi et al., 1998]. It is based on a mathematical formulation that uses lower bounds and dominance criteria. However, heuristics have been preferred instead of exact methods due to substantial limitations of these latter ones. In-depth study of the performance of recent RCPSP heuristics can be found in [Kolisch and Hartmann, 2006]. Heuristics described by the authors, include X-pass methods, also known as priority rule based heuristics, classical metaheuristics, such as Genetic algorithms, Tabu search, Simulated annealing (SA), and Ant Colony Optimisation (ACO). They give a performance comparison of these methods as applied to different standard instances sets, generated by ProGen in the PSPLIB [Kolish and Sprecher, 1996]. Two approaches of Tabu Search, for artificially created dataset instances, but based on real-world instances (got from Volvo IT and verified by experienced project manager), were investigated in [Skowronski et al., 2013].

One of the latest review papers on solving RCPSP by exact methods and heuristics may be found in [Deiranlou and Jolai, 2009], where a particular attention was paid to GAs. The authors introduced a new crossover operator and auto-tuning for adjusting the rates of crossover and mutation operators. In [Zamani, 2013], an effective hybrid evolutionary search method which integrates a genetic algorithm with a local search was presented. Two approaches for solving the problem with GAs and GP are given in [Frankola et al., 2008]. The authors achieved good quality results by the use of GAs. With GP, they described a methodology to evolve scheduling heuristics in a small amount of time. DGP [Keller and Banzhaf, 1999], [Koza et al., 2003] is an adaptation of GP [Koza, 1992] to the optimisation problems. The DGP is quite new (from 1999) and has never been applied to the RCPSP. However, it has already been successfully applied in the design of electronic circuits, control algorithms [Koza et al., 2003], strategy algorithms in computer games, the synthesis of embedded systems [Deniziak and Górski, 2008], etc. Many of the human-competitive results that were produced using runs of genetic programming that employed a developmental process are described in [Koza, 2010]. Reinforcement Learning (RL) is another machine learning algorithm that was used for solving the RCPSP. RL determines of how software agents ought to take actions so as to achieve one or more goals. The learning process takes place through interaction with the JABAT environment [Jedrzejowicz and Ratajczak-Ropel, 2014].

According to [Alcaraz and Maroto, 2001], the optimal solution can be achieved by exact procedures only for small projects, usually containing less than 60 tasks and not highly constrained. Moreover, exact methods may require a significant amount of computation time. Therefore heuristic approaches to the implementation of resource allocation optimization algorithms would be desired to enhance the process. For many problems, restrictions are imposed on how the structure of genotype may be created. GP algorithms handle the problems by constrained genetic operators in the manner, which makes them produce only legal individuals. The method achieved respectable results for the generation of efficient programs in different domains, e.g. mathematical calculations, robot control, text recognition, etc. In 36 cases, obtained results were as good as or even better then known solutions [Koza and Poli, 2005]. However, constrained operators create infeasible regions in the search space, also eliminating sequences of genes which may lead to high quality solutions. In the DGP approach the problem does not exists anyway. Because of separating the search space from the solution space, legal as well as illegal genotypes are evolved, while each genotype is mapped onto a legal phenotype. It is worth to notice that the evolution of an illegal genotype may lead to the legal genotype constructing the expected result. Thus, the whole search space is explored.

III. Motivation

Classical RCPSP as well as its extensions presented in the literature do not encompass some practical problems. In the classical approach the goal of optimisation is to minimise the makespan without taking into consideration the project cost. Moreover, resources are assumed to be steadily available during the execution of the whole project. In spite of that, developers in a software house or resources of an enterprise building houses, for example, may have initial workloads when starting a new project. A goal in such cases is a cost/time trade-off, i.e. to minimize the total cost while satisfying time constraints. Therefore, an extension of RCPSP where resources have already got their own schedules and cost/time trade-offs are dominant is necessary. The problems have been addressed in the literature [Ahn and Erenguc, 1998], [Drexl et al., 2000], but not combined. Together, they make the RCPSP computationally very complex. To our best knowledge there was no attempt to deal with the problem. Satisfactory results in the matter will make it possible to efficiently solve more complex real life problems faster and better, for which there currently is not any sufficient solution.

IV. Adaptation of the DGP for the RCPSP

In the DGP genotype and phenotype are distinguished. A genotype in classical GAs represents a target solution, while

in DGP the genotype comprises a procedure that construct a solution of the problem. So, if the target solution (phenotype) is a sequence of tasks with allocated resources, which is usually created by the project manager, then the construction of the solution will be a method of how the project manager selects a resource to allocate for each of the tasks. Therefore, DGP does not evolve a project schedule but the project manager itself. A genotype defines how the project manager uses resource allocation strategies to create a project schedule. During evolution only genotypes are evolved, while the genotype-to-phenotype mapping is used to create phenotypes. In that way, the quality of the phenotype may be evaluated in order to find procedures constructing the best solution.

An evolution process in DGP is similar to other genetic approaches. It starts with an initial population with POP individuals. Subsequently, pairs of individuals are randomly drawn from the population and subject to the operation of crossover and mutation. Then, the fitness of newly created genotypes is calculated. If they satisfy time constraints, they pass the *life test* and are added to the current population. Thus, the population size in each generation is at most $2 \cdot POP$. Finally, the reproduction operator is used POP times to reduce the population to its former size. It selects the best individuals for the new population that replaces the current one. This iterative process is repeated over many generations until a predefined number of generations (GEN) has been reached.

A. Genotypes and phenotypes

In our method a genotype of the project manager is represented by a binary tree that comprises resource allocation strategies and a way of applying them for the activities. The tree edges represent a division of the list of activities into two subgroups, while nodes specify a location of the division ($node_d$) and a resource allocation strategy ($node_s$) (Figure 1). The strategy, which will be assigned to each of the subgroups is specified in an appropriate child of the node. A resource may be assigned according to one of the following strategies:

1) is the fastest,
2) is the cheapest,
3) allows to start the task as soon as possible,
4) allows to finish the task as soon as possible,
5) causes the smallest increase of the project time,
6) causes the smallest increase of the project cost.

The initial population consists of individuals generated randomly by recursively creating nodes until a pre-established maximum $Tree_{height}$ is reached. An increase of the tree height causes doubling the divisions and hence the number of leafs of the tree. Therefore, in order to get all possible variations of strategies, the number of the leafs (1) should be at least the number of activities in the project. At the beginning, the genotype is a full tree, where each node has one of the strategies assigned with the same probability and a random $node_d$, which is inversely proportional to the tree height. However, it has to be verified whether nodes contain improper values of $node_d$. The dividing point cannot be bigger than the number of activities in currently considered subgroup. One of the repairing mechanisms could be a "deleting repair" that removes all children of the invalid node. The process is similar to withering of unused features in live organisms, like in intron splicing [Watson et al., 1992]. But we used a "replacing repair" that replaces the invalid node by any of its children, instead of removing the entire branch. Therefore, more genetic information will be kept in the genotype.

Fig. 1. Tree node, where $node_d$ - dividing point, $node_s$ - decision strategy

$$Leafs_{num} = 2^{Tree_{height}-1} \tag{1}$$

B. Genotype-to-phenotype mapping

A Genotype-to-phenotype mapping (GPM) is used to transform the tree structure into a sequence of decision strategies, corresponding to the project activities. The procedure is shown on Algorithm 1. GPM is done by traversing the tree in the depth-first order starting from the top node (the root). If a node has children, a $node_d$ is used for dividing currently considered project activities into two subgroups and strategies are assigned to them. The left child defines a strategy for the first subgroup (from the first to $node_d$ task in the currently considered group of activities) and the right child for the other (from $node_d$ task to the last task in the currently considered group of activities) (Figure 2a). Then, subgroups of activities are passed to offspring nodes and the process is continued (Figure 2b). As a result, we obtain a sequence of decision strategies (*strat*), each corresponding to the given project activity (Figure 2c).

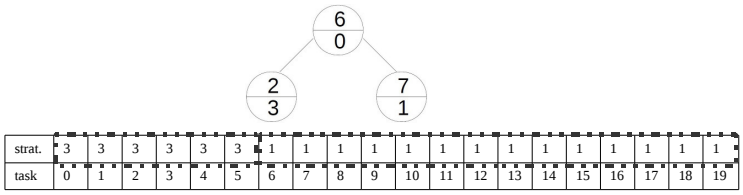
Subsequently, the decision strategies are used to create a project schedule with assigned resources (phenotype). To this end, the following steps have to be carried out:

1) search the project's activities, according to the precedence relationships, in order to find a list of ready-to-start activities,
2) assign the strategies with corresponding activities and execute the strategy to calculate a resource to allocate,
3) calculate a start time for each activity, based on the earliest precedence relationships and the feasible time of a resource,
4) repeat from step 1) until there are activities that are still unassigned.

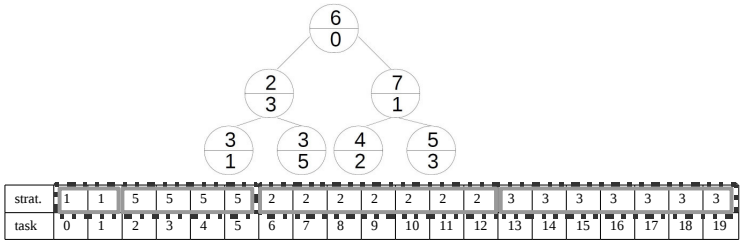
Finally, a feasible project schedule is obtained, which is used for calculating the genotype fitness. It is worth to notice that a genotype is always mapped onto a legal phenotype.

C. Fitness function

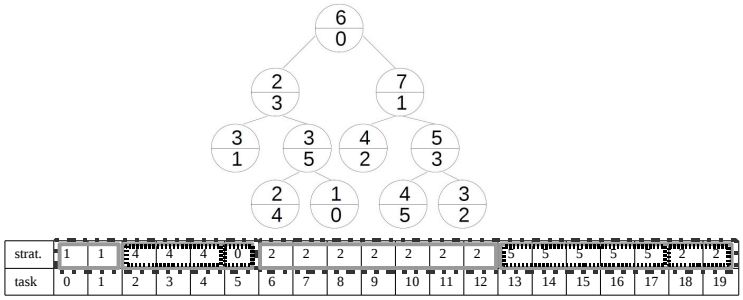
Each individual in the population is measured in order to check the quality of the solution. A numerical value, called fitness, is calculated for the project schedule obtained after



(a) II division



(b) III division



(c) IV division

Fig. 2. Genotype with 6 decision strategies (0-5) represented by a binary tree ($Tree_{height} = 4$) and a sequence of decision strategies (strat.) after the decoding, corresponding to the project activities (task)

Algorithm 1 The procedure of genotype-to-phenotype mapping, where $node$ - currently considered node, i - the index of activity in the list of activities, $size$ - the number of activities in the currently considered group of activities, $strat$ - a sequence of decision strategies, each corresponding to the given project activity

DECODETREE($root, 0, No.of activities$)
function DECODETREE($node$, i, $size$)
  if $node \neq NULL$ **then**
    DECODETREE($left\ child, i, node_d$)
    if $node = Leaf$ **then**
      $strat[i, i + size - 1] \leftarrow node_s$
    end if
    DECODETREE($right\ child, i+node_d, size-node_d$)
  end if
end function

the genotype-to-phenotype mapping. It is defined as the project cost (C), using the following equation:

$$C = \sum_{j=1}^{r} C_e(j) \cdot T_p + \sum_{j=1}^{n} \left(C_u(j) + \sum_{i=1}^{m} T(i,j) \cdot C_e(j) \right) \quad (2)$$

where $C_e(j)$ - cost of task execution per time unit by the resource R_j, T_p - the project duration, $C_u(j)$ - resource R_j unit cost, $T(i,j)$ - safe time estimate of task i being executed by the resource R_j, n - the number of resources used in the project schedule, m - the number of tasks, r - the number of resources in the resource library. The first sum corresponds to the resource maintenance cost in the project. In the second sum, the first element is the resource deployment cost and the second is the cost of the task's execution. The algorithm is set to find an individual with minimal fitness, meaning that genotypes that produce lower project cost are considered to be better ones.

D. Genetic operators

The genetic operations that are performed during the run (i.e. crossover, mutation, reproduction) are based on techniques described in [Deniziak and Wieczorek, 2012]. A crossover is applied with the probability $P_{cross} \in [0,1]$ on a randomly selected pairs of individuals. There are at most $\frac{POP}{2}$ such pairs. Next, the decision trees in pairs are pruned by removing a randomly selected edge. Then, subtrees are swapped between both parent genotypes. Similarly, a mutation is applied on each genotype in the population with the

probability $P_{mut} \in [0, 1]$. Afterwards, one of the following modifications, selected with the same probability, is done on the decision tree:

1) a randomly selected node is changed to another,
2) a randomly selected edge is pruned and the subtree is removed,
3) two random nodes are created and added to a randomly selected leaf.

Modifications are done only when the subtree contains more than one node. If the newly created tree is too high, it is pruned to the allowed height. Then, faulty nodes are removed to preserve the correct tree decoding. Implementation of genetic operators ensures that the correct genotype-tree structure is always kept. Moreover, they neither break precedence constraints nor produce infeasible schedules.

Reproduction copies the best individuals from the current generation to the next generation. We have tested several variants of reproduction such as the ranking method, proportional selection (roulette-wheel selection) and tournament selection. In the tournament selection some number of individuals (called a tournament size TS_{size}) are randomly chosen from the population and a genotype with the lowest fitness is selected. The chance of the individual's being selected in the roulette-wheel method is inversely proportional to its fitness. It is similar in ranking selection, but selection probabilities depend on an individual's position in the ranking. Each individual in the population has a numerical rank based on its fitness.

V. Experimental results

A. Test Instances

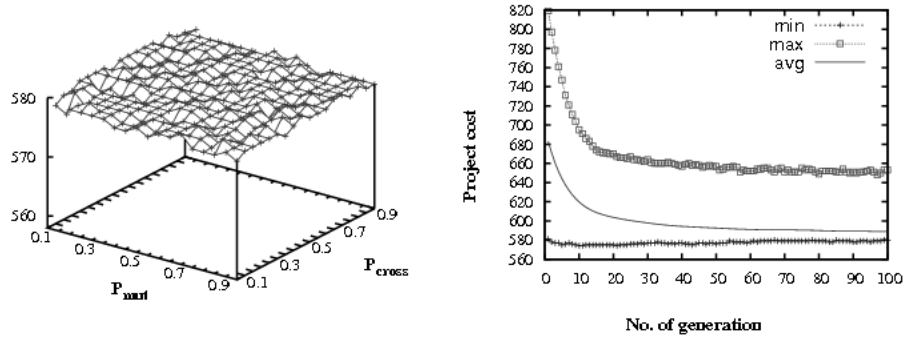
The algorithm described in the paper was tested on projects from PSPLIB, developed by [Kolish and Sprecher, 1996].The library for RCPSP contains 2040 projects with 30, 60, 90 and 120 activities for which either optimal, best-known or lower bound solutions are given. For each problem size, a set consists of 480 instances in groups of ten, which have been systematically generated by varying three parameters: network complexity, resource factor, and resource strength. The parameters have a big impact on the hardness of the project instances [Kolish and Sprecher, 1996]. The set with 30 non-dummy activities is the hardest standard set of RCPSP-instances for which all optimal solutions are currently known [Demeulemeester and Herroelen, 1997]. In our study we used project instances with 30 non-dummy activities. The renewable resources were randomly generated such that the resource development cost $C_u(j)$ and the cost of a activity's execution $C_e(j)$ might vary up to 10% from default values, which were 20 and 1 respectively. They are general purpose resources, so they may execute any of the activities. A single group of the project instances was examined, in which 10 independent runs were performed and the results were averaged. However, we considered an extension of DTCTP where resources have already got their own schedule (initial schedule). To this end, a project instance was randomly drawn from the same group in the PSPLIB. Then, activities from the project were randomly allocated to resources. Such activities cannot be moved and therefore the resources were available only in particular time periods. So even though we take the project instances from PSPLIB, our results cannot be compared with optimal because of a different problem statement. In most tests, the population size POP = 30, the number of generations (GEN) was set to 100 and the Tree height was set to 10, because for bigger values the difference of population sizes has little effect on the results.

B. Main results

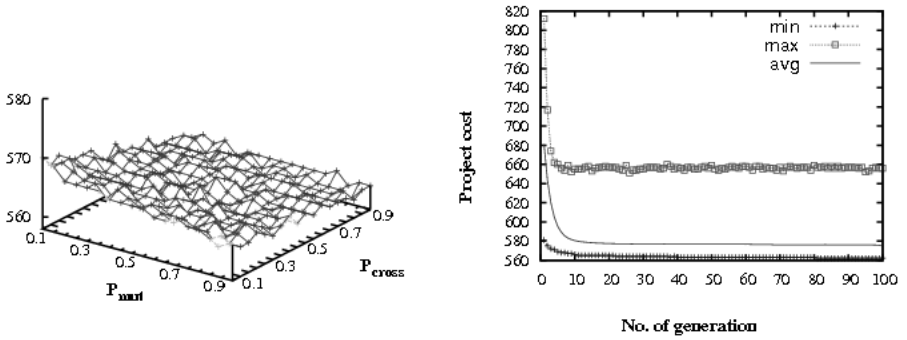
1) The selection method test: At first, we have tested three reproduction methods: ranking, roulette-wheel and tournament selection ($TS_{size} = 3$). The Figures 3 and 4 present the project cost averaged from 100 project schedules. In the roulette-wheel method (Figure 3a), the cost after 100 generations is approximately the same for various probabilities of mutation and crossover. The population contains randomly selected individuals with the probability proportional to their fitness and with no certainty that the best one will be reproduced. At the beginning a population is the most varied and its diversity lowers in further generations. But the best result in every subsequent generation is getting worse. The project cost is almost the same, along with the increase of the probability of both genetic operators, while in other methods it is significantly lower. In other methods the best results were obtained for $P_{cross} + P_{mut} > 1$. In the tournament method (Figure 2b) and ranking method (Figure 3c) there are much more good quality results in generations than bad ones. Good quality results start to dominate in the population very quickly along with the increasing number of generations and therefore the project cost decreases. The convergence of the ranking method is slightly faster than the tournament method. In the former one the rapid fall of the average cost stops after 5 generations while in the latter after 9 generations. Further improvement is very slight, but it occurs till the last generation. However, the best results were obtained for the tournament selection and therefore it was chosen for further examination.

2) Test of various probabilities of genetic operators: Next, tests were executed in order to examine how various probabilities of mutation (Figure 4a and 4b) and crossover (Figure 4c and 4d) influence the algorithm performance. The Figures show the lowest project cost in generations. Usually, the project cost becomes lower along with increasing P_{cross} as well as increasing P_{mut}, because the operators produce more new genotypes and the population is more varied. Thus, the chance of finding the optimal solution is bigger. However, only the best genotypes will be selected to the next generation. The variety of individuals may also be increased by increasing their number in generations. Generally, if the POP is bigger, the results are improved. Yet, the slope of the project cost reduction is similar.

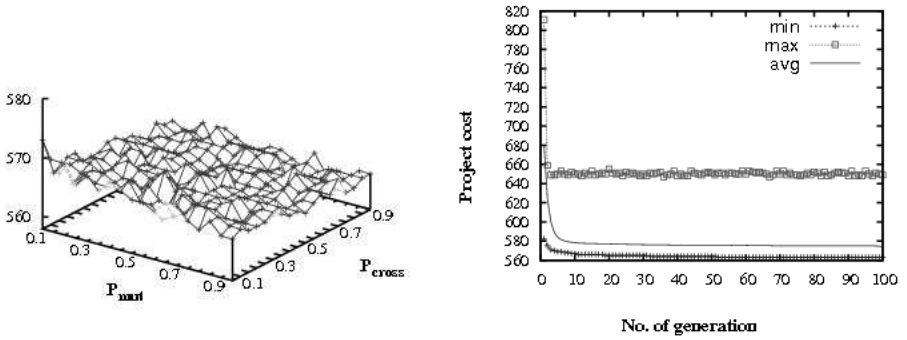
Further tests were performed to study the influence of project time constraints on the final result. Usually, the longer the project time allowed, the more genotypes were passing the *life test* so the population in each generation was bigger



(a) roulette-wheel selection ($POP_{size} = 30$, $Tree_{height} = 10$)



(b) tournament selection ($TS_{size} = 3$, $POP_{size} = 30$, $Tree_{height} = 10$)

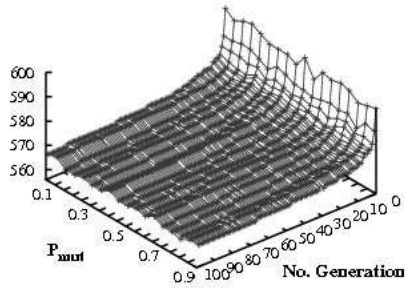


(c) ranking selection ($POP_{size} = 30$, $Tree_{height} = 10$)

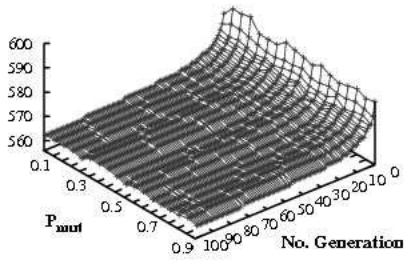
Fig. 3. Minimal cost of the project after 100 generations (left column) and the project cost in generations for $P_{cross} = 0.8$, $P_{mut} = 0.8$ (right column), where min - the lowest project cost, max - the highest project cost, avg - the average project cost, from all individuals of a given generation

and more diverse. Figure 5 shows how a reduction of the deadline affects the distribution of results in generations. The lower the deadline, the lower the number of bad individuals, which were reproduced to next generations. The percentage of newly created genotypes that passed the *life test* fell from 82 (90% of the deadline set) to 36 (60% of the deadline set). However, it did not influence the results. The average project cost, for different time constraints, is close to the best result, which indicates that most individuals in the population correspond to good quality results. Moreover, the convergence of the algorithm is very similar.

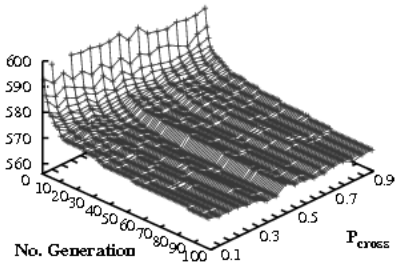
3) Comparison test: Finally, we have performed efficiency test on all 480 project instances where 10 independent runs were computed for each test case. The results were averaged and compared with other methods (Table I). Greedy procedures try to find a resource for each task, in a valid order, according to the smallest increase of the project duration ($Greedy_{time}$) or the project total cost ($Greedy_{cost}$). Another method is a heuristic based on iterative improvements driven by a metric of the gain of optimisation (MAO) [Deniziak, 2004]. It has the capacity of getting out of a local minimum. In [Pawiński and Sapiecha, 2013] the metaheuristic algorithm was adapted to take into account specific features of human resources participating in a project schedule. Their research showed high efficiency of the algorithm for resource allocation. Genetic approaches have similar evolution process



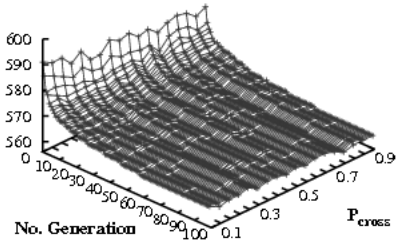
(a) $POP_{size} = 15$, $P_{cross} = 0.8$



(b) $POP_{size} = 30$, $P_{cross} = 0.8$



(c) $POP_{size} = 15$, $P_{mut} = 0.8$



(d) $POP_{size} = 30$, $P_{mut} = 0.8$

Fig. 4. Minimal cost of the project in generations for $Tree_{height} = 10$ and $P_{cross} = 0.8$ (upper row) or $P_{mut} = 0.8$ (lower row)).

TABLE I
THE METHOD COMPARISON RESULTS ($POP = 30, TS_{size} = 3, P_{cross} = 0,8, P_{mut} = 0,8, Tree_{height} = 10$)

Scheduling method	C	T_p	computation time [s]
$Greedy_{time}$	651,89	105,4	70
$Greedy_{cost}$	654,92	106,47	65
MAO	637,94	102,97	4560
GA	619,89	98,57	10062
DGP	599,9	92,69	13650

TABLE II
A COMPARISON OF THE UNCORRECTED SAMPLE STANDARD DEVIATION (S_N)

Scheduling method	S_N
GA	12,83
DGP	4,89

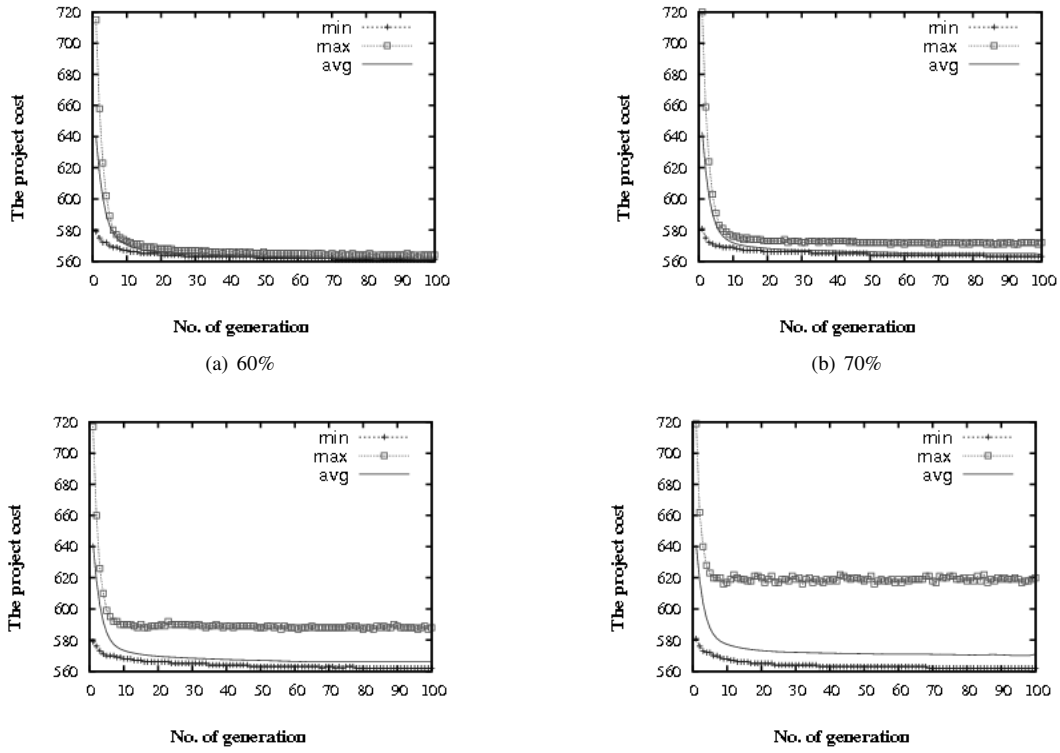
but they differ in a way of coding the genotype. In GA the genotype does not have a tree structure. Genetic operators are performed directly on a sequence of resources corresponding to project activities.

The DGP outperformed the MAO by 5.5% and the greedy methods by 8% as concerns project cost reduction, and by 6% and 12% as concerns project time reduction. Furthermore, the uncorrected sample standard deviation of the DGP was 3-times lower than the deviation of the GA (Table II). However, the DGP was 3-times slower than the MAO and 36% slower than the GA, mainly because of the high number of generations.

VI. CONCLUSIONS

The objective of this research was to introduce and evaluate a new heuristic that can efficiently solve an extension of the RCPSP. It is based on the idea of developmental genetic programming. An algorithm, which was worked out, searches for the best resource allocation strategies in a project. The method of constructing a project schedule takes the form of a decision tree that evolves, instead of evolving the solution itself. The quality of the solution is evaluated after the genotype-to-phenotype mapping.

The fitness function was defined as the project cost. Genetic operators specified for RCPSP were presented as well. To our best knowledge this is the first developmental genetic approach targeting the problem. Three reproduction methods were tested, from which the tournament method ($TS_{size} = 3$) gave the best results. The tournament reproduction ensures that only the best individuals will be selected to the next generation. Then, the influence of various probabilities of mutation and crossover on the algorithm performance was evaluated. Usually, the project cost was lower along with increasing P_{cross} as well as increasing P_{mut}. In the tournament and ranking selection the best results were obtained for $P_{cross} + P_{mut} > 1$. The project cost also decreases as the number of generations increases. Yet, 9 generations is enough



(a) 60% (b) 70%

(c) 80% (d) 90%

Fig. 5. Project cost in each generation for $P_{mut} = 0.8$, $P_{cross} = 0.8$, $POP_{size} = 30$ and with reduced time constraints, where min - the lowest project cost, max - the highest project cost, avg - the average project cost from all individuals of a given generation

to obtain good quality results. Further reduction of the project cost may be achieved by increasing the population size. The influence of the project time constraints on the final results was also tested. The number of bad individuals that were reproduced in subsequent generations was lower when the time constraints were more restricted. But though the genetic operators created 46% less genotypes that passed the *life test*, it did not influence the results. Experimental results showed that DGP is efficient and may be used for solving the extension of the RCPSP. It gives significantly better results than existing methods - it is 5% better than MAO and 8% better than greedy methods.

To our best knowledge this is the first developmental genetic approach targeting the problem. Future work will concentrate on analysing the influence of other parameters of the evolution as well as the influence of different implementations of genetic operators. We will also work on the parallel DGP model to reduce computation time.

International Workshop on Artificial Intelligence in Medical Applications

THE workshop on Artificial Intelligence in Medical Applications – AIMA'2014 - provides an interdisciplinary forum for researchers and developers to present and discuss latest advances in research work as well as prototyped or fielded systems of applications of Artificial Intelligence in the wide and heterogenious field of medicine, health care and surgery. The workshop covers the whole range of theoretical and practical aspects, technologies and systems based on Artificial Intelligence in the medical domain and aims to bring together specialists for exchanging ideas and promote fruitful discussions.

Topics

The topics of interest include, but are not limited to:

- Artificial Intelligence Techniques in Health Sciences
- Knowledge Management of Medical Data
- Data Mining and Knowledge Discovery in Medicine
- Health Care Information Systems
- Clinical Information Systems
- Agent Oriented Techniques in Medicine
- Medical Image Processing and Techniques
- Medical Expert Systems
- Diagnoses and Therapy Support Systems
- Biomedical Applications
- Applications of AI in Health Care and Surgery Systems
- Machine Learning-based Medical Systems
- Medical Data- and Knowledge Bases
- Neural Networks in Medicine
- Ontology and Medical Information
- Social Aspects of AI in Medicine
- Medical Signal and Image Processing and Techniques
- Ambient Intelligence and Pervasive Computing in Medicine and Health Care

Abstract—Proliferation of health related information on the internet is both welcoming and a concern. For instance when solicited information goes wrong, it tends to have dire consequences on the general public. Assessing the quality of internet health information is often difficult but a rational and systematic approach can be useful in evaluating the quality of the services they render to the public. The paper proposes a fuzzy VIKOR framework for evaluating and ranking internet health information providers under a fuzzy environment where uncertainties and subjectivities are catered for with linguistic variables. Linguistic variables with triangular fuzzy numbers (TFN) are used to evaluate weights of the evaluation criteria and the rankings of each internet health information provider. A numerical example is demonstrated using HIV/AIDS online information providers in the most adult prevalent country in the world. The proposed method is compared with TOPSIS and can be applied in evaluating the quality of other specific internet health information providers.

I. Introduction

HEALTH information, until the advent of the internet, was the exclusive preserve of medical professionals. Today, with high-speed broadband, smart mobile devices and wireless networks, more people rely on the internet for a range of health information support [1], [2]. Users often read about specific medical conditions, communicate in real-time with health care providers via chat rooms and answer health assessment questionnaires online [3], [4]. Majority of the people who search online for health advice do so to be better informed and prepared when consulting their physicians or just to reassure themselves of the status of their health. However, while most of the internet health information comes from authoritative sources such as governmental agencies, research institutions, product vendors, medical centres and individual professionals [45], a lot more of them also come from sources who though well-intentioned, tends to misinform and mislead users. This phenomenon breeds mistrust and presents issues of credibility regarding the source or the websites from which information is sought.

In Korea and China where online health information assists the aged in particular to take good care of themselves by adhering to personal care practices and avoiding illnesses [5], [6] misinformation can be fatal to their health. In the US, there are increasing numbers of citizens managing their health mainly from the information they seek online [7], [8] especially those who are unable to access certain health insurance supports. Such people are vulnerable to misleading information.

The growth in the number of people searching for health related information online has seen a corresponding increase with unregulated sites offering unprofessional advice. Additionally, a study in [9] found that health anxious individuals often do not care about the credibility of an online health information forum provided the information is reassuring and allays their fears. Health anxiety [10], [11], raises fears and often misconception about potential severity of ones' illnesses. In another study on changes occurring in the use of e-health services [12], two thirds of the respondents never checked for assurance of privacy of websites visited and 23% could not recollect the specific name of the site used. Whiles this is frightening, more worrying is that majority of the authors of online health information are not health professionals nor trained to author health information [13], [14], [15].

Subsequently, a number of studies have come out with models and frameworks for assessing the quality of online health information. Some of the notable criteria used in evaluating the quality of internet health information are accuracy, authority, currency, disclaimer, design, and security among others. This study makes a contribution by using fuzzy mathematics and VIKOR multi-criteria decision making (MCDM) technique to demonstrate how online health information providers could be ranked on a number of established criteria. The purpose is to guide users in their choice of websites for health related information. The concept and steps in fuzzy VIKOR are explained and a numerical example is performed using the websites of top 4 HIV/AIDS support organizations in Swaziland to show the usefulness of the technique in ranking health related information providers in any topical area.

II. Fuzzy MCDM

Multi-criteria decision making (MCDM) as a modelling and methodological tool is used to deal with complex decision making problems. MCDM has over the years become one of the most well-known branches of decision making [16], [17] applied in many disciplines. Fuzzy logic has proven to be a

978-83-60810-58-3/$25.00

useful and efficient way in approaching MCDM in situations of imprecise or subjective data in our natural language expression of thoughts and judgements. Since Bellman and Zadeh [18] proposed decision making in fuzzy environment, many extended theories and applications have been carried out to tackle various forms of MCDM. Among few of the Fuzzy MCDM applications are [19] where fuzzy Entropy and t-norm based fuzzy compromise programming is used in locating nuclear power plants in Turkey. In [20], a fuzzy linear programming MCDM model is used in allocating orders to suppliers in a supply chain under uncertainty environment, [21] employed fuzzy MCDM to measure the possibility of successful knowledge management. A hybrid fuzzy MCDM approach based on DEMATEL, ANP and TOPSIS is proposed by [22] to evaluate green suppliers and in [23] a conjunctive MCDM approach also based on DEMATEL, fuzzy ANP, and TOPSIS is modelled as an innovation support system for Taiwanese higher education.

Fuzzy logic has been extended to almost all other MCDM techniques such as Analytic Hierarchy Process (AHP), Analytic Network Process (ANP), ELimination and Choice Expressing REality (ELECTRE), Grey Relational Analysis (GRA), Preference Ranking Organization Method for Enrichment Evaluation (PROMETHEE), Technique for Order Preference by Similarity to Ideal Solution (TOPSIS), Weighted Product Model and VIsekriterijumska optimizacija i KOmpromisno Resenje (VIKOR).

III. FUZZY VIKOR METHOD

VIKOR is a compromise ranking method introduced by Opricovic [24]. The VIKOR method first establishes (1) a compromise ranking-list, (2) a compromise solution, and (3) the weight stability intervals for the compromise solution [24], [25]. It then determines the positive-ideal solution and the negative-ideal solution to aid in ranking and selection [26]. The underlying principle of the VIKOR MCDM method is to deal with ranking and selection of alternatives which have multi-conflicting or non-commensurable criteria [27].

As is usual of most MCDM techniques, the VIKOR method was also extended to accommodate subjectivity and imprecise data under fuzzy environment [28]. A number of applications from various disciplines have been carried out using the fuzzy VIKOR method. In [29], fuzzy VIKOR is used in selecting insurance companies in a group decision making process whiles [30] employed fuzzy VIKOR to resolve multi-criteria decision-making problems. The method is used by [31], [32] for supplier selection problems. In [32], however, the method is modified using entropy measure for objective weighting. In [33] fuzzy VIKOR is utilized for optimized partners' choice in IS/IT outsourcing projects. In [34] the compromise method is used to select renewable energy project in Spain. Similarly in [35] an integrated fuzzy VIKOR and AHP methodology is used to plan renewable energy in Istanbul. In [36] a combined form of fuzzy VIKOR and GRA techniques is utilized to evaluate service quality of airports, [37] applied fuzzy VIKOR for material selection and [38] used fuzzy VIKOR in a robot selection. Again in [39], fuzzy VIKOR based on DEMATEL and ANP is utilized in assessing information security risk control. The literature reviewed portrays the underlying principle of the VIKOR method for selecting and ranking problems but seldom applied in evaluation of service quality.

IV. FUZZY SET THEORY

The human language is filled with imprecision, subjectivities and vagueness when used to judge, describe and communicate information. In view of this, Zadeh [24] introduced the fuzzy set theory to model human judgements. The following are some useful definitions of the fuzzy set theory.

Definition 1: Fuzzy Set. Let X be a nonempty set, the universe of discourse $X=\{x_1, x_2, ..., x_n\}$. A fuzzy set A of X is a set of ordered pairs: $\{(x_1, f_A(x_1)),(x_2, f_A(x_2)),...,(x_n, f_A(x_n))\}$, characterized by a membership function $f_A(x)$ that maps each element x in X to a real number in the interval $[0,1]$. The function value $f_A(x)$ stands for the membership degree of x in A. To capture the vagueness and variations in the subjective ratings of a decision maker, a fuzzy number is used. A Fuzzy number is an expression of membership functions of a linguistic term and ascribe a rating set between the interval [0, 1] for subjective ratings. The two most popular fuzzy numbers are the trapezoidal and triangular fuzzy numbers. In this paper we use the Triangular Fuzzy Number (TFN).

Definition 2: Triangular fuzzy number. A triangular fuzzy number (TFN) is expressed as a triplet (a,b,c). The membership function $f_A(x)$ of a triangular fuzzy number is as defined in Eqn. 1

$$f_A(x)=\begin{cases}0 & x<a, x>b\\ \frac{x-a}{b-a}, & a\le x\le b\\ \frac{c-x}{c-b}, & b\le x\le c\end{cases} \quad (1)$$

Fuzzy models that use TFNs prove to be effective for solving decision-making problems where the available information is subjective and vague [19, 20].

Definition 3: Basic TFN Operations: Assuming $A=(a,b,c)$ and $B=(a_1,b_1,c_1)$ are two TFNs, the basic operations on these two fuzzy triangular numbers are as follows:

$$A\oplus B=(a,b,c)+(a_1,b_1,c_1)=(a+a_1,b+b_1,c+c_1) \quad (2)$$

$$A-B=(a,b,c)-(a_1,b_1,c_1)=(a-c_1,b-b_1,c-a_1) \quad (3)$$

$$A\times B=(a,b,c)\times(a_1,b_1,c_1)=(aa_1,bb_1,cc_1) \quad (4)$$

$$A\div B=(a,b,c)\div(a_1,b_1,c_1)=\left(\frac{a}{c_1},\frac{b}{b_1},\frac{c}{a_1}\right) \quad (5)$$

V. EVALUATING QUALITY OF INTERNET HEALTH INFORMATION

The growing interests and efforts at assessing the quality of health information on the Internet have generated several sets of criteria from a number of sources with little research work on

standardizing such criteria. This study first proposes a new set of criteria for evaluating quality of internet health information culled from several sources [40], [41], [42], [43], [44], [45], [46], [47], [48], [49] as shown in Fig. 1. Secondly, the criteria are used to construct a framework for evaluating the quality of internet health information using fuzzy VIKOR method. We propose that the decision makers be composed of consumer health information experts, self-help group representatives, clinical specialists, general practitioners, lay medical publishers, community health Association representatives, health journalists and information security experts. The criteria used in this study are grouped into four main clusters namely: (a) credibility (b) content (c) design and (d) security. With each cluster having a set of sub-criteria, the total criteria used in this study are fifteen (15). The rationale for selecting the four clusters and their sub-criteria are explained below.

A. Credibility

This cluster examines users' trust in online health information [42], [49]. There are four indicators to measure the credibility of a website providing health information. These are the source, context, relevance and disclosure. The most important criterion for judging the credibility of an online health information provider is the source since it helps to defuse user doubts about the credibility of the information accessed.

B. Content

The content of a website providing health related information is equally deemed important for winning users trust. The sub-criteria are accuracy, currency, disclaimer and authority [43], [45]. Accuracy is often regarded the most important criteria for evaluating "content" and seeks for the scientific validity of the information provided. Users expect proven solutions that are rooted in scientific theory [49].

C. Design

Design defines the quality features and the ease of use of a health information website [43]. Though design does not contribute directly to the quality of information on a website, it is a necessary requirement to ensure frequent delivery of information to users. This is made possible through logical organization of the website information for user understanding [45]. The sub-criteria are accessibility, attractiveness and links.

D. Security

Security is essential in a website providing health related information because of the sensitive and confidential information shared in real-time interactions [49]. Some websites provide chat rooms where users seek advice on a range of issues. It is incumbent on the internet health information provider to assure users of their confidentiality. In this proposed framework, security is measured using caveat together with the CIA triad of confidentiality, integrity and availability. Caveat looks at a website's ability to assure consumers through statements that personal information would not be transferred to third parties or even stored [45]. CIA triad [46], [47] is a widely applied model designed to guide and evaluates information systems security policies. The most obvious element of the CIA triad is confidentiality which ensures that data or an information system is accessed only by authorized persons. Confidentiality is achieved through the protection of user Id's and passwords and other policy based security measures [45].

VI. PROPOSED FUZZY FRAMEWORK

The fuzzy VIKOR approach used in this study is organized in the following order. First, the importance weights of the evaluation criteria are determined and then the performance rating matrix is constructed. Second is the computation of the fuzzy best and worst values of the criteria. Normalized fuzzy difference and the separation values are also computed. Lastly, the triangular fuzzy numbers are defuzzified into crisp values to determine rankings of the alternatives and consequently a compromise solution is proposed.

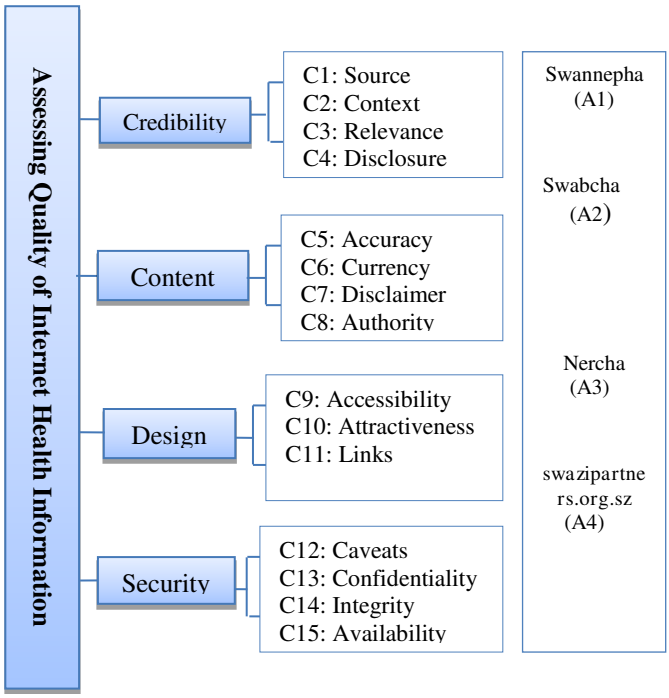

Fig. 1: A framework for evaluating quality of internet Health Information

Step 1: Determining linguistic Variables

The first step in the fuzzy VIKOR method is to determine the linguistic variables; the criteria for evaluating the quality of internet health information. Linguistic terms transformed into fuzzy numbers are used by the experts to rate each linguistic variable. Linguistic terms are qualitative words or phrases of a natural language that reflect the subjective view of an expert about the criteria per each alternative under consideration [50]. In this study, triangular fuzzy numbers are used as shown in Table I and Table II respectively to capture the ratings of the criteria and alternatives on a scale of 0-1.

Table I. Linguistic Scale for the importance of criteria

Linguistic terms	Triangular fuzzy number
Very Low (VL)	(0.0,0.1,0.3)
Low (L)	(0.1,0.3,0.5)
Medium(M)	(0.3,0.5,0.7)
High (H)	(0.5,0.7,0.9)
Very High (VH)	(0.7,0.9,1.0)

Table III. Linguistic scale for ratings of alternatives

Linguistic terms	Triangular fuzzy number
Very Poor (VP)	(0.0,0.0,0.2)
Poor (P)	(0.0,0.2,0.4)
Fair (F)	(0.2,0.4,0.6)
Good (G)	(0.4,0.6,0.8)
Very Good (VG)	(0.6,0.8,1.0)
Excellent (E)	(0.8,0.1,1.0)

Step 2: Determining importance weight of criteria

The evaluation criteria for determining the quality of internet health information providers are supposed to have different importance weights. To determine the importance weight of each criterion, the decision makers rate each criterion using the linguistic terms in Table I. This is expressed in Eq. 6 as vector

$$\tilde{W}: \tilde{W}=\left[\tilde{w}_1,\tilde{w}_2,...,\tilde{w}_n\right] j=1,2,...,n \quad (6)$$

where $\tilde{w}_j$ represents the weight of the jth criterion based on the linguistic preference assigned by a decision maker. Each weight $\tilde{w}_j^k=(w_{j1}^k,w_{j2}^k,w_{j3}^k)$ is expressed as a TFN. These preferences signify the importance attributed to a criterion by a decision maker. The study uses the graded mean integration method [51] to aggregate the decision makers' opinions. The fuzzy importance weight $\tilde{w}_j$ for criterion C_j is computed as:

$$\tilde{w}_j^k=\left(w_{j1},w_{j2},w_{j3}\right) \text{ where, } w_{j1}=\min_k\left\{w_{jk1}\right\},\ w_{j2}=\frac{1}{k}\sum_{k=1}^{k}w_{jk2},$$

$$w_{j3}=\max_k\left\{w_{jk3}\right\} \text{ for } i=1,2,...,m;\ j=1,2,...,n \quad (7)$$

Step 3: Constructing the fuzzy decision matrix

Consider a group of k decision-makers $(D_1,D_2,...,D_k)$ presented with m alternatives $(A_1,A_2,...,A_m)$ against n set of criteria $(C_1,C_2,...,C_n)$ in a typical MCDM problem. A fuzzy multi-criteria decision-making is formally expressed as:

$$\tilde{D}=\begin{array}{c} \\ A_1\\ A_2\\ \vdots\\ A_m\end{array}\begin{array}{c}\begin{array}{cccc} C_1 & C_2 & \dots & C_n\end{array}\\ \begin{bmatrix}\tilde{x}_{11} & \tilde{x}_{12} & \dots & \tilde{x}_{1n}\\ \tilde{x}_{21} & \tilde{x}_{22} & \dots & \tilde{x}_{2n}\\ \vdots & \vdots & \ddots & \vdots\\ \tilde{x}_{m1} & \tilde{x}_{m2} & \dots & \tilde{x}_{mn}\end{bmatrix}\end{array} i=1,2,...,m;\ j=1,2,...,n \quad (8)$$

where, $\tilde{x}_{mn}$ is the rating of alternative A_m with respect to criterion C_j. Note that for a decision maker k, $\tilde{x}_{ij}^k=(a_{ij}^k,b_{ij}^k,c_{ij}^k)$ is a TFN. Similarly as in step 2, the graded mean integration method is used to aggregate the opinions of the decision makers concerning the ratings of the alternatives (websites).This is formally expressed as $\tilde{x}_{ij}^k=\left(a_{ij}^k,b_{ij}^k,c_{ij}^k\right)$ where,

$$a_{ij}=\min_k\left\{a_{ij}^k\right\},b_{ij}=1/k\sum_{k=1}^{k}b_{ij}^k,c_{ij}=\max_k\left\{c_{ij}^k\right\}\ i=1,2,...,m;\ j=1,2,...,n \quad (9)$$

Step 4: Fuzzy best value f_i^* and fuzzy worst value f_i°

The fuzzy best value $f_i^*=\left(a_i^*,b_i^*,c_i^*\right)$ and the fuzzy worst values $f_i^\circ=\left(a_i^\circ,b_i^\circ,c_i^\circ\right)$ are computed respectively using Eq. 10 and 11 below [25], [30].

$$\tilde{f}_i^*=\max_j\tilde{f}_{ij},\ \tilde{f}_i^\circ=\min_j\tilde{a}_{ij}, \text{ for } i\in B \quad (10)$$

$$\tilde{f}_i^*=\min_j\tilde{f}_{ij},\ \tilde{f}_i^\circ=\max_j\tilde{a}_{ij}, \text{ for } i\in C \quad (11)$$

where B is the benefit criteria and C, the cost criteria.

Step 5: Normalized fuzzy difference $\tilde{d}_{ij}$

To obtain the fuzzy difference $\tilde{d}_{ij}$, it is computed as below:

$$\tilde{d}_{ij}=(\tilde{f}_i^*-\tilde{x}_{ij})/(c_i^*-a_i^\circ) \quad \text{for } i\in B \quad (12)$$

$$\tilde{d}_{ij}=(\tilde{x}_{ij}-\tilde{f}_i^*)/(c_i^\circ-a_i^*) \quad \text{for } i\in C \quad (13)$$

where B is the benefit criteria and C, the cost criteria

Step 6: Computing separation Measures $\tilde{S}_j$ and $\tilde{R}_j$

The next step computes the separation $\tilde{S}_j$ of alternative A_j from the fuzzy best value f_i^*. Similarly, the separation of $\tilde{R}_j$ of alternative A_j from the fuzzy worst value f_i° is also computed. These are respectively measured using Eq. 14 and 15:

$$\tilde{S}_j=\sum_{i=1}^{n}(\tilde{w}_j\otimes\tilde{d}_{ij}) \quad (14)$$

$$\tilde{R}_j=\max_i(\tilde{w}_j\otimes\tilde{d}_{ij}) \quad (15)$$

where $\tilde{S}_j=(S_j^a,S_j^b,S_j^c)$ is a fuzzy weighted sum of the separation measure of A_j from the best value f_i^* [27]. Similarly, $\tilde{R}_j=(R_j^a,R_j^b,R_j^c)$ is a fuzzy MAX which refers to the separation measure of A_j from the worst value f_i° where w_j is the importance weight of criterion C_j.

Step 7: Computing the value of $\tilde{Q}_j$

The value $\tilde{Q}_j=(a_j,b_j,c_j)$ expressed in a triangular fuzzy number is computed as following:

$$\tilde{Q}_j=v(\tilde{S}_j-\tilde{S}^*)/(S^{\circ c}-S^{*a})\oplus(1-v)(\tilde{R}_j-\tilde{R}^*)/(R^{\circ c}-R^{*a}) \quad (16)$$

where $\tilde{S}^*=MIN_j\tilde{S}_j,\ S^{\circ c}=MAX_jS_j^c,\ \tilde{R}^*=MIN_j\tilde{R}_j$

$R^{\circ c}=MAX_jR_j^c$ and $v(v=n+1/2n)$ is taken as a weight for the strategy of "majority criteria" (or "maximum utility"), where $1-v$ represents the weight of the individual regret [28]. The best values of S and R are respectively $\tilde{S}^*$ and $\tilde{R}^*$.

Step 8: Defuzifying $\tilde{S}_j$, $\tilde{R}_j$ and $\tilde{Q}_j$

In fuzzy logic, defuzzification is the process of converting the fuzzy numbers into crisp values [50]. The defuzzification is computed by locating the Best Non fuzzy Performance (BNP). A range of defuzzification methods such as Center Of Area (COA), mean of maximum and weighted average method [53] can be used. This paper uses the defuzzification method of COA for ranking fuzzy numbers by [52, 53]. The defuzzification process converts $\tilde{S}_j$, $\tilde{R}_j$ and $\tilde{Q}_j$ into crisp values S, R and Q.

Step 9: Ranking the alternatives

This step ranks the alternatives by sorting the values of S, R and Q in descending order resulting in three ranking lists $\{A\}_S$, $\{R\}_S$ and $\{Q\}_S$ respectively. The index Q_i is the separation measure of A_i from the best alternative. Consequently, the smaller Q_i, the better the alternative.

Step 10: Proposing a Compromise solution

A compromised solution is proposed at this stage where alternative $(A^{(1)})$ is the best ranked by the measure Q (minimum) if the following two conditions are satisfied:

[Condition 1]: Acceptable advantage:

$$Q(A^{(2)}) - Q(A^{(1)}) \geq DQ \quad (17)$$

where $A^{(2)}$ represents the alternative with second position in the ranking list $\{A\}_Q$. Additionally, the threshold $DQ = 1/(n-1)$ where n indicates the number of feasible alternatives.

[Condition 2]: Acceptable stability in decision-making:

The alternative $A^{(1)}$ must be the best ranked by S or/and R. Here if one of these conditions is not satisfied, then a set of compromise solution is proposed consisting of:

1. Alternatives $A^{(1)}$ and $A^{(2)}$ if only condition 2 is not satisfied, or
2. Alternatives $A^{(1)}, A^{(2)}, \ldots, A^{(M)}$ if condition 1 is not satisfied; $A^{(M)}$ is determined by the relation $Q(A^{(M)}) - Q(A^{(1)}) \leq DQ$ for maximum M (the positions of these alternatives are in "closeness").

VII. Numerical Example

This section demonstrates how the fuzzy VIKOR method can be used to evaluate and rank online health information providers. The numerical example in this paper assumes an 8-member decision making team evaluating and ranking the websites of four HIV/AIDS organizations in Swaziland. Swaziland has the world's highest HIV/AIDS adult prevalent rates [54]. The rise in internet rate in Africa leads to reliance on internet for information. In view of this, the quality of information provided by a website on health is crucial. The four websites used in this demonstration are shown in Fig 1. In the following steps, Fuzzy VIKOR is used to demonstrate how to arrive at decision-makers' preferable compromise solution or alternative. The computational illustration of this numerical example is shown as follows:

Step 1: Determining linguistic Variables

The linguistic variables and the alternatives are as shown in Fig. 1. The linguistic terms for the importance weight criteria and the ratings for the alternatives per each criterion used in this paper are as subsequently shown in Table I and Table II.

Step 2: Determining importance weight of criteria

The evaluation is organized into four main clusters comprising 15 sub-criteria for the evaluation of the quality of online health information as shown in Fig 1. This second step in the fuzzy VIKOR MCDM process offers evaluators the chance to choose by rating the most important criteria for the evaluation guided by the linguistic terms in Table I. The linguistic preferences for our assumed eight decision makers concerning the importance attached to each criterion is as shown in Table III below.

Table III. Importance weight of criteria

	D1	D2	D3	D4	D5	D6	D7	D8
C1	VL	M	H	VL	L	L	M	L
C2	M	H	M	M	M	H	H	H
C3	VH	M	H	H	H	VH	M	H
C4	VH	M	H	M	H	M	M	VH
C5	VH	H	VH	VH	VH	H	VH	H
C6	VH	M	H	VH	VH	M	VH	VH
C7	M	M	VH	H	VH	VH	H	VH
C8	L	L	M	H	M	VL	L	L
C9	M	M	H	H	M	L	M	VL
C10	H	M	M	H	H	M	L	H
C11	H	M	H	M	M	H	H	L
C12	H	M	VH	H	VH	VH	M	VH
C13	M	M	M	H	H	H	M	VH
C14	M	H	H	VH	M	L	M	VH
C15	VH	M	M	VH	VH	M	H	H

The graded mean integration method defined in Eq. 7 is used to aggregate the decision makers' opinions regarding the importance weightings of each criterion. The result of such aggregation is shown in Table IV. To determine the importance of each criterion by ranking, the fuzzy numbers are defuzzified. The paper uses the COA (center of area) method in computing the Best Non-Fuzzy Performance value (BNP) to rank the order of importance of each criterion. The BNP value of the fuzzy number $W_k = (L_{wk}, M_{wk}, U_{wk})$ is calculated using the expression in Eq. 18.

$$BNP_{wk} = L_{wk} + [(U_{wk} - L_{wk}) + (M_{wk} - L_{wk})]/3 \quad (18)$$

Table IV. Fuzzy aggregated weights of criterion

	TFN	BNP	Rank
C1	(0.0, 0.35, 0.9)	0.417	15
C2	(0.3, 0.60, 0.9)	0.600	10
C3	(0.3, 0.70, 1.0)	0.667	5
C4	(0.3, 0.65, 1.0)	0.650	7
C5	(0.5, 0.83, 1.0)	0.775	1
C6	(0.3, 0.78, 1.0)	0.692	2
C7	(0.3, 0.74, 1.0)	0.679	4
C8	(0.0, 0.38, 0.9)	0.425	14
C9	(0.0, 0.48, 0.9)	0.458	13
C10	(0.1, 0.58, 0.9)	0.525	11
C11	(0.1, 0.58, 0.9)	0.525	11
C12	(0.3, 0.75, 1.0)	0.683	3
C13	(0.3, 0.63, 1.0)	0.642	8
C14	(0.1, 0.75, 1.0)	0.617	9
C15	(0.3, 0.70, 1.0)	0.667	5

For example, the BNP value for criteria 1 (C1) is computed as follows:

$$=0.0 + [(0.90-0.0) + (0.35-0.0)]/3 = 0.417 \quad (19)$$

By the BNP value computation, the major influential criteria out of the 15 are C5 with a rank of 1 and (C6, C12 and C7) with a rank of 2, 3 and 4 respectively. The least important criterion would be C1 with a rank of 15.

Step 3: Constructing the fuzzy decision matrix

Similarly as in step 2, the decision makers rate the various online health information providers using linguistic terms in Table II. These linguistic judgments would represent the opinions of the evaluators in rating and ranking the four HIV/AIDS organizations. Table V demonstrates assumed ratings of evaluators which have been aggregated using Eq. 9.

Table V. Aggregated fuzzy decision matrix

	A1	A2	A3	A4
C1	(3.18,5.18,7.18)	(4.01,6.01,8.01)	(4.48,6.68,8.68)	(2.46,4.46,6.46)
C2	(3.26,5.18,7.18)	(4.51,6.51,8.43)	(5.34,7.34,9.18)	(2.68,4.68,6.68)
C3	(2.19,4.19,6.19)	(3.85,5.85,7.78)	(4.19,6.19,8.19)	(3.02,5.02,7.02)
C4	(3.21,5.21,7.21)	(4.52,6.50,8.42)	(4.10,6.02,7.85)	(2.19,4.02,6.02)
C5	(3.19,5.19,7.19)	(4.85,6.85,8.69)	(4.53,6.53,8.44)	(3.02,5.02,7.02)
C6	(3.02,5.02,7.02)	(4.69,6.69,8.52)	(5.19,7.19,9.02)	(1.85,3.69,5.69)
C7	(3.10,5.02,7.02)	(4.69,6.69,8.60)	(4.35,6.35,8.35)	(2.85,4.85,6.85)
C8	(4.69,6.69,8.44)	(3.51,5.34,7.34)	(2.51,4.34,6.34)	(2.09,4.01,6.01)
C9	(4.70,6.70,8.61)	(4.36,6.36,8.28)	(3.03,5.03,7.03)	(1.70,3.53,5.53)
C10	(3.08,5.10,7.08)	(4.91,6.91,8.75)	(4.59,6.59,8.50)	(3.25,5.25,7.25)
C11	(3.12,5.12,7.12)	(4.79,6.79,8.62)	(5.29,7.29,9.12)	(1.95,3.79,5.79)
C12	(3.14,5.06,7.06)	(4.73,6.73,8.71)	(4.39,6.39,8.39)	(2.89,4.89,6.89)
C13	(2.58,4.42,6.42)	(2.17,4.09,6.09)	(4.78,6.78,8.52)	(3.58,5.42,7.42)
C14	(3.09,5.09,7.09)	(4.42,6.42,8.34)	(4.76,6.76,8.67)	(1.76,3.59,5.59)
C15	(2.73,5.49,7.34)	(4.45,7.12,8.36)	(2.53,3.78,5.59)	(4.79,6.79,8.68)

Step 4: Fuzzy best value f_i^* and fuzzy worst value f_i°

The study utilizes Eqs. 10 and 11 to determine the fuzzy best and fuzzy worst values for the evaluation criteria. The result of this process is shown in Table VI.

Table VI. Fuzzy best value f_i^* and fuzzy worst value f_i°

Criteria	f_i^*	f_i°
C1	(4.48,6.68,8.68)	(2.46,4.46,6.46)
C2	(5.34,7.34,9.18)	(2.68,4.68,6.68)
C3	(4.19,6.19,8.19)	(2.19,4.19,6.19)
C4	(4.52,6.50,8.42)	(2.19,4.02,6.02)
C5	(4.53,6.53,8.44)	(3.02,5.02,7.02)
C6	(5.19,7.19,9.02)	(1.85,3.69,5.69)
C7	(4.69,6.69,8.60)	(2.85,4.85,6.85)
C8	(4.69,6.69,8.44)	(2.09,4.01,6.01)
C9	(4.70,6.70,8.61)	(1.70,3.53,5.53)
C10	(4.91,6.91,8.75)	(3.08,5.10,7.08)
C11	(5.29,7.29,9.12)	(1.95,3.79,5.79)
C12	(4.73,6.73,8.71)	(2.89,4.89,6.89)
C13	(4.78,6.78,8.52)	(2.58,4.42,6.42)
C14	(4.76,6.76,8.67)	(1.76,3.59,5.59)
C15	(4.79,6.79,8.68)	(2.53,3.78,5.59)

Step 5: Normalized fuzzy difference $\tilde{d}_{ij}$

In this step, the normalized fuzzy difference $\tilde{d}_{ij}$ is computed using Eqs. 12 and 13. For example, $\tilde{d}_{A1}$ is computed as below.

$$\tilde{d}_{A1} = \frac{[(4.48,6.68,8.68)-(3.18,5.18,7.18)]}{8.68\text{-}2.46} \quad (20)$$

$$= \frac{[(4.48\text{-}7.18),(6.68\text{-}5.18),(8.68\text{-}3.18)]}{6.22} = (-0.434, 0.241, 0.884)$$

The rest of the normalized fuzzy differences are calculated in the same manner.

Step 6: Computing separation Measures $\tilde{S}_j$ and $\tilde{R}_j$

The separation measures of $\tilde{S}_j$ and $\tilde{R}_j$ of alternative A_j from the fuzzy best and worst values respectively are computed using Eqs. 14 and 15. The resulting Table VII is as shown below:

Table VII. Index $\tilde{S}_j$ and $\tilde{R}_j$

	A1	A2	A3	A4
C1	(0,0.084,0.795)	(0.0,0.037,0.67)	(0.0,0.0,0.61)	(0.0,0.12,0.90)
C2	(-0.085,1.99,1.0)	(-0.14,0.08,0.65)	(-0.177,0.0,0.53)	(-0.062,0.24,0.9)
C3	(-1.0,2.33,1.0)	(-0.18,0.04,0.72)	(-0.2,0.0,0.67)	(-0.14,0.136,0.86)
C4	(-0.13,0.13,0.84)	(-0.19,0.0,0.63)	(-0.16,0.05,0.69)	(-0.072,0.26,1.0)
C5	(-0.25,0.21,0.97)	(-0.38,-0.05,0.66)	(-0.36,0.0,0.72)	(-0.23,0.23,1.0)
C6	(-0.08,0.24,0.84)	(-0.14,0.05,0.6)	(-0.16,0.0,0.53)	(-0.021,0.38,1.0)
C7	(-0.12,0.21,0.96)	(-0.2,0.0,0.68)	(-0.19,0.04,0.74)	(-0.11,0.24,1.0)
C8	(0.0,0.0,0.53)	(-0.0,0.08,0.7)	(0.0,0.14,0.84)	(0.0,0.16,0.90)
C9	(0.0,0.0,0.51)	(-0.0,0.024,0.55)	(0.0,0.116,0.73)	(0.0,0.22,0.90)
C10	(-0.04,0.185,0.9)	(-0.068,0.0,0.61)	(-0.06,0.03,0.66)	(-0.04,0.17,0.87)
C11	(-0.30,0.17,0.75)	(-0.05,0.04,0.54)	(-0.05,0.0,0.48)	(-0.006,0.28,0.9)
C12	(-0.12,0.21,0.96)	(-0.20,0.0,0.68)	(-0.188,0.04,0.74)	(-0.11,0.288,1.0)
C13	(-0.08,0.25,1.0)	(-0.066,0.28,1.06)	(-0.188,0.0,0.63)	(-0.13,0.14,0.83)
C14	(-0.03,0.18,0.81)	(-0.05,0.04,0.62)	(-0.056,0.0,0.56)	(-0.012,0.34,1.0)
C15	(-0.12,0.14,0.97)	(-0.17,-0.03,0.68)	(-0.039,0.34,1.0)	(-0.189,0.0,0.63)
$\tilde{S}_j$	(-1.185,2.46,12.6)	(-1.84,0.58,10.07)	(-1.84,0.77,10.14)	(-1.13,3.22,13.70)
$\tilde{R}_j$	(0.0,0.25,1.0)	(0.0,0.285,1.07)	(0.0,0.34,1.0)	(0.0,0.38,1.0)

Step 7: Computing the value of $\tilde{Q}_j$

$\tilde{S}^* = (-1.850, 0.588, 10.078)$; $\tilde{R}^* = (0.00, 0.25, 1.00)$, $S^{oc} = 13.69885$; $R^{oc} = 1.069024$.

For example $\tilde{Q}_{jA1}$ is computed using Eq.16 as shown below:

$$\tilde{Q}_{jA1} = \{0.5[(-1.18-10.08, 2.46-0.59, 12.64+1.84)]/(13.69+1.84)\}$$
$$+\{1-0.5[0-1, 0.25-0.25, 1-0]/(1.06-0)\}$$
$$= (-0.82995, 0.06028, 0.93366)$$

By same calculation, the values of the other alternatives are

$\tilde{Q}_{jA2}$=(–0.85130,0.01637,0.88359), $\tilde{Q}_{jA3}$=(–0.85116,0.04898,0.85327)

$\tilde{Q}_{jA4}$=(–0.82831,0.14579,0.96772)

Step 8: Defuzifying $\tilde{S}_j$, $\tilde{R}_j$ and $\tilde{Q}_j$

The defuzzification process converts $\tilde{S}_j$, $\tilde{R}_j$ and $\tilde{Q}_j$ into crisp numbers S, R and Q. The results are shown in Table VIII.

Table VIII. Defuzzified values of S, R and Q

	A1	**A2**	**A3**	**A4**
Q	0.54661	0.016218	0.017031	0.095065
S	4.63946	2.939804	3.021934	5.263415
R	0.416768	0.451442	0.447534	0.460251

Step 9: Ranking the alternatives

The crisp value of the alternatives for Q is ranked from the smallest value to the highest value. The alternatives are ranked as shown in Table IX below.

Table IX. Rank for alternatives

	A1	A2	A3	A4
Q	0.54661	0.016218	0.017031	0.095065
Rank	3	1	2	4

Step 10: Proposing a Compromise solution

In Table IX, the best ranked alternative is A2 which happens to be the best compromise solution. According to the values of Q_j and S_j as shown in Table VIII, the ascending rank of the four HIV/AIDS online information providers in Swaziland is $Q_{A2} \succ Q_{A3} \succ Q_{AI} \succ Q_{A4}$ and $S_{A2} \succ S_{A3} \succ S_{AI} \succ S_{A4}$

Now by the ascending rank order, the HIV/AIDS support organization known as Swabcha (A2), which had the minimum of Q_j and S_j, would be said to have the best quality in terms of provision of online HIV/AIDS information in Swaziland.

VIII. COMPARISON WITH FUZZY TOPSIS

This stage compares the fuzzy VIKOR results from the study with another popular MCDM method called the Technique for Order Preference by Similarity to Ideal Solution (TOPSIS). Fuzzy VIKOR and TOPSIS are both widely used for various selection and ranking solutions. The TOPSIS technique was proposed by [55] but extended to fuzzy TOPSIS by [56]. The technique introduces the shortest distance from the Fuzzy Positive Ideal Solution (FPIS) and the farthest distance from the Fuzzy Negative Ideal Solution (FNIS) simultaneously for the best rank.

In view of this, Fuzzy TOPSIS technique was found ideal in comparison with fuzzy VIKOR since both methods arrive at a scalar (crisp) value in their ranking that considers the best and worst fuzzy values in calculation [56],[57]. They are both found also to be theoretically robust [56]. In Table X, the ranking of the alternatives for both the fuzzy TOPSIS method and the fuzzy VIKOR are presented. The results show that both methods yielded the same order of ranking of the alternatives based on the same data used. Note that in TOPSIS unlike VIKOR, the bigger the value of the relative closeness coefficient, the better the alternative.

Table X: Compared ranking of fuzzy VIKOR and fuzzy TOPSIS results

Alternatives	Fuzzy VIKOR		Fuzzy TOPSIS	
	Results (Q)	Rank	Results (CC_i)	Rank
A1	0.05466	3	0.4600	3
A2	0.0162	1	0.4928	1
A3	0.0170	2	0.4719	2
A4	0.0951	4	0.4085	4

IX. IMPLICATIONS

The growth of the internet means an increase in consumers of online information for a range of purposes. One critical use of the internet is seeking for health information which hitherto was the exclusive preserve of health professionals. Health delivery challenges and shortage of medical professionals in some parts of the world especially in Africa could let people become overly dependent on online health information. To ensure that users access quality online information for improved health, providers of such health related information must be evaluated regularly. To lead in this direction, the proposed fuzzy VIKOR framework could prove handy in ranking health information providers to among other things (1) help users or self-help groups know which websites have the mandate and the competence to educate the public on topical health issues (2) aid health information consumer groups and associations in their resolve to ensuring quality of health information on the internet (3) create competition among specific area health information providers. For example, the evaluation and ranking could introduce competition among diabetes online health information providers or malaria information providers to improve upon their website content and design.

X. CONCLUSION

In this paper, a fuzzy VIKOR framework is proposed for evaluating and ranking internet health information providers. To demonstrate how the framework can be used, a numerical example is carried out using HIV/AIDS organizations in Swaziland who provide internet information related to HIV/AIDS for the Swazis. The organizations used in the study are real organizations providing HIV/AIDS support information and care in Swaziland but the results of the ranking in this paper is just for demonstration purposes.

The study first proposes a new set of criteria for evaluating quality of internet health information. A fuzzy VIKOR framework is then used to demonstrate how this can be carried out experimentally. The results show a methodology that can prove effective in evaluating online health information on any topic. The outcome of results compare favorably to the fuzzy TOPSIS technique justifying its reliability.

***Abstract*—The principal goal of application of information technologies in medicine is improvement of medical care. Modern healthcare systems have to guarantee perfect care of patient. Therefore, the healthcare has to be characterized by high reliability first of all and reliability analysis of such system is an important problem. Most of the reliability analysis methods suppose the investigation of the structure of a system. But the healthcare system consists of heterogeneous components, such as software, hardware, human factor and etc. The structure definition for such system is a complex problem. We propose original approach for the construction of a healthcare system structure based on the monitoring of the system behavior. The monitoring examples are interpreted as Direct Partial Logic Derivatives of the structure function of the healthcare system. The structure function defines the correlation between system components states and system performance level unambiguously.**

I. Introduction

THE applications of information technologies, artificial intelligent methods and systems allow to enhance the quality of the healthcare system. But it is not to obliterate medical errors. It is well-known that about 4–7% people die due to medical errors [1], [2]. The development of a healthcare system with high reliability is one of the ways for solving this problem. In general, the basic reliability concept is defined as the probability that a system will perform its intended function during a period of running time without any failure [1]. A fault is an erroneous state of the system. Although the definitions of a fault are different for different systems and in different situations, a fault is always an existing part of the system and it can be removed by correcting the erroneous part of the system. Therefore, the determination of the fault probability is an important problem that can be decided based on system structure analysis [1]–[3].

A healthcare system consists of some principal components from the point of view of reliability analysis. Two of them have been defined in paper [1]: equipment/device and human factor. Detail structure of human factor and human errors for healthcare system is presented in works [2] and [4]. The healthcare system structure includes three components (technical, human and administrative) in [5]. The technical component consists of two parts as hardware and software. The hardware includes two types of medical devices/equipment that are based on special and standards-based technologies according to [1]. For example, the first type includes the medical decision support system, system for integration electronic medical records or picture archiving communication systems. The second type consists of special medical devices and equipment that can be used for special operation only (as magnetic resonance imaging scanners, for example). The human component of the healthcare system models medical errors. The organization component of the system unites management aspects and maintenance of the healthcare system.

Therefore, healthcare systems consist of heterogeneous components that complicate the definition of the mathematical model of their structure.

Two types of mathematical models are used in reliability analysis: a Binary-State System (BSS) and a Multi-State System (MSS). A BSS allows defining only two states in system/component performance – perfect functioning (presented as state 1) and failed (represented by number 0). The mathematical model based on a BSS permits to describe and investigate two types of system behavior that are system failure and system repair [6]. However, real systems have not only two performance levels and, therefore, one of the main problems of a BSS is to define the boundary between situations in which the system can be regarded as working and situations when it is considered failed [7], [8]. A MSS allows avoiding this problem, because it makes possible defines more than only two states in system/component behavior. Therefore, MSSs permit to investigate the system degradation and improvement. This mathematical model can be used for the analysis and determination of conditions that cause the system fault.

The healthcare system is a complex system and its overall performance can have different levels. Therefore, MSSs are appropriate mathematical model for the representation and estimation of the healthcare system. Most methods for MSS

This work was supported by the grant of 7th RTD Framework Program No 610425 (RASimAs) and grant of Slovak Research and Development Agency SK-PL-0023-12.

reliability analysis suppose the structure function as one of initial data [8], [9]. This function defines the system performance level depending on its components states. But the definition of the system structure function with heterogeneous component is a complex problem [5], [8]. One of possible ways for the definition of such system structure function is monitoring the system behavior as the set of the system performance level changes depending on system component state change (Fig. 1).

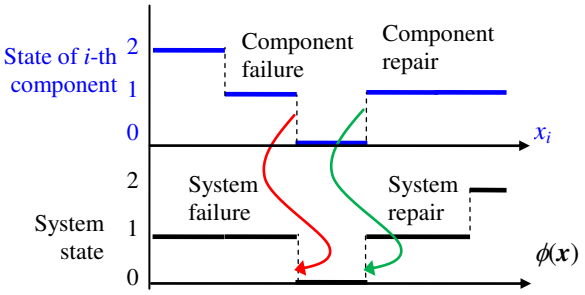

Fig. 1 System reliability interpretations for a MSS

In paper [10] such MSS performance level change depending on the component state change has been defined as Direct Partial Logic Derivative (DPLD) from mathematical point of view. The definition of the DPLD has been proposed in [11] for logic functions. According to this definition, a DPLD with respect to variable x_i allows investigation of the influence of the i-th variable value change on the change of the function value. The application of DPLDs in reliability analysis has been considered in papers [10], [12]. In this paper, we propose a new method for the construction of a MSS structure in form of the structure function by DPLDs. Application and approbation of the method is considered by the example of the typical healthcare system that has been defined in [2].

II. Mathematical Background

A. Structure Function

The correlation between system performance level and states of system components is defined by the structure function. Consider a system that consists of n components and the i-th system component can be in one of m_i states from 0 to m_i -1. Assume m performance levels for the system. Then the structure function of the system is defined as [7], [8]:

$$\phi(\boldsymbol{x}):\{0,\ldots,m_1-1\}\times\ldots\times\{0,\ldots,m_n-1\}\to\{0,\ldots,m-1\}, \quad (1)$$

where $\boldsymbol{x} = (x_1,\ldots, x_n)$ is a vector of system components states (state vector) and state 0 represent the total failure of the system/component while state m -1 (m_i -1) corresponds to perfect functioning of the system (the i-th component).

For a BSS, $m_1 = \ldots = m_n = m = 2$ in (1):

$$\phi(x_1,\ldots,x_n)=\phi(\boldsymbol{x}):\{0,1\}^n\to\{0,1\}. \quad (2)$$

According to definition (2), the BSS structure function can be interpreted as a Boolean function [6].

Every component of a MSS/BSS is characterized by probabilities of its states:

$$p_{i,s}=\Pr\{x_i=s\}, \quad s\in\{0,\ldots,m_i-1\}. \quad (3)$$

Equations (1) and (3), and (2) and (3) constitute the overall definition of a steady-state MSS and BSS.

The typical property of many real systems is their coherency. A system is coherent if it meets the following assumptions [6]–[8]:

a) the system structure function is monotone, i.e. the failure (degradation) of any system component cannot causes the repair (improvement) of system performance level;
b) system components are s-independent, i.e. there is no correlation between states of different components.

Below, we consider only the coherent system.

B. Basic Reliability Characteristics of a System

The basic reliability characteristics of a system are availability and unavailability. The availability is the probability of the system functioning in the fixed time [6]. The unavailability is defined as the probability that the system is failed [6]. Using (2) and (3), the availability of a steady-state BSS can be computed as follows [6]:

$$A=\Pr\{\phi(\boldsymbol{x})=1\}, \quad (4)$$

and its unavailability in the following way [6]:

$$U=\Pr\{\phi(\boldsymbol{x})=0\}=1-A. \quad (5)$$

For a MSS, the availability is defined as probability that the system performance does not fall below given level and, therefore, it should be defined with respect to system performance level [8]:

$$A(j)=\Pr\{\phi(\boldsymbol{x})\geq j\}, \quad j\in\{1,\ldots,m\}. \quad (6)$$

The system unavailability can be defined in the same manner as for a BSS [8]:

$$U=\Pr\{\phi(\boldsymbol{x})=0\}=1-A(1). \quad (7)$$

If we know the mean time between two consecutive breakdowns of a system, i.e. the Mean Time Between Failures (MTBF), then there can be derived other reliability characteristics using system availability and unavailability – the Mean Time To Failure (MTTF) and the Mean Time To Repair (MTTR).

For a BSS, these characteristics can be calculated as the following products [6], [13]:

$$MTTF = A\,MTBF, \quad (8)$$

$$MTTR = U\,MTBF. \quad (9)$$

Other application of the structure function in reliability estimation is importance analysis that can be used to identify the influence of system components on the system performance/availability. There has been proposed a lot of

measures that can be used for this task. These measures are known as importance measures [8], [10], [14] and some of the most commonly used are the Structural Importance (SI), Birnbaum's Importance (BI), Criticality Importance (CI) and Fussell-Vesely Importance (FVI) (Table I).

TABLE I.
IMPORTANCE MEASURES

Importance measures	Meaning
SI	SI concentrates only on the topological structure of the system. It is defined as the relative number of situations in which a given component is critical for the system activity.
BI	BI of a given component is defined as the probability that the component is critical for the system work.
CI	CI of a given component is calculated as the probability that the system failure (degradation) has been caused by the component failure (deterioration) given that the system is failed (not perfect functional).
FVI	FVI of a given component is defined as the probability that the component contributes to the system failure (degradation) probability.

C. Logical Differential Calculus

Logical differential calculus is a special tool that has been developed to analyze dynamic properties of logic functions [11], [15]. In papers [10], [12], there was considered its using in reliability analysis of BSSs and MSSs, respectively. Direct Partial Logic Derivatives (DPLDs) are one of several instruments of logical differential calculus. They allow identifying situations in which the change of a logic variable value coincides with the change of analyzed logic function. In terms of reliability analysis, a DPLD allows finding correlation between component failure/repair and system failure/repair.

For a BSS, we define a DPLD as follows [12]:

$$\partial\phi(j \to \bar{j})/\partial x_i(s \to \bar{s}) = \begin{cases} 1, \text{ if } \phi(s_i, \boldsymbol{x}) = j \text{ and } \phi(\bar{s}_i, \boldsymbol{x}) = \bar{j} \\ 0, \text{ other} \end{cases}, \quad (10)$$

where $\phi(a_i, \boldsymbol{x}) = \phi(x_1,\ldots, x_{i-1}, a, x_{i+1},\ldots, x_n)$ for $a \in \{s, \bar{s}\}$ and $s, j \in \{0, 1\}$.

There exist four DPLDs (10) with respect to the i-th variable and they have the following properties [10], [15]:

$$\begin{aligned} \partial\phi(1 \to 0)/\partial x_i(1 \to 0) &= \partial\phi(0 \to 1)/\partial x_i(0 \to 1), \\ \partial\phi(1 \to 0)/\partial x_i(0 \to 1) &= \partial\phi(0 \to 1)/\partial x_i(1 \to 0). \end{aligned} \quad (11)$$

In the reliability analysis, DPLDs $\partial\phi(1 \to 0)/\partial x_i(1 \to 0)$ and $\partial\phi(0 \to 1)/\partial x_i(0 \to 1)$ can be used to discover situations in which the failure of a given component coincides with the system failure and situations when the repair of the i-th component leads into the repair of the system, respectively. Other two DPLDs make it possible to find situations in which the system failure correlates with the component repair ($\partial\phi(1 \to 0)/\partial x_i(0 \to 1)$) or when the system repair is caused by the component failure ($\partial\phi(0 \to 1)/\partial x_i(1 \to 0)$). However, in this paper only coherent systems are taken into account and therefore there exist no situation in which the component failure can cause system repair or vice versa, and, therefore, these two DPLDs have only zero values for a coherent BSS, which means that they are irrelevant from the reliability point of view [12], [13].

For a MSS, a DPLD with respect to variable i is defined in [10] as follows:

$$\partial\phi(j \to h)/\partial x_i(s \to r) = \begin{cases} 1, \text{ if } \phi(s_i, \boldsymbol{x}) = j \text{ and } \phi(r_i, \boldsymbol{x}) = h \\ 0, \text{ other} \end{cases}, \quad (12)$$

where $\phi(a_i, \boldsymbol{x}) = \phi(x_1,\ldots, x_{i-1}, a, x_{i+1},\ldots, x_n)$ for $a \in \{s, r\}$; s, $r \in \{0,\ldots, m_i - 1\}$, $s \neq r$ and $j, h \in \{0,\ldots, m - 1\}$, $j \neq h$.

From the reliability point of view, the nonzero elements of DPLD (12) identifies situations in which the change of the state of the i-th component from value s to value r causes the change of the system performance level from j to h. Clearly, when $j > h$ and $s > r$ then DPLDs (12) can be used to find correlation between system degradation and component degradation, while for $j < h$ and $s < r$, DPLDs (12) discover situations in which component improvement results system improvement. Specially, when $j > h$ and $s < r$ or $j < h$ and $s > r$, DPLDs (12) discover coincidence between system degradation and component improvement or vice versa.

According to property a) of a coherent system, the degradation of any system component cannot cause system improvement and, therefore, there exist no DPLD (12) that would have nonzero values for $j < h$ and $s > r$ [16]. Property a) of a coherent system can also be interpreted as a statement that the improvement of any system component cannot cause system degradation and this implies that all DPLDs (12) for which $j > h$ and $s < r$ have only zero values [16]. So, the result is that only DPLDs (12) for which $j > h$ and $s > r$ or $j < h$ and $s < r$ can contain nonzero values and therefore only these two types of DPLDs (12) are important from the reliability point of view.

Another point is that we assume that a component of a MSS degrades gradually, i.e. step by step, which means that only the following DPLDs have to be investigated to find correlation between the system deterioration and component degradation [16]:

$$\partial\phi(j \to h)/\partial x_i(s \to s-1), \quad s > 0 \text{ and } j > h. \quad (13)$$

In paper [16], there has been proposed another type of a DPLD for a MSS that is named as DPLD union and that can be defined in the following way:

$$\partial\phi(\downarrow j \downarrow)/\partial x_i(s \to s-1) = \bigcup_{l=j}^{m-1}\left(\bigcup_{h=0}^{j-1}\partial\phi(l \to h)/\partial x_i(s \to s-1)\right) = \begin{cases} 1 & \text{if } \phi(s_i, \boldsymbol{x}) \geq j \text{ and } \phi((s-1)_i, \boldsymbol{x}) < j \\ 0 & \text{other} \end{cases}. \quad (14)$$

This DPLD allows identifying the total influence of the degradation of the *i*-th system component on the system performance level, because it reveals situations in which the analyzed degradation of the component causes the deterioration of the system below specified level *j*.

However, in terms of maintenance, there exist more strategies on how to perform system improvement. Two basic approaches are minor improvement (by one state) and major improvement (by more than one state) [8]. A special type of major improvement is the fully improvement when the component is replaced by a totally new one. The consequences of the minor improvement can be modelled by the following DPLDs:

$$\partial\phi(j \to h)/\partial x_i(s \to s+1) \;\; s < m_i - 1 \text{ and } j < h, \quad (15)$$

and results of the fully improvement as follows:

$$\partial\phi(j \to h)/\partial x_i(s \to m_i - 1), \;\; s < m_i - 1 \text{ and } j < h. \quad (16)$$

In paper [16], the concept of DPLD union (14) was originally developed for the modelling of the system improvement caused by minor improvement of the *i*-th system component:

$$\begin{aligned} &\partial\phi(\uparrow j \uparrow)/\partial x_i(s \to s+1) = \\ &= \bigcup_{l=0}^{j-1}\left(\bigcup_{h=j}^{m-1}\partial\phi(l \to h)/\partial x_i(s \to s+1)\right) = \\ &= \begin{cases} 1 & \text{if } \phi(s_i, \boldsymbol{x}) < j \text{ and } \phi((s+1)_i, \boldsymbol{x}) \geq j \\ 0 & \text{other} \end{cases}. \end{aligned} \quad (17)$$

The union (17) of DPLDs has more informative value than DPLD (15), because it analyzes the total influence of the *i*-th component minor improvement on the system performance level *j*.

D. Minimal Path Vectors and Minimal Cut Vectors

Minimal Path Vectors (MPVs) and Minimal Cut Vectors (MCVs) are special types of state vectors. Firstly, consider two arbitrary state vectors $\boldsymbol{x} = (x_1, \ldots, x_n)$ and $\boldsymbol{y} = (y_1, \ldots, y_n)$. Then using notation $\boldsymbol{x} < \boldsymbol{y}$ means that $x_i \leq y_i$ for any $i \in \{1, \ldots, n\}$ and there exists at least one i such that $x_i < y_i$.

For a BSS, a MPV represents such situation in which failure of any working component results system failure and a MCV correlates with a situation when the repair of any failed component leads into the system repair. So, a state vector $\boldsymbol{x}$ is a MPV if $\phi(\boldsymbol{x}) = 1$ and $\phi(\boldsymbol{y}) = 0$ for any $\boldsymbol{y} < \boldsymbol{x}$. Similarly, a state vector $\boldsymbol{x}$ is a MCV if $\phi(\boldsymbol{x}) = 0$ and $\phi(\boldsymbol{y}) = 1$ for any $\boldsymbol{y} > \boldsymbol{x}$.

In the case of MSSs, MPVs and MCVs have to be defined with regard to system performance level [8]. A MPV for a given performance level j (for $j = 1, \ldots, m$ -1) of a MSS defines such situation in which degradation of any not-failed component by one state causes degradation of system performance to value less than the specified performance level j, or more formally, a state vector $\boldsymbol{x}$ is a MPV for system performance level j if $\phi(\boldsymbol{x}) \geq j$ and $\phi(\boldsymbol{y}) < j$ for any $\boldsymbol{y} < \boldsymbol{x}$ [8], [16]. In the contrast to a MPV, a MCV for a given performance level of a MSS represents such case when improvement of any not perfect working component by one state results system improvement at least to performance level j (for $j = 1, \ldots, m$ -1), i.e. a state vector $\boldsymbol{x}$ is a MCV for system performance level j if $\phi(\boldsymbol{x}) < j$ and $\phi(\boldsymbol{y}) \geq j$ for any $\boldsymbol{y} > \boldsymbol{x}$ [8], [16].

In papers [16], [17], the calculation of MCVs based on DPLDs has been proposed. For a BSS, there was shown that all MCVs can be computed as the special intersection of all modified (extended) DPLDs $\partial_e\phi(0 \to 1)/\partial_e x_i(0 \to 1)$, i.e. for all $i \in \{1, \ldots, n\}$. The extended DPLD can be derived from DPLD (10) as follows:

$$\begin{aligned} &\partial_e\phi(j \to \bar{j})/\partial_e x_i(s \to \bar{s}) = \\ &= \begin{cases} 1 & \text{if } x_i = s \text{ and } \phi(s_i, \boldsymbol{x}) = j \text{ and } \phi(\bar{s}_i, \boldsymbol{x}) = \bar{j} \\ 0 & \text{if } x_i = s \text{ and } \phi(s_i, \boldsymbol{x}) = \phi(\bar{s}_i, \boldsymbol{x}) \\ * & \text{if } x_i \neq s \end{cases}, \end{aligned} \quad (18)$$

where symbol "*" denotes situations for which DPLD (10) is not defined, i.e. situation when the studied component is in state $\bar{s}$.

The intersection of two modified DPLDs defines situation in which the state change of at least one component causes the required change of the system state. This intersection is defined in Table II.

TABLE II.
THE INTERSECTION OF TWO MODIFIED DPLDS

		$\partial_e\phi(j \to \bar{j})/\partial_e x_i(s \to \bar{s})$		
		*	0	1
$\partial_e\phi(j \to \bar{j})/\partial_e x_k(s \to \bar{s})$	*	*	0	1
	0	0	0	0
	1	1	0	1

MPVs of a BSS can be computed similarly, but we use the extended DPLDs $\partial_e\phi(1 \to 0)/\partial_e x_i(1 \to 0)$ instead of the previous one. Then value 1 in the intersection of all considered extended DPLDs identifies state vectors that are MPVs.

The relation between MCVs and DPLDs, defined in paper [17], was generalized for MSSs in paper [16]. This generalization is based on the using of other types of DPLDs that has been named as the extended union of DPLDs and the merge of extended unions. Using union (17) of DPLDs, the merge of extended unions is defined as follows:

$$\begin{aligned} &\partial_e\phi(\uparrow j \uparrow)/\partial_e x_i = \\ &= \begin{cases} \partial\phi(\uparrow j \uparrow)/\partial x_i(s \to s+1) & \text{if } x_i < m_i - 1 \\ * & \text{if } x_i = m_i - 1 \end{cases}, \end{aligned} \quad (19)$$

and it identifies all situations in which the change of system component state by one value causes the transition of the system performance from level less than j to level greater than or equal to j. Therefore, the intersection of merges (19)

for given system performance level j and for all components identifies all MCVs for system performance level j. The intersection of two merges (19) is defined same as the intersection of two extended DPLDs (Table II).

MPVs for given system performance level j can be computed same as its MCVs, but, instead of merge (19), we use the merge of extended unions that is based on DPLDs (13) and (14) and we denote it as follows:

$$\partial_e \phi(\downarrow j \downarrow)/\partial_e x_i = \begin{cases} \partial\phi(\downarrow j \downarrow)/\partial x_i (s \to s-1) & \text{if } x_i > 0 \\ * & \text{if } x_i = 0 \end{cases}. \quad (20)$$

Value 1 in the intersection of all merges (20) for given system performance level j identifies all MPVs for the considered system performance level.

III. Revelation of the System Structure from Direct Partial Logic Derivatives

The structure function is very important in reliability analysis. However, there exist situations that the structure function of the system is unknown and only the consequences of the system components failure/degradation or repair/improvement on the system performance level are known. In these cases, the structure function of the system has to be discovered to find some reliability characteristics of the system. When we know the results of individual system components changes on the system work, then it means that individual DPLDs are known for the system. Therefore, in the next part, we assume that DPLDs are recognized for the analyzed system and we want to identify its structure function from them.

A. Discovering the Structure Function of a Binary-State System

The structure function (2) of a BSS is formally identical with the definition of a Boolean function. Moreover, the structure function of a coherent BSS can be interpreted as a monotonic Boolean function. Therefore, some concepts of Boolean algebra can be used to find the structure function of a BSS. One of these concepts is the idea that every Boolean function can be expressed unambiguously in the form of minimal disjunctive (conjunctive) normal form. Moreover, for a monotonic Boolean function, there exists only one minimal disjunctive (conjunctive) normal form [18]. When we want to find minimal disjunctive (conjunctive) normal form of a monotonic Boolean function, then all prime implicants (implicates) of this function have to be found.

An implicant of a monotonic Boolean function is a set of logic variables whose simultaneous true values imply that the monotonic Boolean function has true value. A prime implicant is an implicant from which no variable can be removed without losing its status as implicant [18]–[20]. In terms of reliability analysis, an implicant can be interpreted as a set of components whose simultaneous work ensures that the system will work. Also, in terms of reliability analysis, an implicant is known as a path set and prime implicant as a Minimal Path Set (MPS) [21].

An implicate of a monotonic Boolean function is a set of logic variables whose simultaneous false values imply that the considered function has false value [18]. In reliability analysis, the definition of implicate corresponds to cut set and the definition of prime implicate coincides with the definition of Minimal Cut Set (MCS). So, a cut set is a set of components whose simultaneous failure causes the failure of the system and it is minimal if no component can be removed from it without losing its status as a cut set [21].

According to the previous paragraphs, the revelation of MPSs or MCSs of the analyzed BSS implies discovering the system structure function. However, in this paper, we assume that the structure function is defined in terms of vectors and not in terms of set theory. Therefore, MPSs (MCSs) have to be transformed into the form of state vectors. This can be done by using the relation between prime implicants (implicates) and MPSs (MCSs). Every prime implicant (implicate) can be transformed in the vector form that is known as minimal true vector for prime implicant and maximal false vector for prime implicate, respectively [22]. In the terms of reliability engineering, a minimal true vector corresponds to MPV while maximal false vector agrees with a MCV. Therefore, based on paper [22], there exists one-to-one correspondence between MPSs (MCSs) and MPVs (MCVs), i.e. a MPV (MCV) corresponds to a MPS (MCS) in terms of state vectors. This implies that the structure function of any coherent BSS can be defined via MPVs or MCVs unambiguously. So, if DPLDs $\partial\phi(1 \to 0)/\partial x_i(1 \to 0)$ for all $i \in \{1,\ldots,n\}$ are given, then we can formulate the next algorithm for finding the structure function of a BSS:

1. Derive the extended DPLDs $\partial_e\phi(1 \to 0)/\partial_e x_i(1 \to 0)$ from $\partial\phi(1 \to 0)/\partial x_i(1 \to 0)$ for every component, i.e. for $i \in \{1,\ldots,n\}$ according to (18).
2. Compute the intersection of all extended DPLDs from the previous step based on the rules in Table II.
3. Define MPVs that agree to value 1 in the intersection, calculated in the previous step.
4. According to the definition of a MPV (section II.D), define the structure function of the system as follows:
   a. if an arbitrary state vector $\boldsymbol{y}$ meets the condition $\boldsymbol{y} \geq \boldsymbol{x}$ at least for one MPV $\boldsymbol{x}$, then $\phi(\boldsymbol{y}) = 1$;
   b. if an arbitrary state vector $\boldsymbol{y}$ meets the condition $\boldsymbol{y} < \boldsymbol{x}$ at least for one MPV $\boldsymbol{x}$, then $\phi(\boldsymbol{y}) = 0$.

Another approach is based on MCVs. In this case, we assume DPLDs $\partial\phi(0 \to 1)/\partial x_i(0 \to 1)$ for all $i \in \{1,\ldots,n\}$ are known (by the way, according to (11), they are identical to $\partial\phi(1 \to 0)/\partial x_i(1 \to 0)$) and then we can reveal the structure function of the coherent BSS in the following way:

1. Derive the extended DPLDs $\partial_e\phi(0 \to 1)/\partial_e x_i(0 \to 1)$ from $\partial\phi(0 \to 1)/\partial x_i(0 \to 1)$ for every component, i.e. for $i \in \{1,\ldots,n\}$ according to (18).

2. According to Table II, compute the intersection of all extended DPLDs from the previous step.
3. Define MCVs that agree to value 1 in the intersection, calculated in the previous step.
4. According to the definition of a MCV (section II.D), define the structure function of the system as follows:
   a. if an arbitrary state vector $\boldsymbol{y}$ meets the condition $\boldsymbol{y} \leq \boldsymbol{x}$ at least for one MCV $\boldsymbol{x}$, then $\phi(\boldsymbol{y}) = 0$;
   b. if an arbitrary state vector $\boldsymbol{y}$ meets the condition $\boldsymbol{y} > \boldsymbol{x}$ at least for one MCV $\boldsymbol{x}$, then $\phi(\boldsymbol{y}) = 1$.

B. Discovering the Structure Function of a Multi-State System

For MSSs, the structure function (1) is a multiple-valued function. Specially, when $m_1 = \ldots = m_n = m$ in definition (1), then the structure function can be interpreted as a Multiple-Valued Logic (MVL) function. In a case of MVL functions and also multiple-valued functions, there exist some normal forms that are equivalent to minimal disjunctive (conjunctive) normal form of Boolean functions. These forms are known as minimal Sum-of-Products (SoP) and minimal Products-of-Sum (PoS). By the way, a minimal disjunctive (conjunctive) normal form of a Boolean function is sometimes denoted as minimal SoP (PoS), however, in this paper, we used term minimal disjunctive (conjunctive) normal form when we deal with Boolean functions and minimal SoP (PoS) in a case of multiple-valued functions.

There exist several approaches for definition of SoP (PoS) [23], but definitions based on vector approach are the best ones for our work. According to this approach, there exist two important types of vectors for monotone multiple-valued functions: lower vectors (or lower 9 (boundary) points) and upper vectors (or upper (boundary) points) [24].

Lower points for value j of a monotone multiple-valued function of m values are minimal vectors for which the function has value j, for $j = 1,\ldots, m$ -1. When all lower points for every value of a monotone multiple-valued function are known, then the function has value j for an arbitrary vector $\boldsymbol{x}$ if there exists at least one lower point for level j that is lower than or equal to $\boldsymbol{x}$ and at least one lower point for level $j+1$ (given that $j < m$ -1) that is greater than $\boldsymbol{x}$. (A vector $\boldsymbol{x}$ is lower than a vector $\boldsymbol{y}$ if $\boldsymbol{x} < \boldsymbol{y}$ (see section II.D) and greater than $\boldsymbol{y}$ if $\boldsymbol{x} > \boldsymbol{y}$.)

Upper points for value j of a monotone multiple-valued function of m values are maximal vectors for which the function has value less than or equal to j, for $j = 0,\ldots, m$ -2. Therefore, if we know all upper points for every value of the considered function, then the function has value j for an arbitrary vector $\boldsymbol{x}$ if there exists at least one upper point for level j that is greater than or equal to $\boldsymbol{x}$ and at least one upper point for level j -1 (given that $j > 0$) that is lower than $\boldsymbol{x}$.

According to the previous paragraphs, every monotonic multiple-valued function can be defined by using all its upper points or all its lower points. A lower point for value j (for $j = 1,\ldots, m$ -1) of a monotonic multiple-valued function $\phi(\boldsymbol{x})$ is defined as vector $\boldsymbol{x}$ that meets the following conditions [15], [24], [25]:

a) $\phi(\boldsymbol{x}) \geq j$,

b) $\phi(\boldsymbol{y}) < j$ for any $\boldsymbol{y} < \boldsymbol{x}$.

This definition is same as the definition of a MPV of a coherent MSS (section II.D). This fact implies that the structure function of any coherent MSS can be defined via MPVs unambiguously.

An upper point for value j (for $j = 0,\ldots, m$ -2) of a monotonic multiple-valued function $\phi(\boldsymbol{x})$ is defined as vector $\boldsymbol{x}$ that meets the following conditions [15], [24], [25]:

a) $\phi(\boldsymbol{x}) \leq j$,

b) $\phi(\boldsymbol{y}) > j$ for any $\boldsymbol{y} > \boldsymbol{x}$.

The definition of an upper point is not equal to the MCV definition of a coherent MSS (section II.D). This is caused by the fact that upper points are defined for values $j = 0,\ldots, m$ -2, while MCVs are defined for $j = 1,\ldots, m$ -1. Therefore, assume that we do substitution $j+1 = l$ in the definition of the upper point. Due to the substitution, the upper point $\boldsymbol{x}$ for $l = 1,\ldots, m$ -1 has the following properties:

a) $\phi(\boldsymbol{x}) < l$,

b) $\phi(\boldsymbol{y}) \geq l$ for any $\boldsymbol{y} > \boldsymbol{x}$.

These properties are same as the properties of a MCV for level l of a MSS defined by the considered monotonic multiple-valued function. This implies that an upper point for value j of a monotonic multiple-valued function corresponds to a MCV for value $j+1$ of the MSS defined by the considered function. Therefore, there exists one-to-one relation between upper points for level j and MCVs for level $j+1$ of a MSS. So, the knowledge of all MCVs allows defining the structure function of the considered MSS.

According to the aforementioned text, we only need to find all MPVs (MCVs) of the analyzed MSS to reveal the system structure. So, if the consequences of degradation of any component on the system performance are known, i.e. DPLDs $\partial\phi(\downarrow j\downarrow)/\partial x_i(s \to s-1)$ for all $i \in \{1,\ldots, n\}$, $s \in \{1,\ldots, m_i - 1\}$ and $j \in \{1,\ldots, m - 1\}$ are defined, then we can formulate the following algorithm for discovering the system structure function:

1. Derive the merge of extended unions $\partial_e\phi(\downarrow j\downarrow)/\partial_e x_i$ from $\partial\phi(\downarrow j\downarrow)/\partial x_i(s \to s-1)$ for fixed performance level j and for every system component, i.e. for $i \in \{1,\ldots, n\}$ according to (20).
2. According to Table II, compute the intersection of all merges (20) of extended unions from the previous step.
3. Define MPVs for given system performance level j that agree to value 1 in the intersection, calculated in the previous step.
4. Repeat steps 1. – 3. for all relevant system performance levels, i.e. for $j \in \{1,\ldots, m - 1\}$.
5. According to the definition of a MPV of a MSS (section II.D), define the value of the system structure function for an arbitrary state vector $\boldsymbol{y}$ as follows:

- if the state vector $\boldsymbol{y}$ meets the condition $\boldsymbol{y} \geq \boldsymbol{x}$ at least for one MPV $\boldsymbol{x}$ for system performance level m -1, then $\phi(\boldsymbol{y}) = m$ -1;
- else if the state vector $\boldsymbol{y}$ meets the condition $\boldsymbol{y} \geq \boldsymbol{x}$ at least for one MPV $\boldsymbol{x}$ for system performance level m -2, then $\phi(\boldsymbol{y}) = m$ -2;
  …
- else if the state vector $\boldsymbol{y}$ meets the condition $\boldsymbol{y} \geq \boldsymbol{x}$ at least for one MPV $\boldsymbol{x}$ for system performance level 1, then $\phi(\boldsymbol{y}) = 1$;
- else $\phi(\boldsymbol{y}) = 0$.

Similarly as in the case of BSSs, the previous algorithm can be reformulated in the terms of MCVs. In this situation, we assume that all DPLDs $\partial\phi(\uparrow j \uparrow)/\partial x_i(s \to s+1)$ for $i \in \{1,\ldots, n\}$, $s \in \{0,\ldots, m_i - 2\}$ and $j \in \{1,\ldots, m-1\}$ are defined, i.e. the influence of minor improvement of any component on system performance level is known. In this case, the following algorithm can be formulated:

1. Derive the merge of extended unions $\partial_e\phi(\uparrow j \uparrow)/\partial_e x_i$ from $\partial\phi(\uparrow j \uparrow)/\partial x_i(s \to s+1)$ for fixed performance level j and for every component, i.e. for $i \in \{1,\ldots, n\}$ according to (19).
2. According to Table II, compute the intersection of all merges (19) of extended unions that were gained in the previous step.
3. Define MCVs for given system performance level j that agree to value 1 in the intersection, calculated in the previous step.
4. Repeat steps 1. – 3. for all relevant system performance levels, i.e. for $j \in \{1,\ldots, m-1\}$.
5. According to the definition of a MCV of a MSS (section II.D), define the value of the system structure function for an arbitrary state vector $\boldsymbol{y}$ as follows:
   - if there is a MCV $\boldsymbol{x}$ for system performance level 1 that meets the condition $\boldsymbol{y} \leq \boldsymbol{x}$, then $\phi(\boldsymbol{y}) = 0$;
   - else if there is a MCV $\boldsymbol{x}$ for system performance level 2 that meets the condition $\boldsymbol{y} \leq \boldsymbol{x}$, then $\phi(\boldsymbol{y}) = 1$;
     …
   - else if there is a MCV $\boldsymbol{x}$ for system performance level m -1 that meets the condition $\boldsymbol{y} \leq \boldsymbol{x}$, then $\phi(\boldsymbol{y}) = m$ -2;
   - else $\phi(\boldsymbol{y}) = m$ -1.

IV. Reliability Analysis of a Healthcare System with Unknown Structure

Consider the human module of the health care system from book [2]. This module is formed by two persons – a doctor and a nurse, and it defines the consequences of the wrong doctor and nurse behavior on a patient health. In the terms of reliability analysis, the nurse and doctor can be interpreted as two independents modules of the analyzed system. The nurse can perform three types of errors and doctor can also make three types of bad decisions. The wrong decisions are caused by facts that are defined in Table III. These decisions can be interpreted as independent components of the human module and their occurrence can caused the human module degradation that is defined as the deterioration of the patient health.

TABLE III.
COMPONENTS OF THE HUMAN MODULE OF THE HEALTH CARE SYSTEM

System modules	System components	$p_{i,0}$	$p_{i,1}$
Nurse	Correct interpretation of doctor's instructions, x_1	0.01	0.99
	Good work environment, x_2	0.02	0.98
	Not-haste, x_3	0.03	0.97
Doctor	Correct diagnosis, x_4	0.04	0.96
	Good Surroundings, x_5	0.06	0.94
	Not-haste, x_6	0.05	0.95

According to Table III, every component of the human module has two performance levels – failed (an error has occurred) and functioning (a problem has not occurred).

In Table IV, there are defined performance levels of the human module.

TABLE IV.
HUMAN MODULE PERFORMANCE LEVELS

System performance levels	Interpretation
0	Patient received an inadequate amount of wrong medication
1	Patient received an inadequate amount of correct medication
2	Patient received a safe amount of incorrect medication
3	Patient received an adequate amount of correct medication

The results of failures of individual components of the human module on the patient health are defined by DPLDs $\partial\phi(\downarrow j \downarrow)/\partial x_i(1 \to 0)$, for $i \in \{1,\ldots, 6\}$ and $j \in \{1, 2, 3\}$, in Table V. For example, the nonzero element (1,0,0,0,0,0) of DPLD $\partial\phi(\downarrow 1 \downarrow)/\partial x_1(1 \to 0)$ means that the failure of the first component causes the total failure of the analyzed system in situation when all other components are failed.

Now, we want to find the structure function of the human module. According to the previous section, we need to find all MPVs of the considered module. For this task, the first algorithm from section III.B can be used.

In the first step, the merges $\partial_e\phi(\downarrow j \downarrow)/\partial_e x_i$ of extended unions have to be derived from DPLDs defined in Table V. For example, the merges $\partial_e\phi(\downarrow 1 \downarrow)/\partial_e x_i(1 \to 0)$ are calculated in Table IX (white columns). In the next step, their intersection has to be computed to identify MPVs for system performance level 1 (gray columns in Table IX). This procedure has to be repeated for other relevant performance levels of the system, i.e. for $j = 2, 3$. After that, all MPVs of the system are known (Table VI) and we can reveal the system structure function according to rules defined in the

last step of the used algorithm. The discovered structure function of the system is presented in Table VII.

TABLE V.
THE CONSEQUENCES OF COMPONENTS FAILURES ON THE PATIENT HEALTH DEFINED BY DPLDS

Component (i)	**System performance level** (j)	**Nonzero elements of DPLD** $\partial\phi(\downarrow j \downarrow)/\partial x_i(1 \to 0)$
1	1	(1,0,0,0,0,0)
	2	(1,0,0,0,1,1) (1,0,0,1,0,1) (1,0,0,1,1,0) (1,0,0,1,1,1) (1,1,0,1,0,0) (1,1,1,0,0,0) (1,1,1,0,0,1) (1,1,1,0,1,0) (1,1,1,1,0,0)
	3	(1,0,1,1,1,1) (1,1,0,1,1,1) (1,1,1,0,1,1) (1,1,1,1,0,1) (1,1,1,1,1,0)
2	1	(0,1,0,0,0,0)

3	(0,1,1,1,1,1) (1,0,1,1,1,1) (1,1,0,1,1,1) (1,1,1,0,1,1) (1,1,1,1,0,1) (1,1,1,1,1,0)

Now, we can use the revealed structure function with combination of data from Table III for computation of system availability (6) and unavailability (7). The final values are in Table VIII. According to results in Table VIII, there is very little probability that the considered human module of a health care system will failed.

V. CONCLUSION

In this paper, a new method for the construction of the structure function based on the DPLDs is considered. This method can be used for the design of the system mathematical model in a case when the initial system has complex structure and correlation between components is not clear defined. The monitoring result of the initial system behavior is interpreted as the set of system performance changes depending on the changes of fixed system component states and these sets are collected for all system components. According to the definition of a DPLD, such sets are interpreted as DPLDs of the structure function. According to the proposed method based on DPLDs, the structure function (1) or (2) of MSS or BSS can be constructed. Then, numerous reliability indices and measures presented in section II.B can be calculated to investigate the initial system.

***Abstract*—The paper presents BPD (Bronchopulmonary Dysplasia) prediction for extremely premature infants after their first week of life. SVM (Support Vector Machine) algorithm implemented in LIBSVM[1] was used as classifier. Results are compared to others gathered in previous work [2] where LR (Logit Regression) and Matlab environment SVM implementation were used. Fourteen different risk factor parameters were considered and due to the high computational complexity only 3375 random combinations were analysed. Classifier based on eight feature model provides the highest accuracy which was 82.60%. The most promising 5-feature model which gathered 82.23% was reasonably immune to random data changes and consistent with LR results. The main conclusion is that unlike Matlab SVM[2] implementation, LIBSVM can be successfully used in considered problem, but it is less stable than LR. In addition, the article discusses influence of the model parameters selection on prediction quality.**

I. Introduction

BRONCHOPULMONARY dysplasia (BPD) is a chronic pulmonary morbidity which affects premature infants [3], [4]. It is most common among children who received prolonged mechanical ventilation to treat respiratory distress syndrome [5], [6] and those with low birth weight. Almost a third of infants with birth weight lower than 1000g [7] are affected. Due to the fact that the disease is poorly understood, many projects are focused on identifying its factors of risk. Since it can not be diagnosed until a 28th day of life [8], it is very important to predict such a result after the end of the first week, which would enable an early prevention of the disease[9]. Therefore, an intensive work has been done to define a classifier, based on static parameters (gathered after birth) and dynamic ones (collected during the first week of life), which would be able to predict the diagnosis. Although several prediction models of BPD [10], [11], [12], [13], [14], [15], [16], [17], [18], [19] used in research have been reported, none of them could be used in common clinical practice due to the variety of reasons and none use SVM.

II. Related works

As mentioned before, there are numerous works related to BPD, its risk factors and prediction [20], [21], [22], [23]. The most popular one is the analysis of static data whose main features are gestational age and birth weight. The other factors considered are admission of surfactant, presence of patent ductus arteriosis (PDA), or respiratory support. In addition, dynamical data (which is much harder to obtain) is analysed in more sophisticated models. Most of such parameters are: arterial blood gas variables like fraction of inspired oxygen (FiO_2) or alveolar-arterial ratio (AA) [24] (which is respiratory distress degree measure); blood gas levels like oxygen saturation of arterial hemoglobin (SpO_2) and its standard deviation, mean value etc. [25] or even time series analysis [26]; heart beat and its derivatives.

$$AA = \frac{pO_2}{p_{ATM} \cdot FiO_2 - pCO_2}, \tag{1}$$

where pO_2— oxygen partial pressure, p_{ATM}—atmospheric pressure, pCO_2—carbon dioxide partial pressure, FiO_2—fraction of inspired oxygen.

Some of the papers introduced race and ethnicity or sex as factors which seem to be promising but require a very big set of data. It should be indicated that the vast majority of studies uses logit regression (LR) in prediction. Best LR models gain about 73% to 82% of accuracy. Many of authors mention use of support vector machine(SVM)[27] in future works, however it is difficult to find them. In our previous work[2] we compared SVM with LR classifiers. Unfortunately, due to internal Matlab SVM library usage results were highly unsatisfactory. The highest accuracy gained was only 79.39%. Moreover, the bigger features set was used the worse results we got. In general, only three and four feature models were able to gain accuracy higher than 70%. That is why we decided to use LIBSVM implementation instead, which gave us a very wide scope of parameters tuning. Although additional parameters highly increased computational complexity of optimal model search, even limited random parameters space exploration gave us quite good results, comparable to LR.

III. General ideas of used methods

A. Logistic regression

Probability of the dependent variable equalling a BPD positive diagnosis ($y_k = 1$), on condition that explanatory variables (features of specific case k) equals $X_k = (x_{1,k}, x_{2,k}, .., x_{n,k})$, we define as:

$$p_k = P(y_k = 1|X_k) = \frac{e^{a_0 + \sum_{i=1}^{n} a_i x_i}}{1 + e^{a_0 + \sum_{i=1}^{n} a_i x_i}}, \tag{2}$$

978-83-60810-58-3/$25.00

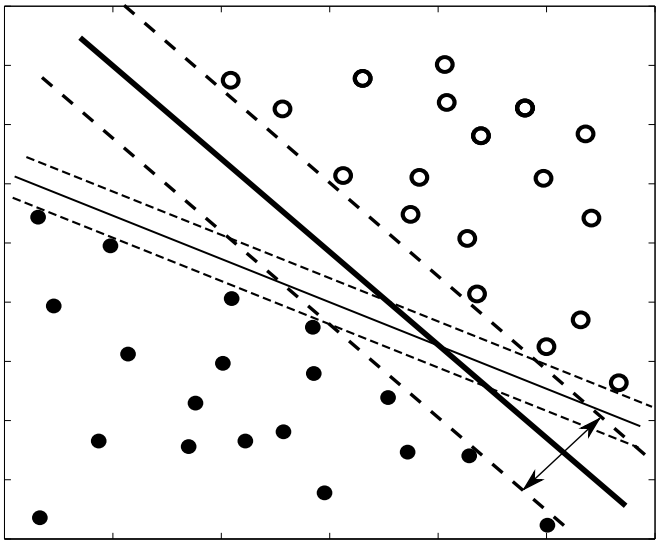

Fig. 1. Maximizing margin in SVM method.

where $x_{i,k}$—explanatory variables (feature values for case k), a_i—regression coefficients, n—number of features.

In contrast to linear regression, where we assume normal distribution of the independent variables and because explanatory variables variance are not equal, we can not use the method of least squares to obtain regression coefficients. Thus they are usually calculated using maximum likelihood estimation, maximizing likelihood function (L) or minimizing its negative logarithm using learning data:

$$L = \prod_{y_k=1} p_k \prod_{y_k=0} (1 - p_k), \tag{3}$$

$$ln(L) = \sum_{k=1}^{m} [y_k \cdot ln(p_k) + (1 - y_k) \cdot ln(1 - p_k)], \tag{4}$$

where k—observation number (learning case), y_k —diagnosis for case k, m—number of observations.

Having a_i regression coefficients, we can easily predict BPD positive diagnosis probability of case X using Eq. 2.

B. Support vector machine

We define the learning data D divided in two classes y as:

$$D = \{(X_k, y_k) | X_k \in R^n, y_k \in \{1, -1\}\}_{k=1}^{m} \tag{5}$$

We are looking for hyperplane

$$W \bullet X + b = 0 \tag{6}$$

which separates classes and provides maximum margin as on Fig. 1, which is the same as the problem of minimizing L :

$$L(W) = \frac{||W||^2}{2} + c \cdot \sum_{k=1}^{m} \varepsilon_k, \tag{7}$$

with conditions:

$$y_k(W \cdot \phi(X_k) + b) \geq 1 - \varepsilon_k \tag{8}$$

where $\varepsilon \geq 0$—slack variable, $c > 0$—penalty parameter for each point wrongly classified, ϕ—kernel function.

Thanks to the kernel functions for non linear separable problems, we can transform original data from n dimensional space to p dimensional ($p > n$, as on Fig. 2), in which there is much higher likelihood that they will be linear separable.

IV. Data and Methods

Data was collected thanks to the Neonatal Intensive Care Unit of The Department of Pediatrics at Jagiellonian University Medical College using our own software. It includes 109 patients born prematurely with birth weight less than or equal to 1500g admitted, no later than on the second day of life. For 46 of them BPD have been diagnosed after fourth week of life.

To build a suitable model 14 different features mentioned in literature were considered:

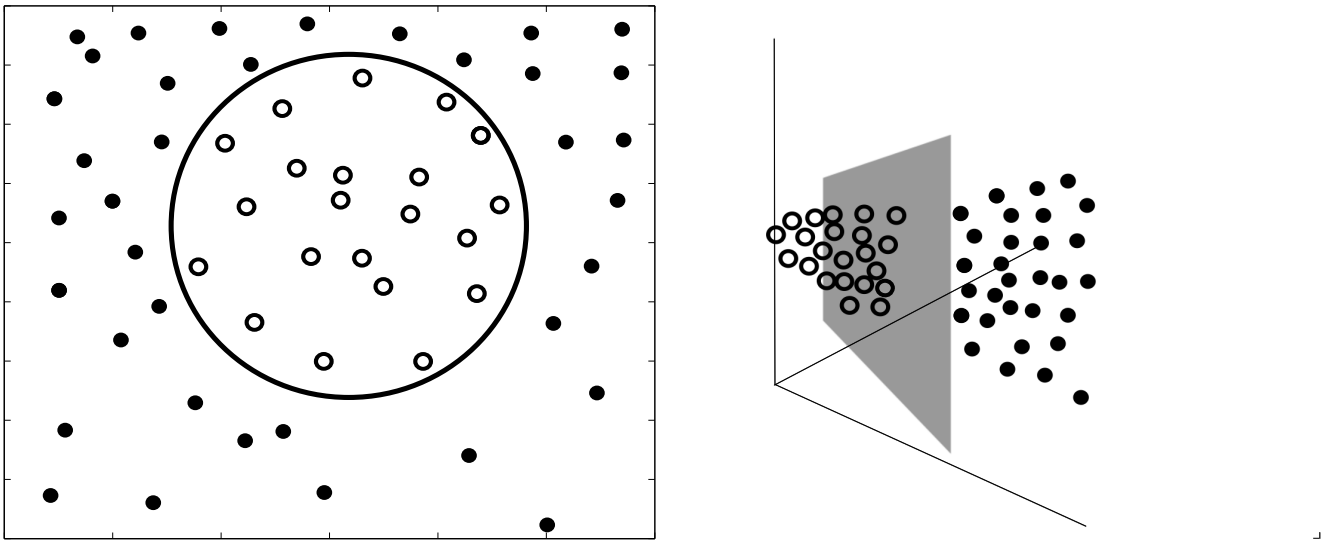
- Binary such as:
  - presence of patent ductus arteriosus (PDA) [28] ,
  - use of a respirator ($RESPIMV$) during the first week of life,
  - administration of surfactant ($SURFACT$) [29] in the same period.
- Real-Valued (values range in parentheses) such as:
  - birth weight ($BWEIGHT$) (550-1500g),
  - gestational age ($GAGE$) (22-34 weeks),
  - alveolar-arterial ratio (AA) (0.05-1) measured during patient admission,
  - a percentage of the time during first week for which the oxygen saturation of hemoglobin was less than 85% ($LOW85$) (0.03%-12.45%) or higher than 94% ($HIGH94$) (14.56%-99.02%),
  - average number of heartbeats per minute ($BPMMEAN$)[5](124.69-161.42 bpm),
  - mean and standard deviation of oxygen saturation ($SPO2MEAN$, $SPO2DEV$) (accordingly 89.89%-98.99% and 1.19-7.98) and their trends (first day to first week ratio: $BPMMEAN\_TR$, $SPO2MEAN\_TR$, $SPO2DEV\_TR$) (accordingly 0.8-1.18 , 0.96-1.07 and 0.51-2.36).

Accuracy (ACC) defined as below was considered as preliminary result measure. The sensitivity(TPR) and specificity(SPC) were also obtained:

$$ACC = \frac{TP + TN}{TP + TN + FP + FN}, \tag{9}$$

$$TPR = \frac{TP}{TP + FN}, \tag{10}$$

$$SPC = \frac{TN}{TN + FP}, \tag{11}$$



(a) data in R^2 space

(b) data transformed to R^3 space

Fig. 2. Making data linear separable with dimensional transformation.

where TP—True Positives, FP—False Positives, FN—False Negatives, TN—True Negatives.

As mentioned before in SVM computation version 3.17 of LIBSVM library was used. Based on a few arbitrary chosen and tested models it has been found that for specified problem C-SVC method is more effective than nu-SVC (range of parameter c (Eq. 7) is from zero to infinity, rather than as in nu always between [0,1]). It has also been discovered that sigmoid kernel function gives better results and is much faster in finding the separating hyperplane than radial basis (RBF) one.

$$K(X_i, X_j) \equiv \phi(X_i)^T \phi(X_j), \tag{12}$$

$$RBF : K(X_i, X_j) = e^{-\gamma ||X_i - X_j||^2}, \gamma > 0, \tag{13}$$

$$Sigmoid : K(X_i, X_j) = tanh(\gamma X_i^T X_j + r), \tag{14}$$

where γ, r—kernel parameters.

As suggested in library documentation, data have been normalized to [-1,1] range and optimization of parameters γ ($\gamma = 2^{-15}, 2^{-14}, \ldots, 2^3$) and c ($c = 2^{-5}, 2^{-4}, \ldots, 2^{15}$) was performed for each model (Fig. 3). Unlike suggested, in presented results we did not use *grid.py* script which provides cross-validation and parameters optimization. This method gives very promising results for considered problem, achieving easily up to 83-86% of ACC, but models found with this method turned out to be very unstable. Any random change of data (removing or adding samples) significantly decreased its accuracy.

It is very important to find a model the most possibly independent on specific learning data. Therefore, we decided to use a method similar to Jacknife [30]: for each pair c and γ parameters calculations were repeated 30 times, each time randomly excluding 30 samples of data and using cross-validation procedure (each patient was treated as a test sample while all other data was learning set) on the rest of it. This way deviation and mean value of accuracy, sensitivity and specificity were obtained, which gives an estimate on the model 'sensitivity' to data structure (it might be important when calculating on such a little data set as 109 patients). It should be mentioned that each time we refer in this paper to ACC, TPR or SPC values we mean average computed as above. The test was repeated once again for the best results, excluding the data of only 10 random patients - it shows wether extension of learning data increases or decreases accuracy and overfitting occurs. Due to the high computational complexity of proposed optimisation procedure only 3375 random models containing 2 to 14 parameters were analyzed - it took more than a week for modern 8-core Intel Core i7 based PC. Nevertheless, such little number of experiments gave satisfactory results.

To compare with LR algorithm we used data from previous article[2], where we reviewed all of the 2^{14} possible combinations of models with exactly same Jacknife and cross-validation procedure.

V. Results

The most essential results are presented in Table II . To compare, in each presented model mean value of ACC, TPR and SPC were obtained with different Jacknife parameters, using both methods: LR and sigmoid SVM with LIBSVM. Where applicable we added RBF Matlab SVM implementation results (as M. SVM) from [2].

According to the assumptions in previous section the highest mean value of accuracy among SVM results gained eight-parameter model with 82.60%. Unfortunately standard deviation of ACC was 5.15, which in contrast to others was

															30	76.83%	83.04%	71.87%	LR	2.93

very high (STD values are presented in Table III). The TPR value was 80.10% and SPC 84.37%, which is a very good result in comparison with the fact that only five of examined SVM models achieved both parameters higher than 80% (see Table I).

Next we present generally the best ACC model which was six-parameter LR which gained 82.79% with TPR=84.20%, SPC=81.73% and standard deviation of ACC as low as 1.11. Both above models give quite good results, but only using specific algorithm (LR or SVM).

In contrast to the above fact, we present next two best five- and six-parameter models which give accuracy higher than 81% for both methods. Particularly noteworthy model is the five-parameter one - it gives respectively 82.23% for SVM and 82.59% for LR of ACC which was the best of examined five-parameter models for both methods. Although the TPR result for SVM was only 77.13%, this model seems to be a very reasonsonable choice with SPC=85.87% for SVM and TPR=84.65%, SPC=81.07% for LR. Even in that case, where standard deviation of ACC for SVM was 3.04, it was about twice higher than 1.49 for LR. An interesting similar 5-parameter model with little lower accuracy is presented in Table I.

Afterwards we made a review of the best accuracy results for each method and each model size:

- 4-parameter models - for LR we succeeded to obtain 82.01% of ACC and only 80.85% for SVM. However, this second model (bolded in Table III) draws attention due to its simplicity, low ACC standard deviation (about 1.4) and ACC higher than 80% for both methods.
- 3-parameter models - 81.29% for LR and 80.57% for SVM are good results just as standard deviation of ACC lower than 1.5, though none of models exceeds the psychological barrier of 80% of ACC for both methods at a time.
- 2-parameter models - SVM results are unsatisfactory due to 76.01% of highest ACC and its standard deviation as high as 5.81. However, LR was able to gain 80.30% of ACC, which is quite interesting.

Lastly, it must be noted that full 14-parameter SVM model gained 76.86% and LR 77.55% of ACC. As a graphic example two-parameter model result was presented on Fig. 4.

VI. DISCUSSION

The first conclusion is that SVM classification algorithm can be almost as accurate as LR and if its parameters are properly chosen it gives rewarding results, even for a complicated multi-parameter model of BPD. The best choice for such a prediction is to use the LIBSVM instead of Matlab's implementation, which gives less control on computation process. Most likely that was the reason why the bigger parameter set we used the worse results we got using Matlab[2]. Although we did not test all possible 2^{14} combinations of parameters (only 3375 random models), nonetheless looking on Table III it can be concluded that standard deviation of accuracy for SVM is much higher than for logit regression. Using bigger learning set (only 10 samples excluded) for best results it reaches even

	LIBSVM	76.01%	5.81	73.04%	2.70

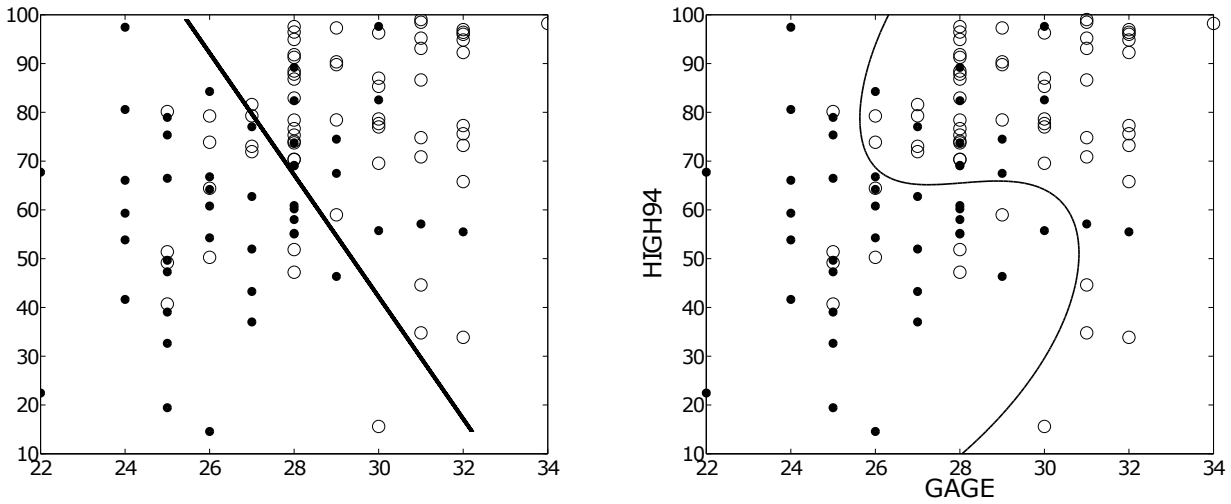
5.81 while for LR it is rarely as high as 1.74. In other words, SVM fits to data very well and even minor random changes of data causes instability of results accuracy. For this reason, when we execute our test procedure for certain model few times, we get results which differ even 2%. According to our observations such an effect occurs mostly for a very high or very low parameter models. For logit regression effect has not been noticed, which may be encouraging to select that algorithm.

We also observed that for almost all cases the more data we exclude from the test results the worse accuracy and deviation we achieve (results with Jacknife exclusion of 10 samples are generally better), which is promising - it shows that overfitting does not occur and classifier is well generalizing to cases not known during learning. The exception from that rule are very high-deviation and some simple two-parameter models mentioned before. In such cases, there is a concern that because of its oversimplification or excessive complication hard learning takes place. For this reason, it seems more secure to use logit regression or four- to six-parameter model.

Analyzing sensitivity and specificity of the best results from Table II we have the following observations:

- for SVM differences between TPR or SPC and ACC are from 1.32% to 6.47%, while for LR 1.06% to 7.8% which is quite similar,
- the exceptions are 2-parameter SVM models, for which this differences were up to 19.33%,
- as mentioned before only five of all the examined SVM models achieved both parameters higher than 80%, which is not a problem for many LR models - all five are presented in Table I.

We confirmed that one of the most important risk factors mentioned in literature [5], [6], [8], [9], [28], [29], [31] is the $GAGE$ which exists in almost all (all presented in Table I and II) of the models with acceptable accuracy. Most classifiers presented in the literature consist $BWEIGHT$ and $RESPIMV$ parameters. Unexpectedly, $RESPIMV$ parameter is indeed present in SVM models in Table I with very good (over 82% of ACC) results, but it is not in any LR model worth to present. However, $BWEIGHT$-containing one was indeed on the third place with 82.67% ACC, but it was the only one in the first twenty, which is a group with ACC higher than 82%. Among the most frequently mentioned parameters there is FiO_2 which depends on the AA (Eq. 1) feature used in our work that is indeed present in the best model, but also only in five others of the best twenty. On the other hand,



(a) Logistic regression

(b) Support Vector Machine

Fig. 4. Prediction result sample for two-parameter ($GAGE$, $HIGH94$).

PDA feature appeared in 15 out of the best 20 models which is consistent with published results [8], [9], [25], [28]. The same situation occurs with $BPMMEAN$ parameter, which is the second most important factor after GAGE especially in LR models - it is in all of the first 20 models. The only one parameter related to SpO_2 which is in more than half of the best 20 classifiers is LOW85. The average importance features are $SURFACT$ and $HIGH94$ while $SPO2DEV$, $SPO2DEV\_TR$, $SPO2MEAN\_TR$ parameters seem to have even less effect on the occurrence of diseases.

As a final conclusion we confirmed [32] that prediction of BPD after 7th day of life is possible with the accuracy higher than 82%, not only with LR but also using Support Vector Machine algorithm. Results are slightly worse than in the Logit Regression method and more attention should be paid on model selection because many of them are sensitive to even small data changes. However, it can be very useful when we have limited set of parameters (above RESPIMV example), which are not so important in LR models as in SVM. Having wide scope of algorithms we can choose the one which is more suitable for our parameter set and thereby obtain better classification results. With that knowledge it is a good idea to construct expert system that would advise which algorithm and model to use having certain parameters measured.

***Abstract*—This paper proposed a comprehensive algorithm for building machine learning classifiers for Breast Cancer diagnosis based on the suitable combination of feature selection methods that provide high performance over the Area Under receiver operating characteristic Curve (AUC). The new developed method allows both for exploring and ranking search spaces of image-based features, and selecting subsets of optimal features for feeding Machine Learning Classifiers (MLCs). The method was evaluated using six mammography-based datasets (containing calcifications and masses lesions) with different configurations extracted from two public Breast Cancer databases. According to the Wilcoxon Statistical Test, the proposed method demonstrated to provide competitive Breast Cancer classification schemes reducing the number of employed features for each experimental dataset.**

I. Introduction

BREAST CANCER is a major concern and the second-most common and leading cause of cancer deaths among women [1]. According to published statistics, Breast Cancer has become a major health problem in both developed and developing countries over the past 50 years. Its incidence has increased recently with an estimated of 1,152,161 new cases in which 411,093 women die each year [2]. At present, there are no effective ways to prevent it, because its cause remains unknown. However, an efficient diagnosis in its early stages can give a woman a better chance of full recovery [2]. Therefore, its early detection can play an important role in reducing the associated morbidity and mortality rates.

Breast Cancer screening has proved to be the best way to detect cancer early. A useful and suggested approach is the double reading of mammograms (two radiologists read the same mammograms) [3], which has been advocated to reduce the proportion of missed cancers, but the workload and cost associated are high. With the support of Breast Cancer Computer-Aided Diagnosis (CADx) systems only one radiologist is needed to read each mammogram rather than two.

There is good evidence in the literature that Breast Cancer CADx systems can improve the AUC performance of radiologists [4] [5] [6] [7] [8], e.g. in [9], it was presented an evaluation of the variation of performance in terms of sensitivity and specificity of two radiologists with different experience in mammography (6 and 2 years respectively), with and without the assistance of two different CADx systems (SecondLook and CALMA). The evaluation was made on a dataset composed by 70 images of patients with cancer (biopsy proven) and 120 images of healthy breasts (with a three years follow up). The results showed that the use of a CADx allows for a substantial increment in sensitivity (up to 15.6%) and a less pronounced decrement in specificity, which was more significant for the least experienced of the radiologists.

However, the performance of current and future commercial CADx systems still needs to be improved so that they can meet the requirements of clinics and screening centers [10] [11].

In this work, we proposed a new method supported on the combination of five Feature Selection Methods (FSMs) and MLCs respectively, for building Breast Cancer classification schemes (i.e. calcifications and mases) that provide the high performance over the AUC curve. The selected FSMs are filter-based methods, which use heuristics (statistics) based on general characteristics of the data rather than a MLC (as wrapper or embedded paradigm) to evaluate the merit of features [12] [13] [14] [15]. As an optimal subset of features is always relative to a certain evaluation function [16], it was used different FSMs with different evaluation function: the traditional CHI-Square Discretization (CHI2) [17] based on the chi-square statistic function, Information Gain (IG) [18] based on the information measure, One-Rule (1Rule) [19] based on rules as a principal evaluation function and Re-

This work was supported by the Breast Cancer Digital Repository Consortium (BCDR - http://bcdr.inegi.up.pt))

lief [20] based on the distance measure. Also, it was used an algorithm developed in previous work [21] named RMean based on a voting function for indexing relevant features (see Algorithm 2, which is revisited here). The proposed method dynamically form subsets of features extracted from resultant rankings (one by each FSM applied) for feeding five machine learning models: Feed Forward Back-Propagation (FFBP) neural network [22], Support Vectors Machine (SVM) [23], Naive Bayes (NB) [24], Linear Discriminant Analysis (LDA) [25] and k-Nearest Neighbors (kNN) [26] respectively. Finally, the selection of the best classification scheme is based on the Wilcoxon Statistical Test [27] [28] following two criteria: (1) the higher obtained AUC value and (2) if there is classification performances tied, the one using less number of employed features is preferred. The method was evaluated on six datasets containing calcifications and masses lesions (with differents configurations) extracted from two public Breast Cancer databases and and it is included a statistical comparison of achieved results.

The remainder of the work is ordered as follows: the Materials and Methods section, overviews the employed databases, FSMs and MLCs. Also, describes in detail the proposed method and the experimental setup design for its evaluation. The Results and Discussion section presents an exploratory comparison based on the obtained AUC scores using the Wilcoxon statistical test [27] [28] to assess the meaningfulness of differences between classification schemes. Finally, Conclusions and Future work are drawn in the last section.

II. Materials and Methods

A. Databases

This work is supported on two public databases: the Breast Cancer Digital Repository (BCDR), which is the first wide-ranging annotated Portuguese Breast Cancer database, with anonymous cases from medical historical archives supplied by Faculty of Medicine - Centro Hospitalar de São João at University of Porto, Portugal [29] and the Digital Database for Screening Mammography (DDSM). For convenience, the DDSM images used in this study were obtained from the Image Retrieval in Medical Applications (IRMA) project (courtesy of TM Deserno, Dept. of Medical Informatics, RWTH Aachen, Germany) where the original LJPEG images of DDSM were converted to 16 bits Portable Network Graphics (PNG) format [30] [31].

The BCDR is composed of 1734 patient cases with mammography and ultrasound images, clinical history, lesion segmentation and selected pre-computed image-based descriptors; each case may have one or more Region of Interest (ROI) with associated Pathological Lesion (PL) segmentations (for different PLs), typically in Mediolateral Oblique (MLO) and Craniocaudal (CC) images of the same breast.

On the other hand, the DDSM database is composed by 2620 patient cases divided into three categories: normal cases (12 volumes), cancer cases (15 volumes) and benign cases (14 volumes); like in the BCDR, each case may have one or more associated PL segmentations, usually in MLO and CC image views of the same breast.

B. Feature Selection Methods

Several types of extracted features (e.g. intensity statistics, shape and texture) from mammograms have been combined to form subsets of features, which extensively provided significant information for lesions classification [32] [33] [34] [35]. However, selecting the most appropriate subset of features is still a very difficult task; usually a satisfactory instead of the optimal feature subset is searched.

The selected methods were all derived from the filter paradigm, because its execution is a one step process without any data exploration (search) involved and are also independent of classifiers [36].

1) CHI2 Discretization: This method consists on a justified heuristic for supervised discretization [17]. Numerical features are initially sorted by placing each observed value into its own interval. Then the chi-square statistic (x^2) is used to determine whether the relative frequencies of the classes in adjacent intervals are similar enough to justify merging. The extent of the merging process is controlled by an automatically set x^2 threshold. The threshold is determined through attempting to maintain the fidelity of the original data.

2) IG method: The IG measurement normalized with the symmetrical uncertainty coefficient [18] is a symmetrical measure in which the amount of information gained about Y after observing X is equal to the amount of information gained about X after observing Y (a measure of feature-feature intercorrelation). This model is used to estimate the value of an attribute Y for a novel sample (drawn from the same distribution as the training data) and compensates for information gain bias toward attributes with more values.

3) 1Rule: This method estimates the predictive accuracy of individual features building rules based on a single feature (can be thought of as single level decision trees) [19]. As it is used training and test datasets, it is possible to calculate a classification accuracy for each rule and hence each feature. Then, from classification scores, a ranked list of features is obtained. Experiments with choosing a selected number of the highest ranked features and using them with common machine learning algorithms showed that, on average, the top three or more features are as accurate as using the original set. This approach is unusual due to the fact that no search is conducted.

4) Relief: This method uses instance based learning to assign a relevance weight to each feature [20]. Each feature weight reflects its ability to distinguish among the class values. The feature weight is updated according to how well its values distinguish the sampled instance from its nearest hit (instance of the same class) and nearest miss (instance of opposite class). The feature will receive a high weight if it differentiates between instances from different classes and has the same value for instances of the same class. For nominal features it is defined as either 1 (the values are different) or 0 (the values are the same), while for numeric features the difference is the actual difference normalized to the interval $[0..1]$.

C. Machine Learning Models

The discrimination between samples of two classes may be formulated as a supervised learning problem, which is defined as the prediction of the value of a function for any valid input after training a learner using examples of input and target output pairs [37]. For the problem at hand, the function has only two discrete values: benign or malignant. Hence the problem can be modeled as a two-class classification problem. A variety of MLCs have been applied in CADx approaches for Breast Cancer detection/classification. The Artificial Neural Networks (ANN) [14] [23] [38] [39], SVM [14] [22] [23] [37] [39] [40] and LDA [41] [42] seem to be the most commonly used type of classifiers. Other less popular, but perform very well are NB [43] [44] [45] and kNN [25] [43] classifiers respectively.

A brief description of these MLCs is given here:

1) FFBP Neural Network Classifier: The FFBP neural network is a particular model of ANN, which provides a nonlinear mapping between its input and output according to the back-propagation error learning algorithm. This model has demonstrated to be capable of approximating an arbitrarily complex mapping within a finite support using only a sufficient number of neurons in few hidden layers (all layers using a sigmoid function as kernel type) [22].

2) SVM Classifier: SVMs are based on the definition of an optimal hyperplane, which linearly separates the training data. In comparison with other classification methods, a SVM aims to minimize the empirical risk and maximize the distances (geometric margin) of the data points from the corresponding linear decision boundary [23].

3) NB Classifier: The NB classifier is based on probabilistic models with strong (Naive) independence assumptions [24]. It assumes that c is a class variable depending on n input features: $x_1, x_2, \cdots, x_n$. The prediction of c can be described by the following conditional model: $p(c|x_1, x_2, \cdots, x_n)$ and according to the Bayes' theorem:

$$p(c|x_1, x_2, \cdots, x_n) = \frac{p(c)p(x_1, x_2, \cdots, x_n|c)}{p(x_1, x_2, \cdots, x_n)}$$

where $p(c)$ is the prior probability of c, $p(x_1, x_2, \cdots, x_n|c)$ is the conditional probability depending on c, and $p(x_1, x_2, \cdots, x_n)$ is the probability of input features. If each feature x_i is conditionally dependent, as the denominator $p(x_1, x_2, \cdots, x_n)$ does not depend on c, which is actually a constant when features are given; the conditional probability over the class variable c can be expressed as:

$$p(c|x_1, x_2, \cdots, x_n) = \frac{1}{z}p(c)\prod_{i=1}^{n} p(x_i|c)$$

where z is a normalization constant. The above NB classifier can be trained based on the relative frequencies shown in the training set to get an estimation of the class priors and feature probability distributions. For a test sample, the decision rule will be picking the most probable hypothesis (value of c) which is known as the maximum a posteriori decision rule using the above model.

4) LDA Classifier: LDA is a traditional method for classification [25]. The basic idea is to try to find an optimal projection (decision boundaries optimized by the error criterion), which can maximize the distances between samples from different classes and minimize the distances between samples from the same class. For the binary classification, observations are classified by the following linear function:

$$g_i(x) = W_i^T x - c_i \quad 1 \leq i \leq 2$$

where W_i^T is the transpose of a coefficient vector, x is a feature vector and c_i is a constant as the threshold. The values of W_i^T and c_i are determined through the analysis of a training set. Once these values are determined, they can be used to classify the new observations (smallest $g_i(x)$ is preferred).

5) kNN Classifier: The kNN classifier is a nonparametric technique called a "lazy learning" because little effort goes into building the classifier and most of the work is performed at the time of classification. The kNN assigns a test sample to the class of the majority of its k-neighbors; that is, assuming that the number of voting neighbors is $k = k_1 + k_2 + k_3$ (where k_i is the number of samples from class i in the k-sample neighborhood of the test sample, usually computed using the Euclidean distance), the test sample is assigned to class m if $k_m = max(k_i), i = 1, 2, 3$ [26].

D. Proposed Method

The proposed method is supported on the combination of five FSMs and MLCs respectively, for building Breast Cancer classification schemes that provide the high performance over the AUC curve.

The employed FSMs are filter methods, which use heuristics (statistics) based on general characteristics of the data rather than a MLC (as wrapper or embedded paradigm) to evaluate the merit of features [12] [13]. As an optimal subset of features is always relative to a certain evaluation function [16], the selected FSMs were: CHI2 discretization [17] based on the chi-square statistic function, IG [18] based on the information measure, 1Rule [19] based on rules as a principal evaluation function, Relief [20] based on the distance measure and the recently developed RMean method [21] based on a voting function (averaging each feature position) for indexing relevant features (see Algorithm 2, which revisited here).

As it is shown in the Algorithm 1, the dataset D and the total of features in the initial subset nS constituted the starting point of the proposed method. Once, this method is a multistep modelling procedure, the application of the k-fold Cross Validation (CV) method [46] to the entire sequence of modelling steps guarantee reliable results [47]. Thus, it was applied 10 times 10-CV before features ranking to avoid giving an unfair advantage to predictors, and before classification step to prevent overfitting of classifiers to the training set [46] (see Algorithm 1 step 3 and 13). The application of FSMs on the processed dataset S_{cv} produced five different ranking of features (see Algorithm 1 step 4 to 8). Then, from each ranking of features, it were dynamically built ranked subset of features with different size S_{ini}.

Algorithm 1 Proposed method

Require: $D[f_1, f_2, f_3, ..., f_n] : n \geq 2$;
$nS \leftarrow$ maximum number of features in the initial subset;
Ensure: $C_{(best)}$; Best classification scheme
1: $C_{(best)} = []; C_{(aux)} = []; S_{ini} = []; S_{cv} = []; D_{cv} = []; R_{CHI2} = []; R_{IG} = []; R_{1R} = []; R_{Rel} = []; L = []$;
2: $nF \leftarrow nS$; Initializing nF
3: $D_{cv} \leftarrow$10-$CV(D)$; Applying 10 times 10-CV
4: $R_{CHI2} = eval(CHI2, D_{cv})$; Ranking by CHI2
5: $R_{IG} = eval(IG, D_{cv})$; Ranking by IG
6: $R_{1R} = eval(1R, D_{cv})$; Ranking by 1R
7: $R_{Rel} = eval(Relief, D_{cv})$; Ranking by Relief
8: $R_{RMean} = eval(RMean, D_{cv})$; Ranking by RMean
9: $L = [R_{CHI2}, R_{IG}, R_{1R}, R_{Rel}, R_{RMean}]$; List of ranking
10: **for** $i = 1 : length(L)$ **do**
11: **for** $j = 1 : trunc(L_i/nS)$ **do**
12: $S_{ini} \leftarrow extract(nF, L_i)$; Extract the first nF features from L_i
13: $S_{cv} \leftarrow$10-$CV(S_{ini})$; Applying 10 times 10-CV
14: $C_{(i,j,FFBP)} \leftarrow eval(FFBP, S_{cv})$ Applying the FFBP
15: $C_{(i,j,SVM)} \leftarrow eval(SVM, S_{cv})$ Applying the SVM
16: $C_{(i,j,NB)} \leftarrow eval(NB, S_{cv})$ Applying the NB
17: $C_{(i,j,LDA)} \leftarrow eval(LDA, S_{cv})$ Applying the LDA
18: $C_{(i,j,kNN)} \leftarrow eval(kNN, S_{cv})$ Applying the kNN
19: $nF \leftarrow nF + nS$; Updating the number of features nF
20: **end for**
21: $C_{(aux)} \leftarrow C_{(aux)} + max(C)$; Higher statistically
22: **end for**
23: $C_{(best)} \leftarrow max(C_{(aux)})$; Higher statistically

These ranked subsets of features were processed by the 10-CV method before feeding the FFBP neural network [22], SVM [23], NB [24], LDA [25] and kNN [26] classifiers respectively (see Algorithm 1 step 13 to 18). In the last step, two important criteria are evaluated in order to select the best classification scheme: (1) the higher obtained AUC value and (2) if there is classification performances tied, the one using less number of employed features is preferred. Both criteria were conducted using the Wilcoxon Statistical Test, i.e. a non-parametric alternative test to the paired t-test, which ranks the differences in performances of two classifiers [27] [28]. This test provided a fairly comparison among all obtained AUC performances, and therefore a reasonable selection of $C_{(best)}$.
The implementation of the proposed method was in JAVA language and the source code of all employed FSMs and MLCs are available in the WEKA data mining software version 3.6 [48].

E. Experimental Setup

This section outlines the experimental evaluation design of the proposed method using two public Breast Cancer databases. That involves the datasets creation and machine learning models configurations are important aspects to be described here.

Algorithm 2 RMean

Require: $D[f_1, f_2, f_3, ..., f_n] : n \geq 2$;
Ensure: R_{Mean};
1: $R_{Mean} = []; R_{CHI2} = []; R_{IG} = []; R_{1R} = []; R_{Rel} = []; D_{cv} = []$;
2: $D_{cv} \leftarrow$10-$CV(D)$; Applying 10 times 10-CV
3: $R_{CHI2} \leftarrow eval(CHI2, D_{cv})$; Ranking by CHI2
4: $R_{IG} \leftarrow eval(IG, D_{cv})$; Ranking by IG
5: $R_{1R} \leftarrow eval(1R, D_{cv})$; Ranking by 1R
6: $R_{Rel} \leftarrow eval(Relief, D_{cv})$; Ranking by Relief
7: $R_{Mean} \leftarrow (R_{CHI2} + R_{IG} + R_{1R} + R_{Rel})/4$; Averaging the features position throughout resultant rankings from steps 3,4,5 and 6.
8: $R_{Mean} \leftarrow sort(R_{Mean}, 'ascendant')$; Sorting in ascendant way the resultant ranking from the step 6.

1) Datasets Creation: A set of 23 image-based descriptors (features) were extracted from the BCDR and DDSM databases to be used in this work. Selected descriptors included intensity statistics, shape and texture features, computed from segmented calcifications and masses in both MLO and CC mammography views. The intensity statistics and shape descriptors were selected according to the radiologists experience (similar to the clinician procedure) and the American College of Radiology (BIRADS-Mammography atlas) [49], which described in detail how to detect/classify pathological lesions. Additionally, texture descriptors were the Halarick's descriptors extracted from the grey-level co-occurrence matrices [50]. An overview of the mathematical formulation for computing features is presented below:

- *Skewness*:
$$f_1 = \frac{\frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x})^3}{\left[\sqrt{\frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x})^2}\right]^3}$$
with x_i being the i^{th}-value and $\bar{x}$ the sample mean.
- *Kurtosis*:
$$f_2 = \frac{\frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x})^4}{\left[\sqrt{\frac{1}{n}\sum_{i=1}^{n}(x_i - \bar{x})^2}\right]^2} - 3$$
with x_i being the i^{th}-value and $\bar{x}$ the sample mean.
- *Area Fraction* (f_3): is the percentage of non-zero pixels in the image or selection.
- *Circularity*:
$$f_4 = 4\pi\frac{area}{perimeter^2}$$
- *Perimeter*: $f_5 = length(E)$ with $E \subset O$ being the edge pixels.
- *Elongation*: $f_6 = \left(\frac{m}{M}\right)$ with m being the minor axis and M the major axis of the ellipse that has the same normalized second central moments as the region surrounded by the contour.

- *Standard Deviation*:

$$f_7 = \sqrt{\frac{1}{n-1}\sum_{i=1}^{n}(x_i - \bar{x})^2}$$

with x_i being the grey level intensity of the i^{th}-pixel and $\bar{x}$ the mean of intensity.

- *Roughness*:

$$f_8 = \frac{perimeter^2}{4\pi * area}$$

- *Minimum* (f_9) and *Maximum* (f_{10}): the minimum and maximum intensity value in the region surrounded by the contour.
- *Shape*:

$$f_{11} = \frac{perimeter * elongation}{8 * area}$$

- *X Centroid*:

$$f_{12} = \frac{min(x) + max(x)}{2}$$

with x being the set of X coordinates of the object's contour.

- *Entropy*:

$$f_{13} = \sum_{i=1}^{L}\sum_{j=1}^{L} p(i,j)log(p(i,j))$$

with *L* being the number of grey-levels, and $p(i,j)$ being the probability of pixels with grey-level i occur together to pixels with grey-level j.

- *X Center Mass* (f_{14}): normalized X coordinates of the center of mass of O.
- *Angular Second Moment*:

$$f_{15} = \sum_{i=1}^{L}\sum_{j=1}^{L} p(i,j)^2$$

with L being the number of grey-levels, and $p(i,j)$ being the probability of pixels with grey-level i occur together to pixels with grey-level j.

- *Median*:

$$f_{16} = \begin{cases} \frac{n+1}{2} & \text{if } length(X) \text{ is odd} \\ \frac{X(\frac{n}{2}) + X(\frac{n}{2}+1)}{2} & \text{if } length(X) \text{ is even} \end{cases}$$

with X being the set of intensities.

- *Contrast*:

$$f_{17} = \sum_{i}\sum_{j} p(i,j)(i-j)^2$$

with $p(i,j)$ being the probability of pixels with grey-level i occur together to pixels with grey-level j.

- *Correlation*:

$$f_{18} = \frac{\sum_i \sum_j [ijp(i,j)] - \mu_x\mu_y}{\sigma_x\sigma_y}$$

with μ_x, μ_y, σ_x and σ_y being the means and standard deviations of the marginal distribution associated with $p(i,j)$.

- *Mean*:

$$f_{19} = \frac{1}{n}\sum_{i=1}^{n} x_i$$

with n being the number of pixels inside the region delimited by the contour and x_i being the grey level intensity of the i^{th} pixel inside the contour.

- *Inverse Difference Moment*:

$$f_{20} = \sum_i \sum_j \frac{1}{1+(i-j)^2} p(i,j)$$

with $p(i,j)$ being the probability of pixels with grey-level i occur together to pixels with grey-level j.

- *Y Center Mass* (f_{21}): normalized Y coordinates of the center of mass of O.
- *Area*: $f_{22} = |O|$ with O being the set of pixels that belong to the segmented lesion.
- *Y Centroid*:

$$f_{23} = \frac{min(y) + max(y)}{2}$$

with y being the set of Y coordinates of the object's contour.

Conformable to the number of patient cases of used databases, it were created six datasets containing calcifications and masses lesions with different configurations: (1) two balanced datasets (same quantity of benign and malignant instances), (2) two unbalanced datasets containing more benign than malignant instances and (3) two unbalanced datasets holding more malignant than benign instances, representatives of BCDR and DDSM respectively. The BCDR supplies several datasets for scientific purposes (Availaible on http://bcdr.inegi.up.pt), we used the BCDR-F01 distribution to form the BCDR1 dataset holding 374 features vectors; BCDR2 and BCDR3 datasets with a total of 287 features vectors respectively.

Due to the wide range of information in the DDSM database, it were considered only two volumes of cancer and benign cases (random selection) to form the DDSM1 dataset holding 582 features vectors; DDSM2 and DDSM3 datasets with a total of 491 features vectors respectively. Figure 1 shows a detailed description of the datasets creation workflow.

2) MLCs Configuration: For all MLCs with the exception of the NB (which is parameterless), 10-CV method [46] was performed on the training set for optimizing the classifiers parameters.

The FFBP neural network was used with a total of hidden layers determined according to the equation (*attributes* + *number of classes*)/2; one output layer associated with the binary classification (benign or malignant); transfer function for all layers based on the sigmoid function and the number of iterations (epochs) were optimized in the range of 100 to 1000 epochs (with an interval increment of 100 units).

The SVM classifier was used with the regularization parameter *C* (cost) optimized in the range of 10^{-3} to 10^3 and the kernel

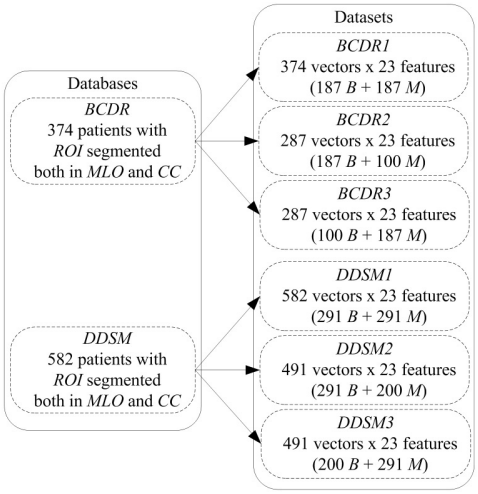

Fig. 1. Datasets creation flowchart; *B* and *M* represent Benign and Malignant class instances.

type based on a linear function, which provided better results respect to others kernel such as: radial basis, polynomial and sigmoid function (from our experimental experience).
The kNN classifier included the estimation of an optimal value k for the size of the neighborhood varying from 1 to 20, and the contribution of each neighbor was always weighted by the distance to the instance being classified.

III. Results and Discussion

According to the experimental setup section, a total of 750 ranked subsets of features containing image-based features extracted from segmented calcifications and masses lesions were analyzed using the proposed method and the straightforward statistical comparison based on the mean of AUC performances over 100 runs highlighted interesting results for balanced and unbalanced datasets respectively.

3) Performance on Balanced Datasets: The higher AUC value obtained in the BCDR1 dataset was formed by the SVM classifier and the RMean method using a total of 15 features (AUC value of 0.8365). This result was statistically superior to the majority of the remaining classification schemes. However, there were others schemes with similar performances statistically at p=0.05 (see Table I). From these results, it is possible to select the FFBP neural network in combination with the CHI2 discretization and RMean method with 5 features as the most appropriate classification schemes in this dataset. They reached an AUC value of 0.8264 and 0.8272 using the minimum number of features respectively.
For DDSM1 dataset, the higher AUC value was obtained by the combination of the LDA classifier and the RMean method using 20 features (AUC value of 0.807). However, this result did not provide statistical evidence to be better than others combinations (see Table I). Similar to the DDSM1 dataset, the combinations formed by the FFBP neural network in conjunction with the Relief and RMean methods using 10 features provided similar performances

TABLE I
Classification schemes with nonsignificant difference in AUC performances for BCDR1 and DDSM1 balanced datasets

Dataset	Best Scheme	Other Scheme	AUC	p=0.05
BCDR1	SVM+RMean+15F (0.8365)	FFBP+CHI2+5F	0.8264	p=0.574
		FFBP+RMean+5F	0.8272	p=0.494
		FFBP+CHI2+10F	0.8219	p=0.359
		SVM+Relief+15F	0.8831	p=0.603
		LDA+RMean+15F	0.8284	p=0.295
		LDA+RMean+20F	0.8279	p=0.286
DDSM1	LDA+RMean+20F (0.807)	FFBP+Relief+10F	0.8061	p=0.592
		FFBP+RMean+10F	0.8056	p=0.475
		SVM+RMean+20F	0.7939	p=0.139

TABLE II
Classification schemes with nonsignificant difference in AUC performances for BCDR2 and DDSM2 unbalanced datasets

Dataset	Best Scheme	Other Scheme	AUC	p=0.05
BCDR2	SVM+RMean+10F (0.8389)	FFBP+RMean+10F	0.8352	p=0.573
		LDA+CHI2+10F	0.8278	p=0.365
		LDA+RMean+10F	0.8284	p=0.403
DDSM2	FFBP+RMean+5F (0.8406)	FFBP+IG+10F	0.8405	p=0.682

statistically (AUC value of 0.8061 and 0.8056 respectively). These results were obtained using a less number of employed features. Thus, both classification schemes were selected as the most appropriated classification schemes in this dataset.

4) Performance on Unbalanced Datasets: The higher AUC performance for BCDR2 dataset was formed by the SVM classifier and the RMean method using 10 features, reaching an AUC value of 0.8389. This result was not statistically superior to obtained results by others classification schemes

TABLE III
Classification schemes with nonsignificant difference in AUC performances for BCDR3 and DDSM3 unbalanced datasets

Dataset	Best Scheme	Other Scheme	AUC	p=0.05
BCDR3	LDA+RMean+5F (0.8611)	FFBP+RMean+5F	0.8562	p=0.592
DDSM3	LDA+RMean+20F (0.807)	FFBP+Relief+10F	0.8061	p=0.592
		FFBP+RMean+5F	0.78	p=0.094
		SVM+Relief+10F	0.7879	p=0.139
		SVM+Relief+15F	0.7853	p=0.126
		SVM+RMean+10F	0.786	p=0.129
		SVM+RMean+15F	0.783	p=0.128
		NB+Relief+10F	0.785	p=0.125
		NB+RMean+10F	0.783	p=0.118
		LDA+Relief+10F	0.7883	p=0.145
		LDA+Relief+15F	0.7877	p=0.139
		LDA+1R+20F	0.7845	p=0.12
		LDA+RMean+10F	0.789	p=0.153
		LDA+RMean+15F	0.7861	p=0.135

using the same number of employed features(see Table II). Therefore, the four combinations presented in the Table II could be considered as the most appropriated schemes for lesions classification in the BCDR2 dataset.

Besides, for DDSM2 dataset the best classification performance was obtained by the combination of the FFBP neural network classifier and the RMean method using 5 features; reaching AUC value of 0.8406. However, this result did not statistically outperform the obtained result by the combination of the FFBP neural network classifier and the IG method with 10 features, attainment an AUC value of 0.8405 (see Table II). Despite the small and insignificant difference in term of AUC performances, the first combination was selected as the most appropriated classification scheme because it reached this results using a less number of features.

The best classification performance for BCDR3 dataset was provided by the combination of the LDA classifier and the RMean method with 5 features, accomplishment an AUC score of 0.8611 (see Table III). This result was not statistically superior to the obtained result by the combination of the FFBP neural network classifier and the RMean method with 5 features, which achieved an AUC score of 0.8562. As both classification schemes reached these results using the minimum number of employed features could be considered as the most appropriated classification schemes for BCDR3 dataset.

In the DDSM3 dataset, the higher AUC value was obtained by the combination of LDA classifier and the RMean method with a total of 10 features (AUC value of 0.7889). This classification result showed nonsignificant difference respect to others combinations, which reached similar AUC performances (see Table III). Despite the several combinations which can be used as a good classification scheme for this dataset. Only the scheme formed by the FFBP neural network and the RMean method stretched the result using the minimum number of features (5). Thus, it was considered as the most appropriated classification scheme in the DDSM3 dataset (see Table III).

Regarding of the classifiers performance, results show that the selection of the most appropriated classifier is dependent on the dataset and the FSM. From Table I, II and III, it possible to read that the best MLC was the FFBP neural network classifier, appearing consistently on every appropriated classification scheme for all datasets. These results were expected since this classifier has demonstrated to be capable of generalizing decision boundary in a more complex features space [25]. Meanwhile the best FSM was the RMean method (see Algorithm 2), which appeared consistently on every successful classification scheme, providing in most cases the minimal subset of features.

IV. Conclusions and Future Work

In this work, it is made a statistical exploration of different classification schemes within the context of Breast Cancer classification. The main contribution it was developed a new and robust method for building machine learning classifiers that combines suitably several feature selection methods with different evaluation function. This method was effective in providing competitive classification schemes for balanced and unbalanced datasets: the FFBP neural network and the RMean method using 5 features was the best scheme for BCDR1, BCDR3, DDSM2 and DDSM3 datasets, attainment an AUC value of 0.8264, 0.8562, 0.8406 and 0.78 respectively. Also, the FFBP neural network and the RMean method with 10 features in the DDSM1 dataset, reaching an AUC value of 0.8056, and the SVM classifier with the RMean method using 10 features for the BCDR2, stretching an AUC value of 0.8399. Regarding to MLCs and FSMs, the FFBP neural network classifier and the RMean method were the best, appearing consistently in the majority of successful schemes. In future work, we plan to assess the performance using others benchmarking datasets with different experimental setup: including clinical and more image-based features to evaluate the sensibility and generalization of the proposed method. Also, it's further integration in a real Breast Cancer CADx system.

Abstract—The main aim of this paper is to advance the state of the art in automated prostate segmentation using T2 weighted MR images, by introducing a hybrid topological MRI prostate segmentation method which is based on a set of pre-labeled MR atlas images. The proposed method has been experimentally tested on a set of 30 MRI T2 weighted images. For evaluation the automated segmentations of the proposed scheme have been compared with the manual segmentations, using an average Dice Similarity Coefficient (DSC). Obtained quantitative results have shown a good approximation of the segmented prostate.

Keywords: Prostate segmentation, MRI T2, hybrid topological method

I. Introduction

PROSTATE cancer is one of the major healthcare problems affecting men's population and is the second most common cancer in men worldwide. An estimated 1.1 million men worldwide were diagnosed with prostate cancer in 2012, accounting for 15% of the cancers diagnosed in men. Considering this worrying data, it is predicted that the number of cases will almost double by 2030 [1]. Consequently, there is an increased demand and interest in advancements and enhancements of current methodologies for prostate cancer diagnosis and treatment planning.

Determination of proper information about the prostate location, its volume and shape of prostate gland are basic task and play essential role in numerous clinical applications. This information is crucial for cancer detection, localization and staging, guided biopsy, radiation treatment planning, but also for surgical planning and image-guided robotic-aided laparoscopic prostatectomy (RALP) with augmented reality (AR). In order to provide accurate information various imaging techniques are used in the clinical practice. Nowadays, trans rectal ultrasound (TRUS) is probably the most common and widespread medical imaging technique employed for cancer detection [2], [3], [4] as well as for guided needle biopsy [5]. This is mainly due to its low cost, portability and real-time acquisition. However, this technique has its own drawbacks. Namely, due to the low sensitivity prostate cancer visualization is poor, its false negative rate is high [6] and often resulting in high rates of rebiopsies.

Therefore, the Computer Tomography (CT) has been proposed as an alternative, and it is mainly used in prostate brachytherapy to determine the placement of the radioactive seeds and also to confirm the seed location post-procedure [7]. On the other hand, CT requires ionising radiation and nephrotoxic contrast media and could not provide differentiation between external and internal prostate anatomy because of the poor soft-tissue resolution.

Therefore, in the last decade high-resolution MRI have been promoted as a valuable alternative to before mentioned imaging techniques, which offers physicians better evaluation of the prostate diseases. In the clinical practice nowadays three different modalities of MR images are normally produced: T2-weighted, diffusion-weighted and dynamic contrast enhanced images. Recently, many scientific works have proved that MRI has very high accuracy in the detection of prostate diseases [8], [9] significantly improving the diagnostic rates. It enables easier image segmentation and determination of prostate shape and boundaries which is the basic step in clinical applications.

Usual MRI prostate examination results with a series of multiple images which are presenting plenty of anatomical and functional data regarding the prostate tissues. Analysis and segmentation of these images in major percentage of the cases in the clinical practice, currently is performed by experienced radiologists who based on their knowledge of the anatomy.

However, manual segmentation of prostate boundaries on multiple images in the MRI series could be extremely difficult and time consuming task, especially for series containing large number of images. Manual segmentation is subjective and could be performed differently by different experts and thus could produce different outcomes.

Because of this, currently there is a huge demand for fast and accurate automatic or semi-automatic segmentation methods for clinical applications.

Development of automatic segmentation algorithms and methodologies faces huge challenges, mainly owing to variability of prostate size and shape from patient to patient,

variable intensity ranges inside the prostate region and tissues of surrounding organs, as well as the absence of clear prostate boundaries.

The main aim of this paper is to advance the state of the art in automated prostate segmentation using T2 weighted MR images, by introducing a topological MRI prostate segmentation method using a set of pre-labeled MR atlas images.

The rest of the paper is organized as follows: in part II we present the current state of the art in automatic medical image segmentation methods, in part III we present the proposed topological method for MR image segmentation, in part IV the evaluation of the proposed method its results and findings about its efficiency are presented. Part V presents the work conclusions and the references are in part VI.

II. Related Work

Prostate segmentation methods based on images acquired using ultrasound, magnetic resonance and computed tomography could be generally divided into four major categories: contour and shape based methods, region based methods, supervised and un-supervised classification methods, hybrid methods [2].

Contour and shape based methods are using the boundary features to segment the prostate. This is very difficult problem since MRI exhibits high soft tissue contrast. To cope with this Zwiggelaar et al. [10] used first and second order Lindeberg directional derivatives, in a polar coordinate system to identify the edges. On the other hand, Samiee et al. [11] used prior information of the prostate shape to refine the prostate boundary. Without prior shape information segmentation was error prone and often significantly different from the anatomical structure. Therefore, Cootes et al. [12] proposed to segment prostate in MR slices using the active shape model (ASM). Slightly different approach which combines two and three dimensional ASMs to segment the prostate using MR images was proposed by Zhu et al. [13]. A three dimensional ASM was built that represented the shape variance of the prostate.

One of the commonly used methods for region based segmentation is the one which lies upon the set of manual segmentations of anatomical structures registered to a common coordinate frame called atlas, which is afterwards used as a reference. These methods are trying to map the pre-segmented images to the querying image by finding a one to one transformation. However, due to variations in image intensities and differences in shapes this matching remains to be a challenging research topic.

For this purposes, various multi-atlas segmentation methods have been analyzed in order to improve the selection of the atlas images which are most similar to the querying one [14]. It should be stressed that the weighting coefficients should favor the atlas images which are most similar to the querying one and thus should contribute more in the segmentation.

Having in mind this, Klein et al. [15] has proposed a multi-atlas approach to segment the prostate using localized mutual information. The registration of the training volumes to the querying one was performed using affine and non-rigid registration.

Álvarez et al. [16] improved this method by taking the advantage of both the inter-individual shape variation and intra-individual salient point representation.

Langerak et al. [17] focused their work pre-selection of atlases before registration by assigning them to clusters and registering only some of these clusters. They are analyzing and registering instances from each cluster and then combining them to an estimate of the target segmentation. By doing so, they claim to achieve the same accuracy with atlas reduction of even 60%.

Sjöberg and Ahnesjö [18] proposed a new multi-atlas based segmentation using probabilistic label fusion with adaptive weighting of image similarity measures. Namely, their method is based on probabilistic weighting of distance maps. Relationships between image similarities and segmentation similarities are estimated in a learning phase and used to derive fusion weights that are proportional to the probability for each atlas to improve the segmentation result.

Xie and Ruan [19] recently proposed a method where they first perform an affine registration to minimize the global mean squared error to coarsely align each atlas image to the target. Afterwards, they use a target-specific regional mean squared error, in order to select a relevant subset from the training atlas. Then non-rigid registration between the training images and the querying one are performed inside previously identified subset only. At the end, using the estimated deformation fields, structure labels are transferred from training to querying images and they are fused based on a weighted combination of regional and local mean squared error, with proper total-variation-based spatial regularization.

Makni et al. [20] proposed a modified alternative of the evidential C-means algorithm to cluster voxels in multispectral MRI, including T2 weighted, diffusion weighted and contrast enhanced images.

In contract to the previously mentioned methods, hybrid ones are combining a priory boundary and feature information. These methods are proven to give superior results in contrast to others in presence of shape and texture variations.

Vikal et al. [21] proposed a method for building an average shape model using the prior shape and size information from manually marked contours. In order to reduce the noise and enhance the contrast they used a stick filter. On the enhanced images they detected the edges by applying the Canny filter. The constructed average shape model was used to discriminate pixels which are out of the model orientation. By applying polynomial interpolation the contour was further refined. The segmented contours obtained in the middle slices were used to initialize other slices towards the peripheral zones in both directions.

III. METHODOLOGY

In order to enable accurate multi-atlas based prostate segmentation, the proposed methodology relies on most similar atlases which can provide robust and precise transformation to the target image. The proposed methodology consists of several steps as presented on the diagram in Fig. 1.

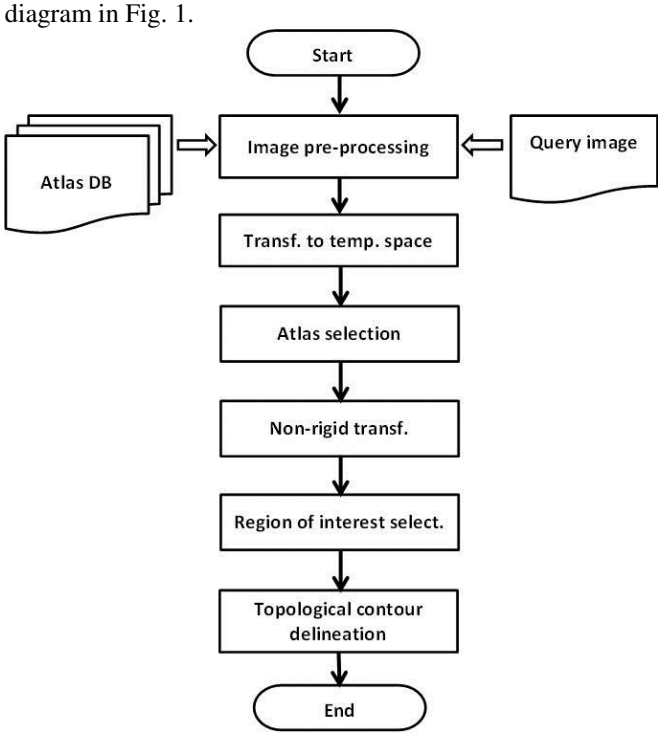

Fig. 1 Activity diagram which describes the whole methodology

Initial step of the proposed method are similar to those proposed in [15], namely appearance-specific atlas selections and a patch-based local weighting strategy for atlas fusion. After some image preprocessing which aims at inhomogeneity correction the top 5 similar atlases are selected for atlas registration based on the intensity differences in the surrounding region of the prostate. Once selected, the similar atlases are non-rigidly registered to a target image. Using the calculated transformation anatomical structure labels of the atlas are propagated to the space of the querying image. The aim of this step in our methodology is to order to derive a region of interest formed by the interception and union of the a priori shapes in the selected atlases, where the prostate contour of a non-segmented sample is supposed to be positioned. The final step is to delineate the prostate contour in the determined region by pixel classification. Namely, pixels within the region of interest are classified as prostate-likely-belonging pixels or prostate-unlikely-belonging pixels, taking into consideration the number of same-position pixels, being part of segmented samples and the intensity difference between a pixel of a non-segmented sample and the same-position pixels of segmented samples. The prostate contour is found as a set of pixels, separating column pixels (row pixels) within the region of interest in two disjunctive sets, having maximized the number of prostate-unlike-belonging pixels in the first set and the number of prostate-likely-belonging pixels in the other set exclusively. Prostate contour of a non-segmented sample is determined in three steps, described as follows:

Step 1: Determine prostate interception and union shape model, according to Definition 1 and Definition 2, over a set of segmented samples, acquiring prostate shapes' knowledge of n segmented same size and type prostate MR images.

Definition 1: A pixel $p[i, j]$ is an interception model pixel if:

$ss_1[i, j] \in$ prostate segment ss_1,
$ss_2[i, j] \in$ prostate segment ss_2,
…
$ss_{n-1}[i, j] \in$ prostate segment ss_{n-1},
$ss_n[i, j] \in$ prostate segment ss_n,
where $ss_i, 1 \le i \le n$ is a segmented sample.

Definition 2: A pixel $p[i, j]$ is a union model pixel if:

$ss_1[i, j] \in$ prostate segment ss_1 or
$ss_2[i, j] \in$ prostate segment ss_2 or
…
$ss_{n-1}[i, j] \in$ prostate segment ss_{n-1} or
$ss_n[i, j] \in$ prostate segment ss_n,
where $ss_i, 1 \le i \le n$ is a segmented sample.

According to previous definitions, if a pixel at position i,j is found as a prostate pixel in all segmented samples, then the pixels is considered as a part of the interception model. If at least one pixel at position i,j is found as a prostate pixel, then the pixel is a union model pixel. Interception pixels are considered as a part of the prostate of a non-segmented MR image.

Step 2: Classify each pixel within the union, but out of the interception as a prostate-likely-belonging pixel or prostate-unlikely-belonging pixel, exclusively according Eq. 1 and Eq.2.

If Eq.1 is satisfied,

$$(n - n_{plb})\text{diff}_{plb} \le (n - n_{pulb})\text{diff}_{pulb} \quad (1)$$

classify the pixel $p[i, j]$ as a prostate-likely-belonging pixel.

If Eq.2 is satisfied,

$$(n - n_{plb})\text{diff}_{plb} > (n - n_{pulb})\text{diff}_{pulb} \quad (2)$$

classify the pixel $p[i, j]$ as a prostate-unlikely-belonging pixel.

Equation 1, 2 parameters are the following ones:

n : Number of segmented samples.

n_{plb}: Number of segmented samples, where pixel at position i,j is part of the prostate segmented region.

n_{pulb}: Number of segmented samples, where pixel at position i,j is not a prostate pixel.

The intensity difference between a pixel $p[i, j]$ of a non-segmented sample and the mean intensity of pixels at position i,j, part of a prostate in segmented samples, is calculated according Eq. 3.

$$diff_{plb} = p[i, j] - (\sum_{k=1}^{n} ss_k[i, j]) / n_{plb} \quad (3)$$

where $ss_k[i, j] \in$ prostate segment of ss_k

The intensity difference between a pixel $p[i, j]$ of a non-segmented sample and the mean intensity of pixels at position i,j, out of the prostate in segmented samples, is calculated according Eq. 4.

$$diff_{pulb} = p[i, j] - (\sum_{k=1}^{n} ss_k[i, j]) / n_{pulb} \quad (4)$$

where $ss_k[i, j] \notin$ prostate segment of ss_k

Value-opposite differences: $(n - n_{plb})$ and $(n - n_{pulb})$ serve as a weight factor for pixel intensity differences: $diff_{plb}$ and $diff_{pulb}$. The smaller $(n - n_{plb})$ is, greater difference $(n - n_{pulb})$ is obtained. Relatively small pixel intensity difference $diff_{plb}$ increases pixel prostate belonging expectation. On the contrary, small pixel intensity difference $diff_{pulb}$ decreases pixel prostate belonging expectation. Combining previous parameters in a single equation (Equations 1, 2), a prostate pixel classifier is derived.

Step 3: Determine prostate contour shape as a set of pixel, separating the union, out of the interception in two disjunctive sets, such as the number of prostate-unlike-belonging pixels in the first set and the number of prostate-likely-belonging pixels in the other set is exclusively maximized.

Applying Equations 1, 2 for pixels of a non-segmented sample, out of the interception, but within the union, each pixel in the region is classified as a prostate-likely-belonging or prostate-unlikely-belonging pixel, exclusively.

Representing with 1 prostate-likely-belonging classified pixels, while with 0 prostate-unlikely-belonging classified pixels, the problem of identification of a prostate contour pixel is simplified to identification of prostate contour pixels, separating same row pixels (same column pixels), out of the interception, but within the union, in two disjunctive sets, such as the number of prostate-unlikely-belonging pixels and prostate-likely-belonging pixels in the sets is exclusively maximized.

For example, if $CP = \begin{bmatrix} p[i, j] \\ p[i+1, j] \\ p[i+2, j] \\ p[i+3, j] \\ p[i+4, j] \\ p[i+5, j] \end{bmatrix}$ is a six pixel same column set, out of the interception, but within the union, being accordingly classified as: $CCP = \{0,1,0,0,1,1\}$, there are 4 prostate contour candidate pixels, without taking into consideration the first and the last pixel. Pixel $p[i+1, j]$ separates classified set CPP in two disjunctive sets: $CPP_1 = \{0,1\}$, $CPP_2 = \{0,0,1,1\}$. The number of prostate-unlikely-belonging pixels in the first set is 1, while the number of prostate-likely-belonging pixels in the second set is 2. The sum equals 3. Similarly, pixel $p[i+2, j]$ separates set CPP in two disjunctive sets: $CPP_1 = \{0,1,0\}$, $CPP_2 = \{0,1,1\}$. Now the number of prostate-unlikely-belonging pixels in the first set is 2, while the number of prostate-likely-belonging pixels in the second set is 2. The sum equals 4. Choosing pixel $p[i+3, j]$ as a prostate contour pixel, the following disjunctive sets are obtained: $CPP_1 = \{0,1,0,0\}$, $CPP_2 = \{1,1\}$. The number of prostate-unlikely-belonging pixels in the first set is 3, while the number of prostate-likely-belonging pixels in the second set is 2. Their sum equals 5. Pixel $p[i+4, j]$ assumed as a prostate contour pixel, decreases the number of prostate-likely-belonging pixels in CPP_2, while the number of prostate-unlikely belonging pixels in CPP_1 remains unchanged.

Therefore, pixel $p[i+3, j]$ is chosen as a prostate contour pixel, since the sum of prostate-unlikely-belonging pixel and prostate-likely-belonging pixels in the disjunctive sets is maximized in that case (Fig.2).

-1	-1	-1
-1	8	-1
-1	-1	-1

Fig. 2 Point detection mask

If the condition given by Eq.5 is satisfied

$$R = \frac{1}{8}(8\,p[i, j] - p[i-1, j-1] - p[i-1, j] - p[i-1, j+1] - p[i, j-1] - p[i, j+1] - p[i+1, j-1] - p[i+1, j] - p[i+1, j+1]) > T \quad (5)$$

then the pixel p[i, j] is a prostate contour outlying pixel.

Discontinuous prostate contour curves are linked together applying standard image morphological operations, such as multiple Dilatation at first, then Erosion, in order to derive one pixel-thin prostate contour. Figure 3 represents the structuring element used in the morphological operations.

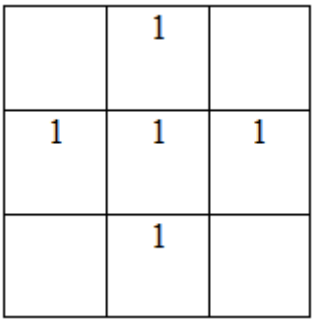

Fig. 3 Morphological operations' structuring element

IV. Experimental Evaluation and Results

For evaluation purposes all the steps described of the proposed methodology and presented in Fig. 1 are implemented in C# programming language. The program was executed on laptop with 4GB RAM memory and equipped with Intel Core i3 CPU with 2.4GHz and 64 bit Windows 7 OS. It has also ATI Mobility Radeon HD 4650 with 1GB dedicated memory. The proposed method was evaluated on 30 training MRI prostate images. The image series used for this evaluation were T2 FSE AXIALS 256x256 pixel. They were obtained from the online Prostate MR Image Database [22]. For each training image, manual segmentation is provided.

A leave-one-out study has been implemented based on each of the training scans using the remaining 29 images as the atlas database. In the sub-database, the top 5 most similar atlases are chosen. Based on these atlases the union and the interception shape model are constructed.

For better visual representation of the obtained results the following coloring convention was used: the red colored region represents the interception model, while the white colored region represents the union, out of the interception, Figure 4.

Pixels within the interception are considered as a part of the prostate. Each pixel within the white colored region is exclusively classified as a prostate-likely-belonging pixel or prostate-unlikely-belonging pixel.

Taking image 000046.00001.001.0013 from the Prostate MR Image Database (http://prostatemrimagedatabase.com/Database/000046/00001/001/0013.html) as a querying image, the result of the classification is shown on Figure 5. Red pixels, out of the interception, but within the union are classified as prostate-likely-belonging pixels, satisfying Equation 1, while the white pixels in the same region are classified as prostate-unlikely-belonging pixels, satisfying Equation 2.

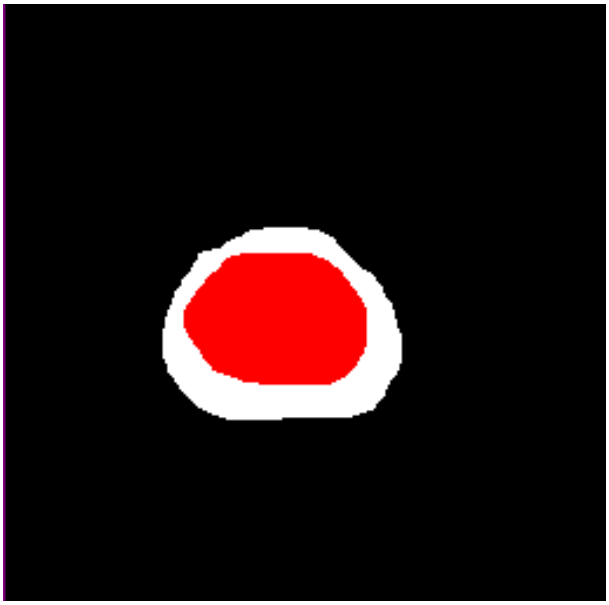

Fig. 4 Interception and union derived model

In Figure 5 blue colored pixels are the prostate contour pixels, determined in the third processing step of the proposed method.

Filtering prostate contour outlying pixels and applying standard region closing morphological operation, using Figure 3 structuring element, the prostate contour of a non-segmented T2 FSE AXIALS database image 000046.00001.001.0013 is obtained, Figure 6.

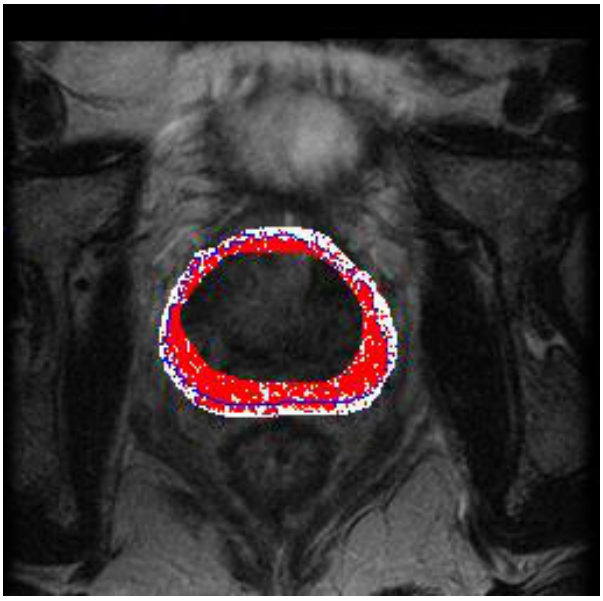

Fig. 5 Method application results

Fig. 6 Identified prostate contour (green), gold standard contour delineated manually by the expert (yellow).

For evaluation of the proposed method, we have used Dice similarity coefficient (DSC) defined as in Eq. 6 compared with the manual expert segmentation.

$$DSC = 2 \cdot \frac{A \cap B}{A + B} \qquad (6)$$

It has been applied on the apex, central and the base region of the prostate. The average of this metric with its standard deviations calculated from the selected image series compared with the corresponding manual segmentation is given in Table1.

TABLE I.
PROSTATE SEGMENTATION QUANTITATIVE RESULTS FOR TRAINING DATASETS

Region	**DSC**
Apex	0.81±0.13
Central	0.82±0.10
Base	0.79±0.17

V. CONCLUSION

Comparing the obtained results a conclusion for prostate shape accordance can be derived, based on the prostate edges' direction compatibility, prostate contour position and prostate surface.

In general, prostate segmentation result in this case depends of two factors. The number of segmented samples used and segmented samples' prostate shape variability, based on what the interception and the union shapes are determined. More segmented samples are considered, with wider prostate shape variability, more accurate prostate contour is obtained. A drawback of the proposed method is the incapacity of detecting prostate segments, out of the derived union region, being part of prostate of a non-segmented sample. On the opposite, prostate segmentation running time is significantly improved, since relatively small segment of a non-segmented prostate MR image is processed.

ACKNOWLEDGMENT

Abstract—Ambient Assisted Living (AAL) aims to improve the quality of daily life for all humans in different periods of life. Neural-Computer Interface (NCI) can be used within AAL environments to provide alternative communication means for impaired persons bypassing the need for speech and other motor activities. By monitoring, analyzing and responding to muscular activity (EMG signals) of users, NCI systems are able to monitor, diagnose and respond to the cognitive, emotional and physical states of users in real time. In this paper we analyze and develop a speller application based on the EMG interface. We analyze requirements for developing interfaces for disabled users and interfaces of known speller applications, and describe the development of the EMG-based speller as a benchmark application. The developed speller has adaptive stimulus rate and allows word selection from dictionary. We evaluate performance and usability of the developed speller using a set of empirical (accuracy, information transfer speed, input speed), ergonomic (NASA-TLX scale) and conceptual (humanistic intelligence) attributes.

I. Introduction

Ambient Assisted Living (AAL) environments comprise assisted technology devices, communication protocols and interfaces used to improve the quality of daily life for humans in different periods of their life [1]. Considering predictions of the demographic changes in society, AAL particularly focuses on elderly people though people with minor disabilities such as motor impairments can benefit, too. The AAL systems are user-centered and specifically are based on the concept of User Interfaces for All [2]. The concept aims at efficiently and effectively addressing the accessibility problems in human interaction with software applications and services while meeting the individual requirements of the users in general, including disabled and elderly people. Following the vision of e-Inclusion, the aim to "leave no-one behind" when enjoying the benefits of information and communication technology [3].

In the AAL environments, Neural-Computer Interfaces (NCI) can be used to provide alternative communication means for persons with disabilities bypassing the need for speech and other motor activities. NCI is similar to Brain-Computer Interface (BCI) in methods used as well as in applications, however it uses the Electromyography (EMG) data rather than the Electroencephalography (EEG) data to establish an interface between human peripheral neural system and computers by recording electrical signals governing muscular movements of a subject. The concepts are particularly suited to the needs of the handicapped as the cores of the smart environments and virtual reality applications. The state of a user is captured using sensors attached to the body. Then a physiological computing system creates a bio-cybernetic neurofeedback loop involving both human users and computers [4], which allows to produce a representation of the user's operational context. The loop may be designed to offer assistance if the user is frustrated or unable to perform the task due to excessive mental workload, adapt the level of challenge to sustain or increase task engagement if the user is bored or demotivated by the task, incorporating an emotional display element into the user interface, or alert for help if the user is not responsive [5].

When developing NCI systems for older adults (over 60) one has to consider that older people often have multiple, minor motor and cognitive function impairments or have slow control over their motor functions [6]. Given the often reported lower skin hydration in the elderly, the skin conductance is lower which leads to lower amplitudes and signal-to-noise ratio of measured EMG signals [7]. They also may also have slower control over muscle activities of the hands, fingers, etc. and decision-making may also be slower. For this group, the motivation to use NCI is completely different from the first group. Therefore, the design of a NCI for older adults should reflect their non-typical EMG profiles or slower response times.

Speller is a typical example of NCI/BCI application, which establishes a communication channel for people unable to use traditional keyboard and still remains a benchmark for BCI and NCI methods [8]. The speller is aimed to help those disabled persons unable to activate muscles traditionally used in communication (hands, tongue) to spell words by utilizing their neural activity. Typically, spellers use signal amplitude information, however integrating it with signal processing methods such as noise and dimensionality reduction methods and user intent prediction techniques can improve the results [9].

In this paper, we analyze the requirements for developing interfaces for impaired users and visual interfaces of known speller applications, describe the development of a speller as a typical benchmark application, and evaluate its performance and usability of the developed speller using a set of empirical (accuracy, information transfer speed, input speed), ergonomic (NASA-TLX scale) and conceptual (humanistic intelligence) attributes.

This work was not supported by any organization

The structure of the remaining parts of the paper is as follows. Section II analyzes the requirements for NCI systems and, specifically, NCI spellers. Section III discusses the interfaces of speller applications. Section IV describes the development of speller application. Section V presents the experimental results. Section VI evaluates the results. Finally, Section VII presents conclusions.

II. Analysis of Requirements for Speller Application

The requirements for speller application can be categorized at different levels depending upon the physical abilities of its users [10]: 1) Users with no physical disability, who may use NCI for entertainment or other conditions where physical movement is restricted. 2) Users with minor impairments (such as older persons). 3) Users with severe physical disabilities, who may wish to use NCI as a secondary input. 4) Users who are almost locked-in (having limited muscle control), who may need to use NCI as a method for communication.

First, the speller must follow general requirements for smart systems to be integrated into the AAL environments. Next, the specific requirements for impaired users (and, specifically, for older persons) must be followed. Impaired users need assistance such as automatic learning of user's behavior to estimate his/her current needs.

Since humans often make mistakes or errors in interacting with machines, for any human-operated system, user interfaces should be designed such that prevent errors whenever possible; deactivate invalid commands; make errors easy to detect and show users what they have done; and allow undoes, reverse, correct errors easily [11].

For smart systems, the following principles (also called "operational modes") of Humanistic Intelligence Framework [12] must be satisfied:

1) **Constancy:** the interface should operate continuously to read signals from human to computer and to provide a constant user-interface.

2) **Augmentation:** the primary task is increasing the intelligence of the system rather than computing tasks.

3) **Mediation:** the interface mediates between human senses, emotions and perceptions and acts as information filter by blocking or attenuating undesired input to decrease negative effects of interaction (such as fatigue, information overload, etc.) as well as to increase positive effects (such as user satisfaction) by amplifying or enhancing desired inputs.

According to Lopes [13], the user interface for persons with disabilities must: support user variability allowing to provide the means to adapt to user-specific requirements; support of a wide range of input devices and output modes; provide minimal user interface design; promote interaction and retain user attention on the tasks; and provide strong feedback mechanisms that may provide rewarding schemes for correct behavior (results).

The requirements for interfaces for impaired users can be formulated as follows [1]: 1) **Limited access to details:** complex and vital details of the system have to be hidden to avoid user overwhelming and trapping. 2) **Self-learning:** detected common patterns in the behavior of the user should be used to automatically create rules or shortcuts that speed and ease up the use of the system. 3) **System interruption:** Impaired users have in most cases no idea how the system is working, therefore easy cancellation of system's activities must be ensured.

In the questionnaire-based study of potential BCI user requirements towards assisted technologies [14], the participants rated participants rated "functionality" (aka effectiveness) as the most important requirement, followed by "possibility of independent use" and "easiness of use".

III. Review of Speller Interfaces

Many different variants of interfaces have been proposed and designed for speller, a de-facto benchmark application of BCI/NCI. Based on the complexity and visual representation of symbols to input, they can be categorized into the following classes:

Linear (or single character) speller: all symbols are shown and each symbol is flashed individually until symbol selection is done [15].

Matrix (or Row-Column) Speller: All letters are arranged in a matrix . First, speller flashes an entire column (Fig. 1, left) or row of characters (Fig. 1, right). Then, single letters are flashed in a sequence, and can be selected. Different matrix sizes can be used, e.g., a 6x6 matrix containing all 26 letters of the alphabet and 10 digits (0-9) [16], or even a full QWERTY keyboard [17].

Fig. 1. Example of matrix speller interface.

Chekerboard Speller [18]: the 8x9 matrix is virtually superimposed on a checkerboard (Fig. 2, left), which the participants never actually see. The items in white cells of the 8 x 9 matrix are segregated into a white 6 x 6 matrix and the items in the black cells are segregated into a black 6 x 6 matrix. Before each sequence of flashes, the items in Fig. 2 (left) randomly populate the white or black matrix, respectively, as shown in Fig. 2 (middle). The checkerboard layout controls for adjacency-distraction errors, because adjacent items cannot be included in the same flash group. The users see random groups of six items flashing (as opposed to rows and columns) because the virtual rows and columns depicted in Fig. 2 (middle) flash.

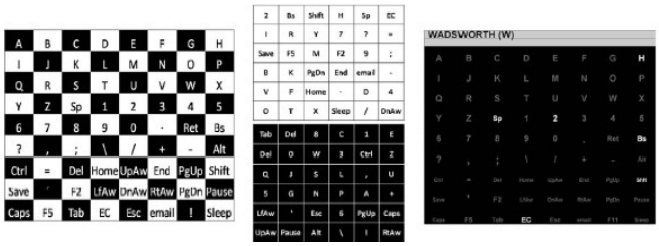

Fig. 2. Checkerboard intherface of the speller [18]

Frequency-based layout accounts for the relative frequency of character occurrence in a language as in Bremen SSVEP-based BCI-speller [19]. It has in the middle of the screen a virtual keyboard with 32 symbols (see Fig. 3) surrounded by five boxes flickering at different frequencies. These boxes correspond to commands for navigating the cursor (indicated by red color), and for selecting the intended character. The application starts with a cursor in the central position corresponding to the most frequent character in English (i.e., "E"). Letters with the higher frequency of occurrence are positioned closer to the center while the less frequent ones are further away. The user can navigate the cursor to the desired letter and confirm his/her choice with the "Select" command. The further the character is located from the center, the more command selections (cursor movements) are required.

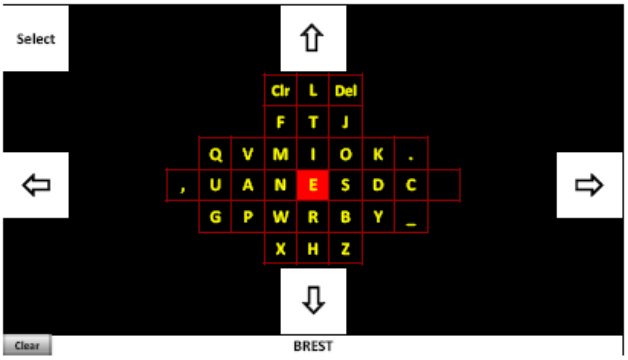

Fig. 3. Interface of the Bremen BCI speller [19].

Region-based Speller: groups of characters arranged into different regions, which contain different subsets of characters (Fig. 4). When the user confirms the selection of the group, the characters of the group are divided into new groups until the desired character is selected. Examples of such interface are 27 symbol triads [20] or 64 symbol quadrants [21].

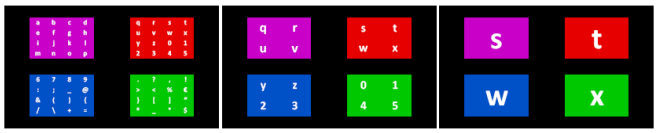

Fig. 4. Consecutive stages to select symbol in the quadrant region-based speller [21]

The Rotate-Extend (REx) paradigm [10] consists of a wheel divided into segments (see Fig. 5). An arrow in the centre of the wheel controls the selection of target segments. One mental class is used to control the rotation of the arrow, and the other class extends the arrow to select the target segment. Example of Rex interface is Hex-o-Spell speller [22], which allows 30 different characters to be typed in. The characters are shown in six adjacent hexagons distributed around a circle. Each hexagon contains five characters and a „go back" command. For the selection of the hexagons, there is an arrow in the center of the circle. After selection, the characters in all hexagons, except for the selected one disappear, while the remaining characters and the „go back" command are mapped into six hexagons around the circle. Using the same arrow-based strategy, the user selects the desired character or decides to go back to the previous level of the interface to correct a mistake. Another implementation of REx interface is Oct-o-spell, where a larger set of symbols is used [23].

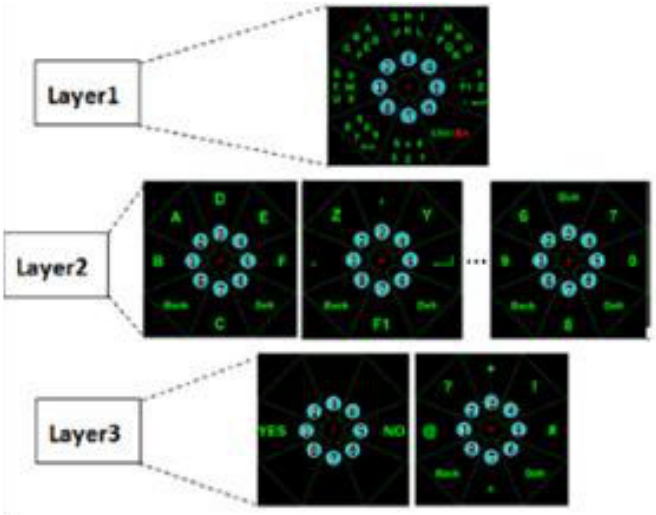

Fig. 5. Interface of Oct-o-spell speller [23]

The overview of visual interfaces of spellers can be summarized as follows. The interfaces can classified according to interface paradigm (linear/single, matrix, chekerboard, frequency layout, region-based, Rotate-Extend), stimulus type (the way each individual character changes, e.g., flashing frequency, color change, distance to target, etc.), stimulus rate (the speed at which individual characters change), stimulus pattern (grouping of symbols in interface), character set (usually includes all letters of the alphabet as well as additional symbols such as numbers, separation marks, etc., enhancing intelligence (additional techniques for improving accuracy of the system and rate of communication such as using language model, word autocomplete, spelling correction or word prediction).

IV. Development of EMG speller

A NCI system generally comprises the following components: (i) a device that records the muscular activity signals; (ii) a signal preprocessor that reduces noise and artifacts; (iii) a decoder that classifies the de-noised signal into a control commands for (iv) an external device or application (e.g., a robotic actuator, a computer program etc.), which provides feedback to the user [24].

Our speller application has three layers as follows: 1) on the lowest layer, the physiological signal is sampled into a data stream of physiological data. Downsampling can be used to decrease amount of data and increase information processing speed at higher levels. 2) On the intermediate layer, data is aggregated and events corresponding to specific patterns of data are generated. Machine learning techniques such as artificial neural networks may be used to recognize such events and generate decisions. 3) On the highest layer, decisions are processed and used to generate control commands for external applications (systems).

The architecture of the developed speller application is shown in Fig. 6. The speller has 6 components: MainReader is responsible for control of data reader which is selected to use. ReaderAPI is public external interface of third-party EMG data reader modules. MainController is responsible for selected control module (executes commands). NiaReader is a third-party module implemented for the OCZ NIA data reader device. SpellingSquare is a third-party module implemented for text input in symbol matrix using the EMG-based commands.

The dashed rectangle separates system components from external components. Components inside the rectangle are considered as system components. Components outside the rectangle are considered as external components. System was developed with respect to maintenance so that external components were easy to add or remove. The external components are sensors (EMG readers), actuators (robot, etc.) controllers or external software. The NetBeans framework was used for development. It provides the opportunity to add third-party components on-demand.

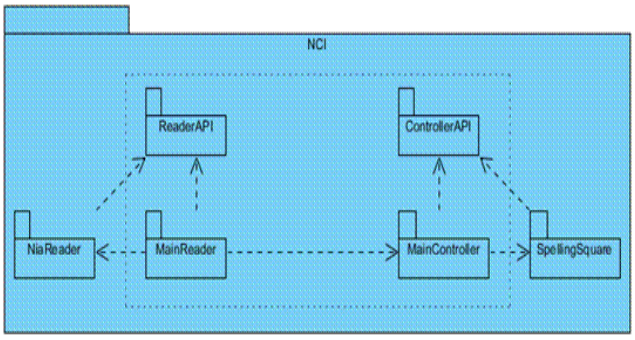

Fig. 6 Architecture of physiological computing system

The feedback to the user is an important aspect of the NCI as it provides the user with information about his/her mistakes as well as motivates the user to increase attention and engagement in the task. The main element of the developed speller application that supports feedback is visual interface (Fig. 7). It contains the representation of the symbol matrix (the size and character set of the matrix is adaptable). The red-colored column indicates the current position of the speller cursor. The cursor moves sequentially from column to column until the user activates the "Select" command. Next, the cursor moves through each symbol in the selected column. After another "Select" command the particular symbol is selected and appears in the text output area. The stimuli rate (the speed of the cursor can vary from 500 to 1500 ms) depends upon the number of input mistakes the user does (the speed increases or decreases automatically to keep the number of mistakes low). The mistake is considered as the "Cancel" command, which exits the selected column or deletes the selected symbol.

The control commands are initiated by the movements of facial muscles (left eye blink for "select" and right eye blink for "cancel"). The user can see the EMG signal feedback in the EMG signal view area of the interface (Fig. 8). The particular control command is performed when the amplitude of the EMG signal is equal or higher than the specified threshold value (marked with yellow horizontal lines). The upper threshold (high positive amplitude) indicates the "Select" command, while the lower threshold (high negative amplitude) indicates the "Cancel" command. The threshold values can be adjusted by the user via settings.

The signal view of EMG, while spelling the word "hello", is presented in Figs. 8 & 9. In Fig. 8, the word "hello" is spelled without mistakes. In Fig. 9, the same example is presented but in this case it contains a few mistakes (wrong selections). For correction of those mistakes cancellation commands must be performed. The spikes indicate the "select" command. One trial (selection of one character) contains two positive signal spikes, the first spike is for column selection, the second for letter selection in the corresponding column.

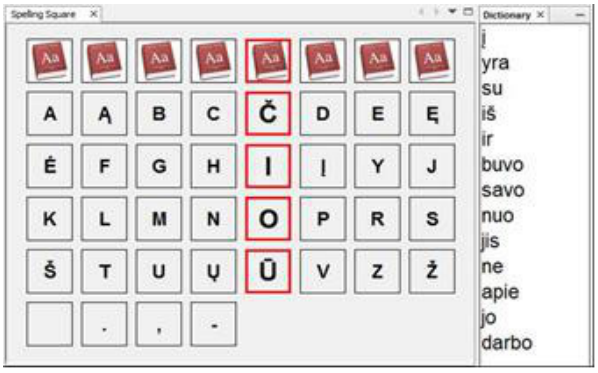

Fig. 7. Interface of developed speller application

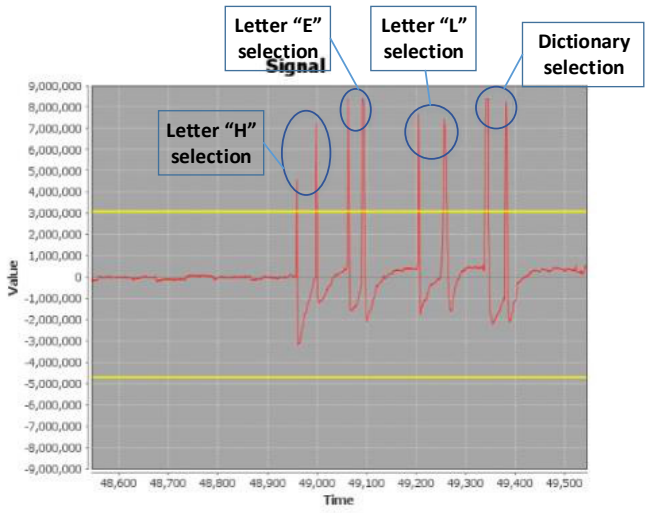

Fig. 8. Signal view of spelling word "hello". In this example no spelling mistakes were made and only three characters ("hel") were selected from the symbol matrix. Dictionary selection was made to complete the word.

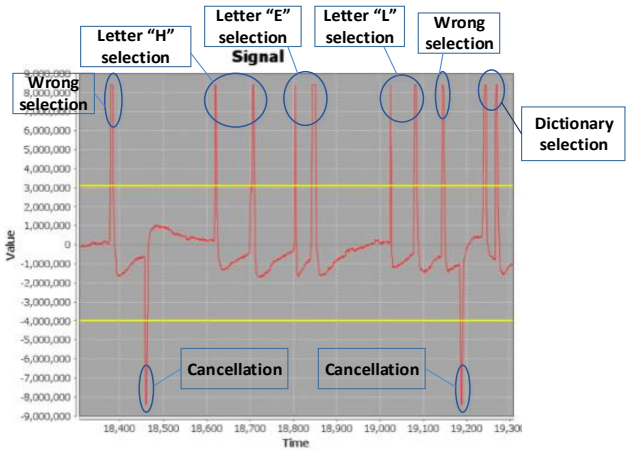

Fig. 9. Signal view of spelling word "hello". This example contains two spelling mistakes therefore after each wrong selection cancellation command was performed. Three characters ("hel") were selected from symbol matrix. Dictionary selection was made to complete the word.

The external dictionary can be used while entering symbols. The dictionary words are filtered using the already entered part of the word and shown to the user based on their frequency in the text corpora of the given language. The frequency value of the word is increased based on its usage frequency by the user. If the user enters a word absent in the dictionary, the dictionary is updated.

V. Experimental Setting

The experiments we performed with 5 subjects (3 males, 2 females), aged 24–54 (mean = 33) year. Subjects did not have any neurological abnormalities, reported normal or corrected to normal vision, and did not use medication. All subjects gave informed consent prior to the experiment.

EMG was recorded using OCZ Neuro Impulse Actuator equipment, which employs three electrodes across the forehead (see Fig. 10). It uses carbon interface fibers injected into a soft plastic as sensors to capture a combination of muscle, skin, and nerve biopotentials.

Fig. 10. The test subject with OCZ NIA device

The test subjects were seated in front of a table, 100 cm away from the liquid crystal display (LCD) showing stimuli. Visual stimuli were presented on a 13.3" size LCD screen with 1360 × 768 pixel resolution and a refresh rate of 60 Hz. Contrast and brightness are set to maximum. The size of each character was 1.5 × 1.5 cm (0.86 × 0.86° visual angle) and the entire speller matrix was 9.5 × 13 cm (5.44 × 7.42° visual angle). Stimuli consisted of intensifications of the rows and columns in sequential order. Intensification was achieved by increasing the size of all characters in the row or column with a factor 500 for 1500 ms. A trial is defined here as spelling of one character. All trials started with the speller being displayed on the screen, together with an instruction indicating which letter to select. Each stimulation sequence was followed by feedback on the screen, showing which letter or group of letters had been selected.

Three text paragraphs were given to the experiment participants. Their task was to input the proposed text paragraphs using speller. All text paragraphs were presented in Lithuanian. The first text paragraph contained 126 characters and its content covered a daily conversation. The second text paragraph contained 111 characters and its content covered a scientific speech. The third text paragraph contained 120 characters and covered a scientific speech with mathematical equations. Each experiment participant repeated the experiment 4 times with different speller settings. The first test was made with basic speller settings. The second test was made with adaptable stimulus time (the stimulus time varied from 500 ms to 1500 ms depending on the amount of mistakes). The third test was made with dictionary. The fourth test was made with both dictionary and adaptable stimulus time. The average accuracy, input speed and bit rate values were calculated. The results of experiments are presented in Section VI.

VI. Evaluation of Results

Quantitatively, the performance of speller application can be evaluated using accuracy, information transfer speed and input speed metrics. Accuracy is calculated as the percentage of correct decisions. Information transfer rate (or bit rate) indicates how much information can be communicated per time unit and is calculated using Walpaw's formula [25]. Finally, input speed is measured as the average time required to input a set of benchmark texts.

The accuracy results of BCI/NCI-based speller applications achieved by other authors are within 80-95% range (80% using EEG-based P300 speller [26], 82.77% using ECoG [9], 84.22% using invasive BCI [27], 87.58% using SSVEP based BCI [17], 87.8% for EOG-based speller [28], 89.5% [29], 91.80% [30], 94.8% for RSVP based speller [31], 90.81% for SSVEP-based speller [32], 95.18% for Oct-o-spell [23]).

The information transfer rate (aka bit rate) of the BCI/NCI-based speller applications achieved by other authors are within 7-41 bits/min (7.43 bits/min [33], 17.13 bits/min [29], 19.18 bits/min [30], 11.58-37.57 bits/min [32], 40.72 using SSVEP based BCI [17], 41.02 using ECoG [9]).

The symbol input speed of the BCI/NCI-based speller applications achieved by other authors are within 1-12 CPM (1.38 CPM for EOG-based speller [28], 1.43 CPM for RSVP based speller [31], 4.33 CPM [30], 4.91 CPM [32], 9.39 CPM using SSVEP based BCI [17], 10.16 CPM [23], 12.75 CPM [34]).

The results of the evaluation developed speller are given in Table I and summarized in Figs. 11-13. Best results in terms of both average and peak information transfer rate and input rate values are achieved when adaptable stimulus rate is used together with the dictionary. However, higher input speed inevitably lead to larger number of errors, therefore, accuracy is lower than using the speller with basic settings.

Table I.
Evaluation of Speller Application

Quantitative metric	Average Value	Peak value
BASIC SETTINGS		
Accuracy	96.29	98.25
Information transfer rate	34.78	41.83
Input speed	6.37	7.57
ADAPTABLE STIMULUS RATE		
Accuracy	88.61	93.64
Information transfer rate	42.53	49.79
Input speed	8.19	9.60
WITH DICTIONARY		
Accuracy	92.65	96.06
Information transfer rate	43.55	49.26
Input speed	8.22	9.35
WITH ADAPTABLE STIMULUS RATE AND DICTIONARY		
Accuracy	89.16	92.53
Information transfer rate	58.69	65.53
Input speed	11.35	12.42

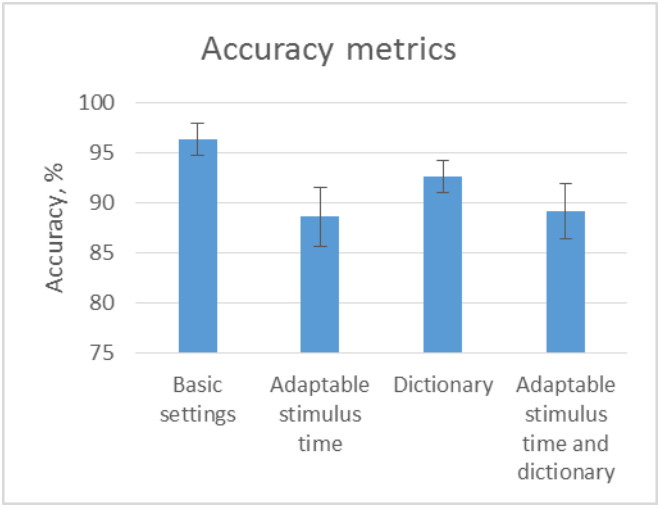

Fig. 11. Accuracy.

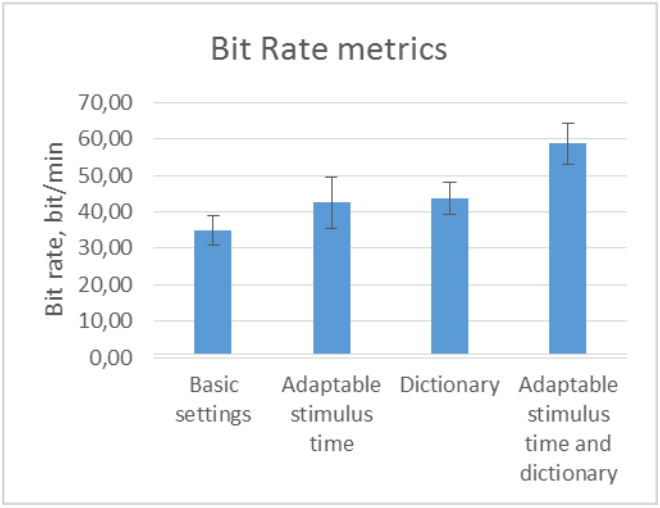

Fig. 12. Information transfer rate

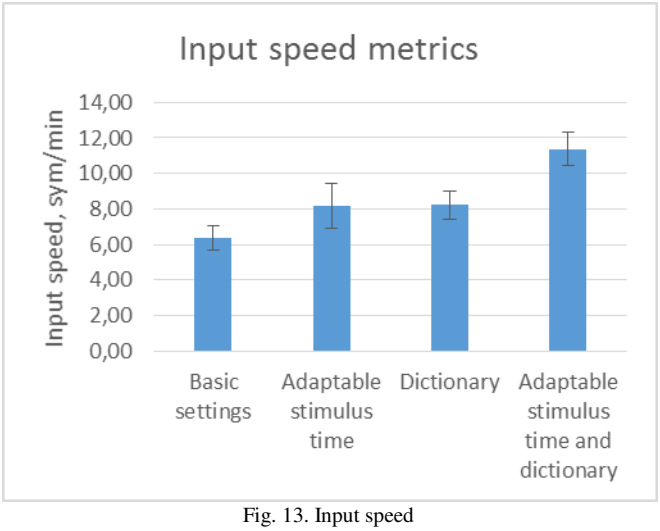

Fig. 13. Input speed

Qualitatively, the speller application can be evaluated based on user's mental workload required to work with this application. Here we use the NASA Task Load Index (TLX) questionnaires [35], a multi-dimensional rating procedure with six subscales: Mental Demands, Physical Demands, Temporal Demands, Performance, Effort, and Frustration.

TABLE II.
EVALUATION OF SPELLER APPLICATION USING NASA-TLX INDEX

NASA-TLX scale	Average value
Mental Demands	52
Physical Demands	66.6
Temporal Demands	45
Performance	48
Effort	67
Frustration	55

The users' subjective workload was assessed with the NASA Task Load Index (TLX), which identifies (1) the overall workload in the different tasks and (2) the main sources of workload. Workload in the TLX is defined as a "hypothetical construct that represents the cost incurred by a human operator to achieve a particular level of performance." The TLX is specifically adequate when interested in detecting the sources of workload. Workload is estimated with six subscales (mental, physical, and temporal demand and performance, effort, and frustration). Participants rated subjective workload for each dimension on twenty step bipolar scales with scores from 0 to 100. A weighting procedure was used to combine the six individual ratings into a global score. To do so, the six scales were combined to 14 pairs and subjects had to indicate which scale of the pair contributed more to their workload. A weighted average technique was then used to compute an overall measure of workload (between 0 and 100) and the relative contribution of each subscale to overall workload.

The NASA-TLX contains six factors (shown in Table III), each of which has 20 levels and is scored from 0 to 100. Small score represents low workload and vice versa. The speller application was evaluated by 5 healthy subjects and the results are presented in Table III. Main sources of workload were physical demands and effort. The average score for the workload factors are less than 56%. This observation indicates that the speller interface is acceptable for all subjects. High scores for "Temporal demand" given by most of the subjects indicate that the speed of the system must be improved further. Low scores for "Frustration" indicate that subjects are interested in using speller application and that the results meet their expectations.

TABLE IV.
EVALUATION OF SPELLER APPLICATION BASED ON THE MANN'S ATTRIBUTES OF HUMANISTIC-INTELLIGENCE SYSTEM

Attribute	Evaluation	Comment
Unmonopolizing	Yes	Speller does not cut the user off from the outside world
Unrestrictive	Yes	User can use other channels of communication at the same time while using the speller
Observable	Yes	Speller can get the user's attention continuously if and the output medium is constantly perceptible
Controllable	Yes	User can control the speller anytime
Attentive	Yes	Speller is context aware, multimodal, and multisensory
Communicative	Yes	Speller allows to communicate directly to other users or spellers

Conceptually, the speller application can be evaluated based on the attributes (Unmonopolising, Unrestrictive, Observable, Controllable, Attentive, Communicative), which every humanistic-intelligence system must have, as formulated by Mann [12] (see Table IV).

VII. CONCLUSION

In this paper we have described the development of the speller application for an assisted living environment using the EMG interface. This system is controlled by voluntary muscular movements, particularly the orbicular ones (i.e., eye blinking). These movements are translated into instructions which allow the text input.

The developed speller application is adaptive (text input speed can be adapted dynamically in response to the user's state) and intelligent (machine learning techniques are used to analyze input data to achieve high accuracy of selection as well as to increase text input speed by using word complete and word frequency features).

The speller has been evaluated empirically (using accuracy, information transfer speed and input speed), ergonomically (using the NASA-TLX scale of subjective workload) and conceptually (using the attributes of Mann's Humanistic Intelligence Framework [12]).

The achieved empirical results are within range of results achieved by other authors, while the ergonomic evaluation suggests that users are interested in using speller application and that the results meet their expectations, yet the speed of the system as well as the usability of its interface could be improved further.

This system can aid people with reduced mobility, extending the time that older people and disabled people can live in their home environment, increasing their autonomy and their confidence.

Future work will focus on going beyond low-level typing to graphical-symbol matrix that allows selection of concepts rather than stand-alone letters. Also the performance characteristics of the speller application will be researched further aiming to maximize usability of the product both in terms of increased speed as well as better ease of use.

ACKNOWLEDGMENT

The work described in this paper has been carried out within the framework the Operational Programme for the Development of Human Resources 2007-2013 of Lithuania „Strengthening of capacities of researchers and scientists" project VP1-3.1-ŠMM-08-K-01-018 „Research and development of Internet technologies and their infrastructure for smart environments of things and services" (2012-2015), funded by European Social Fund (ESF).

The authors would like to acknowledge the contribution of the COST Action IC1303 – Architectures, Algorithms and Platforms for Enhanced Living Environments (AAPELE).

***Abstract*—In medical diagnostics there is a constant need of searching for new methods of attribute acquiring, but it is difficult to asses if these new features can support the existing ones and can be useful in medical inference. In the paper the methodology of discovering features which are less informative while considering independently, however meaningful for diagnosis making, is investigated. The proposed methodology can contribute to better use of attributes, which have not been considered in the diagnostics process so far. The experimental study, which concerns arterial hypertension as one of the civilization diseases demanding early detection and improved treatment is presented. The experiments confirmed that additional attributes enable obtaining the diagnostic results comparable to the ones received by using the most obvious features.**

I. Introduction

IN MEDICAL research the process of diagnosis is usually provided by experts with the necessary knowledge. Towards facilitating this task some automatic actions may be performed, such as feature selection for choosing the set of attributes appropriate for particular diagnostics problem. In most instances the results of the automated selection cover or even improve the expert judgment [1], [2], [3].

The paper deals with cases where attributes regarded as the most informative should be excluded to discover new dependencies and, as a consequence, new therapies. We consider the methodology, which aims at indicating these features from among less meaningful for medical classification, that can be used in automated diagnosis of the disease. The proposed method includes result evaluation by using clustering taking into account independently features indicated by the method and the recognized ones. The obtained clusters are compared to check if the presented methodology can contribute to better use of attributes acquired from new diagnostics process. Presented approach will be investigated for arterial hypertension, which is acknowledged as one of the civilization diseases demanding early detection and improved treatment [4]. The proposed methodology is evaluated by experiments carried out on real data.

The rest of the paper is organized as follows. In Section II relevant work is presented. Next we describe the proposed methodology and discuss classification and clustering techniques, which are expected to be the most appropriate for the considered case. Section IV is dedicated to the experiments conducted on real data. Finally, in Section V, the results and some concluding remarks are discussed.

II. Related Work

The paper addresses an issue of feature selection methods for medical diagnosis supporting. The new contribution of this work is the exclusion of the most informative features to find out additional dependencies among the attributes derived from a modern process of data acquiring. Such an approach was not considered in the literature so far, however the feature selection analysis was the subject of interests of many researchers.

A survey on feature selection methods was presented in [5]. The main objective was to provide a generic introduction to variable elimination which can be applied to a wide range of machine learning problems. The authors described filter, wrapper and embedded methods. Moreover they applied some of the feature selection techniques on standard data sets to demonstrate the applicability of the proposed methods. As the conclusion they pointed out that comparison between feature selection algorithms can only be done on the same data set since each underlying algorithm behaves differently depending on data characteristic.

The problem of factors that are considered as less important for disease diagnosis but still, according to medical literature, deserve to be included in diagnostics process, was mentioned in [6]. However the main goal of that paper was to compare classifiers for the detection of heart disease. The paper presented effects of using automated feature selection and a medical knowledge based on Motivated Feature Selection (MFS) process. MFS combined with the Computerized Feature Selection (CFS) process was analyzed and good performance was observed for Naive Bayes, k-nearest-neighbors and SMO classifiers.

In [7] the research was based on data of clinical diagnosis, symptoms and medical intervention classification for the patients after surgical intervention with recurrent pelvic cyst. The decision tree was used to find the meaningful characteristic as well as classification rules. The experiment results were to help the clinical faculty doctors in effective diagnosing and providing treatment reference for future patients.

The authors of [8] presented a study of a diverse set of machine learning algorithms on a large number of biomedical

978-83-60810-58-3/$25.00

datasets. They concluded that the nature of a given dataset plays an important role on the classification accuracy of algorithms. Therefore it is necessary to choose an appropriate algorithm for a particular data set. However they identified some general rules for machine learning technique selection: using resampling based classifier enhancement techniques (bagging and boosting) over individual classifiers, using boosting on stable algorithms like SMO, JRip, and J48 and recommended using bagging MLP for classification if the nature of a biomedical data set is unknown.

In [9] the efficiency of the classification methods including SVM, RBF Neural Nets, MLP Neural Nets, Bayesian, Decision Tree and Random Forrest methods were compared. Some of the common clustering techniques including K-means, DBC, and EM algorithms were applied to the datasets and the efficiency of these methods has been analyzed. In each case these methods were applied to eight different binary (two class) microarray datasets. As a conclusion the authors stated that the classification success depends on the choice of feature selection methods, the number of attributes and the number of cases (samples). Results revealed the importance of attribute selection in accurately classifying new samples and the importance of integration of the feature selection and classification algorithms.

The advantages of using and perspectives of applications for AdaBoost algorithm were discussed in [10]. The authors stated that the main significance of AdaBoost concerns providing new ideas to theoretical study as well as practical problems. Moreover while most of the machine learning algorithms tend to seek complicated classifiers to improve the accuracy, AdaBoost takes the approach to obtain an accurate classifier by combining simple and weak classifiers whose accuracies are slightly better than random guessing. Besides AdaBoost does not need any parameters except the number of iterations and therefore the authors suggested that it can be used in many practical applications.

The overview of recent research done to analyze the different machine learning schemes on various medical domains leads to the conclusion that experiments are usually carried out by using the limited choice of algorithms from the machine learning repository. Then the technique which gives relatively the best results for the considered domain is selected. There is no guidelines which indicates the best classifier for a particular type of data.

III. Materials and Methods

The proposed methodology of indicating less meaningful features to use in diagnostics process consists of four steps:

- data preparation, which results in the initial dataset,
- classification process, which enables the selection of the set of attributes crucial for the automated diagnosis,
- clustering based on the attributes derived from the previous step,
- verification process by using expert feature selection.

The research will focus on arterial hypertension case study.

A. Data Description

Arterial hypertension is a significant problem in pediatric practice. Therefore, finding effective methods which support early diagnosis of hypertension is a crucial issue for the researchers to solve. The assessment of arterial hypertension include physical examination, manual and twenty-four hour blood pressure measurements and medical imaging derived from two- and three-dimensional echocardiography.

The tissue Doppler echocardiography (TDE) allows exact evaluation of a number of additional parameters that indicate myocardial functions. Many studies confirmed that regional analysis comes from the method of tissue Doppler imaging as a sensitive way to detect clinically silent changes when standard echocardiographic parameters are still within the normal range [11]. This method is mainly used for research carried out for adult population, however Zamojska et al. considered assigning this approach also for children [12].

The initial cardiac data can be characterized by over 50 attributes. All patients undergo physical examination, manual arterial blood pressure measurements (RRmanSBP, RRmanDBP), ambulatory blood pressure monitoring (ABPM-S, ABPM-D), echocardiographic examination to evaluate cardiac function using standard parameters (ejection fraction - EF, shortening fraction - SF and myocardial performance index - MPI) and tissue Doppler examination (systolic mitral annular velocity profile and regional function parameters: velocity, strain, strain rate).

The aim of medical analysis is to evaluate the characteristics of the variables in the data sets of healthy and diagnosed children and to discover the relationships between all the parameters. The process of diagnosis performed by medical expert is mainly based on the blood pressure measurements (either manual or ambulatory monitored). The rest of the attributes are usually supportive for medical staff as each of them separately cannot indicate the disease and multivariate analysis is difficult to perform without any computer support.

B. Classification Task

For the classification purpose we will consider two approaches: decision trees and adaptive boosting. Decision trees represent one of the main techniques for discriminant analysis in data mining and knowledge discovery [13], [14]. They predict the class membership (dependent variable) of an instance using its measurements of predictor variables. They provide higher classification accuracy and offer an easy way to understand graphic representation of gathered knowledge [15]. Moreover decision trees are easy to understand and analyze, as they reflect a hierarchical way of human decision making. Therefore they are the opposite of the 'black-box' approaches where model parameters are not understandable [16] and can be easily understood by human experts [17].

In the paper we have chosen C4.5 for a decision tree algorithm as one of the most popular. Namely J48 algorithm, which is the open source Java implementation of the C4.5 in the Waikato Environment for Knowledge Analysis (WEKA) data mining tool [18] has been chosen.

1) J48 Algorithm: The J48 algorithm is the WEKA implementation of the C4.5 top-down decision tree learner proposed by Quinlan [19]. The algorithm uses the greedy technique. It deals with numeric attributes by determining where thresholds for decision splits should be placed. J48 algorithm employs an automatic procedure capable to select relevant features from the training data. It is able to cut the poor or non-meaningful branches into an efficient pruning process as well as able to handle both continuous and discrete attributes. In handling continuous attributes, J48 creates a threshold and then splits the list into those attributes, which values are above the threshold and the ones, which are less than or at least equal to the threshold value. It enables handling training data with missing attribute values by employing gain and entropy calculations. Therefore the J48 algorithm may cut the poor and non-meaningful branches into an efficient pruning process [20].

2) AdaBoost Algorithm: The possibility of boosting the prediction quality of a weak learner was firstly introduced by Freund and Schapire [21]. The adaptive boosting algorithm (AdaBoost) solved many practical shortcomings of earlier algorithms [21]. The AdaBoost is a machine learning algorithm which feeds an input training set to a weak learner algorithm repeatedly. During these repeated calls, the algorithm maintains and updates a set of weights, which indicate how difficult it is for the weak learner to identify a particular element of the training data set. Initially, all weights are equal. However, after each call, the weights are updated, in the way, which guarantee that the weights of misclassified training set elements grow. This forces the weak learner to concentrate on the difficult elements of the training set. In the study, we use a decision stump as a weak learner algorithm for the AdaBoost classifier. This model is composed of a single-level decision tree (DT), which uses one of the input parameters [22].

C. Clustering

Cluster analysis algorithms group objects taking into account a certain similarity metric. They divide the objects into a predetermined number of groups in a manner that maximizes a similarity function. During investigations of the proposed methodology, two different approaches, commonly used in medical studies ([9]) will be considered: the Expectation Maximization (EM) probabilistic approach and deterministic k-means algorithm.

1) k-means Algorithm: The k-means algorithm divides a data set into k clusters, where k is a user-defined value. The algorithm starts with k random clusters, and then move objects between those clusters to minimize variability within clusters and maximize variability between clusters. In other words, the similarity rules apply maximally to the members of one cluster and minimally to members belonging to the rest of the clusters. Usually, the means for each cluster on each dimension are calculated for assigning objects into the closest ones [23]. In most of the cases Euclidean metric is considered as the distance function for k-means algorithm [24], [25].

2) EM Algorithm: An expectation-maximization (EM) algorithm finds maximum likelihood estimates of parameters in probabilistic models. EM performs repeatedly between an expectation (E) and maximization (M) steps. Within the E step an expectation of the likelihood of the observed variables is computed and then the M step computes the maximum expected likelihood found on the E step. EM assigns a probability distribution to each instance which indicates the probability of its belonging to each of the clusters [25]. By cross validation, EM can decide how many clusters to create. The goal of EM clustering is to estimate the means and standard deviations for each cluster so as to maximize the likelihood of the observed data. K-means assigns observations to clusters to maximize the distances between clusters. The EM algorithm computes classification probabilities, not actual assignments of observations to clusters.

D. Verification of results

In order to confirm the correctness of the obtained results, clusters based on the most meaningful attributes selected by classification algorithm are built. They are compared with groups created by clustering using attributes indicated by experts. If the groups, which are built taking into account two different sets of attributes, are of similar characteristics, then the attributes indicated by classification can be effectively used in diagnostics process.

Methodology verification consists of the following steps:

- classification using all the available features including most informative ones, which results in the feature subset selection,
- clustering based on the attributes derived from the previous step,
- comparison of clusters obtained after exclusion of most informative features with the clusters from the previous step.

IV. Experimental Analysis and Results

The main objectives of the experiments were to prove, that by performing clustering based on particular set of less meaningful features acquired in automated classification, we can obtain the output results close to data sets acquired by using most important attributes derived from the process of feature selection and pointed out by medical experts. The presented methodology was evaluated on the real data, which were gathered for early diagnosis of arterial hypertension in children. The data set was described earlier in the section III-A.

During experiments 2 initial data sets were considered: the first one (A - Study group), consisted of data of 30 children diagnosed with primary arterial hypertension, without being overweight or obese, hospitalized in the University Hospital No 4, Department of Cardiology and Rheumatology, Medical University of Lodz. The second set (B - Control group) consisted of 30 data of children with normal blood pressure. The decision process of this initial judgment (the value of

the dependent variable for our experiments) was performed by medical experts.

A. Data Preprocessing

As the first step all the cases were put together to form one data set consisted of 60 children. We decided to exclude from the process of automatic classification these attributes that are in the straight relation to the expert judgment: manual arterial blood pressure measurements (RRmanSBP, RRmanDBP) and ambulatory blood pressure monitoring (ABPM-S, ABPM-D). Moreover we removed fundus_oculi as the feature that is usually correlated to arterial hypertension but can not determine this disease. As a result we took into consideration 42 attributes listed in table I, where the first column contains names of all selected parameters, the second one describes these parameters and the third column gives the domain definitions.

B. Classification

According to the methodology described in section III we used two classification methods: decision trees and adaptive boosting.

1) J48 Results.: The J48 algorithm has chosen for classification 9 attributes listed in table II out of all the attributes (table I).

As a result we obtained 58 correctly classified instances (96.67%) and 2 incorrectly (3.33%) which made the precision and recall equal to 0.967, the same for both classes.

2) AdaBoost - Results.: The AdaBoost algorithm choose for classification 6 attributes listed in table III out of all the parameters (table I).

Despite the fact that this method has chosen the set of attributes different from the J48 algorithm, the results were satisfactory enough. We obtained 49 instances correctly classified (81.67%) and 11 incorrectly (18.33%). The weighted average of precision was equal to 0.831 (0.757 for the 1st class and 0.913 for the 2nd class) and the weighted average of recall was equal to 0.817 (0.933 for the 1st class and 0.7 for the 2nd class).

C. Clustering

We performed clustering taking into account the sets of attributes selected by classification algorithms in the previous step of analysis (section IV-B).

1) EM Algorithm with J48 Subset of Attributes: Performing EM algorithm we firstly used the same subset of attributes as it was chosen by J48 algorithm. We obtained 2 clusters automatically by using cross-validation [25]. The first cluster consisted of 21 instances: 19 instances from the set A and 2 cases from the set B. The second cluster included 39 instances: 11 from the set A and 28 from the set B.

2) K-means Algorithm with J48 Subset of Attributes: While testing k-means technique with the same subset of attributes as it was chosen by J48 algorithm the number of 2 clusters was indicated. As a result the first cluster consisted of 35 instances. It contains 8 instances from the set A and 27 ones from the

set B. The second cluster included 25 instances: 22 from the set A and 3 from the set B.

3) EM Algorithm with AdaBoost Subset of Attributes: In the third test we executed EM algorithm with the same subset of attributes as it was chosen by AdaBoost. We also obtained 2 clusters automatically by using cross-validation [25]. The first cluster consisted of 21 instances. It was built up of 18 instances from the set A and 3 cases from the set B. The second cluster included 39 instances: 12 from the set A and 27 from the set B.

4) K-means Algorithm with AdaBoost Subset of Attributes: The last run was performed by using k-means technique with the same subset of attributes as it was chosen by AdaBoost algorithm and 2 clusters indicated. Consequently we obtained the first cluster consisted of 24 instances: 18 instances from the set A and 6 cases from the set B. The second cluster included 36 instances: 12 from the set A and 24 from the set B.

The results of all the combinations of methods introduced in section IV-C are presented in table IV, where the first column describes the methods and the last two columns contain the numbers of cases obtained for particular cluster with the reference to the initial data sets A (healthy children) and B (diagnosed children).

It can be easily noticed that in more than 70% of cases group contents were consistent with groups created by the initial expert diagnosis being the result of the most informative attribute analysis.

TABLE IV
THE RESULTS OF CLUSTERING PERFORMED USING PROPOSED METHODOLOGY.

Method	cluster "0"	cluster "1"	% of cases of initial groups

Parameter name	Parameter description
ABPM-S	ambulatory blood pressure monitoring - systolic
ABPM-D	ambulatory blood pressure monitoring - diastolic

D. Verification of results

As the first step in the process of verification we performed classification enabling all the features - also the most informative derived from the standard echocardiography examination. As a result the J48 algorithm pointed to 2 attributes (table V) for the classification task and the AdaBoost algorithm chose 6 attributes (table VI).

After the clustering process we obtained 2 clusters for each combination of methods: EM after J48 classification, k-means after J48, EM after AdaBoost and k-means after AdaBoost. The detailed results are presented in table VII. The first column of the table describes the combination of methods for the classification and clustering. The second and the third columns contain the number of cases in reference to the initial data set of healthy children (A) and data set of diagnosed children (B).

The comparison of results gathered in tables IV and VII allows to conclude that the proposed methodology incorporating less meaningful features produces the cluster structure similar to the clustering based on most informative attributes derived from standard echocardiography. For all the applied algorithms, we obtained more than 60% of cases assigned to the corresponding clusters. The best results were obtained using the combination of J48 classification and EM clustering (80%), and the worst for AdaBoost classification with k-means clustering (65%).

V. CONCLUSIONS AND FUTURE WORK

In medicine, as well as in other fields of science, which include diagnostics techniques, there is a constant need of searching for new methods of attribute acquiring. However it may be difficult to asses if these new features can replace the existing ones and can be useful in medical inference.

In this paper we proposed the methodology of searching for features which are less informative while considering independently, but still meaningful in the process of diagnosis. This approach is mainly useful when new attributes derived from new diagnostics techniques are introduced. These features may

TABLE VI

SF	Shortening fraction
IVSs	Interventricular septum-systole
PWDd	Posterior wall thickness in diastole
SrRRmanSBP	manual arterial blood pressure measurements - systolic
SrRRmanDBP	manual arterial blood pressure measurements - diastolic

TABLE VII
THE RESULTS OF CLUSTERING PERFORMED USING ALL THE FEATURES.

Method	cluster "0"	cluster "1"	% of cases of initial groups
J48-EM	26A / 0B	4A / 30B	93%
J48-k-means	30A / 8B	0A / 22B	87%
AdaBoost-EM	29A / 2B	1A / 28B	95%
AdaBoost-k-means	29A / 7B	1A / 23B	87%

seem to be less meaningful at first and hard to be assessed by medical staff due to multivariate analysis, but the experimental studies confirmed that they enable obtaining the diagnostic results comparable to the ones received by using features recognized as the most informative.

In the first step feature set classification is applied, then taking into account the selected set of attributes clustering is performed. Two different algorithms of classification with two methods of clustering were combined: J48 + k-means, J48 + EM, AdaBoost + k-means, and AdaBoost + EM. During experiments, conducted on real data, we obtain satisfactory results in comparison to the corresponding ones received by cluster analysis carried out by using all the features. Moreover the results did not differ significantly while comparing with the initial groups created by features indicated by experts.

Despite the fact, that the mining methods chosen for the research were widely recommended in the literature as appropriate for medical data, in the future we intend to verify other approaches and build different hybrid solutions to find out methods, which enable discovering new features assuring more precise disease diagnosing.

Middle East Technical University,
Ankara, Turkey
Email: e124572@metu.edu.tr, baykal@metu.edu.tr

***Abstract*—This paper proposes an infrastructure with a global workflow management algorithm in order to interconnect facilities and reporting units on a single access interface, decrease the access time of medical images and increase the efficiency of the reporting process. The inspection and radiologist attributes extracted by *Grid Agent* are modelled using a hierarchical ontology structure based on Digital Imaging and Communications in Medicine (DICOM) Conformance and DICOM Content Mapping Resource and World Health Organization (WHO) definitions. Attribute preferences rated by radiologists and technical experts or inferred by references are formed into reciprocal matrixes. Weights for entities are calculated utilizing Analytic Hierarchy Process (AHP). The assignment alternatives are processed by relation-based semantic matching (RBSM) and Integer Linear Programming (ILP). The results are evaluated based on turnaround time, workload and report quality and compared with the outcomes obtained by applying Round Robin, Shortest Queue and Random distribution policies.**

I. Introduction

DUE to lack of radiologists within the facilities and consultation needs, the business model for radiology practice around the world is formed to include the facility's employing and outsourcing radiology services to non-local radiology groups [1]. Picture Archiving and Communication System (PACS) and Radiology Information System (RIS) are typically designed to handle local radiology communication and workflow management. However, remote accesses for non-local radiologists that serve several sites need to access medical images with a single interface and return medical reports efficiently, which requires speed, quality and workload optimization. Studies on PACS based on data grids [2], [3] propose co-allocation parallel transfer strategies to improve the non-local access interface and reduce the transfer time for medical images. Integration with heterogeneous resources and systems such as RIS and Hospital Information System (HIS) is also crucial for the quality of the service. This can be achieved by employing agents that support DICOM, Health Level 7 (HL7), Hypertext Transfer Protocol (HTTP), Cross Enterprise Document Sharing (XDS) and non-standardized data at regarding sites [4]. Turnaround time of a requested report for an inspection is affected by the radiologist's availability, reporting speed and workload as well as the image transfer time. Therefore, workflow optimization should also be considered in the network and software architecture design. In previous research, multiple types of workflow optimization and semantic matching strategies are evaluated such as reinforcement learning [5], [6], machine learning (SVM, Bayes) [7] and relation based negotiation [8]. In this study, an infrastructure for medical image distribution is proposed and a RBSM algorithm enhanced by ILP is utilized to design medical image distribution strategy based on reporting workflow and efficiency. Subspecialty and quality of report are also critical parameters for teleradiology service. An inspection requiring subspecialty should be assigned to a radiologist with corresponding experience and high quality reports should be promoted in assignment process. In the proposed algorithm, experiences and subspecialties of radiologists are evaluated based on radiologist characteristics [9], [10] and report quality feedback [11] is included in the ontology map for the recalculation of weights by AHP.

II. Methods

Workflow centric network architecture with an enhanced caching, querying and retrieving mechanism is implemented by seamlessly integrating *Grid Agent* and *Grid Manager* to conventional digital radiology systems. *Grid Agent* is deployed on each site which is responsible for rendering and transferring radiology data with PACS, RIS, and Workstations using DICOM protocol and with *Grid Manager*, clients using DICOM, HL7, HTTP, and Real Time Messaging Protocol (RTMP). *Grid Manager* is responsible for the flow management of images between sites and reporting units or distribution of reports based on the report distribution workflow algorithm. *Grid Manager* also enhances the image access time by providing non-local clients to query and retrieve medical images in parallel from multiple *Grid Agents* where medical content is cached during report distribution process. For web clients,

978-83-60810-58-3/$25.00

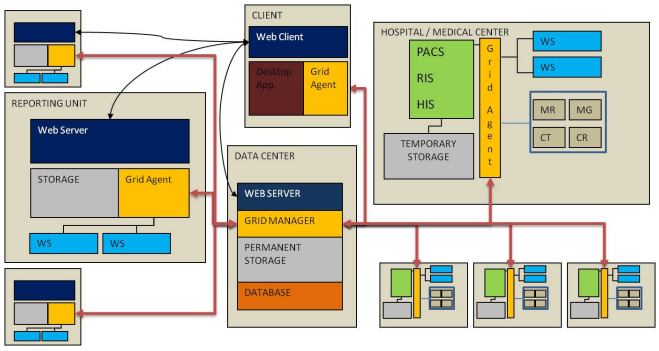

Fig. 1. Workflow centric network architecture with an enhanced caching, querying and retrieving mechanism

Java based open-source DICOM viewer software, *ImageJ*, is customized to stream image instances in parallel chunks.

A. The scenario

A typical data integration, communication and medical image delivery scenario starts with a non-local physician's request for a radiology inspection using the web interface. When the request is received, Grid Manager delivers the imaging request as an Extensible Markup Language (XML) message to the Grid Agent at the regarding medical center. Grid Agent informs the HIS and delivers the Modality Work List (MWL) request to the RIS. When the incoming patient is registered in HIS, Grid Agent is informed which afterwards gets the index of Grid Agents that have patient's data regarding previous examinations from the Grid Manager. Grid Agent pre-fetches the patient's previous medical information and synchronizes PACS and HIS in case a local radiologist examines the inspection. In parallel, Grid Manager automatically assigns the inspection to a remote radiologist after evaluating the experience, report quality, response time and technical adequecy parameters of registered radiologists and corresponding reporting units. Grid Agent at the reporting unit of the assignee receives the updated request list from the Grid Manager and fetches the patient's data including previous examination with the Grid Agent Index and synchronizes the data to PACS in the unit. The non-local radiologist can access the history of the patient independent from the vendor's software and the hospital where the data is acquired. The radiologist at the reporting unit retrieves medical images to be reported from several medical centers on a single interface and generates corresponding reports in RIS or using the web interface. The report is first delivered to the Grid Manager, then to the Grid Agent at the regarding medical center and finally to HIS.

B. The architecture

Teleradiology data serving and sharing architecture is composed of three main components: *Grid Manager* and *Data Center* forming the central node and *Grid Agent* forming the distributed network at the site nodes.

1) The Grid Agent: Grid Agent software is developed to run on an open source media server Red5 which also includes an embedded Tomcat servlet container for JEE Web Applications and supports streaming and shared object communication over RTMP. DICOM and HL7 messages are handled by asynchronous Java threads using dcm4che and HAPI Java libraries. The communication between Grid Agents and Grid Manager is accomplished using encrypted XML messages using HTTP and RTMP protocols.

2) The Grid Manager: Grid Manager is developed to run on Red5 and is specialized to send and receive encrypted XML and SOAP messages or DICOM files utilizing DICOM, HTTP or RTMP protocols. It communicates with Grid Agents and performs database, indexing and file operations at the center. Grid Manager has the Grid Index which includes the patient examination map cached by Grid Agents. The index is in shared object form so that a change in the index is pushed to all agents with the help of RTMP protocol. The caching mechanism at the agents provides the redundancy of the medical data so that the data achieve is distributed and web server maintenance costs are prevented.

3) Data Center Architecture: The central server is composed of the Application, Database and File Operation Layers. Grid Manager forms a bridge between these layers. The Database layer is implemented with open source Postgresql software. The database instances are implemented in shards to deliver large scale loads. Application layer is implemented with Red5 media server and File Operation layer is implemented with Tomcat Servlet Container.

4) The clients: Clients can query and retrieve medical images in parallel from multiple Grid Agents where medical content is cached during the pre-fetching and synchronization processes. For web clients, Java based open-source DICOM viewer software, ImageJ, is customized to stream image instances in parallel chunks. A query that is directed to the grid agent in a hospital by workstations is also directed to other grid proxies. Consequently, the query is performed at every hospital and central web server. Grid Manager provides the Grid Agent and consequently workstations with the result list and the images or data can be retrieved by the help of Grid Manager. Parallel downloading and efficient query algorithms in the Grid Manager enhances the bandwidth usage and time delay.

C. Medical Image Delivery Optimization

1) Problem statement: In order to claim that a radiologist is the optimum choice as a reporter for an inspection, parameters such as experience of the radiologist, response time, workload quota of the radiologist, technical adequacy of the reporting unit that the radiologist is located have to be evaluated.

Experience of the radiologist: Based on the expertise area of the radiologists or experiences on practice, radiologists may be better equipped in certain modalities, diseases or body systems. With reference to the studies that have been carried out on the association between radiologist characteristics and

interpretive performance of diagnostic radiology, a hierarchical structure is defined.

Response time: Response time is another important parameter that should be taken into account while estimating the most suitable reporter for the inspection. A radiology inspection for diagnostic purposed should be reported typically in 48 hours while an urgent inspection should be reported in at most 4 hours. The factors effecting the response time are inspection file delivery time depending on the inspection file size and reporting unit bandwidth, radiologist availability time based on the schedule and radiologist reporting time based on the modality, protocol and statictical data. The statistical data for response time is populated as the radiologists save their reports corresponding to inspections related with a certain set of modality, disease, body part and anatomy.

Workload quota of the radiologist: In order to achieve an efficient reporting process and to balance incomes, each radiologist should be assigned with inspections within certain workload limits. However, every reporting process is not equal in effort. The work load and payments of reporting processes are determined according to the "Performance Point Documentation (SUT)" announced by the Turkish Ministry of Health [13]. "Performance Point Extension Proposal" proposed by the Turkish Society of Radiology is used to strengthen the estimations on the average reporting time. In urgent cases, response time is much more important than the workload quota and expertise area; therefore, expertise area and workload quota are evaluated as secondary importance in emergency situations.

Technical adequacy of the reporting unit: Based on the inspection distribution scenario within this study, it is assumed that the radiologists are located in reporting units, where the assigned inspections are synchronized for access. Therefore, the technical infrastructure of the reporting unit effects the response time and the capacity of reporting service. Bandwidth of the unit affects the response time, while storage capacity and performance of the workstations determine the technical adequacy of the reporting unit. The medical monitor resolution is also taken as a requirement parameter as inspections of certain modalites need high resolutions for investigation.

2) Rendering entities into ontology maps: Ontology maps include the main nodes of Experience, Response Time, Workload and Technical as illustrated in Fig. 3. Experience is evaluated by the assessment of subquantities for each subnode Modality, Body Part, Anatomy and Disease. Similarly each node is connected hierarchically to subnodes having a weighted relation based on AHP. The input for the assessment process is provided by the inspection DICOM file. Each DICOM file provides entites that determine experience, response time, workload and technical requirements as illustrated in Fig. 2. *dcm4che* open-source DICOM Java library is used to render inspections in DICOM format. The modality of inspection, body part and anatomy examined, protocol requested, file size, series and slice numbers, resolution data are rendered into XML for RBSM and ILP processes. It is assumed that the pre-diagnosis is either embedded into the inspection or

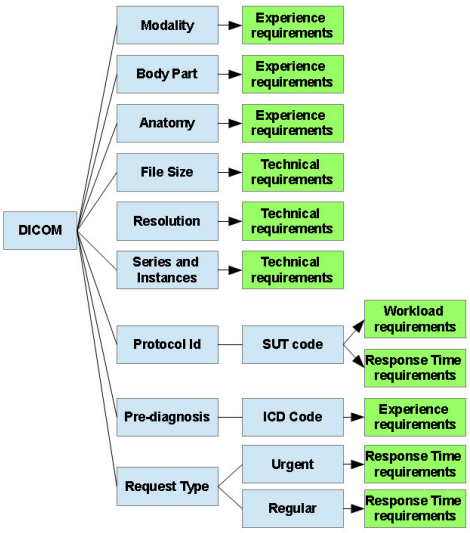

Fig. 2. DICOM file structure. The file structure is rendered to obtain components and these components are used to form the ontology map of the inspection DICOM file.

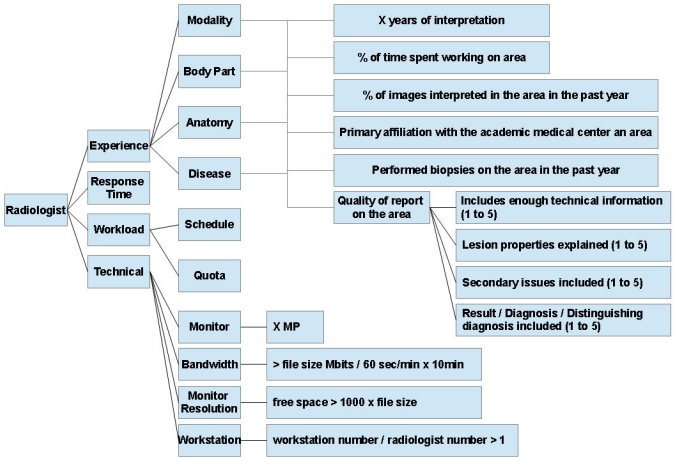

Fig. 3. Ontology map to calculate weights and ratings in inspection assignment to radiologists

entered manually by the report requester as 10^{th} revision of International Classification of Diseases (ICD-10) code. The attributes rendered in the inspection files of DICOM format are used to derive the demand criterias for the radiologist.

3) AHP Process: The pairwise comparison for each entity of the problem is represented by a pairwise comparison matrix.

The weight w_l for each entity l at hierarchical level k of the ontology map including n entities is calculated using pair-wise

comparison matrix element a_{lm} by the following equation:

$$w_l = \frac{\sqrt[n]{\prod_{m=1}^{n} a_{lm}^{(k)}}}{\sum_{l=1}^{n} \sqrt[n]{\prod_{m=1}^{n} a_{lm}^{(k)}}}, \quad l, m = 1, 2, \ldots, n \qquad (1)$$

4) RBSM Process: Ratings are evaluated with a recursive relation based semantic matching process [12] by normalizing the sum of multiplicative weights with the following equation:

$$r_l^{(k-1)} = \frac{\sum_{m=1}^{M} w_m^{(k)} r_m^{(k)} q_m c_{lm}}{\sum_{l=1}^{L} \sum_{m=1}^{M} w_m^{(k)} r_m^{(k)} q_m c_{lm}}, \qquad (2)$$

l=1, 2,...,L, m=1, 2,...,M where L and M are the number of entities at levels $k-1$ and k of the ontology map respectively. q_m is equal to 1 if the qualitative or quantitative condition is satisfied by the potential assignee on entity m and 0 otherwise. c_{lm} is the binary value representing the presence of the connection between entities l and m in the ontology map.

5) ILP Process: The ILP process is formulated by defining the function to be maximized

$$J = \sum_{i=1}^{S} \sum_{j=1}^{R} r_{ij} x_{ij}, \quad i = 1, 2, \ldots, S, \quad j = 1, 2, \ldots R \quad (3)$$

for S inspections and R radiologists where x_{ij} is 1 if inspection i is assigned to radiologist j or 0 otherwise; and r_{ij} represents the resultant rating for each potential assignment calculated by the *RBSM Process*. The constraints are defined as the following:

Assignment constraint: Each inspection is assigned to one and only one radiologist.

$$\sum_{j=1}^{R} x_{ij} = 1 \qquad (4)$$

Workload constraint: The sum of assigned inspection estimated effort e_i should not exceed radiologist's workload l_j.

$$\sum_{i=1}^{S} e_i x_{ij} \leq l_j \qquad (5)$$

Storage constraint: The storage free space s_j in the server at the reporting unit should be at least C_1 times that of the incoming inspection with file size f_i in bytes.

$$\sum_{j=1}^{R} \frac{s_j}{f_i} x_{ij} \leq C_1 \qquad (6)$$

*Bandwidth constraint:*Transfer time of an inspection with file size f_i in bytes to a reporting unit with bandwidth b_j in bits per second should not take more than C_2 seconds.

$$\sum_{j=1}^{R} \frac{8 \times f_i}{b_j} x_{ij} \leq C_2 \qquad (7)$$

Response time constraint: The response time which is equal to the sum of transfer time of the inspection file, radiologist availability time $t_{a,j}$ and radiologist's inspection specific average reporting time $t_{r,ij}$should be less than the requested time $t_{req,i}$. This is typically 4 hours for urgent cases.

$$\sum_{j=1}^{R} \left(\frac{8 \times f_i}{b_j} + t_{a,j} + t_{r,ij} \right) x_{ij} \leq t_{req,i} \qquad (8)$$

ILP process is implemented using the *lp_solve* Java library *OptimJ*.

TABLE I
SIMULATED PRE-DIAGNOSIS ENTRIES AND MODALITY, BODY PART, ANATOMY INFORMATION RENDERED FROM THE DICOM FILES FOR 100 SAMPLE RADIOLOGY INSPECTIONS.

Onthology	**Glossory**
Modality	MR, CT, DX, MG
Body Part	Head, Leg, Throax, Knee, Shoulder
Anatomy	Skull, Leg, Upper Abdomen, Lower Abdomen, Shoulder, Spine
Disease	C39 : Malign neoplasm of inspiration system and inner thorax organs, C50 : Malign neoplasm of breast, C71 : Malign neoplasm of brain, C76 : Malign neoplasm of thorax, C78 : Malign neoplasm of rectum, D43: Neoplasm of brain and central neural system, S02 : Skull and face bone fracture, S42 : Shoulder and fore arm fracture, S82 : Calf and knee fracture, S83 : Dislocation, sprain or strain of knee and ligaments

D. Experimental Design

The performance of the proposed algorithm is tested using 100 sample radiology inspections. A simulation test bed is adopted with 4 imaging facilities and 3 reporting units, 1 data center and 2 non-local clients as virtual machines on different subnets. 6 radiologists working in 3 reporting units are registered and their experience, reporting unit technical capabilities are defined using the web interface. Round robin, random, shortest queue distribution policies are compared to RBSM and ILP distribution algorithms.

III. RESULTS

The results are evaluated based on experience rating, response time success rate and workload average deviation values.

Experience rating is a normalized value between 0 and 1 where higher experience rating is required for better reporting quality.

Response time success rate for policy p is defined as

$$sr_p = \frac{1}{S} \sum_{j=1}^{R} \sum_{i=1}^{S} s_{ij,p} x_{ij,p} \qquad (9)$$

TABLE II
EXPERIENCE RATING, RESPONSE TIME SUCCESS RATE AND WORKLOAD AVERAGE DEVIATION VALUES FOR THE APPLIED DISTRIBUTION POLICIES: ROUND ROBIN, RANDOM, SHORTEST QUEUE, RBSM AND RBSM+ILP.

	Round Robin	**Random**	**Shortest Queue**	**RBSM**	**RBSM +ILP**
Experience Rating	0.34	0.37	0.40	0.75	0.71
Response Time Success Rate	0.74	0.72	1.00	0.93	0.99
Workload Avg. Dev.	2.73	3.60	1.94	0.49	0.28

where $s_{ij,p} = \begin{cases} 1 & t_{ij,rep} \leq t_{i,req} \\ 0 & otherwise \end{cases}$
for reporting time of inspection i by radiologist j, $t_{ij,rep}$ and requested reporting time for inspection i, $t_{i,req}$. The maximum possible value for sr_p is 1 and higher is the response time success rate, better is the distribution policy.

Workload average deviation for policy p, ld_p, is a measure of how efficient the radiologist resources are utilized indicating the distance from the load limit.

$$ld_p = \frac{1}{R} \sum_{j=1}^{R} \frac{\left| \sum_{i=1}^{S} e_i x_{ij,p} - l_j \right|}{l_j} \tag{10}$$

where e_i is the estimated time to report the assigned inspection i and l_j is the workload of radiologist j. The minimum possible value for ld_p is 0 which means the assignment workloads are equal to the defined workload limits for each radiologist. Therefore, distribution policy can be evaluated as more successful in terms of workload efficiency when ld_p approaches 0.

IV. DISCUSSION

The proposed architecture increases the efficiency of reporting process for teleradiology applications and provides a process centric network structure with an enhanced caching, querying and retrieving mechanism.

Shortest Queue policy has the highest response time performance; however it is inefficient in experience rating and workload distribution. Applying only RBSM gives the highest experience ratings, but integrating ILP with RBSM ratings provides a better response time success rate and the best performance for workload distribution with a small optimization trade off in experience rating. RBSM and ILP based image delivery also prevents bandwidth, storage or hardware related locks and latencies.

V. CONCLUSION

The proposed infrastructure decreases the storage costs, reporting costs, turnaround times and increases report quality and effectiveness of resultant treatments. The adaptation of medical sites and reporting groups to the architecture only requires the integration of Grid Agent into the present systems deployed on these sites which decreases integration costs and provides high interoperability.

The response time and report quality statistics for each radiologist are updated in real time. Therefore, it is considered that the proposed solution can be even more efficient and accurate in real case scenarios. Also the recalculation of weights based on the satisfaction level feedback for response time, report quality and workload distribution enhences the algorithm to make more accurate decisions.

***Abstract*—In this paper, we present an application which aid an evaluation of the arterial diameter changes, based on ultrasound videos. The designed, implemented and verified algorithm uses the techniques of image processing, image analysis and pattern recognition, such as filtering, profile plot analysis and active contour method. Except determining the artery diameter over time it is also able to retrieve ECG from ultrasound video. The results obtained for both signals are synchronized, therefore it is possible to obtain the artery diameters in R wave points, which is a novel approach. Experiments were performed to assess the software validation by comparing the outcomes obtained with the evaluated algorithm with those manually-acquired – the correlation is high. This is the first stage of the research in which we will build the cardiovascular predictive model to search for the new cardiovascular factors.**

I. Introduction

INCREASED risk of cardiovascular diseases is related to endothelial dysfunction, which can be assessed based on the ultrasonic monitoring of brachial artery diameter changes in response to the temporal closure of the vessel. During the examination, videos containing the brachial artery representation in B-mode and M-mode are simultaneously captured (left and right side in Fig. 1). B-mode is a 2D image of the brachial artery in the longitudinal plane. A single scan line placed along B-mode is used by ultrasound device to generate M-mode representation, which describes how the structures intersect with that line in time.

Manual measurement performed on such videos is operator-dependent, prone to mistakes and time-consuming. Moreover, it is impossible to perform continuous measurement manually, due to frames quantity (30 frames per second).

In this paper, we present an application which can aid an evaluation of the arterial diameter changes, based on ultrasound videos. The designed, implemented and verified algorithm uses the techniques of image processing, image analysis and pattern recognition, such as profile plot analysis and active contour method [9]. Except determining the artery diameter over time it is also able to retrieve ECG from an M-mode ultrasound. The results obtained for both signals are synchronized, therefore it is possible to obtain the artery diameters in R wave points, which is a novel approach introduced in our algorithm.

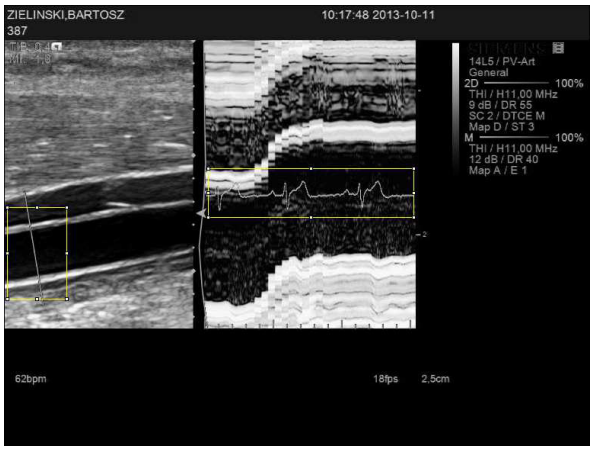

Fig. 1. The example of the first frame from the ultrasound video with B-mode and M-mode on the left and right side, respectively.

The test set includes baseline, occlusion and post-deflation videos and images obtained from 20 patients, together with the automatically and manually-measured values. Such test set was used to conduct analyses, results of which were investigated.

II. The medical aspects of the paper

The endothelium, forming the innermost, unicellular layer of arteries, plays a key role in the homeostasis of blood vessels. Properly functioning endothelial cells, in response to shear stress (SS) variations produce certain particles that may cause dilation or constriction of the vessel. Increased SS results in releasing vasodilators such as Endothelium-Derived Relaxing Faxtor (Nitric Oxide), Endothelium-Derived Hyperpolarizating Factor and prostacyclin, causing a local increase in the vessel diameter. Disorders in the excretion of these substances can be associated with the early endothelial dysfunction, which among others is related to increased likelihood of cardiovascular diseases [2], [7].

One of the most commonly used method for non-invasive assessment of endothelial function is the flow mediated-

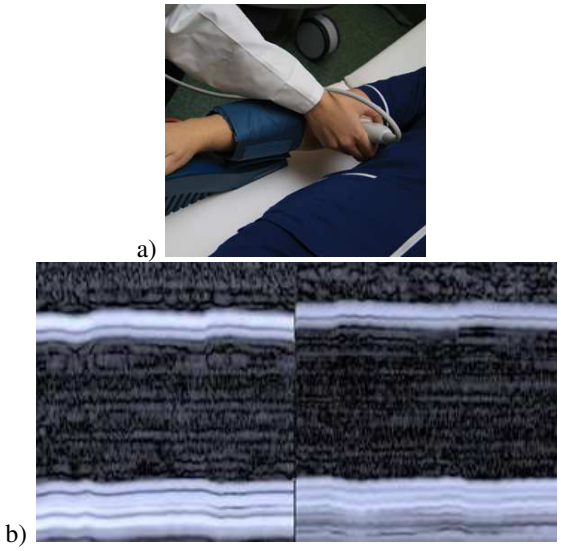

Fig. 2. Cuff and ultrasonic probe placement – a. M-modes of the arterial baseline (left side) and its dilation after releasing the cuff (right side) – b.

dilation (FMD) study. It is based on the ultrasonic monitoring of the brachial artery diameter changes in response to the temporal closure of the vessel (ischemia). Artery closure is achieved through the pressure cuff inflation on the limb (see Fig. 2a). After releasing the cuff the shear stress acting on the endothelial cells in the vessel wall is augmented as a result of increased flow, causing a reactive hyperemia [3]. The arterial diameter varies between 2 and 5 mm and its change ranges from 0 to 25% (see Fig. 2b). The accurate calculation of such a small variation would be difficult due to the limitations of the standard USG, therefore artery imaging is performed using a high frequency ultrasound probe (7-14 MHz).

III. The existing methods

Most of the FMD measurements in the literature are done by tracing the vessel boundary manually. Such a process is time consuming and error-prone. Therefore, several authors proposed some automated methods for this task. In [5] the authors proposed a robust automated measurement of the vasodilator response by automatically locating the artery using a variable window method and global constraint deformable model for vessel wall boundary detection. Geminiani et al. [6] used a robust edge detection algorithm, called "mass center of the gray level variability". Faita et al. [4] introduced the localization algorithm of the artery tunics based on a new mathematical operator called the first order absolute moment and on a pattern recognition approach. Bartoli et al. [1] utilized a spline model (deformable template) that detects the artery boundaries and track them all along the video sequence. The a priori knowledge about the image features and its content is exploited in this approach. Kaneko et al. [8] developed a method of measuring the change in the thickness and the elasticity of the brachial artery during a cardiac cycle using the so-called phased tracking method for the evaluation of the mechanical property of only the intima media region.

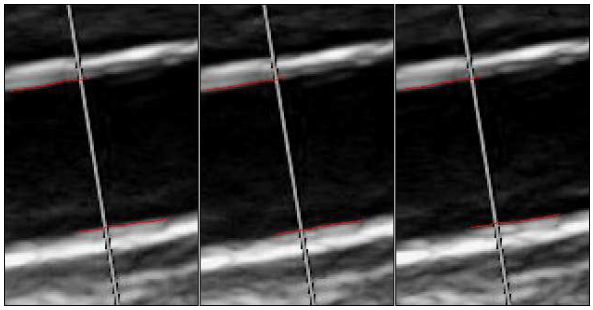

Fig. 3. The successive steps of the artery diameter analysis.

Our approach is based on profile plot analysis and active contour method. As opposed to the existing models, our algorithm, except determining the artery diameter over time, also retrieves ECG from M-mode and is resistant to the additional line in B-mode. The existing commercial medical applications for FMD measurement, such as Quipu FMD Studio[1], or MIA Vascular Tools 5[2] do not return the partial results like continues artery diameter. On the other hand, such partial product is necessary to conduct medical research. Other algorithms are sold only with the new machinery, like Ultrasonix products[3]. Our approach does not depend on any machinery.

IV. The algorithm

The presented algorithm can be employed for artery diameter measurement and FMD study. It is a semi-automatic technique, which operates on the basis of two regions of interest (ROI) selected by the operator in the first frame of the ultrasound video (see Fig. 1). First ROI contains a fragment of B-mode with scan line (left yellow rectangle in Fig. 1). The ECG representation is selected as the second ROI (right yellow rectangle in Fig. 1).

The first ROI is given together with the initial outlines of the arterial walls, which are automatically tracked at the following frames of the video (see Fig. 3). The second region of interest is analysed fully automatically.

A. Determining the artery diameter over time

The algorithm for determining the artery diameter over time works for both outlines independently and is based on the active contour method [9]. In both cases, it starts with the outline containing 2 points (beginning and end of the section given by the system operator), which is decomposed to obtain series of 10 points with the same distance between successive elements.

Representing the position of a snake parametrically by v(s), we can write its energy functional as [9]:

$$E^*_{snake}(v) = \int E_{int}(v(s)) + E_{image}(v(s)) + E_{con}(v(s))dx. \quad (1)$$

[1]http://www.quipu.eu/fmd.php
[2]http://www.mia-llc.com/products/vascular_fda.htm
[3]http://www.ultrasonix.com/research/clinical

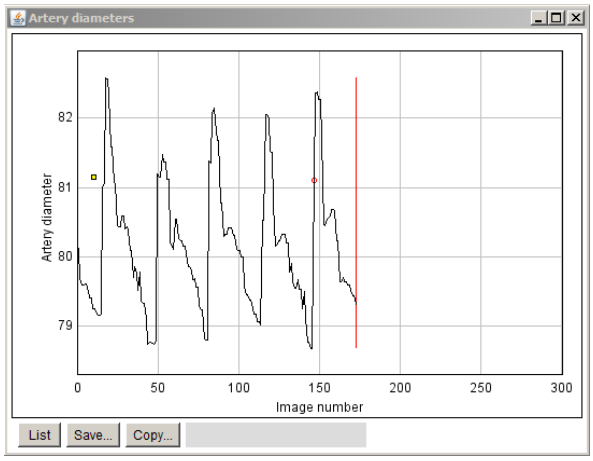

Fig. 4. The partial result of the artery diameter analysis.

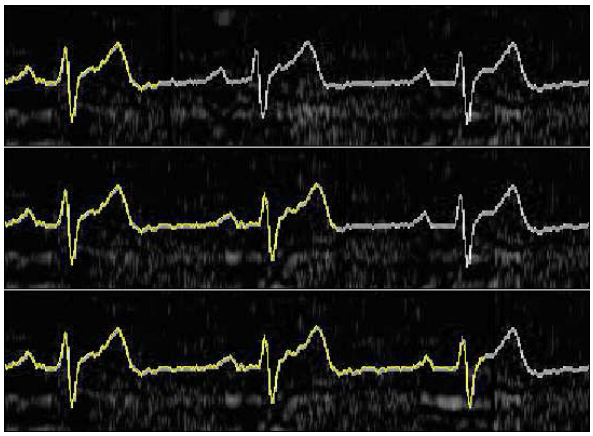

Fig. 5. The successive steps of the ECG retrieval analysis.

Internal spline energy contains a first-order term controlled by α, and a second-order term controlled by β:

$$E_{int}(v(s)) = \frac{\alpha|v_s(s)|^2 + \beta|v_{ss}(s)|^2}{2}, \quad (2)$$

The first-order term is responsible for stretching and the second-order is responsible for bending. The values of both factors were initially set to 0.5, to prevent extensive stretching and bending. Those preliminary values proved to be accurate (see Section VI) and therefore were not explored more specifically, but we are plan to do it in the future.

The total image energy can be exposed as a weighted combination of the three energy functionals:

$$E_{image}(v(s)) = w_{line}E_{line} + w_{edge}E_{edge} + w_{term}E_{term}, \quad (3)$$

$E_{line} = I$ is the image intensity itself, $E_{edge} = -|\nabla I|^2$, and E_{term} is terminal functional utilized in order to find terminations of line segments and corners. The value of w_{edge} was set to 1 to promote the edges, while both other factors were set to 0, not to promote darker or lighter regions. Moreover, the Gaussian blur is applied to an image before computing ∇I and then it is scaled to $[0, 1]$. With reference to such approach, the factor γ responsible for step size was set to 0.

Functional E_{conv} responsible for external constrain forces was currently omitted, but we plan to use it in the feature to promote parallelism between both outlines.

The endpoints (P_1 and P_{10}) are treated differently than the other points. Their x coordinate left unchanged, while their y coordinates are obtained using linear approximation computed for the outline. It is necessary, because otherwise the outlines would shrink into two points. In the last step of the iteration, each outline is modified so that the distance between the successive points is the same and successive iteration begins.

Active contour method works as long as distance between the outlines from the successive iterations is bigger than $0.000001mm$. As the result of such analysis for each frame, the sequence of the artery diameters is obtained (see Fig. 4).

B. ECG retrieval from M-mode

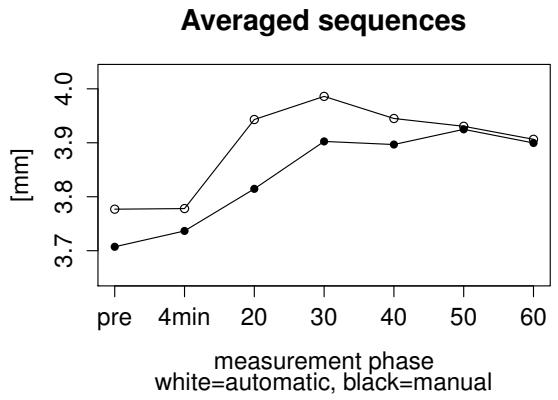
The algorithm for ECG retrieval is based on M-mode which is cyclic (see Fig. 1). Therefore, in order to retrieve ECG it finds the most differing columns of two successive video frames. For each of them the profile plot is generated and then analysed to determine the pixels with the maximal values. Thanks to such approach, the analysis is invariant to noise and equipment type (see Fig. 5).

V. Experiments

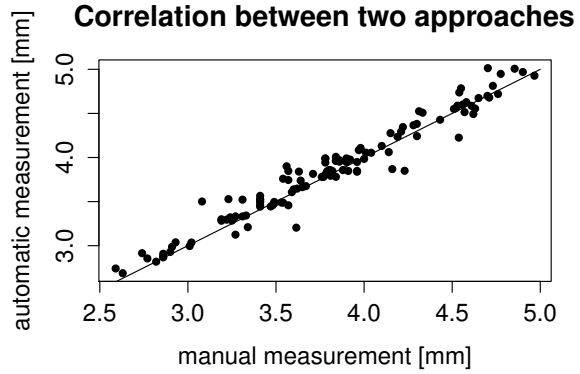
The software validation was performed by comparing the outcomes obtained with the evaluated algorithm with those manually-acquired. The test procedure is as follows. Before the test a pressure cuff is placed on the patientâĂńs forearm and the 14-MHz ultrasonic transducer is placed on the upper arm (proximal to the cuff), fixed on a tripod. During the whole test videos containing the brachial artery representation in B-mode and M-mode are simultaneously captured (Fig. 1). A baseline video is recorded for 10 seconds. Thereafter arterial occlusion is created by inflating the cuff for 5 minutes to about 50 mmHg above patientâĂńs systolic pressure. The last, 60-second video is recorded continuously from 5th second after the cuff deflation.

Hence, there are 7 points in time where the measurements are taken: baseline (called "pre" in the following graphs), arterial occlusion ("4min") and 5 points in time after cuff deflation (in 20th, 30th, 40th, 50th and 60th second). The software tracks the wall borders using B-mode video representation and it displays arterial diameter changing in time as a result. After a calibration it is possible to determine vesselâĂńs peak value. The manual diameter measurements were performed using M-mode images captured every 10 seconds after the cuff deflation, starting from the fifth second. The diameter was measured in each image at R wave points (an average from three measurements).

The data come from the tests (both manual and automatic) done for 20 patients. Fig. 6a shows the averaged sequence of measurements for both approaches. The results for the baseline, arterial occlusion and 30s are almost identical. Both



a)



b)

Fig. 6. Averaged manually and automatically obtained sequences – a. Correlation between manual and automatic measurements – b.

approaches give similar results also for 40, 50 and 60s. For 20s point we can see the larger difference between manual and automatic approach. This is due to the problems with manual measurements mentioned earlier – they are operator-dependent and more prone to mistakes. There is also a threat of missing the right value due to 10 second intervals between measurements. In the initial phase the ultrasonic transducer can be still tuned to capture the good quality image of the artery. As one can see from Fig. 6a, automatic method works better, because the pressure in the 20th second after cuff release should be much higher than it follows from the manual measurement. The automatic measurements follow the right scheme here.

Correlation between manual and automatic measurements is shown in Fig. 6b. Each point in this figure represents a measurement from one phase (baseline, cuff occlusion, 20s, 30s, 40s, 50s or 60s) for one patient. The correlation is 0.98. This means that in general the automatic method is well aligned with the manual one, so we can claim that the method is accurate. The points lying farther from the $y = x$ line refer mainly to the situation from 20th second presented in Fig. 6a, where the operator can make an inaccurate measurement (this will be one of the topic of the future research). The mean difference between manual and automatic measurement was $-0.055mm$. The mean differences split by phase is shown in Table I.

TABLE I
DIFFERENCE BETWEEN MANUAL AND AUTOMATIC MEASUREMENTS SPLIT BY PHASE (IN MILLIMETRES).

phase	pre	4min	20	30	40	50	60
diff	-0.13	-0.09	-0.19	-0.15	-0.11	-0.07	-0.006
stddev	0.56	0.26	0.34	0.34	0.27	0.19	0.08

The automatic measurements are slightly larger than the manual ones. This is due to the fact that the operator might use her own method of marking the diameter, with endpoints lying closer to each other than in the automatic case. Hence, in case of the manual measurement there may be a systematic error. However, this doesn't matter, as the main metric used in the subsequent analysis is the FMD, defined by the formula $FMD = \frac{pdh-b}{b} \cdot 100\%$, where pdh is a peak diameter in hyperemia and b is a baseline value. The FMD is a ratio-type metric, so systematic error doesn't affect the differences between automatic and manual measurements given in terms of FMD.

VI. Concluding remarks

In this paper we presented an application for monitoring the changes in arterial diameter, based on ultrasound videos. It was validated by comparing its outcomes with those acquired manually. The tool turned out to be very accurate and outperforms manual measurement process. Except determining the artery diameter over time it is also able to retrieve ECG from an M-mode ultrasound. The results obtained for both signals are synchronized, therefore it is possible to obtain the artery diameters in R wave points, which is a novel approach introduced in our algorithm (see Fig. 7).

This is the first stage of the research in which we will build the cardiovascular predictive model to search for the new cardiovascular factors. Therefore, the following will be introduced during the further part of the work. First, both regions of interest shown in Fig. 1 will be selected automatically, together with the initial outlines of the arterial walls (see Fig. 3). Second, we will quantitatively describe the artery diameter over time in terms of its characteristic components, such as the slope of its initial part and length of the plateau. As the result, the software will be used to evaluate a distensibility of arterial wall (e.g. carotid).

4th International Workshop on Advances in Semantic Information Retrieval

RECENT advances in semantic technologies form a solid basis for a variety of methods and instruments that support multimedia information retrieval, knowledge representation, discovery and analysis. They influence the way and form of representing documents in the memory of computers, approaches to analyze documents, techniques to mine and retrieve knowledge. The abundance of video, voice and speech data also raises new challenging problems to multimedia information retrieval systems.

We believe that our workshop will facilitate discussions of new research results in this area, and will serve as a meeting place for researchers from all over the world. Our aim is to create an atmosphere of friendship and cooperation for everyone, interested in computational linguistics and semantic information retrieval. The ASIR'14 workshop will continue to maintain high standards of quality and organization, set in the previous years. We welcome all the researchers, interested in semantic information retrieval, to join our event.

Topics

The workshop addresses semantic information retrieval theory and important matters, related to practical Web tools. The topics and areas include but not limited to:

- Domain-specific semantic applications.
- Evaluation methodologies for semantic search and retrieval.
- Models for document representation.
- Natural language semantic processing.
- Ontology for semantic information retrieval.
- Ontology alignment, mapping and merging.
- Query interfaces.
- Searching and ranking.
- Semantic multimedia retrieval.
- Visualization of retrieved results.

***Abstract*—Many of current web search engines rely on inverted index-based data structures as document information store. Since and inverted index is a map from individual document words to their respective locations, such data structure destructs semantic links between the words, and thus does not support structural user queries. In other words, such systems can only find the documents that contain user-specified words. In this paper we propose to create semantic links between the terms contained in inverted index, and in such way create a semantic network. This network will preserve the internal structure of the stored documents, and will enable the users to perform structural queries. Both structural-saving indexation and structural user search query allow to save semantic speech meaning of the text while search process.**

I. Introduction

Today all popular search engines operate with inverted index [1],[2],[3], which provides the grounds for high-quality keyword-based search. The main idea is to create a mapping from every token to a list of its positions in the documents, indexed by the search engine. While both page ranking and linguistic algorithms can offer rather acceptable results for the users, the very idea of processing non-linked keywords, extracted from texts, imply non-semantic search only.

Thus, today's semantic networks, implemented both by commercial companies and and open communities are not fully utilized by the search engines. Powerful linguistic and statistic functions, implemented in modern search engines, are not used to their full extent.

A. Preserving semantic links

The main idea of the present work is to store not inverted index, but sentence structure with link to it's source page position. The base sentence structure consists of three elements: predicate, subject and object, called a triplet. This idea is presented in the Figure 1. Each page is parsed to get linked tokens, constituting the elements to be saved to the database with sentence links and source page positions. The tokens form an oriented graph or a semantic network. Subjects in such graph serve as objects for other subjects and vice versa. This structure is similar to RDF [5] (Resource Description Framework), which describes knowledge using a directed graph.

Search process is implemented with RDF queries over the semantic network. The user enters a triplet in form of three words, which is searched in database of linked documents (a semantic network). In the future, the user will be able to use natural language as a query language. In this case, the system will be able to process not only triplet words, but also other syntactic forms. This means that the indexer will have to process the source documents using an extended RDF scheme, which would contain also adjectives, adverbs, and other parts of speech (POS).

A query triplet can be searched in the database using a simple straightforward comparison or with the methods used in many popular search engines, such as synonyms dictionary and TF-IDF[1][4].

TF-IDF can be implemented as a coefficient of relevance, which influences the document position in the resulting list.

Our search algorithm is not intended to replace traditional inverted index search engines, and can be implemented within an additional module, or serve as a basis for a specialized fact search engine in a knowledge graph.

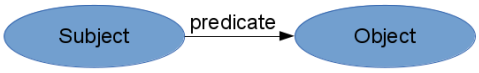

Fig 1: RDF

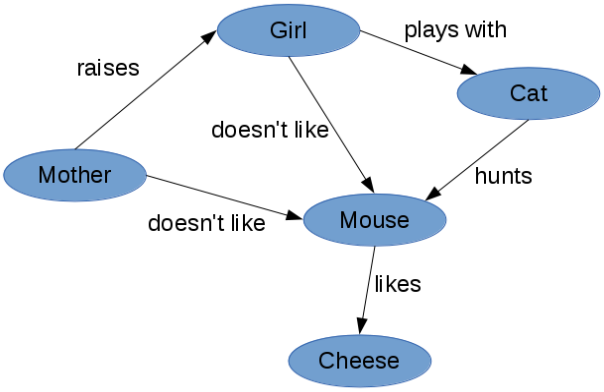

Fig 2: Semantic network

[1]TF-IDF is numerical statistic dimension defining document relevancy in document collection. Result depends on word frequency in current document and inverse frequency in other documents.

B. Basic search engine functions

Our search engine indexing mechanism (robot or spider) solves the following problems:

1. Detecting document external links
2. Useful content detection
3. Semantic structure parsing

C. Useful content detection

For useful content detection we used an artificial neural network, as suggested in [6]. Many of web-pages sources are divided into separate strings containing HTML markup and text, despite it doesn't influence to page rendering. Also we empirically devided HTML tags into two groups: simple and special. Simple tags collection contains text decorating tags like "<b><i><s>". Special tags set contains the others one. Our neural network detects whether a given string contains meaningful text or non-meaningful webpage elements.

While exploring HTML documents we found such regularities:

1. Useful content usually is absent at the beginning and ending of the article.
2. A string is probably useful if the presence of HTML tags inside the string is low.
3. Longer strings are most probably useful.

We used neural network with thr following input parameters:

1. Document string number expressed in percents.
2. A string length expressed in percents. 100% is the longest document string.
3. Relation between simple HTML tags and text chars.
4. Relation between special HTML tags and text chars.

Every parameter except the first one is repeated two more times: for the previous string, and for the next one. The characteristics of our neural networks are shown in Table I.

We trained the neural network using 50 English Wikipedia pages. This method allowed us to quickly get a content parser, having 83% decision accuracy. As a neural network engine we used Encog Java library.

D. Database

Our system uses two DBMS: a NoSQL graph-oriented Neo4J DBMS, and a NoSQL document-based MongoDB. In order to store tokens with minimal overhead, we employ tries (see Figure 3).

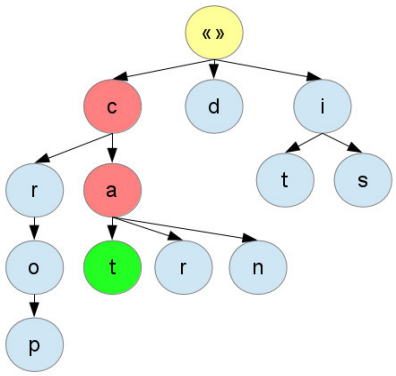

Fig 3: Trie

Tries are supported by Neo4J DBMS that stores all data as a graph, and provides handy ways to traverse graphs, and search and retrieve individual vertices.

To store RDF-like links we used a NoSQL document-based DBMS MongoDB to achieve structureless storage organization, and high speed. In our case, the web spider saves parsed sentences into the documents, containing document index of a predicate, an object, subject, and a link to a word trailing letter in a trie. This structureless organization allows us to add new part-of-speech elements without restructuring the database. Also this allows us to model any sentence structure with optional adjectives or participles.

II. Structure parsing algorithm

A. Common work algorithm

To get a parsed sentence, the system performs the following steps:

1. Anaphora resolution
2. Sentence segmentation
3. Token boundaries identification.
4. Part-of-speech tagging of the tokens array.
5. Syntactic parsing of the POS-tagged sequences.

During components selection we tried to use the subsystems, containing English language and preferentially Russian language model.

Table I.
Neural network characteristics

# Layer	Neurons count	Function
1 Output	1	TanH
2	4	TanH
3	7	TanH
4	11	TanH
5	12	TanH
6 Input	9	Linear

B. Anaphora resolution

Anaphora (coreference) resolution systems are less developed, but there are some systems available:

1. OpenNLP
2. CherryPicker
3. JavaRAP (pronoun coreference system)
4. BART
5. ARKref (rule-based)
6. ARS

According to the recommendations provided in [7], we have chosen ARKref as a main anaphora resolution module. ARKref is a deterministic, rule-based system that uses rich syntactic and semantic information to make antecedent selection decisions.

C. Identifying sentence and token borders; POS tagging

This spider system is implemented as a separate unit with a separate API. For sentence and token borders identification, there are many ready solutions available, and this topic is widely covered in the literature. For now, our system works mainly with the English language, but as we might want to extend the list of supported languages in the future, we so we selected an extensible open source Java TreeTagger system. TreeTagger is fast, and has low RAM and CPU consumption with availability of various language models. TreeTagger can be quickly replaced with any other tokenizer.

D. Dependency parsing

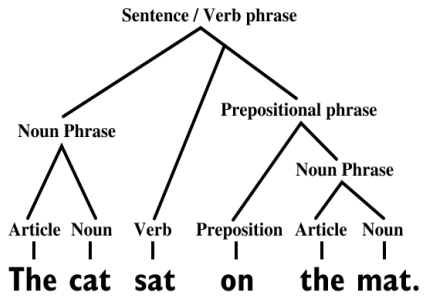

Fig 4: Constituency parsing

Firstly we tried to use Standford NLP Parser as a main sentence processing instrument, but we faced high RAM and CPU consumption. Furthermore, Stanford Parser uses constituency[2] grammars that do not reflect well the structure of languages with relaxed word order, such as Russian. For such languages dependency grammars are usually considered more appropriate.

Following the recommendations in [8], we have chosen MaltParser for best parsing quality from the list of available parsers.

To train the parsing system to recognize any particular language, a deeply annotated text corpus (a treebank) is needed. For each word in a Treebank, the following data is required:

1. Word position in the sentence
2. Word
3. Grammatical attributes
4. Head word position
5. Dependency type

MaltParser contains pre-trained models for English, French, and Swedish. For other languages, it is necessary to create a malttab training set. For the Russian language, the treebank is available as a part of "National Russian language corpus"

III. Implementation

A. The platform

Our search engine consists of two main parts: the search indexer (spider) and the web interface. As most of the NLP software is written in Java, the spider is also written in Java. Since some of the NLP systems operate with space-consuming language models, some heavy weight modules were separated from the base system and made available via RPC API. Thanks to this approach, the system has an ability to use several servers that process different languages (i.e., it is horizontally scalable). Such RPC-available modules are: the anaphora resolution system, the POS tagger, and the dependency parser. For easier development, we have chosen Apache Thrift RPC framework for every isolated component.

As mentioned above, the application stores data in two databases: graph-based Neo4J and document – based MongoDB. The web interface is written in JavaScript/JQuery and operates using Java Spring-based REST API. The component diagram is shown in Figure 5.

All components are implemented in similar ways, and each of them uses a multi-threaded RPC framework, and thus performs multi-threaded text processing.

B. Indexer component

The Indexer component's ("Spider" in the components diagram) aim is to get the next page from the list of links, to process it by calling other components' RPC API and to save the results into the database. Furthermore, this component extracts the links to the new documents to be analyzed, and adds them to the general links list.

This component works with other modules via RPC framework Apache Thrift, that is used due to the simplicity of cross-platform code generation, its lightweight protocol (as opposed to XML-RPC or SOAP), simple implementation and multithreading. At the present time, the system does not support language detection, but the system can operate via RPC with several other processing servers, handling different natural languages. To test the system, we used English Wikipedia as the data source.

C. Anaphora resolution

The anaphora resolution module operates with raw text (cleaned from HTML markup), and replaces pronoun or noun anaphors with their antecedents. As a result, the spi-

[2]Constituency grammar is based on Chomsky's generative grammar. Parsers based on constituency grammars try to divide sentences into smaller word groups until the individual tokens are identified. The example of phrase-structure (constituency) parsing is shown in Figure 4.

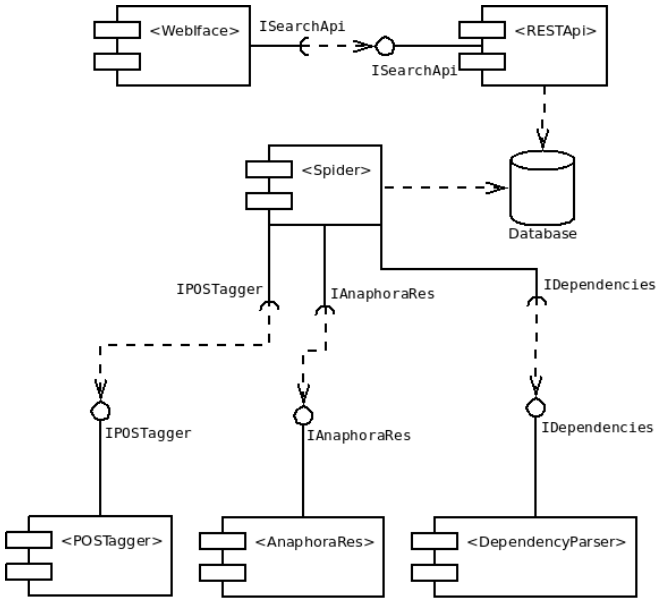

Fig 5: Components diagram

der gets two text versions: the raw text and the text with resolved coreferences. The latter document is being processed in other modules, but both are saved to the database. The anaphora resolution module is a multithreaded server. The number of threads is set up in the server configuration.

D. POS tagging and Dependency finder

These components are marked as "POSTagger" and "DependencyParser" in the components diagram.

Component class diagram for these modules is similar to the coreference resolution component it uses RPC-server classes, singleton configuration classes and other.

MaltParser makes output data in the CoNLL format, similar to the malttab format.

E. Web interface

The web interface is a web application, written in JavaScipt/JQuery. The current web interface allows the user to input three words: subject, predicate and object, to be sent to the server via the REST API. The system processes the query and finds the list of suitable sentences in the database.

REST API is implemented with Java Spring framework.

Using separate processing modules leads to ability of search query NLP processing. This would allow users to make queries as usual sentences.

IV. Related work

[9] also proposed similar semantic network storing approach. Author offers to store RDF structures like a graph using object-oriented databases.

[10] describes a system that processes automatic text sentences tagging for further text managing analyzing or searching.

Our system novelty essence is the approach to process, store and search text data. The method novelty lies in transformation text into RDF-like semantic network and following triplet search over the prepared semantic network index.

V. Conclusion

Our research aim was to try to create a semantic-powered search engine that uses NLP technologies. During the development we have analyzed different information retrieval and NLP instruments and methods, such as syntactic parsing, POS tagging, and coreference analysis.

As the result, we got a semantic sentence-structure search engine prototype. Currently, the system has the following limitations:

1. System processes English-language documents only.
2. The useful content extraction module reliably parses Wikipedia documents only.
3. The current system operates only with triplets. It cannot process adjectives or adverbs.
4. The system does not use any synonyms dictionary.

Finally, system searches triplet like three English words contacted with "AND" boolean operator and it is unusable in current state as providing search service is very poor concerning to internal Wikipedia search (cause Wikipedia is used as testing data source). Search engine returns result with given wittingly right query i.e. known triplet from known document.

Also sentence parsing system is very poor at the moment. We parsed part of Wikipedia for system test. The result is presented in Table 2.

Using synonyms dictionary, a more diverse knowledge-base as a data source, and coreference resolution improvements should make results better.

Table II.
Experiment results

Comment	Value
Total indexed documents	1401
Total parsed sentences	17226
Average parsed sentences in document	12
Average sentences in document	26
Result	54% of document information is lost

***Abstract*—In this paper a model of textual events composed of a mixture of semantic stereotypes and factual information is proposed. A method is introduced that enables distinguishing automatically semantic prototypes of a general nature describing general categories of events from factual elements specific to a given event. Next, this paper presents the results of an experiment of unsupervised topic extraction performed on documents from a large-scale corpus with an additional temporal structure. This experiment was realized as a comparison of the nature of information provided by Latent Dirichlet Allocation and Vector Space modelling based on Log-Entropy weights. The impact of using different time windows of the corpus on the results of topic modelling is presented. Finally, a discussion is suggested on the issue if unsupervised topic modelling may reflect deeper semantic information, such as elements describing a given event or its causes and results, and discern it from pure factual data.**

I. Introduction

UNSUPERVISED probabilistic topic modelling is one of the most widely applied information retrieval techniques, in particular in researches on large-scale corpora. Its main assumption states that text documents are mixtures of topics which may be treated as a multinomial probability distribution over words. These distributions might be created with the use of a couple of methods [1], [2], [3].

In this paper we present the results of experiments in which we attempted to extract deeper semantic information from postprocessed results of unsupervised probabilistic topic modelling methods. It is worth emphasizing that unsupervised methods—despite their utility in information retrieval—cannot directly retrieve semantical relations from texts [4], [5]. Some introductory premises were presented by the authors in [6], such as the hypothesis, that although unsupervised topic modelling does not reflect directly semantic prototypes, those prototypes can be inferred from the extracted topics. This paper provides additional research in the discussed subject and presents new results that prove our hypothesis.

The size of the corpus we operated on was millions of documents. Moreover, it possessed an additional temporal structure.

The framework of the experiments presented in this paper is an integral part of a large scale project related to security and intelligence analysis. The suggested approach permits to find in an analyzed text elements related to the specific semantic prototypes (i.e. mental models) of the events described within and to discern them from pure factual information, given that a sufficiently large corpus is available. Discussed technique may be a first step towards creation of a method for automatic semantic prototype identification. Such methods are essential in a security and intelligence analysis as they can be applied in an automatic identification of objects and their properties in full-text sources.

We start our paper with a short overview of works related to the presented subject - it is included in Section II. Section III introduces and explains the concept of semantic prototypes, firstly described in [7]. Subsequent Sections focus on the experiments of unsupervised topic extraction performed in order to present a method of discerning semantic prototypes from factual information: Section IV introduces corpus used in our experiments, Section V describes the method itself. Results of the experiments are presented and discussed in Section VI. We conclude our paper in Section VII. At the end of the paper, in Section VIII, suggestions of future work are discoursed.

II. Related work

Latent Semantic Analysis (LSA) is an original word/document matrix rank reduction algorithm which extracts word co-occurrences in the frame of a text. As a result, each word in the corpus is related to all co-occurring words and to all texts in which it occurs. The LSA algorithm may be applied in various domains—from a text content comparison [8] to an analysis of human association norm [9]. Unfortunately, there is still little interest in studying the linguistic significance of LSA-made associations.

Latent Dirichlet Allocation (LDA), presented by David Blei, Andrew Ng, and Michael Jordan in 2003, is one of the best known generative model used for topic extraction. It assumes that a collection of documents may be represented by a mixture of latent topics, however words creating each topic are chosen according to a multinomial Dirichlet distribution of fixed dimensionality over the whole corpus. LDA is a technique based on the „bag of words" paradigm and it can infer

978-83-60810-58-3/$25.00

distributions of topics e.g. with the use of variational Bayes approximation [10], [11], Gibbs sampling [2] or expectation propagation [12].

Some recent research was focusing on finding if the relationships coming from the unsupervised topic extraction methods reflect semantic relationship reflected in human association norms. A comparison of human association norm and LSA-made association lists can be found in [4] and it should be the base of the study. Results of the other preliminary studies based on such a comparison: [5], [13], [14], show that the problem needs further investigation. It is worth noticing that all the types of research referred to, used a stimulus-response association strength to make a comparison. The results of the aforementioned research have shown that using unsupervised topic extraction methods one is able to create associations between words that are strongly divergent from the ones obtained by analysing the human generated associations.

As it has been already noticed, the methods mentioned above are not able to retrieve additional semantic information, however in this paper we introduce some postprocessing methods that may be useful in a semantic text classification.

III. Semantic prototypes

The notion of a semantic prototype comes from cognitive theory [7] where a notion is represented by its elements with their features. So, according to this model, a notion of a „bird" would be „composed" of such elements and features as „feathers", „beak" and „ability to fly". Semantic prototypes can also be discussed in the context of event descriptions that occur in texts. Prototype theory has also been applied in linguistics for mapping from phonological structure to semantics.

In a domain of natural language processing, this approach is reflected in so-called content theories. A content theory is used to determine a meaning of phrases and information they carry. One of the classic and most known elements of content theory is the Conceptual Dependency theory that was invented and developed by Robert Schank [15]. His main goal was to create a conceptual theory consistent in every natural language. The theory's main assumptions were: the generalization of representation language and inference about implicitly stated information. The first assumption means that two synonymous sentences should have identical conceptual representations. The second one states that all the implicit information has to be stated explicitly by inferring it from explicit information. Each sentence can be then represented in a form of conceptual dependency graph built of three types of elements: primitives, states and dependencies. Primitives are predicates that represent a type of an action, states specify the preconditions and results of actions and dependencies define conceptual relations between primitives, states and other objects [16]. Accordingly to the Conceptual Dependency theory we may represent the event of „tea drinking" by a sequence of events: „tea making", „cup operating", „tea sipping" and so on, that are composed of action, object etc.

The described event model proved itself to be very useful in many applications [17] and we found it very suitable to quantifiable comparisons to unsupervised topic modelling methods [18].

From that theory we deduce our model of an event - its prototype - a compound structure of actions, actors, states, and dependencies but also composed of preconditions and results, being events themselves. This event model reflects also very well the semantic structure of a text. If a document describes an event, it is almost always presented in the context of the causes of the event and the resulting consequences. This will be reflected in various topic models that will tend to reflect that most texts are represented as a linear combination of multiple topics. Determining from such combination which topic (event) can be classified as a cause and which is an effect would be very interesting, but that issue is beyond the scope of this paper.

On the other hand, the modelled text is composed not only of events, but also features of those events specific only to that instance of the event. As such, a text can be seen as having two aspects - the main event of the text intermingled with the elements of cause and result events and factual features that are specific to that single event. The latter aspect would relate to places, actors and contextual information. The former aspect would relate to generic elements that are common to similar events that occur in the corpus.

This paper focuses on unsupervised identification and retrieval of those two different event model aspects of texts.

IV. Corpus

The experiment was conducted on a subset of a 30-year worldwide news archive coming from the New York Times. That corpus has been chosen as it is interesting for a number of reasons:

- it is freely available,
- some interesting research results have been obtained based on it [19],
- it is quite comprehensive in terms of vocabulary and range of described event types,
- its relatively large size (approximately 90.000 documents per year, for a total of 2.092.828 documents spanning the years 1981-2012) gives an ample opportunity to experiment with various document time spans without impacting noticeably its event scope representiveness and lexicon balance.

After a set of trials with various time spans ranging from months to 15 years, the most pronounced effects of the experiment described below could be obtained by comparing two time spans - one covering 6 months and the other covering 4 years. Those sub-corpora contain over 45.000 and 350.000 documents, respectively.

V. Method

We based the data of our experiment on the term/document matrix populated with Log-Entropy weights [20]. More precisely, the value a_{ij} in the matrix corresponding to the i-th

word and j-th document can be expressed as the usual ratio of a local and a global weight:

$$a_{ij} = e_i \log(t_{ij} + 1)$$

where:

$$e_i = 1 - \sum_j \frac{p_{ij} \log p_{ij}}{\log n}$$

for n - the total number of documents, t_{ij} is the number of times the i-th word occurs in the j-th document and $p_{ij} = \frac{t_{ij}}{g_i}$, with g_i the total number of times the term i occurs in the whole corpus.

After building an LDA model (with d dimensions), we obtain a matrix v of size $n \times d$ composed of elements $v_j k$ describing how much the topic k impacts the document j. The v_{jk} matrix contains per design only non-negative values.

Each topic is in turn represented by a vector of probabilities describing how much a single word participates in this topic, in the form of a $N \times d$ matrix w (for N - the size of the lexicon).

As all the values in the matrices v and w are non-negative, their product contains the cumulative impact of each word for each document, summed over the range of all topics. For each document j and word i, what we will call the word model matrix m of size $n \times N$ composed of elements m_{ji}, is obtained by multiplying the document weights with the topic model $m = vw^\top$.

For a given document j we will now analyze the rank of words in the sorted vector m_{ji}, for each word i.

VI. Experiment

We based our experiment on a subset of the New York Times corpus described above. The two compared subsets were spanning 6 months and 4 years, respectively. We focused on the representation of the news item related to the accident of Kursk, the Russian submarine that sank on 12th August 2000. In order to affirm the results of our experiments, additional tests were performed, focusing on the information about the terrorist attacks launched upon New York City on the 11th September 2001. Their outcome is discussed in the second part of this Section.

The experiments were performed using 2 methods of topic modelling: LDA based on a term/document matrix populated with Log-Entropy weights and the pure Log-Entropy model based on the mentioned matrix. These models were computed basing on texts from a 4-year article span. Additionally, the Log-Entropy model was built on texts from a 6-month range in order to observe the changes resulting in considering different time windows. Finally, a ratio of Log-Entropy results from the 6-month and 4-year ranges was calculated so that we could better analyze changes that took place in models built in different time windows.

A. The accident of Kursk

Below is a fragment of the input text used for the primary experiments focusing on the accident of the Russian submarine Kursk:

A Russian submarine plunged to the seabed in the Barents Sea on Sunday during a naval exercise, possibly after an explosion on board, officials said today. They said the submarine was badly damaged, and was trapped at least 450 feet below the surface. They said they did not know how many of the more than 100 crew members on board were alive or how long they could survive. Tonight the navy began preparing a desperate attempt to rescue the crew. But navy officials said the odds of saving the men were slim. The submarine, called the Kursk, was not carrying nuclear weapons, the navy said, but was powered by two nuclear reactors, raising concerns about possible radioactive contamination. But Russian officials said the reactors had been turned off, and officials in Norway said a scientific vessel in the area had detected no signs of a radioactive leak. A flotilla of ships and rescue vessels was on the scene off Russia's northern coast in rough weather tonight, frantically searching for ways to reach the men. Navy officials said they intended to mount a rescue attempt on Tuesday. News reports said rescue workers had been trying to hook lines to the submarine to bring it air and fuel. If the sub lost power, the men could suffocate and the submarine's compartments could turn unbearably cold in the frigid waters. The navy's commander, Adm. Vladimir Kuroyedov, said, „Despite all the efforts being taken, the probability of a successful outcome from the situation with the Kursk is not very high." The White House spokesman, Joe Lockhart, said that President Clinton had been briefed about the accident, and that his national security adviser, Samuel R. Berger, had told Foreign Minister Igor S. Ivanov that the United States was willing to help.

Results presented below are very similar to the ones described in [6], with the exception of unnecessary terms that carry no importance and that we were able to exclude.

In order to properly understand the results of LDA-based modelling, one has to look at the analyzed event - the sinking of the Kursk submarine - in a more general way as an accident of a naval vehicle that happened in Russia.

After analysing which words are the highest ranked in our model (30 words with the highest score are presented in Table I), it may be observed that LDA model distinguished words that may be somehow connected with:

- vehicles: ship (ranked 2nd with score 0.00418), vessel (7th, 0.00246), plane (8th, 0.00238), boat (11th, 0.00229)
- transport: port (1st, 0.00434), airline (3rd, 0.00304), flight (4th, 0.00276), airport (5th 0.00271), tunnel (15th, 0.00200), pilot (25th, 0.00169), passenger (26th, 0.00168)
- Russia: Russia (6th, 0.00252), Russian (9th, 0.00236), Moscow (28th, 0.00157)
- sea (except for the already mentioned port, ship, vessel, boat): navy (10th, 0.00232), sea (13th, 0.00209), harbor

TABLE I
TOP 30 WORDS BASED ON THE LDA MODEL (THE KURSK ACCIDENT)

29	shipping	0.00153479445129
30	state	0.00145645985742

(14th, 0.00201), naval (27th, 0.00164), shipping (29th, 0.00153), water (49th, 0.00121), sailor (54th, 0.00119)

- accidents: besides many of the words already mentioned, the word crash (33rd, 0.00139) is significant.

These words are very general and are common terms used while describing some event. It has to be emphasized that there is no word specific for a given event. They were filtered out in accordance with the nature of LDA that rejects words characteristic for just a narrow set of documents and promotes words that are specific to extracted topics. Therefore, we cannot expect highly ranked terms that would be strictly connected with the accident of the Kursk submarine but rather words related generally to accidents or vehicles, transport, sea and Russia.

These words are very general and descriptive. Using them, it is not possible to state anything specific („factual") about the nature of a given event, its causes or consequences.

Analysing the results of the Log-Entropy model calculations, we are able to see that the highest ranked words are more specific than in the case of the LDA model.

TABLE II
TOP 30 WORDS BASED ON THE LOG-ENTROPY MODEL IN A 4-YEAR TIME WINDOW (THE KURSK ACCIDENT)

27	Nilsen	0.07615887534697596
28	breathable	0.07448263140205012
29	Komsomolet	0.07436551614837245
30	stricken	0.07292194644563503

Table II presents the 30 highest ranked words according to the Log-Entropy model in 4-year time window. Among them there are ones that are related to the causes of the main event:

- *reactor* (6th, 0.13190), *nuclear* (13th, 0.10490), *radioactive* (26th, 0.07876): despite the fact that in case of Kursk accident reactors shutting down is rather a consequence, many news described also some previous submarine accidents caused by malfunction of nuclear reactors
- *accident* (16th, 0.09975): some „accident" as a reason of submarine sinking
- *pressurized* (18th, 0.09732): media reported that the lack of pressurized escape chambers was the reason why the crew was not able to get out of a submarine
- *sank* (23rd, 0.08470): „the submarine sank" as a the central event
- *stricken* (30th, 0.07292): „submarine was stricken" as a reason of the accident

Words that can also be found as related to the consequences of the discussed accident:

- *minisub* (ranked 3rd with score 0.20723): a minisub was sent with a rescue mission
- *Thresher* (7th, 0.12577): USS Thresher was a submarine, which sinking was frequently compared to the accident of Kursk
- *rescue* (10th, 0.11232) and *crew* (12th, 0.10625): rescue crew was sent in order to help sailors
- *Kuroyedov* (22nd, 0.08621): Fleet Admiral Vladimir Kuroyedov was in charge of navy when Kursk sank and therefore after the accident spoke with the media very often
- *Lockhart* (25th, 0.08163): Joe Lockhart was the White House spokesman that talked to the media after the accident of Kursk and informed about the American president's offer of help
- *Nilsen* (27th, 0.07616): Thomas Nilsen is a Norwegian researcher that wrote a report on Russian fleet. He was also interviewed by media after the accident
- *Komsomolet* (29th, 0.07437): K-278 Komsomolet was a Soviet nuclear-power submarine that was mentioned frequently in many reports on Soviet/Russian fleet after the accident of Kursk
- *stricken* (30th, 0.07292): „stricken submarine" as a consequence of the accident

These words are much more specific than in the case of those extracted by the LDA model. They strictly concern this event and describe its causes and consequences.

At first sight, the results of Log-Entropy model calculations in 6-month time window are very similar to the previous ones. We can see the same elements that we identified as the cause of the accident (*sank, stricken, reactor, nuclear*) and its consequences (eg.: *minisub, Thresher, rescue, crew, Kuroyedov*). However, the results yielded in these two time windows differ in scores. In order to analyze how the rank of particular words changed, we calculated a ratio of each word's score in two time span windows - spanning 4 years and 6 months. Having in mind that changing the time window practically does not change the local weight of a given term but changes its global weight, this ratio would emphasize these changes as a comparison of each word's global weights while similar local weights would become irrelevant.

As the Table III presents, it turned out that the words that could be used in describing causes and consequences of the Kursk sinking are now much more emphasized. Moreover, the most specific for this particular event words are stressed, while terms that could be used in descriptions of other, similar accidents (e.g. reactor, nuclear, radioactive, rescue, crew) have lower rank. Besides, new interesting words appeared when considering a ratio-based ranked list of words:

- *Kuroyedov* (ranked 3rd), *minisub* (ranked 4th), *Nilsen* (ranked 6th): they are still high ranked as the most specific words for this particular event
- *seabed* (ranked 5th): as a consequence of the accident, the submarine was plunged to the seabed

29	sunk	1.01187373966
30	sunken	1.01048072834

- *torpedo* (ranked 8th), *torpedoes* (ranked 22nd): an explosion of one of torpedoes that the Kursk was carrying, has been recognized as the main reason of the accident
- *Ivanov* (ranked 23rd): in time of the Kursk sinking Sergei Ivanov was the head of the Russian Security Council, therefore was highly involved in this case, so his name was often mentioned as a consequence of this accident
- *hull* (ranked 25th): after the accident, the rescue crew tried to get into the submarine through its hull
- *slim* (ranked 35th): day after day the chances of saving sailors were slimmer

It seems very interesting how calculating of the ratio helped with finding new words describing causes and consequences and how it distinguished terms that are specific for a given event. It also emphasized changes that occurred in different time windows.

B. September 11 terrorist attacks

Some additional tests needed to be launched in order to affirm results obtained in the previously performed experiments.

A fragment below exemplifies the input text used in the subsequent experiments, focused on the September 11 terrorist attacks on New York City:

> *Hijackers rammed jetliners into each of New York's World Trade Center towers yesterday, toppling both in a hellish storm of ash, glass, smoke and leaping victims, while a third jetliner crashed into the Pentagon in Virginia. There was no official count, but President Bush said thousands had perished, and in the immediate aftermath the calamity was already being ranked the worst and most audacious terror attack in American history. The attacks seemed carefully coordinated. The hijacked planes were all en route to California, and therefore gorged with fuel, and their departures were spaced within an hour and 40 minutes. The first, American Airlines Flight 11, a Boeing 767 out of Boston for Los Angeles, crashed into the north tower at 8:48 a.m. Eighteen minutes later, United Airlines Flight 175, also headed from Boston to Los Angeles, plowed into the south tower. Then an American Airlines Boeing 757, Flight 77, left Washington's Dulles International Airport bound for Los Angeles, but instead hit the western part of the Pentagon, the military headquarters where 24,000 people work, at 9:40 a.m. Finally, United Airlines Flight 93, a Boeing 757 flying from Newark to San Francisco, crashed near Pittsburgh, raising the possibility that its hijackers had failed in whatever their mission was. There were indications that the hijackers on at least two of the planes were armed with knives. Attorney General John Ashcroft told reporters in the evening that the suspects on Flight 11 were armed that way.*

Table IV presents top 30 results of LDA-based modelling performed in a 4-year time span window. As previously, we are able to perceive some groups of words, linked together by a certain topic:

- war: attack (ranked 1st with score 0.00270), war (8th, 0.00176), military (13th, 0.00163), force (29th, 0.00113)
- United Stated of America: Bush (2nd, 0.00266), American (6th, 0.00184), York (24th, 0.00121)
- terrorism (except for already mentioned attack, force): anthrax (3rd, 0.00203), terrorist (18th, 0.00143)
- public service: police (4th, 0.00196), security (20th, 0.00139), firefighter (38th, 0.00099)
- Afghanistan: Afghanistan (5th, 0.00190), Taliban (7th, 0.00183)
- aircraft: airline (9th, 0.00175), plane (23rd, 0.00123), airport (25th, 0.00118), flight (28th, 0.00114)
- society: state (14th, 0.00161), government (17th, 0.00146), president (22nd, 0.00124), nation (26th, 0.00115), administration (32nd, 0.00104), country (42nd, 0.00098)

As it was observed previously, LDA-based modelling rejects words that are specific for a given event. The highest ranked terms are general and cannot be linked with any factual information. As one can see, there are no words that are characteristic for the September 11 terrorist attacks but rather words that could be related to any document focused on the subject of war, terrorism, United States of America and so on.

TABLE IV
TOP 30 WORDS BASED ON THE LDA MODEL (THE SEPTEMBER 11TH TERRORIST ATTACKS)

no.	Word	LDA model score
1	attack	0.00270258155503
2	Bush	0.00265822334759

29	force	0.00112785897603
30	time	0.00107041659097

These conclusions are very similar to the ones drawn in case of the previous experiments.

The results of Log-Entropy model calculations are also analogous to the case of documents related to Kursk accident, including the possibility of distinguishing causes and consequences of a given event, however we decided not to present them for the reason of shortening the paper.

Bigger expressiveness might be attributed to the ratio of each word's Log-Entropy model score in two time span windows - spanning, as previously, 4 years and 6 months.

Table V presents 30 words with the highest ratio of Log-Entropy model score in two forementioned time span windows. As it might be noticed, there are much more terms that are related to the particular event - September 11 terrorist

TABLE V
TOP 30 WORDS BASED ON THE LOG-ENTROPY MODELS RATIO (THE SEPTEMBER 11 TERRORIST ATTACKS)

no.	Word	Log-Entropy ratio
1	terrorist	1.57893538599
2	attack	1.42460445953
3	Afghanistan	1.42152193493
4	Osama	1.40325332485
5	Taliban	1.36639135448

24	inhalation	1.13484053252
25	plane	1.12086607749
26	disaster	1.09775233687
27	twin	1.08233678639
28	airline	1.08152641944
29	Vesey	1.08150236466
30	militant	1.07469496007

attacks. In this case, more general words that could be used in any other description of attack, war, etc. are less stressed.

Moreover, we are able to distinguish words that could be considered as causes and consequences of the given event:

- *Osama* (ranked 4th with score 1.40325), *bin* (7th, 1.33451), *Laden* (10th, 1.31110): Osama bin Laden was the founder of terrorist organisation al-Qaeda which was responsible for launching the attacks
- *Afghanistan* (3rd, 1.42152), *Afghan* (6th, 1.34763), Kabul (9th, 1.31278): the war in Afghanistan (with the capital in Kabul) was one of the consequences of terrorist attacks on 11th of September 2001
- *hijacker* (8th, 1.32412), *hijacked* (11th, 1.26364453579), *hijacking* (14th, 1.22261): the planes were used as destructive weapons, because they were hijacked
- *aftermath* (17th, 1.19022): the usage of this word indicates an introduction of a given event's consequences
- *Ashcroft* (21st, 1.16229): on 11th of September 2001 John Ashcroft was an Attorney General who, in consequence of the terrorist attacks, was a supporter of passage of one of the main antiterrorism acts (USA Patriot Act)
- *rubble* (23rd, 1.13928), *disaster* (26th, 1.09775), *crashed* (31st, 1.07208), *perished* (36th, 1.06022): these are some words used to describe the consequences of an attack
- *rescue* (33rd, 1.07091), *rescuer* (35th, 1.06506), *evacuated* (39th, 1.05352): in a consequence of the terrorist attack, rescue crews tried to help people and evacuate then from the World Trade Center

Again, it proved that Log-Entropy model discerns more factual data than LDA-based model. Moreover, calculating of the ratio of score obtained in two time span windows helped us to find new interesting terms and stress the changes of results in different time windows.

VII. CONCLUSION

In this paper we extended our work introduced in [6] where we introduced the concept of the text being a structure consisting of a mixture of event descriptions and factual information. Additional experiments performed on the second subset of the large-scale corpus proved again that some methods of postprocessing the results of unsupervised methods could help model an event in a semantically meaningful way, reflecting its semantic structure. Moreover, by comparing the results of Latent Dirichlet Allocation (LDA) and Vector Space Model methods we were able once more to observe how the former distinguished descriptive and general information, while the latter emphasized more specific terms. This specific information could be useful in description of event's causes and consequences.

However, it has to be stressed that the method of discerning causes and consequences of a given event is not a subject of our work and would be an interesting topic of future work. In our paper we tried to distinguish causes and consequences more or less accurately without any advanced method.

VIII. FUTURE WORK

This paper presents the new experiments and affirms the authors' hypothesis discussed already in [6] that by comparing the results of topic modelling and vector modelling coming from different subsets of a corpus, varying by time scope and size, the obtained information can be additionally graded by the level of its generality or specificity. That in turn can show us a way to create a method for discerning semantic prototypes (general description of events) from factual information (specific to events).

However, as seen in the preliminary results above, this hypothesis is supported by manually verified examples that do not scale to a more generic case. Thus, the current ongoing research focuses on creating a metric being able to assess automatically the level of generality or the amount of facts in a specific result. Such a metric takes into consideration factors related to the relative amount of Named Entities in the results, the distance from various text clusters obtained via topic modelling etc. By defining such a metric, crucial parameters for a correct fact versus semantic prototype extraction method

can be automatically determined. Some of the parameters currently considered are: the chosen time window relative and absolute sizes (the analyzed corpus covers over 30 years of press notes), the time shift of the window time frame relative to the analyzed event (preceding, succinct or just surrounding), the topic modelling methods settings.

The long term goal of this research is the creation of a method for automatic semantic prototype identification. Pure unsupervised methods, as those presented in this paper, are not the only venue of approach considered. A parallel research is conducted, based on human based association networks, as presented in [4]. We expect to obtain valuable results coming from the convergence of both approaches.

ACKNOWLEDGMENTS

The research reported in the paper was partially supported by grants "Advanced IT techniques supporting data processing in criminal analysis" (No. 0008/R/ID1/2011/01) and "Information management and decision support system for the Government Protection Bureau" (No. DOBR-BIO4/060/13423/2013) from the Polish National Centre for Research and Development.

***Abstract*—The goal of this research is to design the approach to automated development of service-oriented architecture of information systems based on ontology. The approach presented in the paper is based on methodology of system and ontology design. Novelty of the approach is in application of semantic closure of system functions as clustering criteria. The results of the research were used in practice for design of e-university knowledge database. This paper is a part of the author's PhD thesis.**

I. Introduction

APPLICATION of ontology in information systems design tasks became widely used mostly in recent years. On one hand, ontology is based on sophisticated mathematical tool - formal logic. On the other hand, expressive graphical notations developed for it make its application not more complicated than other modeling languages. In papers [1], [2], [3], [4] approaches to generation of information system structures based on system ontology and structure samples are presented. Generation of system ontology based on descriptive models is a critical task as for existing system modification as well as one of steps for system design. Issues of system ontological description development based on project documentation and views in modeling languages are described in papers [5], [6], [7], [8].

Possible solution for tasks of systems modernization and integration using knowledge database is suggested in [9], [10], [11], [12], [13]. Papers [14], [15], [16], [17], [18] are devoted to issues of knowledge databases design for information systems based on ontological approach.

One of the main characteristics of service-oriented architecture is a loose coupling of systems components that provides for support of system modifiability and scalability. The task of the architect designing a system based on service-oriented architecture is to develop system structure that provides for minimum relations between different services. Architect decomposes functions into services in accordance with functions semantic. Functions working mostly with the same fragment of subject area will be related to the same service, while functions that are not related by semantic will be related to different services. Possessing knowledge of functions semantic, this task can be automated to a large degree. This paper suggests approach to solving automation task based on system ontology. Services structure development automation allows, on one hand, partially reduce load on the architect in solving routine tasks. On the other hand, given large quantity of initial data the application of suggested methods allows creating system prototype that can be used by the architect.

II. Ontology of service-oriented system structure

To solve task of design automation, it is required to reflect system elements in ontology. The main structural elements for service-oriented system are services and their operations (functions). Services and functions cannot exist on its own, they always relate to some business process that they implement, as well as possess information on physical objects of a system - contents. Knowledge of system structure, as well as of semantic of processed information, is required during system modernization. This is why it is feasible to perform ontological engineering of subject area with the purpose of developing separate ontology containing subject area semantic. Information system structure ontology in notation IDEF5 is given in Fig. 1.

Concept $Entity$ describes all contents of a subject area that are described in subject ontology. $Entity$ serves as super-concept for all contents of the subject area ontology. Concept $Process$ presents business process of the subject area. Samples of this concept are developed based on the results of system analysis of the subject area. In accordance with Zachman's model, business processes are reflected in concept view. To model business processes the visual modeling languages can be used: UML [11], BPMN [12], IDEF0 [13]. Description of business processes given in notations can be brought to ontology as suggested in [10], [14], [15]. Concept $ProcessFunction$ describes functions that provide for completion of business processes. Concept $Service$ describes information systems services. Concept $ServiceOperation$ describes operations of a service. Service operation is used to perform one or more functions in business process.

The following assumptions are used as limitations:

- each business process consists of at least one function;
- each function can write or read information from at least one content;

978-83-60810-58-3/$25.00

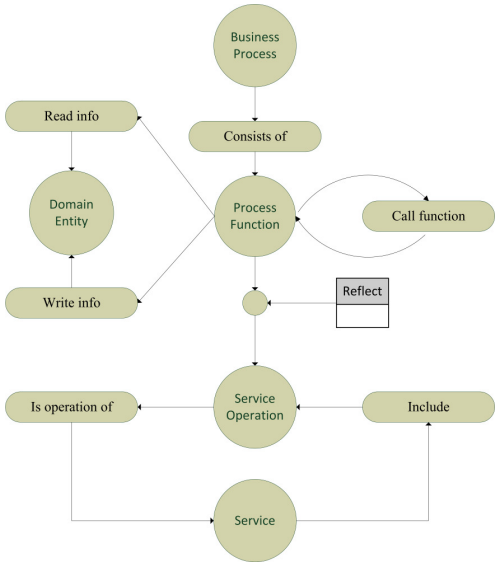

Fig. 1. Ontology of service-oriented system structure

- business process function can call for another function of this or another business process;
- service consists of at least one operation.

Role $ConsistsOf$ determines membership of function in business process. Role $Call$ is used to express call of one function from another. Role $ReadInfo$ sets reading relations between a function and a content of subject area, role $WriteInfo$ sets writing relations. Role $Include$ determines inclusion of operation into service composition. Reverse role $isOperationOf$ sets functional relation of function membership in service. Role $Reflect$ is introduced to reflect service operations at business processes functions.

III. Formalization of service-oriented system structure for automation of its development

Task of generation of services set S comes to clustering task for system functions set $F = \{f_1, \ldots, f_n\}$ with unknown quantity of clusters.

Functional maximizing semantic closure between functions of one service is used as criteria of clustering quality:

$$G = \sum_{i}^{k} \sum_{f_x \in S_i} SI(f_x, f_i) \rightarrow \max \qquad (1)$$

Where k is the number of clusters, f_i is the center of cluster S_i, SI is the similarity functions between f_x and f_i business process functions.

Function of cluster elements similarity (SI) calculates measure of semantic closure for two functions f_x and f_y of subject area in accordance with the following relations:

$$SI(f_x, f_y) = \sum_{i=1}^{n} w_i SI_i \qquad (2)$$

$$\sum w_i = 1$$

$$SI_{BP}(f_x, f_y) = \frac{|\exists Process.ConsistsOf.f_x \sqcap \exists Process.ConsistsOf.f_y|}{|\exists Process.ConsistsOf.f_x \sqcup \exists Process.ConsistsOf.f_y|}$$

$$SI_{ER}(f_x, f_y) = \frac{|\exists f_x.ReadInfo.Entity \sqcap \exists f_y.ReadInfo.Entity|}{|\exists f_x.ReadInfo.Entity \sqcup \exists f_y.ReadInfo.Entity|}$$

$$SI_{ER}(f_x, f_y) = \frac{\exists |f_x.WriteInfo.Entity \sqcap \exists f_y.WriteInfo.Entity|}{|\exists f_x.WriteInfo.Entity \sqcup \exists f_y.WriteInfo.Entity|}$$

Where $SI_{BP}(f_x, f_y)$ defines semantic closeness as a ratio of the cardinality of the subset of business processes, which connected by $ConsistsOf$ role with both functions f_x, f_y, to the cardinality of the subset of business processes, which connected by $ConsistsOf$ role with any of the functions f_x, f_y.
$SI_{ER}(f_x, f_y)$ - defines semantic closeness as a ratio of the cardinality of the subset of entities, which connected by $ReadInfo$ role with both functions f_x, f_y, to the cardinality of the subset of entities, which connected with $ReadInfo$ role with any of the functions f_x, f_y.
$SI_{ER}(f_x, f_y)$ - defines semantic closeness as a ratio of the cardinality of the subset of entities, which connected by $WriteInfo$ role with both functions f_x, f_y, to the cardinality of the subset of entities, which connected with $WriteInfo$ role with any of the functions f_x, f_y.

Service structure obtained as a result of algorithm performance meets the requirement of weak system relatedness.

IV. Experimental evaluation of the method

Experimental evaluation of the suggested method was performed using processes of educational portal of East Kazakhstan State Technical University developed within the program of grants financing No. state registration 0112PK01674 (2012-2014), as application of e-university knowledge database. The fragment of electronic portal chosen for method evaluation included:

- processes: Curriculum development (P1), Education program expertise (P2), Choice of individual educational path (P3), Selection of graduates by qualification (P4);
- contents: Goal of educational program (E1), Results of educational program learning (E2); Educational program (E3), Module (E4), Course (E5), Competence (E6), Student (E7);
- functions: Search of module prerequisites (F1), Evaluation of completeness of educational program (F2), Evaluation of correctness of educational program (F3), Evaluation of goals and results of educational programs

(F4), Generation of courses module (F5), Course search (F6), Module curriculum generation (F7), Evaluation of curriculum (F8), Search of alternative modules (F9), Evaluation of influence of individual curriculum of a students on results of education (F10), Generation of individual student curriculum (F11), Search of graduates by required competencies (F12).

Relations of functions and processes by role $ConsistsOf$ were determined based on process model of educational portal. They are presented in table II.

Data of table II shows that some system functions are involved in few processes at the same time, which makes it impossible to use processes as main criteria for functions uniting.

Based on the results of the analysis of information calls to database, functions relations with subject area contents by roles $ReadInfo$ and $WriteInfo$ were chosen. They are presented in table III.

Results of calculating measure of semantic closure of functions SI in accordance with (2) are given in table I.

Obtained evaluation of semantic closure was used for functions clustering. Algorithm FOREL was used to perform clustering. Experiment was conducted for neighbor elements search radius of 0.76 - average value of distance matrix composed from one complements of semantic closure matrix elements. The following clusters were obtained for search radius:

- F1;F5;F6;F7;F9;F10;F11;F12;
- F2;F3;F4;F8;

There are no linear call sequences in obtained clusters, therefore, all obtained functions can be presented as service operations.

As the results of experimental evaluation showed, set of developed services conforms to services, which were designed empirically without using automation means.

Results showed:

1) functions close by semantic entered into one cluster;
2) functions with weak relations, not depending on used neighbor elements radius search, were chosen into separate cluster (service);
3) distribution of functions with high degree of relatedness depends on clustering parameters that allows identify those functions during further attempts varying neighbor elements search radius;
4) when radius close to average of distance matrix is used, formed clusters to a larger degree conform to services formed during empirical designing without using automatic generation of system structure.

The following services can be conditionally highlighted based on clusters formed using search radius 0.76:

- data search and input;

- analysis and expertise.

Identification of functions with high degree of relatedness allows designer to perform optimization of process model, in order to reduce relatedness of system elements.

V. Conclusion

Accumulated experience in information systems design can be formalized in form of knowledge database that will allow automating routine operations related to designing. Generation of architecture elements and realization of system as well as documentation and interface, allows designers to concentrate on solving application tasks. Semantic of functions relations with business-processes and subject area fragments can be used to solve task of developing information system services. Clear indication of such semantic in form of ontology allows automating process of system functions clustering into services.

***Abstract*—This paper is focused on using computer timeline based interfaces in the domain of history learning. The paper explains what kind of problems do historians and learners face when they deal with chronologically ordered historical information. We review existing approaches and software tools that support timelines. Based on the timeline metaphor ontological model, we examine major features of existing software tools and introduce some novel elements that might be considered as requirements for further implementations.**

I. Introduction

AWARENESS technology and pervasive nature of current software transform the university curriculum and computer-assisted learning and teaching environments dramatically. Today software has a strong impact both on technology sensitive disciplines and on liberal arts [1]. Specifically, for the domain of computer-assisted language learning (CALL), Beatty mentioned that current CALL is *"an amorphous or unstructured discipline, constantly evolving both in terms of pedagogy and technological advances in hardware and software"* [2]. Vice versa, the latter observation can be applied not only to language learning but to various areas of technology-driven education as well.

Let's consider history learning. One definition of history is *"a chronological record of significant events (as affecting a nation or institution) often including an explanation of their causes"* [3]. Hence, above all others, learning history means learning events, their causes and dependencies. Chronology tables, or timeline charts, are used traditionally in numerous history monographs, biography books, science reviews, and so on. As the number of events and contexts increases, one feels hard to manage all the related information. Timelines created by using special software tools don't simply provide a way to record and store event-related information by using computer databases (and this is kind of computer assistance too). Furthermore, they are designed to provide a specific interface to deal with chronology information in a way that is fast impossible or hardly implementable without computers. Existing solutions include such features as timeline zooming, group editing, nesting timelines, attaching multimedia information, managing references to geography maps, association with information about history artifacts, 3-d visualization, to cite a few. This albeit incomplete list illustrates a real technology-driven transformation of the *active learning* space achieved with help of the computer and software technology of the day.

The focus of this work is to examine problems that historians and history lovers face when they deal with chronologically ordered information. We try to analyze the timeline metaphor from the ontological perspective in order to discover concepts and features which aren't supported by existing timeline visual interfaces and software solutions.

The remaining text of the paper is organized as follows. In section II we analyze the timeline metaphor in the most common sense. Section III lists existing tools using the timeline metaphor to model time related data and processes. We review basic user interface layout types and major stereotypes and features implemented in selected software tools. In section IV we pay special attention to several approaches used as a kind of formal foundation in timeline processing software. In section V the timeline ontology is introduced with deeper analysis of modeling timeline and event associations. We explain main elements of the map of timeline related concepts and examine requirements for novel features that are missed in the existing applications including event associations, alternate time scaling with respect to different chronology styles, and regional zooming. In section VI we describe user interface elements supporting timeline and event associations and discuss their implementation in the prototype application.

II. A Timeline metaphor

Time is an immanent attribute of information. Whatever we have as a subject context (e.g. history, literature, music, computer programs, linguistics, etc.), events, concepts, documents, art and engineering artifacts appear and develop in time. Even text semantics and word relatedness often change in time. Attention to temporal information attributes and to possible changes of word usage over time can affect the degree of semantic relatedness [4]. Thus, capturing time related information is an important and complex issue in semantic information retrieval.

In many engineering areas (including software design), visualization is one of known ways to decrease system com-

978-83-60810-58-3/$25.00

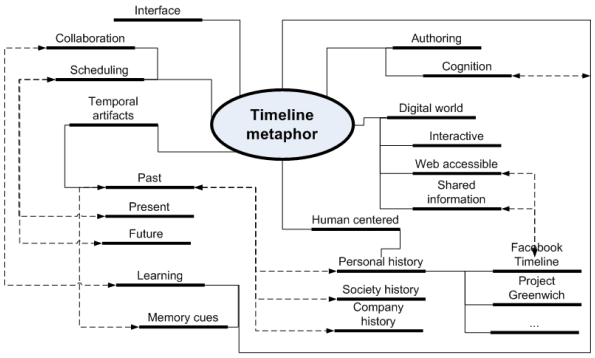

Fig. 1. Timeline metaphor as a map of concepts

plexity and to improve system perception by learners and collaborators. Now let's go back to the history learning issues. Timelines is one of visual ways to organize, manage and display information about events. Wikipedia defines a timeline as *"a way of displaying a list of events in chronological order, sometimes described as a project artifact"*. There might be different kind of events: historical events, cultural events, project milestones or tasks, scheduled appointments, transportation time marks, etymology study points or even research paper publication dates. Thus, on the one hand, timelines are really multidisciplinary visual formalism. On the other hand, it is one of ways to support systematic learning of history related disciplines (like history itself, history of the art, natural science, astronomy, and others).

Despite timelines are usually linked to a graphic design with using bars labelled with dates and associated with event descriptions, Wikipedia timelines (however strange it might be) are presented mostly in textual or table based forms. This makes difficult to zoom events representation to make more emphasis on more important events, to recognize connections between different timelines, to visualize difference of events density in different periods of history, or to highlight different contexts related to the same timeline. Figure 1 shows the sketch of the timeline metaphor in form of a brainstorming map of concepts.

Timelines are more than an attractive and intuitive way to visualize historical information. Project management and collaborative work organization is currently a vast area of using a metaphor of the timeline. It allows combining the broader project view of planned and completed activities with coordinated end user oriented facilities focused upon the specific tasks and events related to the team members [5], [6].

More data people tend to collect, more interests grow in finding out new models to organize information retrieved from the data. Timelines became one of human-computer ubiquitous interfaces used for recording, structuring and browsing personal history [7]. Furthermore, a metaphor of the timeline provides a special searching interface which might be considered as an obvious implementations of the concept of temporally-oriented non-navigational searching: users are open

TABLE I
TIMELINE IMPLEMENTATIONS (PART I)

Name	*Main focus*	*Description*
SmartDraw[a]	Workflow, business processes	Commercial business chart software supporting flowcharts, decision trees, cause and effect diagrams, timelines, etc. Timelines are focused on modeling company workflow, office workers management, information flow, reporting and documentation.
Asana[b]	Team and project management	Commercial packages for teamwork organization based on task and responsibility centered model of the project process flow.
Timelime[c]	Workflow, planning	Supports creating timelines for daily activities, team works, calendar related events and task grouping.
Matchware Education[d]	Mind mapping, project management	Timeline component is a part of the MindView application. Support fixed selection of time periods scaling (standard, daily, weekly, historic and geological). Supports look and fell interface.

[a] http://www.smartdraw.com/examples/timelines
[b] http://www.asana.com
[c] http://timelimeapp.com
[d] http://www.matchware.com/en/products/mindview/education/timelines.htm

for suggestions since they might have no clear preliminary understanding what document they are trying to locate [8]. What is more, people often prefer browsing over direct search even if the search target is known: *"the interface intelligently emphasizes potentially relevant items on a timeline, so that an item can easily be recognized and selected for further inspection"* [9].

III. STATE OF THE ART

Let us introduce existing tools that use the timeline metaphor for the needs of history learning and explain their focus, current features, and layout models they are based on.

A. Tools

Table II cites examples of solutions that interest us at most since they can be used as elements of computer-assisted history learning space. Note that a British Library project seems to be a little bit apart of other history chronology based solutions since it represents an approach to expose the *museum collection artifacts* by using the timeline view, without direct relation to the historical event-based context-dependent editable timelines. Table I lists examples of timeline tools used in business oriented applications like project scheduling, staff management, or task planning.

There are three basic types of timeline layouts used by existing implementations:

- **Time centered layout** uses the event snippets positioned along the timeline bar with detailed descriptions and links to the external resources appeared as popup elements. The *Vistorica* web site is an example (see Figure 2). In the

TABLE II
TIMELINE IMPLEMENTATIONS (PARTII)

Name	*Main focus*	*Description*
Timeline Maker[e]	Presentations	The solution is integrated with PowerPoint and supports timeline diagramming for better presentations.
TimeGlider[f]	History, project planning	Text based representation with abilities to attach graphics. Support several configurable event categories and map tags.
TimelineJS[g]	History, education, personal planning	Web based application for automatic timeline generation from Google spreadsheets input data. Support event layout by using multi-row timelines.
TimeToast[h]	History, education, personal history	Web based application supporting simple timeline construction able to be shared share and categorized by using predefined categories (music, film, science and technology, business, politics, biography, art and culture, personal, history). Popular timelines are listed on the web site.
Tiki-toki[i]	History, education, presentations, personal history	Web based application for creating timelines in very visual way (which include 3d-visualization).
Vistorica[j]	History, education	Historical persons centered application. Names and events are managed by using a set of predefined contexts (events in Europe, science and technology, European works, mathematics and engineering, humanities, culture, economy, politics, military). Integration with geography information is supported.
Chronozoom[k]	History, education	Huge open API and history learning experimental platform for managing user-defined timelines with rich GUI supporting zooming, creating nested and shared timelines linked to a big variety of media resources. Education perspective is one of dominating reason.
British Library[l]	Education, featuring museum collections	The application uses timelines to support exploring the library artifact collection represented collection items chronologically ranging from medieval times to the present day.

[k] http://www.chronozoom.com
[l] http://www.bl.uk/learning/histcitizen/timeline/acceessvers/index.html

Vistorica there is also a special area to represent event related geographic locations.

- **Topic centered layout** shifts focus to the event detailed description while timeline bar serves as a navigation interface. The *TimelineJS* illustrates an idea (see Figure 3).
- **Container model** shown in Figure 4 is introduced in the *Chronozoom* project where a timeline is considered as a container of exhibits with one or more artifacts illustrating the event related topic.

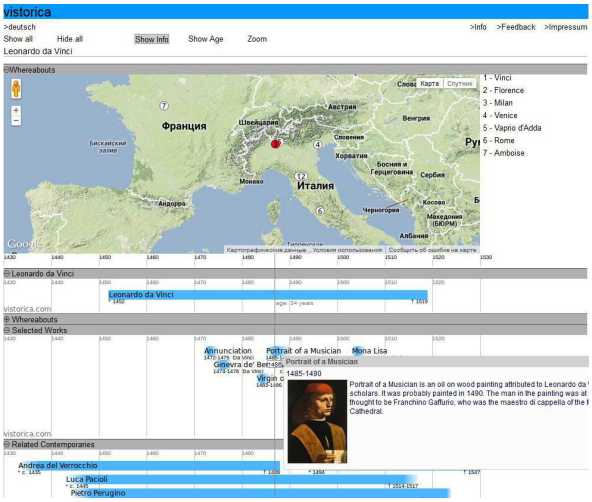

Fig. 2. Time centered layout in *Vistorica*

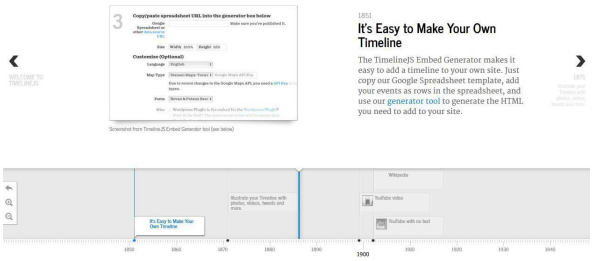

Fig. 3. Topic centered layout in *TimelineJS*

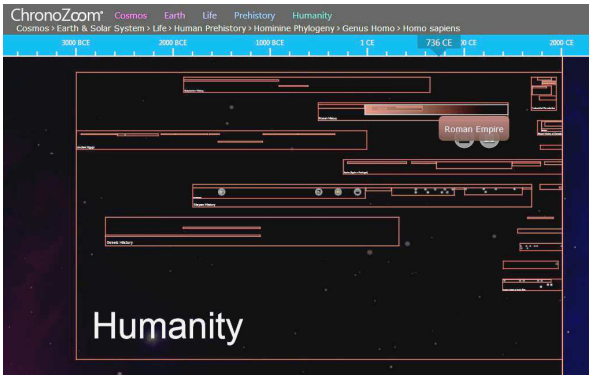

Fig. 4. *Chronozoom*'s container model

B. Features

Table III lists major features that general purpose timeline tools support. Through learning and educational perspectives, Chronozoom seems to be potentially the most powerful open-source platform for history visualization [10].

Despite many interesting features and layout concepts can be found in existing implementations, there is a space for further improvements with respect to human centered and history learning centered views. In the following sections we propose some feature concepts aimed to improve requirements for further implementations.

IV. Related Work

There is a variety of research works on generating document summaries to be included into the list of retrieved documents while searching [11], [12]. The main idea is to evaluate the semantic meaning of the document paragraphs and choose the paragraphs with the best meanings for the summary. In the area of timeline visualization, there are aspects of constructing relevant summaries for using them as timeline event headlines. In the work [13] the authors investigate possibilities to construct timeline summaries from collections of news articles available on the web. The main difficulty concerns the problem of choosing the most meaningful news which relate to the event date: the relevant information can be found not only in news appeared exactly on some certain date. They may be published *after* or *before* the analyzed date and have references to this date. The complexity of this task grows if we take into account huge amount of news reports received from numerous websites. Users are often interested only to catch the main idea of the news from such a flooding news stream and to discover how do the news appeared on different dates relate to each other. News summarization in the form of timelines may help to reach this goal. Xu et al. introduced a cross-media evolutionary summarization approach which states the formal model that helps deciding whether the news (texts and images) obtained from a certain media or posted by a certain author is the best candidate to be included into the final timeline [14]. They apply an idea of collecting recommendations to the domain of news selection: each candidate news can *"recommend"* the others and in turn can be "recommended". The candidate's authority increases if s/he gets more positive recommendations. Furthermore, recommendations from a more authoritative candidate make other candidates' authority increasing (thus, in a certain sense it is similar to the model used to evaluate research work impact and productivity by using the H-index). This approach can be used as a foundation to automate the process of selecting authoritative and reliable event descriptions to be included into the timeline.

V. Timeline Concept

As a rule, an event has temporal, spatial and schematic attributes associated with it. That's why investigating relationships, dependencies and correlations between events organized in the chronological order is of much importance [15].

In computer assisted learning systems, the content dependent facilities are necessary in order to express better event semantics and associations. Jouault and Seta cite an example of some military battle description [16]. In addition to timeline positioned events like the battle, the armistice, the treatment

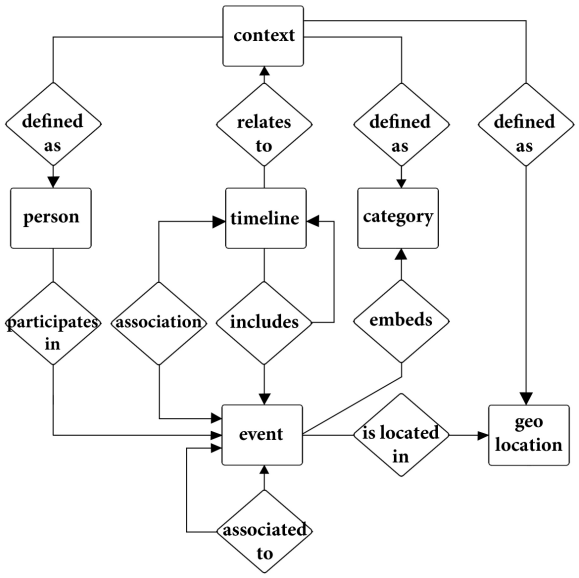

Fig. 5. Core of the timeline ontology

and so on, there are things which are not events but which should be represented in coordination with the timeline (combatant armies, countries that signed a treaty, persons involved to the events, etc.). Every such artifact may have a link to the related timeline. Thus, the associations are as much important as the events.

Here is the list of main timeline ontology entities shown in Figure 5:

- **Event (historical event, artifact)**. Event description is usually represented by the headline summary and associated with date or date range information as well as with links to related resources.
- **Category**. A category represents the event or timeline specific domain (e.g. history, architecture, countries, music, arts, etc.).
- **Timeline context**. A context may have similar sense as an event category, but may also relate to geographic locations, persons or other user defines contexts.
- **Geographical location**. It includes data about geographic coordinates, links to economy, political or cultural contexts bound to geography.
- **Person**. A person indication may be important due to his or her participation in some event. A person may define a timeline context too.
- **Event associations**. Associations are ontology elements that are poorly supported in software tools surveyed in Section III, except the implicitly existing temporal associations. However within the framework of history learning and analysis, associations are very important properties.

When teaching history, an instructor might require shifting learner's focus from the timelines or events themselves to the associations, for example:

- How (and why) two (or more) events are related to each other;
- For what reasons an event can be considered as a cause or a consequence of another one;
- How timelines are related, or how events do affect certain timelines;
- What is the similarity between sets of events in different timelines.

Figure 6 introduces possible associations to be considered as a part of the user interface. We borrowed the *Chronozoom*'s concept of a timeline container and added some supplementary constructs to the picture.

The task of comparing *industrial revolution* periods in Russian and Japanese history serves us as an example. When a teacher (or a learner) considers the industrial transformations in Japan after the long era of Tokugawa family dominance, the events that occurred in Japanese industry, its transportation system, or naval building couldn't be analyzed without paying attention to the *Meiji reconstruction* period, so these two timelines are deeply related. For the case of Russia we can cite an example of *constructivist* trends in architecture which are in strong relation with *industrialization* processes. From the other point of view, the constructivism timeline is affected by the certain event from *Kazimir Malevich*'s biography: Malevich is generally thought as an inventor of the term *"constructivism"*, so there is a dependency between the event and the timeline. Some events may be related despite they are relatively distant: the Russian cruiser *"Aurora"* was a battleship participated in the *Tsushima battle* and later won renown with the blank shot that symbolically started the *October revolution*.

The Figure 6 highlights the issue of implicit conversions that humans often do. An entity considered as an event in one timeline context (e.g. the *Tsushima battle* within the boundaries of *1904-05 Russo-Japanese war* timeline) may be transformed to a timeline if we analyze the battle in details. Unfortunately, there is no direct interface feature that takes this aspect into account.

The next aspect we would like to mention is timeline scales. In all the implementations that we surveyed, the only used time scale refer to traditional (western christian) chronology. However, other traditions to deal with chronology exist and often required to represent timelines in better correspondence to national and cultural contexts and to individual preferences of a historian, to cite a few:

- Russian orthodox church calendar;
- Japanese chronology which refers to their own history pe-

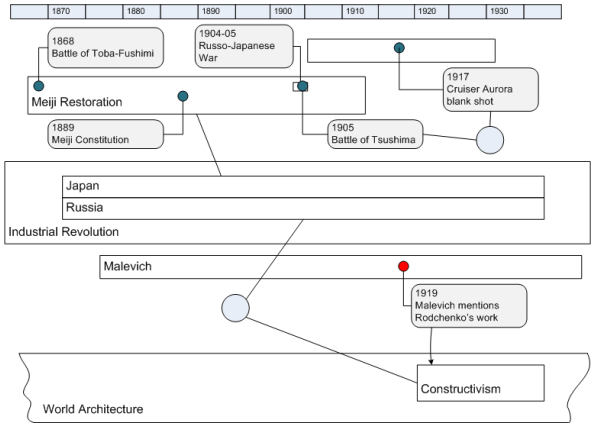

Fig. 6. Artifact associations

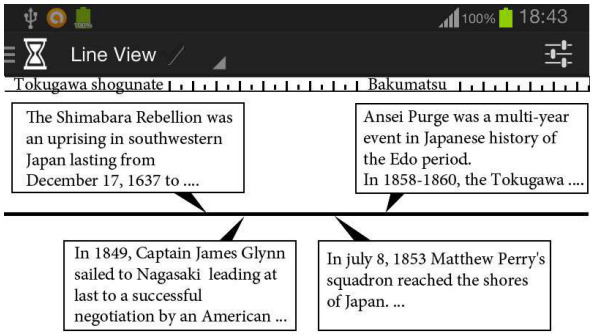

Fig. 9. Headlines and a timeline bar focused view

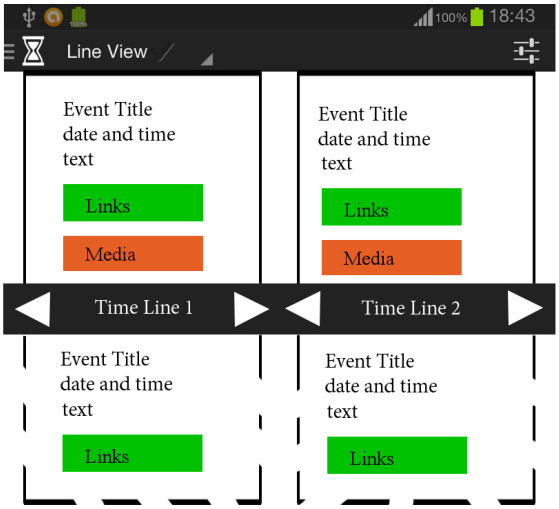

Fig. 10. Descriptions and comparing focused views

riodization like Jōmon, Yayoi, Kofun and to the Japanese era calendar scheme (nengō) referred to the Imperial practice;

- Chinese Han calendar;
- Non-traditional chronologies.

For certain timelines, historians might require possibility to use parallel subchronologies like for a case of the French Republican Calendar used by the French government for about 12 years from late 1793 to 1805 during the French Revolution. Therefore, an alternate timeline might inherit the core chronology but use parallel time scales as Figure 7 illustrates for the selected events represented earlier in Figure 6.

There are speculative feature concepts that are subjects of further discussions. While learning history people sometimes tend to analyse relationships between very distant events. In this case the possibility can be useful to zoom in or out only some selected time regions allowing focusing on event relationships rather than on the chronology. Figure 8 illustrates this issue.

At last, historians often learn parallels between events in quite different time periods (for example, comparing French and Russian Revolutions). In this case a *"shift and fix"* concept can probably serve the idea: virtually moving one timeline over time with fixing another "in place". It seems that digital timelines can assist such kind of history analysis quite easy and therefore provide a space for a process similar to natural science experiments.

VI. Android Prototype Application

A. Interfaces

We started implementing timeline views described in the previous section while developing an Android prototype application. There are two traditional views. The view focused on event headlines allows showing events related to one or more categories attached to the time bar. The view focused on event descriptions allows managing detailed event information and comparing detailed descriptions related to the selected timelines as Figure 9 and Figure 10 illustrate.

In addition to traditional views we design the interfaces for map and grid views (shown in Figure 11) which are timeline

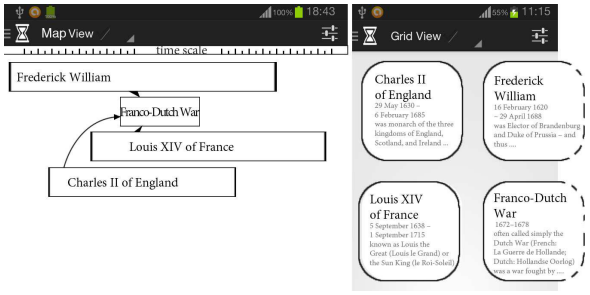

Fig. 11. Map and grid timeline views

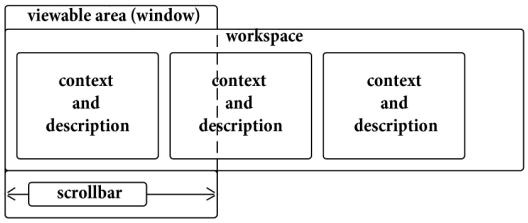

Fig. 12. Sliding window model

association centered. The map view (inspired by a concept of a semantic network) highlights possible relationships between timelines. The map view is aimed to facilitate navigation between related timelines. Evidently, a number of associated timelines can also be considered as a context. The grid view inherits a general concept of a sliding window (see Figure 12) and serves as a kind of an organizational view. It supports timeline arrangements from the user's point of view (similar to application icons) with no direct implications to the timeline relations. For portable devices it is essential to have switching between different views.

B. Database

Currently the application uses its own database aimed to store two types of events. The first group includes events created manually by the user. The second one corresponds to the events grabbed from the Wikipedia used as a history knowledge source. The database structure shown in Figure 13 is developed according to the timeline ontology model presented earlier.

Below the selected database tables are listed with brief descriptions.

All_Keywords table contains keywords used for searching within the *Author*, *Category*, *Geo*, *Person* and *TimeLine* tables.

Synonym table contains keyword synonyms with respect to the context of tables where the data are to be searched. The latter option is necessary since two keywords may be synonyms within the context of one table while keeping independence for another table.

Author_Keyword, *Category_Keyword* and *Person_Keyword* are auxiliary tables used for searching.

Author corresponds to the event description origins: who did create the event description and what was the source.

The *Timeline*, *Context*, *Category*, *Persons*, *Event*, *Association* and *Geo* tables relate to the respective timeline ontological entities. Specifically, the *Geo* table is connected with other tables (*Continent*, *Country*, *Nationality*, *City*, etc.) representing different aspects related to the geographical location, political or social associations.

The *Person_geo* table contains information about geographical locations related to a specific person.

The *Event_and_Person* table connects events with persons involved.

The *Links* table contains links to the external resources related to the event.

Despite the database structure may change in the future revisions, it is nevertheless useful to explain better timeline related entities and their associations.

C. Future work

Except implementing modules depending on designed interfaces, further steps have to be taken to communicate with external services like *Chronozoom* by using their open API. The idea is to consider portable application as an interface which would fit better the requirements and stereotypes of a mobile device user. Another challenging problem (which refers strongly to teh domain of semantic information retrieval) is how to extract relevant information about event associations automatically.

VII. Conclusion

Increasing interests to timeline modeling can serve as an example of how new tasks and user interfaces appear as consequence of computing and web technology and applications development. People create timeline based visual interfaces and visual representations of temporal data to improve knowledge acquisition. Information retrieval algorithms and related information processing techniques are not only about accessing some content rapidly and precisely but also about enabling better human or society understanding of explored phenomena, their relations and their mutual dependency with other phenomena and artifacts.

Historians can use timeline based tools while learning, researching or teaching historical periods discoverable with respect to different national and cultural contexts. Indeed, there is a good reason explaining why do many books on history contain chronology tables. Similar to natural sciences where setting up an experiment is a usual way of study, timelines created with computer tools make arranging learning experiments for history education easier. We may collate similar periods in different cultures, or, conversely, analyze comparable events that took place in different epochs and in different places. We are able even to model prefigured events and historical hypotheses.

In so doing, developers are able create a better framework implementing a concept of active learning in tight cooperation with recent achievements of information retrieval methods and software technology.

***Abstract*—This paper presents a commercial semantic-based system for the Romanian tourism. The Lela system exploits both open linked data from Romanian and international sources, and also proprietary databases in the tourism domain. We present the process of creating the linked data set, based on: i) engineering the LELA Romanian tourism ontology, and ii) populating the ontology by linking open data. The system also provides a natural language interface for the Romanian language. The queries are automatically translated into SPARQL based on a controlled vocabulary derived from the Lela ontology.**

***Index Terms*—Semantic information retrieval, Query interfaces, Natural language processing, Linked Data, Tourism ontology**

I. Introduction

LELA is an intelligent blogging-platform designed for providing personalized information about Romanian touristic places. The user can query both subjective and objective information about places of interest. This is possible because Lela uses a custom made semantic annotation tool for blog posts, that identifies points of interest(POIs) and extracts their features and the sentiments expressed about them. The extracted data is used to annotate posts thus allowing their semantic indexing. Lela also provides a Natural Language Question Answering mechanism that allows users to express queries in Romanian language.

II. System architecture

The Lela system relies on the Lela ontology that we engineered for the Romanian touristic domain. The ontology is automatically populated using two methods: i) linking structured data from various sources in the touristic domain, and ii) using natural language processing of available touristic blogs. In the architecture of the system (figure 1) the *Data Collector* module is responsible for the first task, while the *Data Extractor* structures information from blogs in Romanian language. The *Question Answering* module handles queries in natural language against the assertions in the Lela ontology.

The *Data Collector* module identifies and imports relevant information related to Romanian points of interests by linking touristic information from open data provided by the Romanian agencies, complemented with relevant knowledge from Wikipedia, DBpedia, or Freebase. Data is collected using

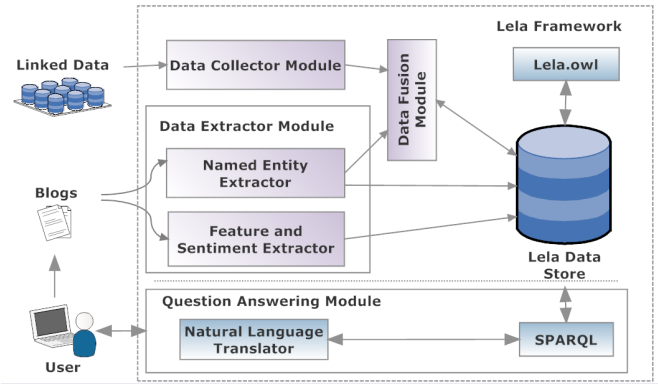

Fig. 1. LELA system architecture.

available SPARQL endpoints or source specific APIs. As information related to the same POI is usually available in more than one data source, we have developed a customized *Data Fusion* module, aiming to identify individuals described in different data sets. Based on information such as geospatial location and textual description, the equivalent individuals are linked via the *same-as* relationship and the various information asserted is fused.

Lela framework provides also a blogging platform where Romanian bloggers can write their stories about the places they have visited. In order to respond to the specific needs of bloggers that already built a readers community and an online reputation via their own blogs built on platforms such as WordPress, Drupal, Blogger, Tumblr, *etc.*, we will provide custom plug-ins for each one of the systems mentioned above, that will allow the semantic indexing of blog posts. Even though the content published on those blogs will not be copied on our platform, it will be available for Lela users to query and explore. This way we will acquire subjective information (stories, opinions) related to POIs.

The *Data Extractor* module analyses the available blogs in order to: i) perform Name Entity Recognition for the main concepts in the Lela ontology: points of interest, accommodation, restaurants or touristic activities; ii) assert different relationships between individuals in the ontology, as they appear in

the blogs, and iii) identify sentiments expressed in relation to each feature of a specific concept in the ontology. For instance, for the `Accommodation` concept, we are interested in opinions regarding features like `location`, `view`, `comfort`, `furniture`, `service` or `value for money`. The facts corresponding to these features (e.g., `Hotel X` serves `good food`) are stored into the ABox using the `Match` concept, which references the blog post that was analyzed, and the position inside the text for the POIs and opinions that were identified(”matched”) by the system.

For opinion detection, we used a machine learning technique based on Conditional Random Fields (CRFs) [1]. We employ this technique in order to find an appropriate labeling for blog sentences, regarded as sequences of words. The labels we try to detect describe the position in a sentence of a word which refers a specific instance of a concept (e.g. ”Grand Hotel Italia”), a specific feature we are interested in (e.g. ”cazare (accommodation)”) and the associated opinion (e.g. ”bun (good)”). For opinion polarity, we used the WordNet-Affect for Romanian [2].

The module which labels the text uses a model generated in the training phase, starting from a set of 200 manually labeled phrases. This set is further expanded by replacing some words of interest (especially the opinion adjectives like ”good”) with their synonyms, thus obtaining more training examples. A set of attributes has been selected for describing each word in the training set, and among them are the word’s Part-Of-Speech, whether the word belongs to an entity of interest and the type of entity. For example, let us consider the sentence ”Am fost la Transilvania International Film Festival si mi-a placut” (I was at the Transilvania International Film Festival and liked it). The attributes associated with the word ”Transilvania” will have the following values: ”NNP” for the Part-Of-Speech, ”B” for the attribute which specifies the name of the entity starts here and ”EVB” for the attribute specifying the word starts the name of an event.

The model generated based on the training example could be improved by expanding the set of examples and/or attributes. A separate module allows adding new attributes (”features” in CRF terminology) and computing their corresponding values before generating the new model. Once this is done, the new model is used to detect the entities the text is talking about, their specific features and the opinion on them. The opinion information gets stored in the A-Box as explained above and can refer either a feature of a concept instance or a pair Activity-Location (e.g., ”skiing” in ”Predeal”).

The opinions concerning each feature of a specific instance are aggregated into a quality score for that particular feature. The function which performs this takes into account both the detected opinion polarities (on a scale from -2/very bad to +2/very good) and the weights specified by the user for each feature s/he might be interested in, according to their importance from his/her point of view. When the discovered Named Entities are not recognized as Romanian POIs available within the Lela Data Store, they are added to the data store as new instances.

III. Linked data creation process

The process of creating the Lela linked data set consists of three main steps: i) engineering a Romanian tourism ontology, ii) developing of data collection and data fusing modules, iii) publishing the resulting data sets.

A. Definition of a Romanian tourism ontology

To develop the Lela ontology, we follow the methodology in [3] and we also enact various ontology design patterns [4].

The later is described in KRSS syntax[1]. The four axes of the Lela-core ontology are `Accommodation`, `Activity`, `EatingAndDrinking` and `PointsOfInterest`, denoted by `POI` (line 1 in figure 2). Apart from those, Lela ontology also offers special classes for describing events, price, infrastructure, contact details, facilities of each point of interest, etc. The main properties defined in our ontology have restricted domains and ranges (figure 2 lines 3-6) which are used to facilitate reasoning among the top level concepts. The partition design pattern [7] was used to partition the top level of the ontology.

Beside the top level concepts, we also introduces the concept `Match` for representing the relations between the touristic places and the blog posts that POIs appeared in. This concept was modelled by enacting the *n-ary ontology design pattern* [7]. The goal was to combine several information about a tourism blog (see fig. 3) regarding: subject of the blog according to the concepts in Lela (line 12), computed score about an instance in the ontology (axiom 13), or provenance information like author, starting and ending text index (text position) which relates to an identified instance in our ontology. As an example, the individual `m1` of type `Match` is related to the blog `b100` via the role `fromBlogPost`.

The point of interest `mateicorvin` is related to the same match `m1` by the relation `hasSubject`. The positive score

[1]For a detailed explanation about families of description logics, the reader is referred to [5], while for the complete KRSS syntax to [6].

```

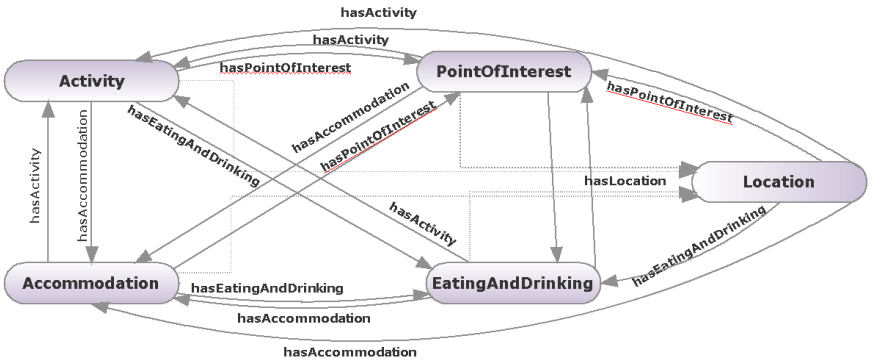

Fig. 2. Top level of the Lela-core ontology module.

of 0.8 in line 22 is computed with a basic opinion mining algorithm from the blog post.

B. Data collection and fusion

We focused on discovering and selecting the relevant open data sets for the Romanian tourism domain. Touristic points of interest are collected from tow sources: i) the available *POI data* sources (Wikipedia, Freebase, DBPedia, Geonames, Wikisherpa, Wikitravel) and ii) Named Entity recognition from touristic blogs. Data fusion is performed in AllegroGraph and saved as a triple store[2], while RacerPro server is used for reasoning on the Lela ontology.

The following sources were exploited: *Wikipedia*, *DBpedia*, *Geonames*, *Freebase*, *Wikisherpa*, *WikiTravel* (table I). A proprietary dataset from Cluj4All (www.cluj4all.com - Recognos' own database about Cluj-Napoca with over 7000 described objectives, from which 1000 relevant touristic points) was also included. The data sets provided by various Romanian governmental agencies were used containing information for Romanian museums, churches, and historical points.

Wikipedia has categorized pages, and some of it's textual content tagged. There are very few consistent patterns followed by the content generators or authors (an exception would be the infobox content in the right side). However we observed that similar tags were used for describing the Romanian touristic objectives, and similar naming conventions for pages. For example, we retrieved values from page that respected the pattern "List_of_places_from_Cityname" from (http://ro.wikipedia.org/wiki/Lista_locurilor_in_Cluj-Napoca).

[2]Available at http://www.recognos.ro/lela/LelaLinkedDataSet.nq

TABLE I
LINKING AVAILABLE DATASETS.

Data set	Available at	Description
Romania Museum Guides	http://data.gov.ro/dataset	Descriptive data and geolocations of 967 museums in Romania
Wikipedia	http://wikipedia.ro	Various categories about Romanian touristic places
Freebase	http://www.freebase.com/	Community-curated database of well-known people, places and things - some about Romania
Geonames	http://www.geonames.org/	Covers all countries and contains over eight million place names - some about Romania
Wikisherpa	http://www.wikisherpa.com/	Data from wikiTravel in a more structured way
DBpedia	http://dbpedia.org/	Structured data from wiki to other external resources
Cluj4All	cluj4all.com	Around 7000 objectives about Cluj-Napoca

TABLE II
LINKING LELA ONTOLOGY WITH DBPEDIA.

Lela concepts	DBpedia concepts
POI	Museums, Castles, Towers, Churches, Cathedrals, Monuments, OutdoorSculptures, Bridges, Parks, Zoos
Activity	Cinemas, Theater, Activity, Shopping
Accommodation	Hotel
EatingAndDrinking	Restaurant

DBpedia organizes its data into triples, and data is linked to external data sets [8].

We queried the DBpedia database for 5 main cities (Bucharest, Cluj-Napoca, Timisoara, Brasov and Sibiu) following a predefined mapping of the 4 main Lela classes to the DBpedia specific classes (table II). A simple example for such

```
SELECT distinct

            FILTER (!contains(str(?subject), "List_of")).
}}
```

Fig. 4. Querying DBpedia for the `Museum` category.

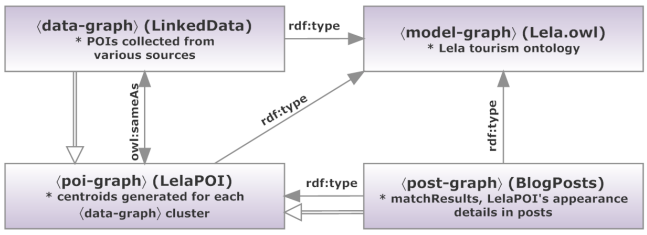

Fig. 5. LELA graph relations.

a query is shown in figure III-B, where where we extracted geospatial data, image, category, abstract and Wikipedia link for all instances of the Wikipedia' `Museum` category. *Geonames* has it's own category and ranking system for objectives. We retrieved the Hotels, Restaurants and Point of Interest for the above mentioned cities. *Freebase* and *Wikisherpa* have similar data collection processes. We accessed these resources through their APIs, and stored the obtained values in the Lela data store. Finally, we imported the xml and xls data from the government provided sources, and the Cluj4All private database.

The above cited data sources have many POIs that are relevant for the tourism domain or for Romania in general. However we only considered those POIs that satisfied both constraints at the same time, for the 5 most significant Romanian cities. As a result, the import process collected around 5.000 POIs, but the data was still noisy, as it contained many overlaps in the form of several instances of POIs collected from different sources semantically describing the same object. In order to overcome this issue, a fusion algorithm was applied. In order to make this process easier, we stored the data in several independent graphs, as the triple store solution we used - AllegroGraph - offers the possibility to partition data for an easier management. The reasoning mechanism can also be applied on the graph-level, not taking into account the several other graphs that might exist in a triple store. This proved to be helpful, when dealing with a bigger amounts of data.

In figure 5 the graph partitioning is shown. We created four separate graphs. The ⟨*model-graph*⟩ contains the TBox details of the Lela ontology. It includes the tourism taxonomy concepts and relations between them, as well as the object and data properties. The ⟨*data-graph*⟩ contains the external data, imported as triples. This graph uses some properties defined by the ⟨*model-graph*⟩ (concepts, label properties for names etc). In the fusion process, in the ⟨*data-graph*⟩ a representative element is created for each group of objectives semantically describing the same element. These groups are called by us POI clusters, and the representative element is the centroid POI. These centroids are saved separately in the ⟨*poi-graph*⟩, and we call them LelaPOIs. They have their derived properties from the cluster data, they also have a `owl:sameAs` property referring their original sources (instances from ⟨*data-graph*⟩). This process supports more efficient query plans, that exploit data from remote sources only when additional information related to a given POI is explicitly requested. Because of the `owl:sameAs` property, AllegroGraph allows us to get any details from data graph. The fourth graph is the ⟨*post-graph*⟩, which contains the blog post related information, like the a blog post's content or the matching details, after the post analysis.

The corresponding algorithm is summarized in Algorithm 1. In a first step, the algorithm finds all the instances that have the same wikipediaUrl, and link them with `owl:sameAs` property. The wikipedia urls are not ambiguous, so the operation will be correct. In a second step, it finds all the instances that have the same freebaseUrl, and if there is `owl:sameAs` between them, then add it.

Thirdly, it checks equality of label values(compare lela:hasName properties). If perfect match found and the objects are located in the same place, and no equality still reported, then link them with `owl:sameAs`.

Fourthly, the algorithm finds all the instances that have the same Web page. If there is no `owl:sameAs` link between them, adds it. Two additional steps have been also applied:

1) *Fusion cities* that have been read and imported from an xls document with cities and instances that have been imported from other resources like Geonames, Freebase.
2) *Fusion counties* that have been read and imported from an xls document with counties/instances that have been imported from other resources (Geonames, Freebase or others) - based on the previously mentioned information and same `lela:hasName` property.

Finally, based on the previously generated groups (a group is considered as a series of elements related by the `owl:sameAs` property) a special instance for each cluster is created in ⟨*poi-graph*⟩ (recall figure 5). The centroid of the group is asserted as an instance of the corresponding most specific concept from the Lela ontology.

C. Saving and publishing the resulting data sets

The data collection process resulted in the import of approximately 5.000 instances, some of them semantically describing the same point of interest, without any flag pointing out their equality. To eliminate this issue, the instances were grouped into clusters, based on characteristics such as their names, wikipedia pages, spatial coordinates, etc. For each cluster, the centroid was selected to became an instance of the `LelaPOI` concept. The centroid and the other individuals in the cluster are linked via a specific `similarity` relationship asserted in the LELA ontology. The unified data set is stored in a local AlegroGraph triplestore [9]. Currently the triplestore contains around 3.200 unique tourism objectives collected for five cities. The points of interest are described by 40.697 of RDF triples.

IV. Querying the linked data set in controlled language

To explore the linked dataset we provide a natural language query interface. The queries can be expressed in a controlled vocabulary for the Romanian language. The queries in natural language are automatically translated into SPARQL. The translation is based on three grammars that we developed in the Grammatical Framework [10], [11]:

1) one abstract grammar, derived from the Lela ontology;
2) one concrete grammar for the Romanian language
3) one concrete grammar for the SPARQL.

First, the abstract grammar in figure 6 is based on the main concepts and roles of the Lela ontology. The concepts in Lela are represented as categories in the grammatical framework, while roles as functions (lines 31-32). Individuals in the ontologies are modelled as instances of generic type *Object* (line 33). Activities are encapsulated as VerbPhrases (i.e., the verb VSki for the ski activity in line 35). Various eating and drinking activities are modelled with a specific verb phase (i.e., *EatingandDrinkingVerbPhrase* in line 36). The function introduces in line 36 is used to represent eating and drinking activities with parameters (i.e., eating pizza). The query template in line 37 is used to match against queries which include modal verbs (i.e., where can I eat pizza?).

Second, the concrete grammar for the Romanian language (figure 8 defines the controlled natural language used to query the system. The relevant verbs in the tourism domain are

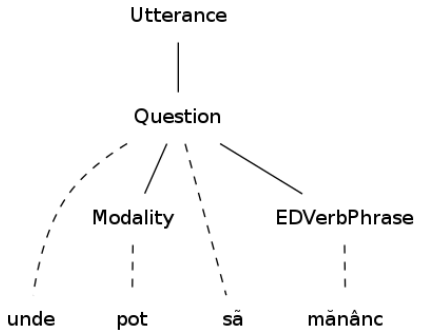

Fig. 7. Parse tree for ”Where can I eat?”. The pronoun is missing because the flexional form of the predicate `EDVerbPhrase` is enough to deduce the agent of the query.

specified (like drink in line 1, eat in line 2, sky in line 3) v_beschX are functions for smart paradigms of a language that provide different inflexion of verbs for different persons, numbers and tenses for the Romanian language. Romanian specific parsing rules are used here to define equivalence between related queries. For instance, specific to the Romanian language is to commit the pronoun in questions like ”Unde pot să mănânc?” (Where can I/We/You eat?), instead of ”Unde pot eu să mănânc?” (Where can I eat?) we define new forms for pronouns `ifemAbsent_Pron` (lines 44-48). The corresponding parse tree is depicted in figure 7, where the personal pronoun does not appear for the Romanian version of the query, as it can be deduce from the verb's flexional form.

Thirdl, the concrete grammar for SPARQL was develop to automatically translate the controlled natural language into a formal query. GF uses the grammars both for parsing and linearizing, therefore a translation from a Romanian phrase to a SPARQL query is done by (1) parsing in the grammar of Romanian language followed by (2) linearising the obtained parsed tree in SPARQL concrete grammar. For each verbal phrase, we give the corresponding SPARQL statement together with the name of the variable that is to be included in the SELECT clause of the query. The grammar in figure 9 is used to translate questions related to eating, drinking or other touristic activities (such as `SkiActivity`), queries which include modal verbs. The SPARQL grammar is exemplified in figure 10. The three queries in Romanian language illustrated in figure 10 are: ”Where can we play badminton?”, ”Where can I ski?”, ”Where is the Agape restaurant?”. The resulted SPARQL code can be used to directly query the Lela ontology

The system allows *qualitative queries* i.e., ”What is the atmosphere at Pizzeria Napoli?”, ”Which is the best restaurant with Romanian cousin?”. Answering to these queries exploits the knowledge provided by the opinion analyser module. The qualitative query ”Which restaurants have good food?” in figure 11 is matched against two concepts in the Lela ontology: i) intersection between `Food` and `Good` and ii) the concept defined by those instances whose role `QuisineQuality`

```
> p "unde putem sa jucam  badminton"
    |l -lang=triple
SELECT ?where, ?activity where {
 ?activity rdf:type ex:BadmintonActivity.
 ?where ex:hasActivity ?activity .
 ?match rdf:type Match . ?match hasSubject
 ?where. ?match hasScore ?score }
ORDER by Desc(?score)

>p "unde pot sa schiez" |l -lang=triple
SELECT ?where, ?activity
WHERE { ?activity rdf:type ex:SkiActivity.
      ?where ex:hasActivity ?activity .
      ?match rdf:type Match .
      ?match hasSubject ?where.
      ?match hasScore ?score }
ORDER by Desc(?score)

>p "unde este restaurantul Agape"
    |l -lang=triple
SELECT ?location where
    { ex:id342451 ex:hasLocation ?location}
```

Fig. 10. Queries in Romanian language automatically translated in SPARQL.

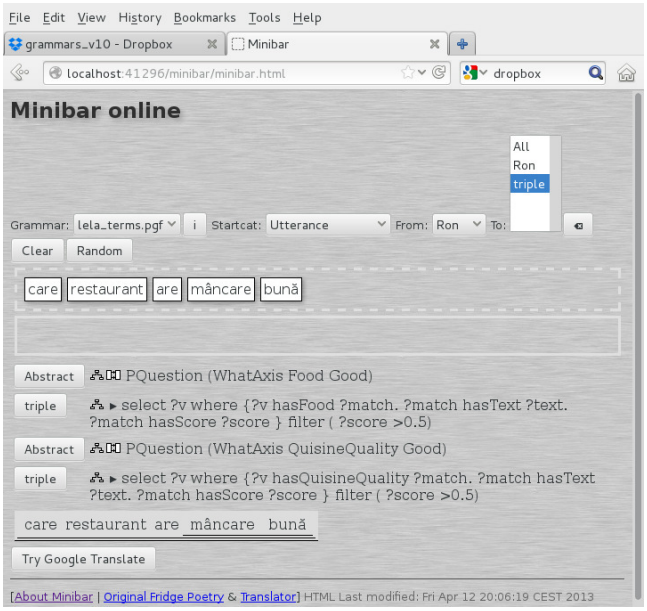

Fig. 11. Qualitative queries filter the results based on the available opinions on the topic of the query.

points towards the concept `Good`. The corresponding SPARQL queries filter the results to those instances classified by the opinion analyser module as positive (that is $?score > 0.5$).

The Romanian grammar is used to generate all the flexional forms of the vocabulary in order to guide the user to generate grammatically correct queries (12). In our case, the vocabulary is restricted to touristic terms from the Lela ontology. After typing a word, the system displays all the possibilities to complete the question in the defined controlled natural language.

To sum up, the translator of from Romanian language to SPARQL is able to handle the following types of queries in

```
41. VDrink = mkVP (v_besch73 "bea");
42. VEat   = mkVP (v_besch52 "manca");
43. VSki   = mkVP (v_besch10 "schia");
44. QWhere&ModVerbPhrase m vp =
45.   mkQS (mkQCl where_IAdv (mkCl (mkNP ifemAbsent_Pron) (mkVP m  vp)))
46.  |mkQS(mkQCl where_IAdv (mkCl (mkNPweAbsent_Pron) (mkVP m vp)))
47. ifemAb&sent_Pron =
48. P.mkPronoun [] "mine" "mie" [] [] "meu" "mea" "mei" "mele" Fem Sg P1 ;
```

Fig. 8. Concrete grammar for the Romanian language.

```
VDrink = {v="?eatdrink"; body="?eatdrink rdf:type ex:EatingandDrinking."};
VEat =   {v="?eatdrink"; body="?eatdrink rdf:type ex:EatingandDrinking."};
VSki =   {v="?activity"; body="?activity rdf:type ex:SkiActivity."};
QWhere&EatingandDrinkingDModVerbPhrase  x y ="select "++ y.v ++ "where {"
       ++ y.body ++
       ++ ``?match rdf:type Match . ?match hasSubject "++ y.v ++"."
       ++ "?match  hasScore  ?score }"
       ++"ORDER by Desc(?score)";
```

Fig. 9. Part of the grammar developed to translate a query into SPARQL.

Fig. 12. Guiding the process of constructing queries: (top) after the word ”ce” (what/how) is types only the grammatically correct flexional forms remain (bottom) the SPARQL version for the query ”How is the food at Agape restaurant?”.

which for each type several linguistic patterns are modelled: 1) Retrieving location of various elements from the Lela ontology (Accommodation, Eating and Drinking, Activities, POIs, etc.); 2) Identifying and describing simple activities (swim, walk) and compound activities (play badminton); 3) Handling queries containing reflexive or verbs with direct object; 4) Handling questions in which the subject is not explicitly expressed; 5) Enhancing verbs with modalities (can, should, may, etc.); 6) Qualitative queries.

V. Discussion and related work

Natural Language to SPARQL. To our knowledge, this is the first system which translates queries from the Romanian language into SPARQL syntax. The system relies on a domain-dependent controlled vocabulary in the tourism domain. For the English language, various systems do exist [12].

The *QuestIO* system [13] is open-domain, with the vocabulary automatically derived from the data existing in the knowledge. The system was designed to handle language ambiguities and incomplete or syntactically ill-formed queries by enacting fuzzy string matching and ontology similarity metrics. We focused on several specific difficulties for the Romanian language like: i) the inconsistent use of diacritics and special symbols, or ii) the flexibility of the sentence structure, which allows questions with or without pronouns.

The ONLI+ system [14] is a portable ontology-driven question answering system for English language. Similar to our work, the RacerPro system was used to reason on the ontology and to retrieve data. Differently, the translation is between English and nRQL, while in our case between Romanian and SPARQL, where both nRQL and SPARQL are recognized by RacerPro.

Another notable effort in the context of Semantic Web is the combination between between ACE and GF from [15]. Approaches for verbalization based on ontology is introduced in [16] for English and Greek languages. A controlled natural language for editing ontology is presented in [17] based on Attempto Controlled English (ACE) language.

Linking tourism data. Regarding the link data component, a similar approach is the tourism linked data set in [18], based on the European statistics data from 1985 about 150 cities in Europe. The Lela system complements linked open data with information extracted from blogs to offer both subjective impressions about places and objective data. Besides DBpedia, YAGO2 [19] focuses on automatically extracting and publishing structured knowledge from Wikipedia. While the DBpedia taxonomy is manually developed and maintained, YAGO integrates the WordNet taxonomy, which leads to a

higher number of classes in YAGO. Expanding our system to manage this richer taxonomy is one of the directions we intend to pursue as future work.

Romanian language processing. For the Romanian language several large annotated corpora do exist (George Orwell's novel 1984, Plato's Republic, ROCO), lexicons (WEB-DEX, CONCEDE, EUROVOC) [20] with the corresponding tools for exploiting these dictionaries (http://dexonline.ro/unelte) None of these resources deal with translation between a natural language and a formal language. We argue that such a translator can trigger various practical development at the application level. A Romanian grammar was developed by [21] that includes 866 grammatical rules and 320 affixes, which have been used for the development of a morphological vocabulary of cca. 30,000 words. For the natural language part of our work we based on the resource library for Romanian developed in [22]. Our morphological vocabulary was generated only for the tourism domain, with the goal to translate natural language queries into SPARQL. Our system for translating Romanian language queries into SPARQL syntax fills, in our view, an important gap among the existing linguistic resources for Romanian language [20].

VI. Conclusions

This paper introduced the Lela commercial product, which intends to be a semantic-based info-point for touristic information in Romania, offering both objective information and subjective impressions about places of interest. It provides data for the 4 main axes: accommodations, eating and drinkings, destinations and activities, with a special focus on the latter one. In order to provide these data, the system integrates Open Linked Data with subjective opinions expressed in articles to generate added value. The system also offers semantic search functionality through the Romanian natural language query interface, which translates the Romanian questions into SPARQL based on a controlled vocabulary derived from the developed LELA touristic ontology.

We are currently applying the natural language processing module to the task of populating the touristic objectives in Lela ontology with specific features identified in Romanian blogs.

The system is intended to be available for public use on http://www.lela.ro by the end of 2014.

Abstract—In recent years, the concept similarity measure has received wide attention in many applications, such as ontology construction, text analysis, image retrieval, etc. Currently, the concept similarity measure depends on the information mining in various knowledge bases, like dictionaries, ontologies, image annotation labels, and search engines. However, these knowledge bases usually only contain semantic information. With the development of the Internet and the popularity of the digital imaging devices, a lot of images and related texts have appeared, which help us to further mine the concept similarity relationships. The concept similarity is the outcome of human subjective perception. In addition to analysis of semantic information, the content of image itself precisely provides the visual perception information, which also plays an important role in the access of concept similarity relationships. To integrate both image semantic and visual information, in this paper we propose an ontology concept similarity measure that simultaneously utilizes the image semantic annotations and visual features to optimize the ontology-based metrics. The experiment result on the Corel dataset demonstrates the effectiveness of our proposed method.

I. Introduction

THE concept similarity plays a critical role in ontology construction and multimedia analysis. It is widely used in different researches and applications, such as ontology learning, semantic disambiguation, text clustering, and information annotation and retrieval.

Generally speaking, semantic similarity quantitatively describes the similarity degree between concepts. Traditional metrics assess the concept similarity relationships by exploiting one or several knowledge bases like corpus and ontologies. With the quick development of the Internet and the popularity of the digital imaging devices such as webcams, phone cameras, and digital cameras, a lot of images and related texts have emerged and formed a much rich knowledge base. For instance, Flickr provides free services for uploading and sharing images, where some necessary information such as titles, descriptions, and labels is usually required. As a large knowledge base, the text information can be used to evaluate the semantic similarity between labels [1]. In this paper, we consider the words 'label' and 'concept' refer to the same thing. However, such way only considers the correlation of text information around images, ignoring the indispensable effect of image visual information. Google search engine stores a wealth of network text resources, which can also help define the semantic similarity of concepts [2]. Compared with ontologies, there are several problems with concepts similarity measure only depending on the above knowledge bases: there is a lot of noisy data resulting inaccurate similarity measure; the concept definition is inexplicit, and cannot be used to distinguish synonyms or antonyms.

To address these problems, we propose an ontology concept similarity measure named OVS that simultaneously integrate both image semantic and visual information. Based on the ontology semantic similarity metrics, OVS exploits the images' visual features and related semantic annotations to optimize the semantic similarity relationships, which are more consistent with human cognition. Compared with traditional methods, the OVS integrates the semantic annotations around images with a variety of semantic knowledge in ontology such as hierarchical structure and semantic relationships, forming a richer semantic knowledge base. Meanwhile, we take images' visual information into consideration, utilizing visual knowledge base to optimize the concept similarity relationships. Integrating multiple knowledge bases together enables our approach to comprehensively express the semantic similarity relationships between concepts.

The main contributions of this paper are summarized as follows:

1. We propose a concept similarity measure by taking both images' visual features and semantic annotations into consideration.
2. We further propose an ontology-based concept similarity measure, which integrates both ontology semantic relationship and visual similarity measure.

The rest of this paper is organized as follows: Sec. II summarizes the existing ontology-based concept similarity measures. Sec. III introduces a novel ntology concept similarity measure named OVS based on the integration of image semantic and visual information. Sec. IV introduces the experiment and the last section is summarization of this thesis.

II. ONTOLOGY-BASED CONCEPT SIMILARITY MEASURES

An ontology is a formal, explicit specification of a shared conceptualization [3]. 'Formal' refers to the fact that the ontology should be machine readable, while 'Shared' reflects the notion that an ontology captures consensual knowledge. The characteristics mentioned above make an ontology be a reliable structured knowledge base. With the rapid development of the Semantic Web, a large number of universal ontologies and domain ontologies are generated and widely applied to knowledge-based systems, particularly, the measure of concept similarity.

One of the most widely used ontologies is Wordnet. It is an English semantic dictionary which is domain-independent. A synset corresponds to a concepts. Wordnet describes more than 100,000 English concepts and multiple semantic relationships between those concepts, such as hyponymy, part-of, synonymy, and antonymy, of which the hyponymy occupies nearly 80%. By connecting the related concepts together with multiple semantic relationships, Wordnet becomes a hierarchical structure or network structure. Based on this, researchers can mine the semantic similarity relationships of concepts with the methods like graph model.

Ontology-based concept similarity measures can be divided into four categories: the path-based method [4]-[7], the feature-based method [8], the IC(Information Content)-based method [9]-[12], and the gloss-based method [13][14]. In this section, we will introduce these methods and analyze the advantages and disadvantages of them.

Ontology can be modeled as a directed graph, in which a vertex represents a concept and an edge represents the hyponymy relation between two concepts. To calculate the similarity of concepts, the most direct method which is proposed by Rada et al. [4] is to compute the shortest path between two concepts, which follows the assumption that the concepts are more similar as the path is shorter. However, this method only considers the path between concepts, which cannot convey the similarity relationships of concepts precisely. Thus, several researches have taken the depth of the concept in the ontology into consideration [5][6]. Furthermore, multiple semantic relationships of concepts in the ontology are exploited, in addition to the hyponymy relations, to measure the semantic similarity relationships of concepts [7].

The advantage of the path-based method is the briefness in computation with the graph model, while faces the disadvantages that:

1. It only considers the shortest path between concepts within the ontology, ignoring the rich semantic knowledge of it.
2. The weight of every edge is identical in this approach. However, in the real sense, the semantic distance of each edge may not the same, which depends on the hierarchy granularity and degree of details described by concepts.

When two concepts are from different ontologies, the path-based method cannot calculate the semantic similarity of the concepts. Luckily, feature-based method can adapt to it. Feature-based method count the common part of property features between two concepts. If the common part is large, the concepts are similar, otherwise not. The property features can be extracted from a variety of semantic information like hypernym. This method describes the similarity degree of concepts more precisely by taking the common characteristic and the difference of concept properties into consideration. However, it usually depends on a large ontology like Wordnet.

In order to make up the lack of path-based measure, Resnik [9] proposed an IC-based method. He tried to utilize the IC shared by concepts to calculate the semantic similarity. IC can be derived from the frequency of concept appearance in a corpus, and the shared part of two concepts is represented by the LCS(Last Common Subsumer). But there is a problem: in terms of two concept-pairs with the same LCS, they will get the same similarity score. To address this problem, Lin [10] and Jiang & Conrath [11] proposed methods to improve Resnik's method. They both considers the IC of two concepts as well as the IC of their LCS, to represent the concepts more comprehensively. The key point of this method is the access of IC, which depends on the corpus after text processing or the ontology with rich concepts. The accuracy of IC-based measure, to some extent, is influenced by the analysis of these knowledge bases.

The gloss-based method was first applied to semantic disambiguation. Lesk [15] compared the glosses of a word in a phrase with the glosses of others, finding the most similar sense as the sense of the word in this phrase. The glosses were described in a dictionary. Then Banerjee & Pedersen [13] replaced it with Wordnet and introduced the ontology in. The premise of this method is the existence of a perfect corpus, including detailed gloss of words. Wordnet can satisfy the requirement which provides the hierarchical structure of concepts and abundant semantic glosses.

III. ONTOLOGY CONCEPT SIMILARITY METHOD BASED ON IMAGE SEMANTIC ANNOTATIONS AND VISUAL FEATURES

In Sec. II, we summarize different categories of the ontology-based concept similarity measures. In general terms, the measure of concept similarity is extracting a variety of semantic information based on different knowledge bases, to find the semantic similarity relationships between concepts. Ontology provides a variety of knowledge sources for semantic similarity measure, which contains a wealth of information on the concept gloss information and other semantic relations with a hierarchical structure based on the hyponymy relations. However, they are all semantic information based on text whether the glosses or the multiple semantic relations of concepts. As mentioned above, there are a lot of images and related semantic annotations on Flickr. Some researchers have tried to use the image semantic

annotations to obtain the similarity relationship of labels. With the fast growing of images on the Internet and the research and application of ontology in image analysis, annotation and retrieval, the visual information of images is richer. And from a visual point of view, we are more likely to perceive whether two concepts are similar. Therefore, we propose an ontology concept similarity measure named OVS based on the integration of image semantic and visual information, which optimize the ontology-based method with images' semantic annotations and visual features, to obtain more consistent concept similarity relationships with human cognition.

A. Semantic and Visual Relations based on Labeled Images

The images in the web usually carry some labels expressing certain semantic concepts. Making use of annotation relationships between images and concepts in terms both semantic and visual correlations, we can obtain more powerful concept similarity measure.

Suppose there are N images, each of which is annotated by one or several labels from M concepts. Then we denote the pairwise similarity relationships between multiple concepts from both semantic and visual aspects using a symmetric matrix R with each element r_{ij} representing the similarity between concept c_i and c_j. The similarity matrix R consists of a semantic relation matrix and a visual relation matrix respectively characterizing the correlations between concepts and images based on the semantic annotations and visual features.

The semantic relations matrix S is a matrix of $M \times N$. Each element of S is expressed as followed.

$$s_{ij} = \begin{cases} 1 & \text{if image j is annotated by concept i} \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

Visual relations matrix V is also a matrix of $M \times N$. Each element of V represents the similarity between the visual features of concepts and images. Each concept i corresponds to a subset of images annotated by it. The visual features of concept i then can be described by the subset of images. We take the average of all these images' visual features from the subset as the visual feature of concept i. With the visual features of concept i by f_i and that of image j represented by f_j, we calculate the element v_{ij} of V as followed. In this paper, we choose SIFT to be the visual features of images, as it has demonstrated its out-performance in some benchmark evaluation comparing with various global features and local feature descriptors.

$$v_{ij} = \cos(f_i, f_j) = \frac{\langle f_i, f_j \rangle}{\|f_i\| \|f_j\|} \quad (2)$$

In practice, not every image shows strong similarity to its concept due to the visual variation of each concept, which will assign a lot of undesired images with small similarity to each concept in the dense matrix V. In order to make the visual relations matrix V robust to the variations, we only select the top k concepts with highest similarity for each image, thus forming a sparse visual relations matrix V. The smaller the value of k, the more sparse the visual relations matrix V (the value of k is determined in Sec. IV.C.1).

B. Concept Similarity based on Image Semantic and Visual Relations

To incorporate both semantic and visual relations in the labeled image sets, we adopt a linear combination of V and S to get a comprehensive relations matrix VS,

$$VS = \mu * V + (1 - \mu) * S \quad (3)$$

where μ in (0,1) is the weighting factor, which balances the contribution of the semantic and visual information (the value of μ is determined in Sec. IV.C.2) in the concept similarity measure.

Based on the fused relation matrix $VS = [y_1, \ldots, y_m]^T$, where the m-th row y_m is the comprehensive relations vector of concept m. If two concepts share close semantics, then their comprehensive relations vectors should be very similar. Therefore, we employ the cosine similarity between the comprehensive relation vectors as the semantic similarity between two concepts.

$$r_{ij}^{VS} = \cos(y_i, y_j) = \frac{\langle y_i, y_j \rangle}{\|y_i\| \|y_j\|} \quad (4)$$

By calculating the pairwise similarities between all concepts, we can obtain the similarity matrix R based on image semantic annotations and visual features. The above method for the concept similarity measure is named VS method.

In practice, the semantic annotations of the image are often incomplete, which leads to the sparsity of the semantic relations matrix S. In this case, the method only relying on image semantic annotations hardly obtains an accurate semantic similarity relationships of concepts. However, the VS method introduces the image visual information in Sec. III.A which hopefully compensates for the lack of semantic information.

One problem in the process of calculating the visual relations matrix V when only a few limited labels are available is that, the incompleteness of the semantic information will result in the bias of the visual feature center of each concept, which will adversely affect the visual relations matrix V. To solve the problem, attempts(like EM algorithms) that iteratively find the near-optimal visual feature center of each concept can be adopted.

C. Ontology Metric with the Concept Similarity

We have presented a concept similarity measure VS based on image semantic annotations and visual features. In this section, we will utilize it to optimize the metrics based on ontology. Ontology provides a wealth of semantic knowledge, especially the universal ontology (e.g. Wordnet), which does

not depend on specific areas and is more consistent with the human conception. On the other hand, the human visual perception is also the important factor that affects the judgment of the concept similarity. The visual feature of the image is one general way to precisely express the concept of human visual perception. Therefore, fusing the combination of both semantic and visual relations into the traditional ontology metric can effectively compensate for the lack of the rich and complex relations in ontology.

Specifically, we adopt the parameter weighting method [16]-[18] to calibrate the ontology similarity metric using the concept similarity R based on the semantic relations and visual relations extracted from a number of labeled images. Since the sparse semantic annotations in images usually introduce certain bias in the similarity measure, it is better to fuse the ontology metric and concept similarity measure in a robust way. In this paper, we propose a novel method named OVS in short, which adopt the popular exponential production to robustly incorporate the visual-semantic relations in the ontology metric. Namely, for any two concepts c_i and c_j, their final ontology-based concept similarity is as followed.

$$r_{ij}^{OVS} = r_{ij}^{O} \exp(r_{ij}^{VS}) \quad (5)$$

In the above formula, r_o is the concept similarity based on ontology while r_{vs} is the concept similarity based on image semantic and visual information.

IV. Experiment

A. Methods for Comparison

In order to verify the effectiveness of the method OVS we propose, we conduct several comparative experiments with two kinds of metrics, which are metrics based on the ontology and metrics based on the image semantic and visual information, as shown in Table I.

TABLE I.
METHODS FOR COMPARISON

B. Evaluation Benchmark and Indicator

The objective evaluation of concept similarity is very difficult as the concept similarity is a human's subjective perception. To compare the methods fairly, some scholars have constructed artificial evaluation datasets as the groundtruth. This dataset contains a number of concept-pair, judge by a group of people with a similarity score. The average of valid data is the similarity of the concept-pair. In early, Rubenstein & Goodenough [19] and Miller & Charles [20] constructed those datasets, which are widely used to evaluate and compare the similarity measure. The current popular datasets are WordSim-353 [21], MEN [22], RWS [23], etc. MEN is constructed by Elia Bruni, containing 3000 concept-pairs with high frequency of appearance, in which the similarity is in the range of 0-50. We choose Corel [24] to calculate the concept similarity, which contains 260 concepts. Based on the consideration of the above two aspects, we selected overlap portions of MEN and Corel as the target concept, which contains a total of 96 concepts, composing 118 concept-pairs.

Considering the artificial evaluation of concept similarity and the metric result as two sequences, their relevance is the indicator to judge semantic similarity metrics. The correlation is 1 if the scores are both exactly the same , which means that the results of the semantic metrics is consistent with human perception, while correlation of 0 means that the result of semantic metrics and the result of human perception are completely irrelevant. Currently the most widely used methods are the Pearson and Spearman correlation coefficient. Pearson correlation coefficient is calculated as

$$\rho_p = \frac{N\sum x_i y_i - \sum x_i \sum y_i}{\sqrt{N\sum x_i^2 - (\sum x_i)^2}\sqrt{N\sum y_i^2 - (\sum y_i)^2}} \quad (6)$$

In the above formula, $x_1,x_2,\ldots,x_n$ and $y_1,y_2,\ldots,y_n$ are the result of human judgment and semantic metric. Spearman correlation coefficient is usually considered to be the Pearson correlation coefficient between the variables after ranking. We need to rank the sequence first. If the rank is identical, the Pearson and Spearman correlation coefficients are equivalent according to the equation (6). Otherwise it is calculated according to the following formula,

$$\rho_s = 1 - \frac{6\sum_{i=1}^{N} d_i^2}{N(N^2-1)} \quad (7)$$

where d_i is the difference of x_i and y_i.

C. Results and Discussion

In order to verify the effectiveness of the method OVS, we conduct several comparative experiments with two kinds of metrics, which are metrics based on the ontology and metrics based on the image semantic and visual information.

1) The Impact of the Sparse Degree of Visual Relations Matrix

In Sec. III.A, we consider removing the interference data of visual relations matrix V, and only selecting the first k concepts with highest similarity of the image, thus forming a sparse visual relations matrix V. The smaller the value of k is, the higher the sparse degree of V is. In this section, we take the experiment to evaluate the value of k.

Parameter μ is the weight factor for the image semantic and visual information. $\mu = 0$ means to calculate the semantic similarity matrix R with only image semantic annotations, while $\mu = 1$ means to calculate R with only image visual features. We take the case of $\mu = 0$ as our basis, to calculate the top 10 similar concepts of each concept on Corel. And then we calculate the top 10 similar concepts with different values of k in the case of $\mu = 1$. After all, the accuracy of the top 10 similar concepts with different values of k, with respect to the case of $\mu = 0$ is seen as the index to judge the sparse degree of V. As the number of labels belonged to a image is limited, we set the range of k as 10 or less. The result is shown in Fig. 1.

As Fig. 1 shows, with the increasing of k , the sparse degree of V decreases and the accuracy of top 10 similar concepts decreases accordingly. It is obvious that the value of k should be as small as possible. But if the value of k is too small, it will cause the over lost of the information in V. So in the following experiment, we take k = 5.

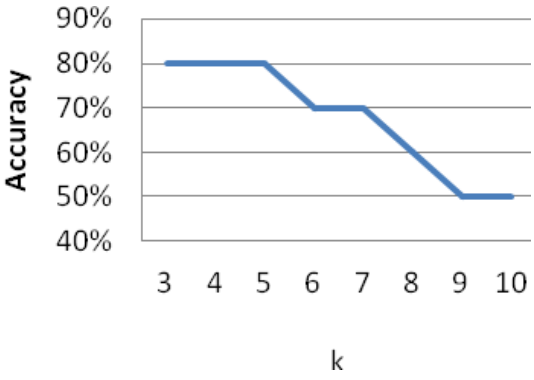

Fig. 1 The accuracy of top10 similar concepts with different values of k

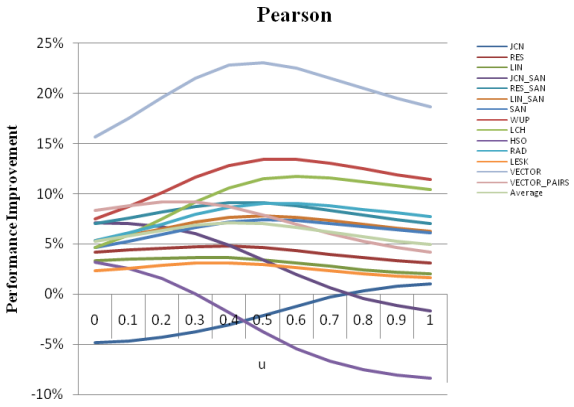

Fig. 2 Performance Improvement of Pearson correlation coefficients

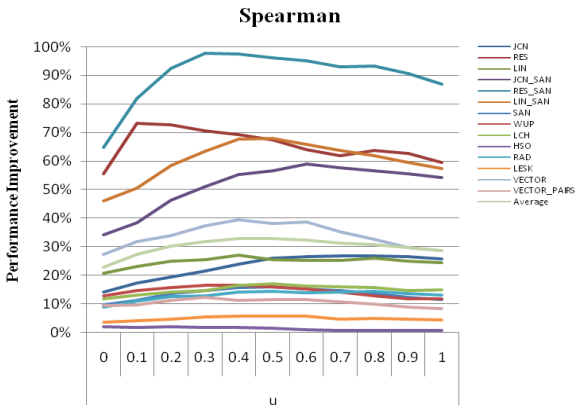

Fig. 3 Performance Improvement of Spearman correlation coefficients

2) The Choice of Weighting Factor μ

In Sec. IV.B, we propose the evaluation benchmark and index of semantic similarity metrics. First, we calculate the semantic similarities of the target concept-pairs with the ontology-based metrics listed in Table I, and then calculate the correlation coefficients of every single result of those metrics with human judgment. Secondly, based on those ontology metrics in Table 1, we utilize OVS method proposed in Sec. III.C we calculate the semantic similarities of the target concept-pairs separately, and then calculate the correlation coefficients of these results with human judgment. Finally, we calculate the correlation coefficients promotion of results based on OVS with respect to the results of ontology-based metrics, and the result is shown in Fig. 2 and Fig. 3.

As Fig. 2 and Fig. 3 shows, each curve represents the change trend of the correlation coefficients promotion of the

OVS method based on every ontology-based metrics with different value of μ. Due to the different methods to get the concept similarity, which leads to different rank, Pearson and Spearman correlation coefficients are not the same. But the changing trend of promotion with different value of μ is almost the same. In Fig. 2, except that the Pearson promotions of OVS based on JCN, HSO, JCN_SAN metrics vary monotonically with different value of μ, the promotions of OVS based on other ontology-based metrics get the maximum value with the value of $\mu \in (0.3,0.6)$. We also can find the similar conclusion for Spearman promotion. Based on the analysis above, in the sequent experiments, we take the optimal value $\mu = 0.5$.

3) Evaluation of Concept Similarity Method

As Fig. 2 and Fig. 3 shows in Sec. IV.C.2, the concept similarities based on OVS get a promotion with respect to ontology-based metrics, except JCN, HSO and JCN_SAN. We also can get the same conclusion from Table II.

In addition, we can also get the idea from Table II that the path-based and gloss-based methods among the ontology-based methods have the best effect whether they are based on ontologies alone or based on the OVS, especially for the LCH metric, while IC-based methods have the worst. However, the IC-based methods get a promotion after the optimization of OVS. It is clear that the OVS method integrating the image semantic annotation and visual features together can achieve better performance than ontology-based methods. We also can find that in most cases the OVS method based on ontology metrics have a better effect than the VS method we proposed in Sec. III.A. Thus, we believe that the concept similarity relationships derived from ontologies and image semantic and visual information together is superior to the methods of ontologies or image semantic and visual information.

V. CONCLUSION

In this paper, we summarize the concept similarity methods based on ontology, and presents an ontology-based concept similarity method OVS integrating the image semantic and visual information. Firstly, OVS get concept similarities with different ontology-based metrics, then compute another concept similarity with the image semantic annotations and visual features as a knowledge base, and finally integrate the two kinds of measurement, constituting a new concept similarity measure. In the experiments, we discuss and determine the OVS method parameter value and compare the methods based on ontology and image semantic and visual information with the evaluation benchmark of human judgment. The result verifies the effectiveness of the proposed method OVS.

In this paper, we measure the concept similarity relationships on the Corel dataset, which contains less visual information than the images in the network. As future work, we plan to apply our method to large datasets like Imagenet and applications like image annotation and retrieval.

1st Complex Events and Information Modelling

COMPLEX Events and Information Modelling (CEIM). Event modelling is a method of intelligent analyzing streams of information (data, percepts) about things that happen (events), and deriving conclusions from them. The goal of CEIM is to identify meaningful events and respond to them appropriately and quickly. We define the complexity of the event as both the complexity of the modelled physical phenomenon (fire, weather, chemical reaction, biological process) as well as the heterogeneity of the data (digital images, percepts, sensory data, natural language, semi-structured and structured data). In addition, the emphasis should be placed on the intelligent aspect of these models. This means that systems should semi- autonomously perceive their environment and take action.

The workshop on Complex Events and Information Modelling provides an interdisciplinary forum for researchers and developers. The workshop is mostly intended for applications of Artificial Intelligence in Fire Safety domain, but we also encourage researchers from other fields: health care, smart buildings, ubiquitous computing, process mining and others. The workshop covers the whole range of theoretical and practical aspects, technologies and systems and aims at bringing together specialists for exchanging ideas and promote interdisciplinary discussions.

Topics

- Artificial Intelligence techniques in Fire Safety,
- Data Assimilation and Smart Buildings,
- Evacuation models,
- Cognition and Decision Making models during Emergency,
- Sensory data storage representation and processing,
- Ubiquitous computing,
- Uncertainty modelling,
- Automated reasoning,
- Risk Management,
- Knowledge Discovery, Data and Process Mining,
- Decision Support Systems,
- Knowledge Modelling.

Heuristic to Build RCC8 for Event Locations

Majed Ayyad
University of Trento.

Trento, Italy
Email: ayyad@disi.unitn.it

Abstract—**Events that are detected and reported by humans to actionable knowledge bases in multi-tier responding agencies have signi cant amount of spatial information. Humans have intuitive ability to triage repeated or duplicated events based on their spatio-temporal information. However, this cognitive process is not modeled easily and human ability is limited in situations where large number of events are reported simultaneously. The likelihood of two events to be the same is higher if they occur on the same place and time. In this work, we focus only on calculating location equivalence of events. For this purpose we use RCC8 theory to represent spatial relations between regional locations. The algorithm designed approximates the arbitrary shape of regions into circles and build region connection relations based on the size of the circle. The end result is a region of circular tiles with explicit RCC8 relations that could be used to reason on the relation between the locations of events. Additionally, we outline some experiments to evaluate the precision and recall of the results based on the used corpus. These results indicate that although the task is challenging, automated methods are capable of building spatial regional relations between events.**

I. Introduction

DESPITE advances in technology and ubiquitous computing, a large volume of events are still detected and reported by human beings. Statistics about emergency rooms or command and control rooms still report about receiving hundreds of calls per day from the public. In such situations, operators log each call and forward it to a dispatcher or commander. Typically , dispatchers and operators sit next to each other, so they can rapidly share information among one another in case the system is jammed with calls and there are emergencies to reply to. The efficiency of this system is measured by the number of abandoned calls and the response time of the first responder (the dispatched resource to the event site). To improve both elements, commanders could benefit from having a system that can work on the triage of events logged by operators and improve the decision making process before taking any action. In such situations, there is a need to triage repeated or duplicated events in real-time. We call this as the event matching problem which is the process of finding similarity between two events and is computed as 3-tuples $<e_1, e_2, R>$, where R specifies a similarity relation. Possible forms for R are : equivalence (=), sub-event ($\subset$), and mismatch ($\perp$).

Davidson[2] and Quine [3] argue that two events are identical if they occupy the same portion of space and time. Therefore, for two events to match or (when x= y ? ; if x an y are events) is to find the necessary and sufficient conditions for identical events. The matching criteria depends on a set of elements which we can summarize as : time, location, physical objects, cause and effect, existential conditions and properties. Therefore to match two events we need to calculate their time equivalence , location equivalence, causal equivalence and properties equivalence using other arguments such as participants and objects.

Comparing the location of two events is not always a straight forward, especially when events are reported using natural language. Different qualitative spatial relations are used to express the location of an event with other spatial entities. For the orientation aspect, events are described using qualitative terms such as “north of”, “in front of”, ”behind”, etc. Many approaches and calculi have been used to express the orientation of one object on reference to another. Most approaches use points as the basic spatial entities and use different versions of JEPD orientation relations. Distance qualitative relations are also used when describing the location of events. For the distance aspect, terms such as “near”, “far”, “close to” are commonly used. As mentioned by [7] combining the orientation and distance aspects is called positional information

In this work, we use the Region Connection Calculus (RCC8) theory to partially solve the event matching problem. A location is defined as an inherently grounded spatial entity, a location includes geospatial entities such as countries, mountains, cities, rivers, etc. It also includes classificatory and ontological spatial terms, such as edge, corner, intersection[4]. The location element covers both locations and places (where a place is considered a

978-83-60810-58-3/$25.00

functional category), and is assumed to be associated with a region whenever appropriate[10]

The main objective of this paper is to demonstrate how connectedness relations between geographical spaces could be calculated automatically. The following five topological relations between locations are built: (1) Equal (2) Externally Connected (3) Disconnected (4) Tangential Proper Part, and (5) Non-Tangential Proper Part. In this work, and by using a dataset of a country we build RCC8 relations between cities, towns, villages, suburbs and points of interests.

For this purpose , we use an approximation technique to represent a region as circular shape. Furthermore, we represent a country map from circular tiles. The radius of the circle is calculated based on the type of the region being a city or a hamlet as an example. Other parameters are also considered if available such as the area and population of a region. We show that our heuristic algorithm to build RCC8 relations between country regions and places is likely to achieve acceptable results

This paper is organized as follows. Section 2 includes background information on RCC8. Section 3 describes the estimation problems and their formulation. Experimental results are presented in Section 4 and the paper is concluded in Section 5.

II. The Region Connection Calculus

A. RCC8 relations

There are different aspects of space related to describing the event location on reference to another object. The location of an event could be expressed using a combination of orientation relations, distance relations and topological relations. While orientation and distance relations are important, in this paper we focus only on topological relations. Topology in mathematics concerned with the most basic properties of space, such as connectedness, continuity and boundary, while in qualitative spatial reasoning, the focus is on mereotoplogy [5].

In the Region Connection Calculus, regions are the basic spatial entities and relationships between spatial regions are defined in terms of the binary relation C(x; y),meaning spatial entity x connects with spatial entity y, which is true if and only if the closure of region x is connected to the closure of region y, i.e. if their closures share a common point[7]. Using the relation C, many versions of RCC could be found for instance RCC1, RCC2, RCC3, RCC5, RCC8, RCC15, and RCC23. The most common used and researched version is RCC8, which defines the following eight Jointly Exhaustive and Pairwise Disjoint (JEPD) relations : disconnected (DC), externally connected (EC), partially overlaps (PO), equal (EQ), tangential proper part (TPP), nontangential proper part (NTPP), tangential proper part inverse (TPPi) and nontangential proper part inverse (NTPPi) [8]. The intended meaning of these relations is illustrated in table (1).

B. Reasoning using RCC Relations

Since events are spatio-temporal entities, it is natural to use spatio-temporal reasoning to reason about the location of events. Studying how people report about the location of events, we notice that qualitative knowledge is used to express the event location as could be seen from the following example:

Event 1 : 8 Palestinians are arrested across the West Bank

Event 2: Thursday eight Palestinians arrested from Jerusalem, Jenin and Hebron, according to local and security sources.

In these two events , the event location is expressed using different qualitative representations which are used with different levels of granularity and expressiveness. When performing reasoning about the location of the two events, we may need to know if West Bank contains Jerusalem, Jenin and Hebron. Other aspects of event locations are usually described qualitatively, such as distance, orientation and topology.

Furthermore , There are many places that share the same or similar names (“AL-Tireh” :a neighborhood in Ramallah city;“AL-Tireh” : a Village in Ramallah region and “AL-Tireh”: a village north of Jenin city) . Also some places have multiple names(e.g. AL-Manarah square is also called Lions square). Some places are called after the most famous point of interest found near that place.

With RCC we can reason if two events have the same location by using the connection relations as explained in the

TABLE I.
DEFINING RCC8 RELATIONS[10][13]

Name	Symbol	Relation	Meaning	Definition
Equals	EQ	EQ(x,y)	X is identical with y	X = Y
Disconnected	DC	DC(x,y)	X is disconnected from	X ∩ Y = ∅
Externally Connected	EC	EC(x,y)	X is externally connected to y	i(X) ∩ i(Y) = ∅, X ∩ Y 6= ∅
Partially Overlap	PO	PO(x,y)	X partially overlaps y	i(X) ∩ i(Y) 6= ∅, X 6⊆ Y, Y 6⊆ X
Tangential Proper Part	TPP	TPP(x,y)	X is tangential proper part of y	X ⊂ Y, X 6⊆ i(Y)
Non-Tangential Proper Part	NTPP	NTPP(x,y)	X is non-tangential proper part of y	X ⊂ i(Y)

following rules :

Disconnected: Since one event cannot take place into two separate locations , and we have two events with disconnected locations, we can deduce that these are two different events .

$$\frac{(e_1\ in\ x) \wedge (e_2\ in\ y) \wedge (\boldsymbol{DC}(x,y))}{e_1\ \not\cong\ e_2}$$

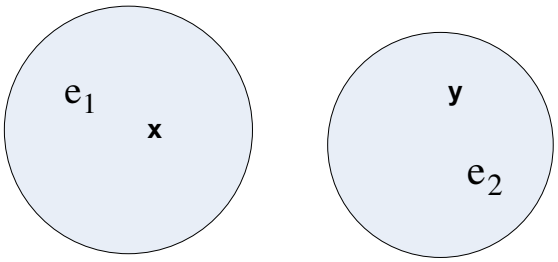

Fig. 1 Disconnected regions

Equal: If the two regions are equal , then at least one condition is met in the matching criteria, therefore it is possible that these two events are matched.

$$\frac{(e_1\ in\ x) \wedge (e_2\ in\ y) \wedge \left(\boldsymbol{EQ}(x,y)\right)}{e_1\ \cong\ e_2}$$

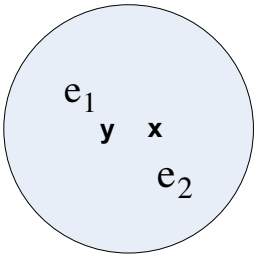

Fig. 2 Equal regions

As in the following two events, if we know that Radio street and Al-Ersal street are the same street from our knowledge base then this condition is met.

Event 3 : On 11 May 13, 11:14 hrs, reportedly, a car accident was reported in Radio street

Event 4 : On 11 May 13, 11:18 hrs, a car accident was reported in Al-Ersal street

Externally Connected: with externally connected regions, there is a possibility that the two events are taking place at the border of these two regions, therefore it possible that these two events have equal location and therefore a possible match.

$$\frac{(e_1\ in\ x) \wedge (e_2\ in\ y) \wedge \left(\boldsymbol{EC}(x,y)\right)}{e_1\ \cong\ e_2}$$

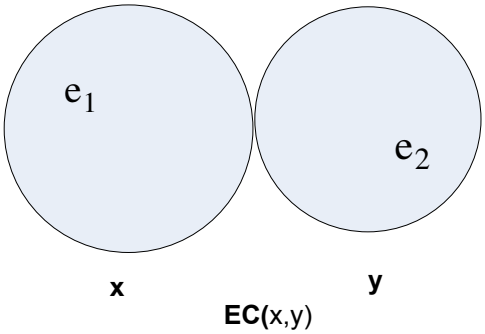

Fig. 3 Externally Connected regions

Event 1 : On 31 Mar 13, 0930 hrs, approximately 40 people demonstrated at DCO Beit-EL, NE Ramallah. It ended peacefully at1440 hrs.

Event 2 : On 31 Mar 13, between 0945-1200 hrs, families protested near City Inn Hotel, NE Ramallah against prisoners conditions.

Non tangential proper part: The semantic of the non tangential proper part is that region R1 is totally inside region R2 and that they are not equal and do not share any border.

$$\frac{(e_1\ in\ x) \wedge (e_2\ in\ y) \wedge \left(\boldsymbol{NTTP}(x,y)\right)}{e_1\ \cong\ e_2}$$

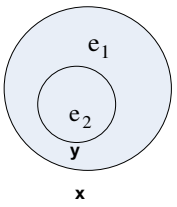

Fig. 4 Equal regions

Event 1 : A house in fire , in Jaffa street , second floor , near store AL-Manara close to AL-Families park

Event 2 : A smoke is seen ,near supermarket AL-Manara in Ain-Munjid area.

In these two events , Al-Families park is located in Ain-Munjid area.

Tangential proper part: in TTP relations, there might be more than two regions involved in the event. If x,y, and z are regions then y and x might be connected through a TPP , also y and z might be connected through a TPP**.**

$$\frac{(e_1\ in\ x) \wedge (e_2\ in\ y) \wedge \left(\boldsymbol{TTP}(x,y)\right)}{e_1\ \cong\ e_2}$$

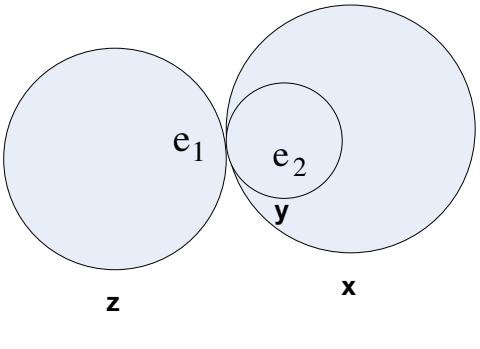

Fig. 5 Different TPP relations

Event 1 : A teen is injured in clashes near Jerusalem
Event 2 : A 17-year-old student was injured Thursday morning during clashes in the town of Abu Dis.

A main advantage for using RCC to reason about the location of events is that as examined by [9] , RCC is structurally similar to the way people reason about space and is a model of people's conceptual knowledge of spatial relationships).

III. Calculating RCC Relations

A. Region Ontology

In this paper all the examples are taken for events located in populated places. A populated place is an area of land inhabited by people. Therefore cities, villages , hamlets , towns, townships ,etc. are type of populated places. By definition, what mainly characterize an entity from another is its area. It is common to find the following definitions: a village is small human settlement, or a city is a large settlement and a hamlet is just a few dwellings[12]. Location and regions are more important for our work, however places are sometimes used to describe a region by its functional place like “city center”. A city center is a circle on a map to indicate the center of the city and it is only perceived by the human mind.

We have noticed that the three themes of geography (location, place and region) are used to describe where an event occurred or is happening. An observer uses `relative location` to describe the event when the observer is not familiar with the area. Also `absolute locations` are used when the observer knows the address of the event. Functional locations such as ‘city center’ or `formal` name such as ‘ name of the city’, or `vernacular` region such as ‘at the south area of the city’ are all used to describe an event location.

To model our regions, we use a region ontology where the country regions are classified into populated places and administratively declared places as shown in Figure

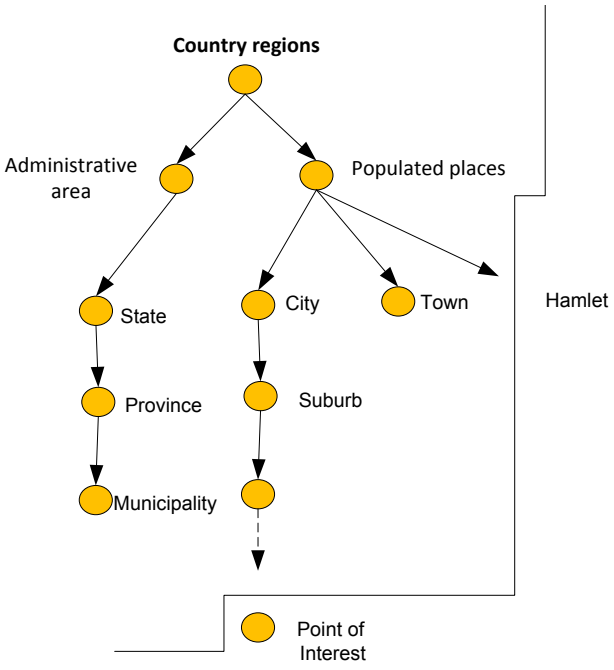

Fig. 6 Classification of a Country Region

Populated places are classified into `extended entities` such as city and `non-extended` entities such a point-of-interest. All populated places are disjoint classes and are continuous and have no holes. Suburbs and neighborhoods are part of a larger entity and is represented in one of the following forms :

NTPP: a suburb(S) has an NTTP relation with a town (T) if a suburb lies in a town and shares no border with it. The relation is denoted by S NTTP T

TPP: a suburb(S) has a TTP relation with a town (T) if a suburb lies in a town and shares borders with it. The relation is denoted by S TTP T

EC and **DC ,** this relation holds between suburb of a larger entity such as a city or town.

B. The Algorithm

The proposed methodology for calculating RCC between geographical regions is to approximate the exact region tiles by circular tiles as shown in Table (2). In the case of a country regions, the frame of reference is the partition of the country into cells which share boundaries but do not overlap. RCC relationships could then be calculated by using the longitude and latitude of the region as the center of the cell and then calculating the distance between cells.

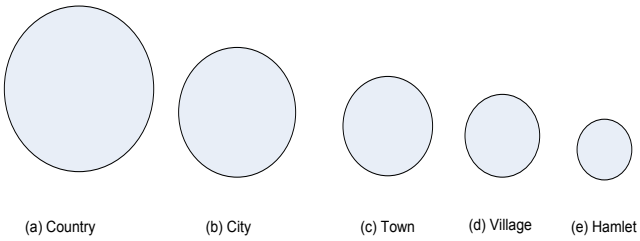

Fig. 7 Region Classification based on approximate area size

The difference between each type is identified by a set of features specially the size of the region. By comparing the distance between center of the cells and the reference distance, we can calculate the following relations:

Disconnected (DC): if two cells, R1 and R2, share no border then the relation between them is denoted by R1 DC R2. This is calculated using the following formula

DISTANCE(R1, R2) > (2* α + c) ; α denotes a constant that represents the maximum radius of a town and c denotes an error margin constant

Externally connected (EC): if two regions, R1 and R2, share borders then the relation between them is denoted by R1 EC R2.

DISTANCE(R1, R2) < (2* α + c)

Equals (EQ): the relation between each town, or any other location type, and itself is denoted by R1 EQ R2.

DISTANCE(R1, R2) < c

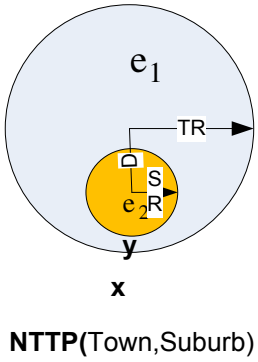
Both DC and EC relations are bidirectional. The algorithm is basically divided into three main parts : (1) calculates relations between town or cities (2) calculates relations between suburbs and towns (3) calculates relations between point of interests and suburbs or town with no suburbs. Following pseudo code illustrates how to calculate relations among towns in a country.

Pseducode for RCC8 Relations among towns/cities

```
Declare region Radius α // represents the maximum radius in meters
Declare c //  denotes an error margin constant defined in meters

Input region dataset containing longitude, latitude, place name
TOWNS_SET = FIND_ALL_LOCATIONS_BY_TYPE ("TOWN")
POIS_SET = FIND_ALL_LOCATIONS_BY_TYPE ("POIS")
SUBERBS_SET = FIND_ALL_LOCATIONS_BY_TYPE
("SUBERB")
BEGIN
   Build RCC8 Relations among  towns
   Build  RCC8 Relations among Suburbs and Towns
   Build RCC8 Relations among places of interests, towns and suburbs
   and towns
END
Output  set of Relations between all regions {EQ,DC ,EC} //
same type.
```

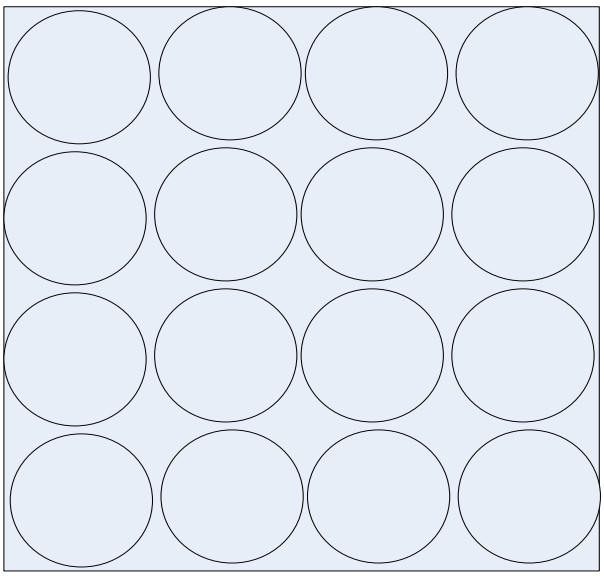
C. Building Town Suburb Relations



NTTP(Town,Suburb)

Fig. 8 NTTP(Town, Suburb)

TABLE II.
(A) APPROXIMATION USING CIRCULAR TILES (B) EXACT REGION TILES



(a) Approximation using circular tiles

(b) Exact region tiles

The second part of the algorithm is concerned with building the relations between towns and suburbs.

TownRaduis > Distance + SuburbRaduis + Constant

This part of the algorithm try to build the town or city suburbs only based on the input data which are are the lat,lon and suburb name.

D. Building Suburb- Suburb Relations

Building the suburb-suburb relations , follows the same approach for towns except we limit the comparison among a city or town suburbs.

Externally connected (EC): if two regions, S1 and S2, share borders then the relation between them is denoted by S1 EC S2.

Equals (EQ): the relation between each suburb, or any other location type, and itself is denoted by S1 EQ S2.

DISTANCE(S2, S2) < c

E. Building POI Relations

Specifying the relations among points of interests, villages, suburbs and towns: a point of interest can be located either in a village, suburb (town). The set of relations are all the relations listed above considering the semantics and the context of point of interests. At this stage we are mainly considering the NTPP relation between a point and a region (suburb,village and town).

NTPP: a POI(S) has an NTTP relation with a town (T) if a POI lies in a town and shares no border with it. The relation is denoted by S NTTP T

IV. Experimental Results and Validation

country region. All experiments were conducted on an Intel(R) Core(TM) i7 2.00 GHz running 32-bit Windows 7 Operating System with 4 GB of RAM.

A. An illustrative example

To build the data set for this experiment, we used Palestinian regions . We collected the shape

Figure 6 –

Fig. 9 Map of a region from a shape file

files from different municipalities like the one in Figure (6) and loaded the shape files into **PostGIS**/PostgreSQL database using the right coordination system for the selected region. The total spatial entities for this experiment is 5957 entity classified as shown in table ().

TABLE II.

SPATIAL ENTITIES PER TYPE

Type	Count
locality	144
hamlet	23
village	323
pois	5337
suburb	39
region	7
town	81
Border Crossing	1
city	10

The challenging question at this point is how to select the best radius for each region type. Obviously the algorithm will produce wrong results if the radius is chosen too small or too large. In order to select the best radius, we created a visual map that can help the user to select the best radius. As shown in figure (7) , choosing a radius of 800 meter will create more relations than 400 meters. Also we enhanced the algorithm by considering the area of the region. If the area of the region is found, then we can calculate the radius using the formula Area = sqrt((Area)/3.14) and thus we can get more reliable address

B. Validation of results

To develop our ground truth database for region relations, we had to build up the relations manually from existing maps. The ground truth data might include attribute data about the area size or population size of the region. However, not all towns or cities have these attributes filled. At this moment, we manually built the EC relationship between all towns, cities and villages. Also suburbs relations were built for two cities. Point of interests relations with their suburbs are built for nine suburbs.

The results are validated by computing precision , recall as shown in table

TABLE IIII.

EC PRECISION AND RECALL PER REGION

Region Id	**Total EC Relations (GT-Expert)**	**EC relations Built By System**	**EC relations Built (True) <true positive>**	**EC relations missed**	**EC relations Built (false) < false positive>**
94	8	6	5	3	1

91	6	2	2	4	0
236	8	9	7	1	1
196	9	8	8	1	0
177	6	8	6	1	2
…..					

For each region , we calculate the EC relations manually as shown in column (2). Column-3 represents the total relations built by the algorithm for each region ; column-4 shows how much of the calculated relations are true; column-5 shows how much relations are missed and column-6 represents how much relations are false.

- A – Number of relevant relations not retrieved
  B – Number of relevant relations retrieved
  C – Irrelevant relations retrieved

$$Precision = \frac{|B|}{|B|+|C|};$$

$$Recall = \frac{|B|}{|A|+|B|};$$

Precision = 0.82926829

Recall = 0.90265487

C. Discussion of results

Since the approach relies on approximating the area using a circle region. Selecting the radius (R) might produce wrong results as shown in the following cases. When the radius R is much smaller than region radius (RR) (R << RR), the algorithm creates no relations between the two regions. This is equivalent to region A is disconnected from region B . This could be improved by using the area of the region to calculate the radius and overriding the estimated one.

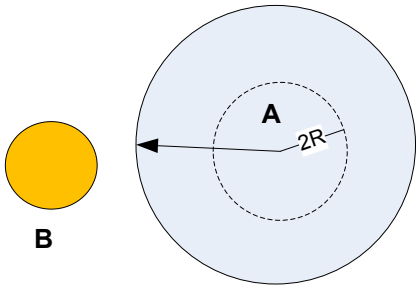


Fig. 10 City radius larger than double of selected radius

A second case occurs when the selected radius R is much larger than region radius (R >> RR)

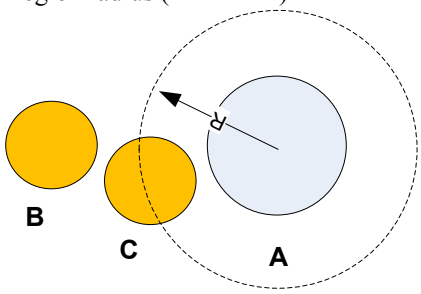

Fig. 11 City radius less than double of selected radius

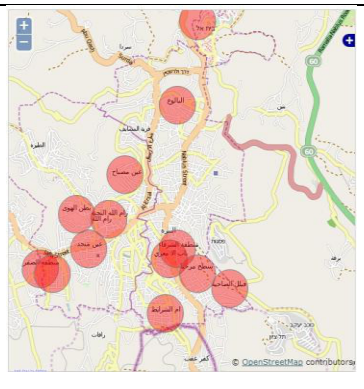
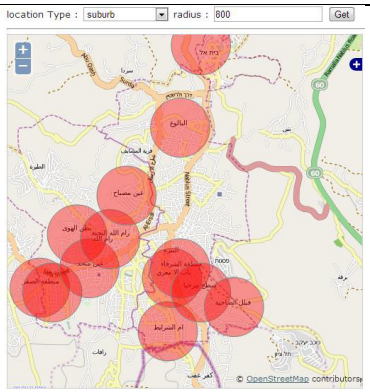
When region radius is much lesser than selected radius , it is possible to make an EC relation with a region although there is another region in between. This is equivalent to having the following relations : a) A Externally connect to B b) A Externally connect to C c) C Externally connect to B

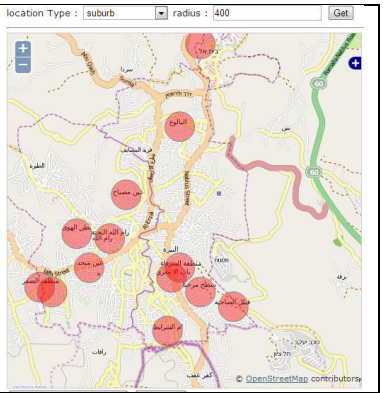
TABLE IIV.
DIFFERENT REGION RADIUS BASED ON VISUAL MAP



(a) Radius 500 meter



(b) Radius 800 meter



(c) Radius 400 meter

II. Conclusion

Using an automated method to build RCC relations between geographic regions is challenging especially if data has only attributes related to longitude and latitude. Although locating events is best done by its address, which is the more accurate among other methods like post address or boundary, the boundary approach in many rural areas is the only option available. However, from our experiments we found encouraging results. With such results it is now possible to use the new data set to find automatically the matching relationships between a pair of events such as in the two events presented earlier:

Event 1 : "8 Palestinians are arrested across the West Bank "
Event 2 : "Thursday eight Palestinians arrested from Jerusalem, Jenin and Hebron, according to local and security sources". Since Jerusalem, Jenin and Hebron has NTPP relationships with West Bank, we can infer that the location of these two events is the same.

However, we did not consider the issue of integrating topological relation with other binary relations such as distance constraints and directional constraints. In future research, the similarity measure between location A and location B is computed using the three types of constraints.

An approach to discover false alarms in monitoring system of the copper mine

Bartłomiej Karaban, Jerzy Korczak
Wroclaw University of Economics.
ul Komandorska 118/120,
53-345 Wrocław, Poland
{bartlomiej.karaban,jerzy.korczak}@ue.wroc.pl

***Abstract*–The key task of telecommunication systems in deep mining is to ensure safety and continuity of production. These systems, despite modern and innovative infrastructure monitoring solutions, are not free from drawbacks. The occurrence of false alarms of damage to infrastructure is the practical problem which causes many negative effects, such as increasing the cost of the current operation of the system, information overload of operators, and service errors. In this paper a method for detecting false alarms in the communication system of the copper mine is proposed, presenting some rules that provide useful knowledge extracted from the database. A variety of experiments were carried out on real data from the telecommunications system operating in the copper mine KGHM Polska Miedź S.A.**

I. Introduction

SAFETY at work in the mine, good organization, and continuity of production requires an efficient and effective system of monitoring the state of the telecommunications installation, machinery, equipment and employees [1]. One of the important functions of a telecommunication network monitoring system is to collect and provide operators with information about the status of communication with network devices, the presence of voltage, time, location of failure, and values of parameters of the equipment, as well as the dangers of the failure [2]. For the system operator, information about the failure means loss of connectivity in excavations in which these devices are installed.

This article presents research focused on a well-known and difficult problem occurring in automated monitoring systems - the problem of identifying false alarms about the lack of communication with the device network infrastructure [3]. Let it be noted that the monitoring systems in the mine, and this fact is also confirmed by our study, always generate an alarm about the lack of communication in cases of actual loss [4].

The diagnosis of false alarms and minimizing their occurrence is one of the current problems in design and operation of automatic monitoring systems [5]. One of the eligibility criterion alarms is its duration. In practice, in cases of short duration of the alarm, operators treat it as a false alarm. This approach results in "anticipation" at the end of an alarm condition (restoration of communication), which causes delays in reporting failures to the service, making their duration longer [4]. A large number of alarms also cause adverse effects such as information overload for operators, the resulting operating errors and increase in the cost of the system operation.

The article discusses how the diagnostic system operates in one of the mining companies belonging to KGHM Polska Miedź SA. This system informs the operator about damage which has the status of a fault or breakdown. A fault is an event that causes a break in the functioning of communications. Any damage where the effect is different than the loss of communication we call a breakdown [4].

The aim of this publication is to present a method of automatic recognition and classification of alarms, allowing for the extraction of new, useful information and rules for the identification of false alarms generated by the monitoring system.

The following section describes the telecommunication system of the mine . Section 3 presents the method of data exploration. The results of experiments are discussed in the section 4. The experiments carried out on real data extracted from the system database are also presented.

II. The telecommunication network in the mine

In telecommunication systems operating in the mines of KGHM Polska Miedź SA, technical and organizational solutions were applied, ensuring a very high level of reliability of their work. The majority of the systems have very modern and innovative solutions. The most important of them are: a global mine communication system, a system of emergency propagation, and a radio communication system which where the database was used to discover false alarms [6].

The radio system used consists of the physical components and software packages that within a data communication system allow one to carry out the telecommunication functions, administrative services and diagnostics. The main element of the system is the Mine Station, which serves as a node that sets the connection, the monitoring application server and administrative point of connection of the terminals. The Mine Sta-

978-83-60810-58-3/$25.00

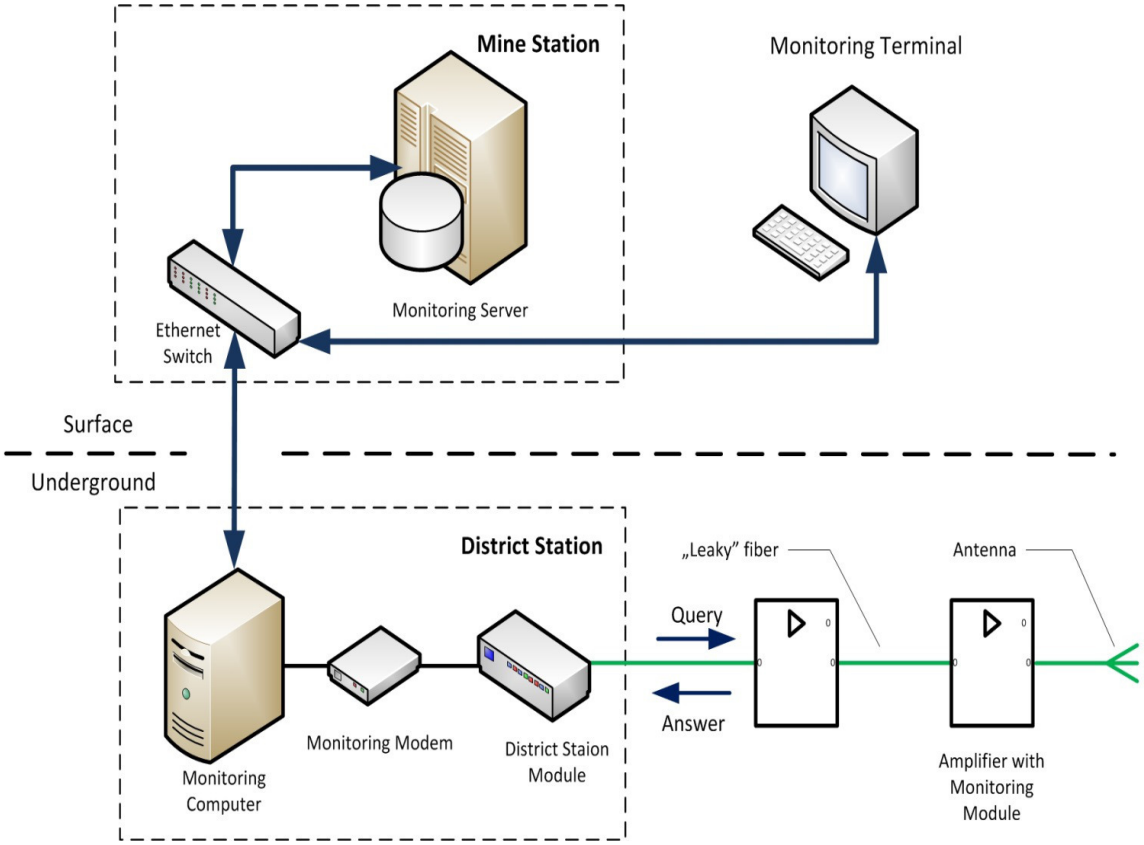

Fig 1. Diagram of the monitoring system

tion is connected with fiber optic links in District Stations installed at the bottom of the mine. District Stations are equipped with modules and modems monitorings that "interrogate" the network devices to determine their communication status and to control operating parameters. An "enquiry" about the "presence" of the device is sent approximately every 11 minutes; if there is no response, then an alarm is activated which indicates lack of communication with the device [4].

The described elements of the monitoring system are illustrated in Figure 1

The system described is a modern solution in terms of hardware and application, with a high degree of reliability dedicated to deep mines. A particular advantage is the graphical interface Monitoring Portal, allowing a quick and intuitive way to locate the location of the failure in the network. One of the interesting features of the system is the ability to "poll" the ad hoc device selected by the system operator, which greatly speeds up the execution of maintenance work. The Monitoring Portal map window is shown in Figure 2. As you can see, the color red is signaled by the failure of infrastructure elements for the lack of communication, information that can be read in the dialog caused by the operator by clicking on the device. Despite the advantages indicated in the monitoring system, it is not devoid of drawbacks. The most important one is the generation of false alarms about the lack of communication in the excavations.

III. THE METHOD OF EXPLORATION DATABASES DIAGNOSTIC

G. Piatetsky-Shapiro defines the process of data mining and knowledge discovery as "the process of nontrivial extraction of potentially useful and previously unknown information, or general patterns existing in databases" [7].

Referring to the specific problem of recognition and classification of alarms, it is possible to use two approaches well described in the literature: supervised or unsupervised classification. The main difference between them is *a priori* knowledge about the target class. Due to the possession of information whether a given historical alarm was true or false, it was desirable to apply a supervised classification.

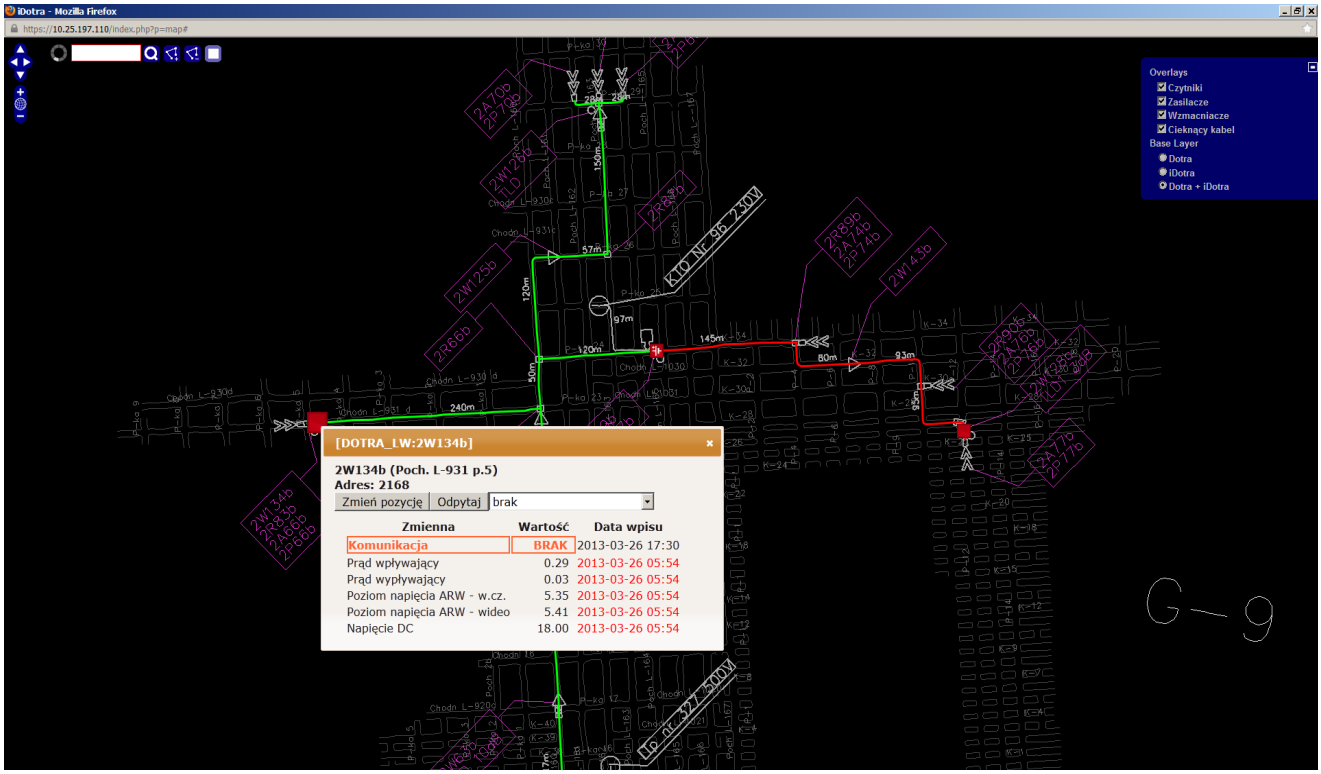

Fig 2. Map of the antenna system of the mining branch, with the window of the amplifier parameters (scale 1:7500)

There are many supervised classification methods, which include: logistic regression, discriminant analysis, neural networks, genetic algorithms, SVM, Naive Bayes, CN2, and inductive decision trees (IDT). It is not possible to use many of these methods, they are dedicated for the quantitative variables, while the alarm is mostly described using symbolic attributes. In contrast, methods such as SVM, Naive Bayes, and inductive decision trees do not have this restriction, therefore these methods were considered to be applied [8].

Many experiments and tests of several methods for classification were carried out in the project, amongst which we identified inductive decision trees. For choosing this method, several conditions appealed. The first condition resulted from a fundamental principle of inductive inference leading to the generalization of observations and facts in the form of rules and statements. An analyst who has domain knowledge should verify the authenticity of the generated rules and model the tree, as long as these rules are pragmatic enough to apply them to solve the problem. Another important advantage was the simplicity of interpretation derived rules in both graphical and decision rules. The last advantage, which prompted us to use tree induction, is the ability to control the complexity and generality of generated rules. The weakness of the IDT is the possibility of generating too large and too deep a tree, which might overfit and generate erroneous classifications [9].

There are many measures of evaluation of classifiers, such as sensitivity, precision, specificity or accuracy [10]. The studies demonstrate that the most important objective is to assure that all true alarms will be identified, then the number of false alarm would be minimized. In our approach the discovery will be focused on the minimization of the error of the first kind (False Positive rate), specifying the number of false alarms which were classified as true. The second important quality measure in this project was the precision, which takes into account the number of real alarms misclassified as false. In general, when choosing a classifier, we strive to achieve a compromise between readability and usability rules and maximizing the value of these measures. The first criterion is considered more important in the case of a small difference in the assessment of classification.

The process of data mining has been carried out according to the methodology CRISP-DM [2], using the data mining platform Orange. The data mining process is shown in Figure 3. The first step was the data preprocessing was performed (highlighted by orange color), part of which was done using MS EXCEL and MS ACCESS. The next step concerned the data analysis (box of brown contour), after which the model was built and applied to explore the data using the chosen methods of classification (box with a green outline). The last step was to evaluate the selected models (box with blue outline).

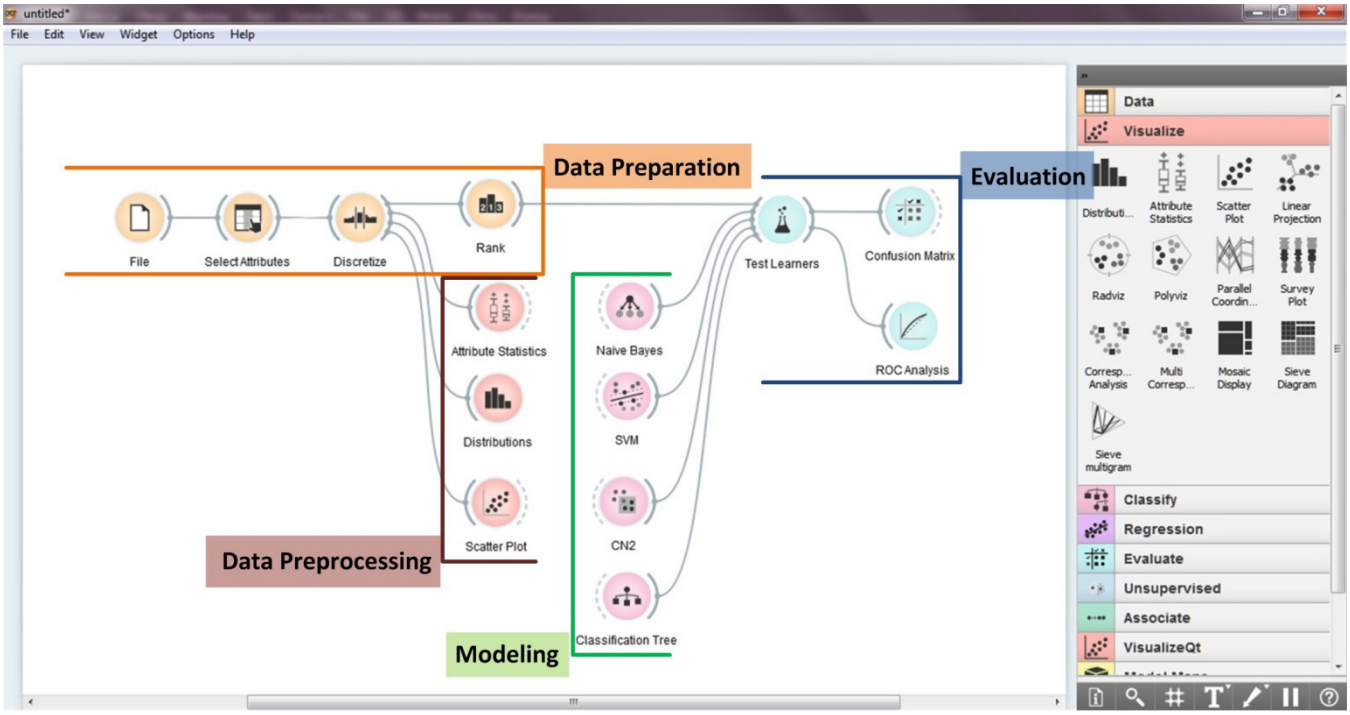

Fig 3. Schema of data mining process using Orange platform

The next section presents the process of building a model of a decision tree induction, and evaluation in comparison with other classifiers (SVM, Naive Bayes and CN2).

IV. Experimental Results

The analyzed data was real data extracted from: system monitoring, technical documentation, and system entries in the service log and saved in the Monitoring Database. The data set was randomly selected and contains 1316 observations from 01.05.2012 to 18.05.2012. In a first stage, there were necessary transformations of attribute values carried out in order to use the data in the selected classification algorithms. For example, one of the attributes ("duration") was discretized (by equal density intervals). The transformed data were rang using the Gain Ratio criterion, then the attributes selected that were used for modeling.

In order to recognize and classify false alarms a two-step approach was carried out. In the first step, the rules that classify the true alarms with the greatest possible "purity" were discovered. In the fig.4 this set of rules is named RulesTP. The algorithm is the following:

After inducing rules that cover all true alarms, in the second step the rules to discover false alarms were generated.

In fig.5 two sets of false are alarms are shown; the blue one illustrates the false alarms indicated by the current system, but the rose one shows the false alarms generated by the RulesTP.

As indicated and justified in the third section, the decision tree induction algorithm based on entropy (IDT) was chosen [11]. During the experiments about 100 variants of decision trees were generated by changing the value of various parameters such as the tree pruning ratio and the number of class attributes describing the duration of the alarm.

In the first series of experiments, the number of class attributes was specified: "duration" to 10 (the maximum for the reduction in the package Orange). The controlled parameter was the minimum number of observations in the leaf, which value after 10 experiments was set to 5.

A tree was generated in which the 6 leaf nodes of

Fig 4. Text of rules named RulesTP

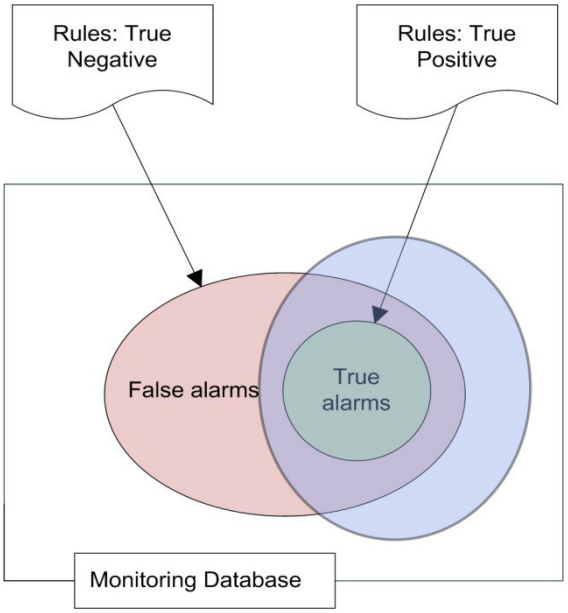

Fig 5. Schema of alarms identification by the rules

attribute "duration" contained only observations of false alarms were aggregated, which resulted in the reduction in their number from 10 to 5. The indicated change negatively affected the quality of all four classifiers. The obtained specificity ratio (TN) worsen the value than in previous experiments.

In the last series of experiments, the parameter to halt the tree construction has been changed. Just as in the first series of experiments, during the test the number of observations in the leaf was monitored, at which point the construction of the tree was stopped. The values of the parameter ranged from 1 to 10. Satisfactory results in terms of measures of quality and usability of the generated rules were obtained for the trees with minimum two observations per leaf.

In about 100 experiments, hundreds of decision rules were generated. The article presents only four of the ten rules that provide useful, previously unknown knowledge about the false and true alarms generated by the monitoring system. One of these rule was the following:

IF
alarm_ occurrence(t) = ‘stoppage’
∧ alarm_retreat_miners_work(t+1)= ‘miners_overlay’ v ‘miners_relay’
THEN true_alarm

The indicated rule covers 39 cases of "purity" of 100%. After analyzing the cases, it turned out that the rule identifies alarms which arose as a result of switching off the electrical switchboard during the weekend. Application of this rule increased besides of efficiency of alarm recognition indicated the switchgears which due to the communication requirement that should be maintained in a continuous operation. This information was forwarded to the electrical services at the mine.

The next rule that identified the true alarm was more complex, namely:

IF
alarm_occurence(t) = ‘mining’
∧ alarm_duration> 5 hours and 30 minutes
∧ alarm_occurence_miners_work(t) = ‘blasting_work’
THEN true_alarm

The rule allows to identify the cases where the loss of communication occurs most likely as a result of conducting blasting work. This rule covers only three cases (the "purity" of leaf 100%), however, taking into account the information it provides, we can identify the situation in which there is damage to the telecommunication line because of conducting blasting work. Such information provided to service may reduce the incidence of such situations; it helps to reduce system failures and the costs associated with damage to the network. Duration of alarm in the last o rule may seem too long. Such situations are due to the specific nature of the work environment in the mine (climatic and geological conditions), work organization (logistics, time to arrive to the place of accident), and the difficulties encountered in removing failure (signs of non-access to dangerous places).

Having analyze the generated rules, it was noted that in each of the created trees after the aggregation of classes of "Alarm Duration" (third series of experiments), there is the following "strong" rule of "purity" of 96.5% covering 800 alarms:

IF
alarm_occurence(t) = ‘mining’
∧ alarm_duration ≤ 45 minutes
THEN false_alarm

This rule is a useful new piece of knowledge about the alarm time threshold below which an alarm can be considered with high probability to be false. The value of this threshold is approximately 45 minutes..

The next rule classifies the alarms of long duration:

IF
alarm_occurence(t) =’mining’
∧ alarm_duration > 5 hours and 30 minutes
∧ alarm_occurence_miners_work(t) = ‘miners_relay’
∧ alarm_retreat(t+1) = ‘stoppage’
THEN false_alarm

It should be noted that in practice it is particularly difficult to determine the authenticity of such alarms.

The rules provided provide useful knowledge about a false alarm of long duration. As indicated in the introduction, operators often use heuristics when trying to determine the veracity of a given alarm. So far it has been assumed that the false alarm takes no more than two hours. Based on the first rule, it can be induced

that in 45 cases the alarms of about 5.5 hours duration were the false alarms ("purity" of the leaf = 100%), which exemplifies the existing heuristic assumptions.

V. CONCLUSIONS

Telecommunication systems in the mining industry play a key role in terms of safety, good organization and continuity of production. That is why it is necessary to monitor the state of the telecommunication infrastructure. Despite modern and innovative solutions discussed, the monitoring system is not free from inconveniences.

This paper proposes a method for the detection of false alarms about the lack of communication in the mine and the acquisition of new, useful knowledge from data. In about 100 experiments controlling the initial conditions of detention tree construction and the number of classes of the attribute "Alarm Duration" using the inductive decision trees, information about the duration threshold value has been found below which the alarm can be considered objectively false. Another very important and previously unknown piece of information is to identify individual devices that are deprived of the power supply in the days when there is no mining work, resulting in a loss of communication. Another potentially useful rule applies to identification of devices that can be damaged by blasting work.

The results obtained give encouragement to undertake further research on the diagnosis and extension of alarm recognition, signaled by the monitoring system in the mine.

***Abstract*—Virtual reality (VR) has become a popular approach to study human behavior in fire. The present position paper analyses Strengths, Weaknesses, Opportunities, and Threats (SWOT) of VR as a research tool for human behavior in fire. Virtual environments provide a maximum of experimental control, are easy to replicate, have relatively high ecological validity, and allow safe study of occupant behavior in scenarios that otherwise would be too dangerous. Lower ecological validity compared to field studies, ergonomic aspects, and technical limitations are the main weaknesses of the method. Increasingly realistic simulations and other technological advances provide new opportunities for this relatively young method. In this position paper, we argue that VR is a promising complementary laboratory tool in the quest to understand human behavior in fire and to improve fire safety.**

I. Introduction

STUDIES on fire evacuation seek to understand how occupants react when they are confronted with fire emergencies. Various disciplines, such as safety engineering, computer modeling, human factors, and psychology contribute to this field of research, all aiming to better understand human behavior in fire (HBiF) and ultimately to improve safety. One of the biggest challenges in this field is the access to ecologically valid and at the same time experimentally controlled empirical data (see for example references [1, 2]). Researchers in HBiF need safe, objective, reliable, and valid methods of data collection. The scope of this position paper is to discuss how virtual reality (VR) studies complement other well established research methods, such as case studies, unannounced drills, field studies, laboratory studies, and hypothetical studies [3-6].

The present article seeks to analyze **S**trengths, **W**eaknesses, **O**pportunities, and **T**hreats (SWOT) of VR research on HBiF. SWOT analysis originates in the management literature and has been applied to VR in the context of rehabilitation research [7].

I. VR in Fire Evacuation

VR has been defined as a "real or simulated environment in which the perceiver experiences telepresence" (the feeling of being present in a virtual environment) [8]. Note that this very wide definition implies that VR is not limited to computer generated environments or any specific technology. In a way, a real world laboratories can also be seen as virtual environments. However, for the scope of this article, VR refers only to computer generated simulations. The experience of telepresence comprises the illusion of being in the place displayed by the VR technology, and the illusion that events happening in the virtual environment (VE) are plausible and real [9]. Note that this definition does not imply the use of any specific technology. However, VR systems generally use computer generated visual and auditory simulations to immerse participants into a VE. Although less immersive systems – such as simulations on desktop computers [10] – can be used to study HBiF, the present paper mainly addresses highly immersive VR systems using CAVE (Cave Automatic Virtual Environment) systems, Powerwalls, or head mounted displays (HMD). These systems allow the presentation of highly realistic interactive visual and auditory stimuli to participants. Enhanced multimodal systems extend VR with olfactory [11, 12] and proprioceptive stimuli like wind, heat, or motion [13].

Paul Pauli and Andreas Mühlberger are shareholders of a commercial company that develops virtual environment research systems for empirical studies in the field of psychology, psychiatry, and psychotherapy. Mathias Müller is executive officer of the same company. No further potential conflicting interests exist.

The presentation of this paper was supported by the German Academic Exchange Service (DAAD).

VR has become a well-established method in other research fields such as traffic behavior [14], and clinical, social, or experimental psychology, e.g., for the psychotherapy of phobias [15], post-traumatic stress disorder [16], and for rehabilitation [7]. However, the usefulness of VR for HBiF is still under discussion and the method needs to be validated. *Ecological* validity can be assumed, if participants show similar behavioral, emotional, cognitive, and psychophysiological reactions in VR and in the real world [17]. The extent of emotional responses to a real world or virtual laboratory scenario is not necessarily the same as one might expect in a real fire emergency. Ecological validity does not mandate that participants have to believe that a simulated fire scenario is real. In fact, perceptual input (e.g., a visual simulation) can elicit emotional reactions, such as fear reactions, even if participants know that what they see is a simulation [18]. These reactions are probably of a lower intensity, however, future research is necessary to shed light on this question in the context of HBiF. More importantly, VEs have to be designed in a way that the observations from participants' behavior allow valid conclusion for real world scenarios. One study found promising results by comparing participants' behavior in VR evacuation scenario with real world case studies [19]. Other studies found HBiF comparable in conventional laboratory and VR simulated tunnel emergency scenarios [20, 21]. Note that similarity of two forms of artificial experimental methods (VR and classical laboratory studies) does not warrant ecological validity. There are still not enough studies systematically comparing virtual and real HBiF. In related research fields, however, validation studies have repeatedly demonstrated the ecological validity of VR. For example, several driving simulator studies documented ecological validity of VR simulations in terms of driving behavior, as well as the ability to elicit adequate emotional responses to VR [22-24]. In addition, several validation studies of virtual driving simulators demonstrated similar behavior in the real and the virtual world [25-28].

So far, VR has been used in several studies on diverse aspects of human behavior in fire, such as evacuation from buildings [10, 19, 29-32], occupant behavior in road tunnel fires [33-35], fire training [36-40], and other areas of safety and security research [41-43].

If proven sufficiently valid, VR will be a promising route to gain objective and reliable insights in HBiF. Results from VR studies can be used to test theories of HBiF, verify and validate evacuation models [44], and be integrated into VR training measures [29, 45].

II. VR in Comparison to other Methods

Table I compares six different empirical research methods, which gather data on HBiF, on several important aspects such as the degree of experimental control, experimental setting, and the type of data that can be collected with each method.

In *hypothetical studies* have been used in evacuation research [46]. Participants are usually either shown videos or are instructed to imagine a certain scenario and then asked how they would react in that situation. Another example would be data acquisition from experts who evaluate the outcome of a given hypothetical scenario. These scenarios can be in the form of an interview or questionnaires. Data

TABLE I.
COMPARISON OF RESEARCH METHODS

	Hypothetical study	**"Classical" lab experiment**	**VR experiment**	**Field studies**	**Drills**	**Case Studies**
Setting	laboratory	laboratory	laboratory	real-world	real-world	real-world
Experimental control	yes	Yes (less than in VR)	yes	limited	no	no
Setting	laboratory	laboratory	laboratory	real-world	real-world	real-world
Type of data	subjective (statements from participants or experts)	subjective, objective (behavior & psycho-physiology)	subjective, objective (behavior & psycho-physiology)	subjective, objective (behavior)	subjective, objective (behavior)	subjective, objective (behavior)
Possibility of use of stressors	no (only hypothetical)	limited	limited	limited	limited	yes
Ecological validity	low	medium	medium	medium	high, if unannounced; limited, if announced	high
Possibility of adjusting experimental setting	yes	yes	yes	limited	no	no
Possibility of exact replication	yes	yes	yes	limited	no	no
Time and cost intensity for data collection	very low	low	low	high	medium	-
Automatic data collection possible	yes	yes	yes	limited	limited	no

from hypothetical studies is always subjective as they reflect the participants' personal opinion, knowledge, or experience. Subjective data, although being prone to bias, can be highly useful to gain insights into how occupants experienced an event or to reconstruct chains of events.

In *"classical" laboratory studies* real world scenarios are transferred into the controlled environment of a laboratory. Here, causal effects can be investigated with experimental methods by manipulating independent variables and measuring dependent variables (e.g., behavior, subjective data, and physiological data). Participants have to be assigned randomly into at least two experimental conditions for a true experiment which vary only in one condition (the independent variable). It is crucial that laboratory studies are ethical acceptable. That is, the experimenter may, for example, only use stimuli/stressors that are not actually harming the participant.

In *VR experiments,* participants can be confronted with simulated fire emergencies. Simulations of fire emergencies can be presented to participants in an extremely controlled way. VR experiments allow the convenient recording of behavioral and physiological data with a very high resolution as well as the collection of subjective data. In comparison to other methods, the presentation of stressors (e.g., flames) is ethically less critical compared to classical laboratory and field studies.

In *field studies,* emergency scenarios can be reenacted in a naturalistic setting outside of a laboratory. Unlike in laboratory settings, field studies are usually in less controlled environments (although certain infrastructures like road tunnels are highly controllable). Similar to classical laboratory studies and VR experiments, field studies use subjective and objective data (recorded behavior).

Drills are either announced or unannounced practice scenarios in real world settings. Although very similar to field studies, the focus of drills is usually on practicing emergency procedures. They allow the observation of occupant behavior under naturalistic conditions in a specific location. Similar to field studies, observational data and self-report data can be acquired.

Case studies refer to the descriptive, exploratory or explanatory analysis of a real fire emergency. Subjective self-report data from occupants and analysis of closed-circuit television footage can be used to reconstruct the events of a real emergency.

In addition, mixed methods may help to overcome limitations of individual methods. For example it is possible to modify participants experience in real world settings using augmented reality, or increase the immersiveness of a VR system by adding real elements (for example objects that participants can touch) to a VR study.

When planning studies on HBiF researchers have to consider certain factors and restrictions (See Table I). These include the necessary degree of experimental control, the choice of setting (laboratory or real-world), or the type of data required (subjective vs objective) and whether or not it is important to be able to adjust or replicate the experimental scenario during data acquisition. There are also factors related to the efforts necessary for the realization of a study. Efforts can be financial (e.g., costs for hard and software, personnel, participant recruitment, or lab space in VR experiments) but also whether or not data can be collected and processed automatically (e.g., with tracking devices) or has to be extracted from video footage.

These comparisons do not necessarily reflect strengths or weaknesses, rather factors that should be considered when deciding on which research method is most suitable for a certain research question. The methods discussed here do not provide the best solution for every research issue. There are arguments for and against the use of each method to address specific concerns. In this section, the VR studies are analyzed with respect to key aspects of a research question.

II. SWOT Analysis

SWOT analysis refers to the analysis of **S**trengths, **W**eaknesses, **O**pportunities and **T**hreats of a given method or product [7]. The present SWOT analysis (Table II) aims to uncover internal strengths and weaknesses of VR as a research tool in HBiF and to identify its surrounding conditions (opportunities and threats). A detailed description of SWOT analysis can be found in reference [7].

- Strengths refer to inherent resources and capacities of VR helping to gather objective, reliable, and valid empirical data on HBiF.
- W*eaknesses* describe inherent shortcomings, limitations, and problems of VR to achieve its goal.
- *Opportunities* comprise surrounding conditions or trends from which VR research will potentially benefit and which is promising to overcome weaknesses.
- *Threats* are surrounding conditions which are detrimental to the use of VR as a research tool in HBiF and which need to be overcome.

I. Strengths

Internal validity is possibly the most important strength of VR studies. Entire VEs can be easily controlled. Stimulus control and experimental stimulus manipulation is a key feature in investigating cause and effect relations [47]. It is extremely difficult to impossible to control the environment in field studies, drills, and even classical lab studies. For instance, in VR smoke can be numerically calculated and then repeatedly presented in exactly the same way to several participants. "Real" smoke, even in the controlled environment of a classical laboratory study, will always vary, and consequently visibility conditions may change across observations. Lack of experimental control limits the reliability and consequently the internal validity of these methods.

Replication. VR studies can be replicated to the last detail, given the usage of the same or comparable equipment. One major criterion for empirical studies is that they can be/should be reproducible. Replication refers to the

repetition of a study using the same methods but different participants and experimenters. Studies need to be replicated in order to test their reliability and validity and to test their generalizability and the role of confounding variables. Real world studies, especially field and case studies, provide data for only one specific event and are extremely difficult to replicate.

Ecological validity refers to the degree with which the methods of a study represent the real world scenario that is being examined. VR offers a similar degree of ecological validity as classical laboratory studies, but depending on the research question one method or the other may be more suitable. For example, certain features of a fire emergency, such as the visual simulation of flames, may be simulated with higher control in VR but other features (e.g. touch) may be more difficult but not impossible to simulate in VR (e.g. using a mix of virtual and real elements). However, simulation of heat or olfactory cues is possible but still limited as it is both technically challenging to present olfactory stimuli in an experimentally controlled manner. Ecological validity of VR studies is higher than in hypothetical studies since the latter require the ability of participants to correctly imagine a scenario. High – but not absolute – ecological validity of VR studies can be assumed if the visualization, observed behavior, and task difficulty of a simulated fire emergency is realistic, i.e., based on valid models and representative of real world events. VR simulations can have the same degree of visual realism as simulations in classical laboratory studies.

All laboratory experiments including VR studies, however, are abstractions of reality and therefore some loss of ecological validity is inherent to the method in comparison to real events [47]. Even the most sophisticated field experiment and the most advanced VR simulation on human behavior in dangerous situations cannot (and should not) claim absolute ecological validity. Participants will always know that they are taking part in an artificial situation. However, this is true for all methods compared in the present article with the exception of unannounced drills and case studies. Knowing that one takes part in a study and/or that there is no real danger, may lead to systematic biases in participants' responses.

External validity refers to the question whether the results of a study can be generalized from the experimental setting to other situations or populations [48]. VR and other laboratory studies allow controlling confounding factors and thus studying general underlying effects in HBiF is possible. Results from uncontrolled studies (e.g., drills, case studies, and to some extent also in field studies) cannot not be generalized because confounding variables are not controlled.

Safety for participants. VR allows the controlled simulation of perilous scenarios, such as extreme tunnel fires, without putting the participants at risk of a physical harm. That is, VR studies are ethically less problematic than field studies since it is possible to simulate catastrophic and life threatening situations without risking to physical harm participants. However, there are also limitations for VR studies (see *Threats*).

Real-time feedback. Precise tracking of various parameters as well as the highly controlled visual input technologies allow to give participants and researchers immediate feedback of behavior, performance, and even psychophysiological processes. For example, task-performance or physiological parameters such as heart rate can be displayed online during trials. This allows the experimenter to have real time access to data. Real time feedback for participants can be used to test training measures (e.g., fire evacuation training).

Multi-modal simulations. In theory, simulation of any modality is possible. To date, combined simulation of visual and auditory stimuli are very well developed. Olfactory, nociceptive, or thermoceptive simulations are also possible, however, still less technologically advanced.

Precise measurement. Precise tracking technology allows accurate analysis of various aspects of participants' behavior (e.g., full body tracking, head movement, eye tracking) with extremely high sampling rates.

Psychophysiological monitoring. In addition to behaviors, psychophysiological parameters such as heart rate or skin conductance can be measured easily in a VR laboratory. Measuring physiological correlates of behavior while being immersed into a VE allows researchers to analyze emotional reactions (e.g., fear reactions) to simulated emergencies.

Low costs. Once a VR system is set up, it can be used, in theory, infinitely. Virtual scenarios can be re-used and easily modified. With the decrease in prices for hardware and software (some VR simulation software are even free to use), VR experiments have become more and more affordable. Although costs for individual studies vary significantly, VR studies are generally cheaper than field studies. However, setting up a complete complex VR laboratory such as CAVE systems is cost intensive and requires space but is relatively affordable to run.

Repeated measurements. Participants can easily be immersed repeatedly into VEs and repeated measurements in identical scenarios are possible. Recreating identical conditions is complex or even impossible with other methods (See also *Replication*). Repeated measurements can be used to test, for example, training measures aimed to improve HBiF.

Flexibility. Experimental settings in VR can be adjusted easily, allowing to run pilot studies and to quickly develop minor alterations of the experimental set-up.

Control of confounding variables. There are many variables that potentially confound the effect of a given independent variable but are not of primary interest (e.g., minor changes in starting positions, left/right turning preferences). These can be easily controlled in VR and laboratory studies but is difficult to impossible in other designs.

Independent of imagination abilities/willingness of participants. Producing highly immersive VEs reduces the variance in participants' response caused by individual

differences in the ability and willingness to imagine a given scenario. Hypothetical studies rely on the ability of participants to imagine a scenario. Here, researchers have no control of the ability and willingness of participants to imagine, for example, a fire evacuation from a high-rise building.

Participant recruitment. Although not an important strength of VR studies, it is worth mentioning that recruiting a sample for a VR study has less restrictions than recruiting for a drill or field study. In field studies, the experimental set-up is often only available on limited occasions and may be time and cost intensive to install. For example, certain infrastructures such as underground public transportation systems or road tunnels may only be accessible to researchers at a very limited time or during certain hours of the day making data collection difficult. Once a VR scenario has been set-up it can be repeated, in theory, at any given time which allows longer and more flexible time-windows for data collection.

II. Weaknesses

Need for confirmation/validation. To date, there are still not enough validation studies. These are necessary to test the assumptions that behavior in a simulated scenario can predict or be transferred to "real" HBiF.

Non-intuitive interaction methods. Although VEs are interactive, participants often need devices like gamepads to navigate in and interact with the virtual environment. This always reminds the participants that they are in an artificial scenario, and if the scenario is not well designed, may bias behavior. For example, evacuation times may vary depending on how well participants can handle their navigation device. However, developments in input devices may partially address this weakness (See also *Opportunities*).

Inter-individual differences in ease of interaction with VR. Depending on various factors, such as age or experience with VR, participants may have difficulties when using VR. For example, participants who have a lot of experience using 3D video games may find it easier to navigate in a VE. Participants, who have less experience with computers (e.g., elderly participants) may need longer practice sessions before they can navigate without limitations in a VE.

Technical limitations. Visual input as well as well as interaction methods are still limited. Although visual simulation of virtual environments has improved tremendously in recent years, the current simulations will always be recognized as such by participants. Such imperfections (e.g. in model rendering, spatial resolution, field of view (for HMDs), graphic update rate, lags between head tracking and visualization) of VEs may lead to artifacts [49]. Especially the simulation of behaviorally realistic virtual humans is still challenging. Another technological limitation is the need for interaction tools, such as game pads or HMDs, to immerse into and interact in the VE. For example, navigation, even in a highly immersive CAVE system is either limited to a few square meters or participants have to use interaction devices. These technical challenges may limit the immersiveness of a VR system and lead to a lower experience of presence.

Technology-induced side effects. Prolonged exposure to VR may cause symptoms of nausea and vertigo (simulator sickness; for a review on simulator sickness, see references [49, 50]). The incidence of these side effects depends upon characteristics of the VR system (e.g., display field of view, lag between tracking device and update of the visualization) and participants [51]. Such side-effects need to be considered when planning and evaluating the ethical innocuousness (e.g., participants need to be able to terminate the experiment whenever they want to).

TABLE II.
SUMMARY OF A SWOT ANALYSIS FOR VR IN FIRE EVACUATION RESEARCH.

Strengths	Weaknesses	Opportunities	Threats
• Internal validity • Replication • Ecological validity • External validity • Safety for participants • Real-time feedback • Multi-modal simulations • Precise measurement • Psychophysiological monitoring • Low costs • Repeated measurements • Flexibility • Control of confounding variables • Independent of imagination abilities/willingness of participants • Participant recruitment	• Need for confirmation/validation • Non-intuitive interaction methods • Inter-individual differences in ease of interaction with VR • Technical limitations • Technology-induced side effects • Efforts	• Intuitive and natural navigation • Graphical developments • Multi-modal simulation and feedback • Usability for researchers • Exchange of 3D-scenes or experiments	• Failure to show ecological validity • Ethical challenges • Side-effects due to interaction with other medical conditions • Misleading expectations • Technical faults

Efforts. Setting up a highly immersive VR laboratory is time and cost intensive. [49]. Creating plausible VEs is also complex (the differences between less immersive and simple environments and complex highly immersive VEs is extreme) and requires expertise with special hard- and software systems. Given the rapid developments in this type of technology, constant investment may be required to stay up-to-date.

III. Opportunities

Intuitive and natural navigation. Although, highly immersive VR systems, such as CAVE or HMD systems, allow participants to move freely with their whole body within the VE [52], even the most advanced systems still have movement restrictions and participants have to use navigation and input devices. Advances in tracking technology, innovative interaction devices, and VR systems that allow natural navigation (e.g., bigger CAVE systems or wireless HMDs and walking platforms) may reduce the weakness of limited space and non-intuitive interaction devices, e.g. [52]. These advances promise even better immersion into VEs and consequently improved ecological validity.

Graphical developments. The dramatic improvement of graphical simulations allows more and more photorealistic simulation of fire emergencies. In addition, numerical calculated fire and smoke have been successfully implemented into VR simulations [37]. Similar to the advances in navigation devices, improved realism of simulations will lead to increased experience of presence for participants and better ecological validity.

Multi-modal simulation and feedback. The integration of multi-modal simulations for visual and auditory simulation extended by kinesthetic, olfactory, haptic, thermoceptive simulation allows the simulation of more complete scenarios. For examples, see references [53, 54].

Usability for researchers. The widespread use of VR technology depends highly on its usability for researchers. Recent developments in easy to use VR tool kits make VR technology more accessible. The improved cross platform compatibility helps the use of VR over different platforms and operation systems.

Exchange of 3D-scenes or experiments. Researchers can easily exchange 3D models or even entire experiments with each other. This may foster cooperation between laboratories and also lead to the development of standard scenarios which could be used as references and thus increase comparability of different VR studies.

IV. Threats

Failure to show ecological validity. This is the biggest threat to VR as a research tool to study HBiF. Systematic validation of VR for HBiF has still not demonstrated its range of applicability. Future studies are clearly necessary to test the ecological validity of VR to study HBiF.

Ethical challenges. Scientific studies on HBiF have to comply with ethical standards such as the Declaration of Helsinki which define ethical standards for studies with human subjects [55]. Even though most participants are aware that a virtual fire provides no threat to them, some participants may still experience extreme fear. Just as with any other method, VR research needs to ensure that the experienced fear cannot lead to longer lasting difficulties for participants such as traumatization, especially if one has in mind that VEs are getting closer and closer in means of realism to real scenarios. In addition, a VR system that causes extreme side effects (e.g., seizures or strong nausea) would be ethically unacceptable.

If participants cannot differentiate between a simulated and a real scenario, which may be the case, for example, with small children, the same ethical restrictions as with other methods apply.

Side-effects due to interaction with other medical conditions. Some scenario for HBiF may be particularly risky in causing side-effects in interaction with pre-existing medical conditions. For example, studies using flashing lights may cause seizures in at-risk populations; patients with specific phobias (e.g., of tunnels or heights) may experience extreme fear; Simulation of fire emergencies may induce flashbacks in participants who previously have experienced a traumatizing event. Other methods, however, bear similar risks.

Misleading expectations. The expectation that VR experiments can completely replace real world tests and holistically covers all aspects of human behavior in fire is misleading. Similar to classical laboratory experiment, VR allows investigating general underlying processes of HBiF and testing specific aspects (e.g., the effect of safety installations on evacuation behavior). The conclusions from these studies may even lead to changes in the design of real world safety installations. However, HBiF is highly complex; one can never exclude that individual decision-making, behavior, and experience in a specific real scenario may differ significantly from trends found in VR studies.

Certain *technical faults* in the implementation of a VR system (e.g., jitter errors, discrepancies in simulation or tracking latency) even can reduce the immersiveness and even may increase side-effects like simulator sickness.

III. General Discussion

The present position paper provides a SWOT analysis for VR as a research tool to study HBiF. We provided an overview of various methods used in HBiF and systematically compared VR to these methods.

The biggest strength of VR is surely its ability to create highly immersive, externally valid, highly controlled, and safe experimental set-ups. The biggest weakness is the reduced ecological validity in comparison with field and case studies, as well as the lack of validation studies specifically for HBiF. These studies should compare VR experiments with the results of other laboratory experiments and field studies.

The diverse methods used to study HBiF always have to trade-off between ecological validity and experimental control. For instance, case and field studies in real world

settings provide almost perfect ecological validity. However, strict experimental control is impossible to achieve here, and financial and logistic efforts as well as ethical limitations need to be considered. Hypothetical studies need to consider less strict ethical limitations and are easier to realize, but rely heavily on the ability of the participant's imagination and are prone to response biases.

Field studies are often characterized by the combination of setting and participants, e.g., real world settings with participants that naturally are in these settings. In the evacuation area, this allows doing unannounced experiments. This can never be achieved in VR or other laboratory experiments, as participants need to be recruited and enter the VR-lab (or ask them to put on some equipment). At most, participants may be "deceived" by telling them that they will take part in one study and then exposing them to something else. However, this is easily feasible in classical laboratory studies but requires more efforts in VR studies. It can be argued that affects the external validity of a study.

The differentiation between ecological and external validity is important. Ecological validity refers to how good a research method represents reality. External validity describes how well study results can be transferred to other situations and generalized over populations. Whereas ecological validity is not, external validity is a prerequisite for the overall validity of a study. A study, can be ecologically valid (e.g., the results from an unannounced drill) but not generalizable to other settings, populations, cultures etc., if it lacks experimental control and, therefore, internal validity).

I. What can we study in VR?

VR can be used to design complex laboratory experiments on HBiF. It allows studying how occupants react to fire cues, such as flames or smoke; it allows collecting precise behavioral and psychophysiological data during controlled simulated events. Virtual scenarios can be designed with an extremely high level of detail. That way, we can use VR to study underlying processes of HBiF (e.g. phenomena like risk perception of occupants, social influence, architectural influences, way-finding abilities in smoke, etc.). That way, VR studies can contribute to a better understanding of HBiF.

In addition, evacuation concepts for large complex buildings can be tested in VR making it possible to identify potentially problematic evacuation routes *before* a new building is constructed. This is particularly useful since evacuation models implemented in simulation software tools still oversimplify HBiF (e.g., some models assume that occupants always take the shortest route to an emergency exit [33]).

It is important to note that VR cannot replace any of the other methods mentioned above but is complementary. VR studies can be used in experimental pilot studies in order to test a number of possible factors that may theoretically be influencing HBiF (e.g. various design aspects of safety equipment). Then, those factors deemed as the most important ones in VR can then be tested in field experiments or used to predict behavior in case studies or drills.

II. What can we not study in VR?

Virtual reality is not reality. Participants will always know that they take part in an artificial situation. It is impossible to generate situations in which participants' would risk actual physical harm. Extremely perilous situations may induce effects (e.g., extreme fear) which are not attainable with artificial scenarios, which in turn may affect behavior. Only observations from real events and to some degree unannounced drills may have this effect. It is impossible to investigate these parts of HBiF using VR laboratory studies.

III. Conclusion and positioning statement

We argue that VR is a powerful approach to study HBiF. VR allows shedding light on aspects of occupant behavior that were previously impossible to investigate under controlled conditions. Although we identified several weaknesses and limitations of the method, the most important one being the need for validation studies, it seems possible that these can be overcome, either by technical progress or by combining several different research approaches (triangulation approach). None of the state of the art research methods (including VR) are able to validly grasp all aspects of HBiF, and VR does not aim to replace any of the other presently established research methods. We see it as a promising complementary laboratory tool in the quest to understand HBiF and to improve fire safety.

A Framework for Dynamic Analytical Risk Management at the Emergency Scene

From Tribal to Top Down in the Risk Management Maturity Model

Adam Krasuski*

***Abstract*—We present a framework designed for the risk management at the emergency scene. The system that implements the framework is focused on supporting an Incident Commander during the fire and rescue actions. The system is able to assess and manage the risks with the use of sensory data, ontology modelling and reasoning techniques from AI domain. Within the framework we propose the novel approaches for perceiving and modelling the emergency scene, for reasoning, for assessing the state and the relations among the objects at the scene, for assessing the risk mitigation and for communicating the risks to the Incident Commander.**

***Keywords*-Fire Service, Decision Support, Risk Management, Sensory Data, Domain Ontology**

I. Introduction

EMERGENCY scene is considered one of the most challenging decision making environments [1]. The safety and the success of the fire & rescue (F&R) action depends strongly on the evaluation of the risks at the emergency scene. The *Incident Risk Management* is the principal consideration of an Incident Commander (IC) in order to ensure the safety of the rescuers. Therefore, prior to deciding upon the tactics, risks must be assessed. The IC must identify the threats and the vulnerabilities (subjects to threats) as well as assess the risks and implement all reasonable control measures. The risks must be recognized and controlled before committing rescuers into the danger zone.

In the State Fire Service of Poland there are no regulations that impose an obligation of risk assessment. There are no procedures or habits that introduce the methods of risk assessment or management. The management of F&R actions is regulated according to the general procedures. The procedures in the scope of the evaluation of the emergency scene distinguish reconnaissances: initial, complete and continuous. However, even the experienced ICs are not able to distinguish how these reconnaissances differ from each other, and what exactly should be done within the instance of each of these reconnaissances.

Having the incident – in the scope of the risks – poorly evaluated there is also a problem with proper controlling (by leading) the processes emerging during the F&R action. Therefore, the safety of rescuers and success of the F&R action depends strongly on the experience, knowledge and skills of individuals. The risk management maturity model [2] defines such a process management as *tribal and hectic*. The management of the emergency scene is ad-hoc and chaotic. The success depends primarily on individuals heroics, capabilities and verbal wisdom. The emerging processes are unpredictable, poorly controlled and reactive.

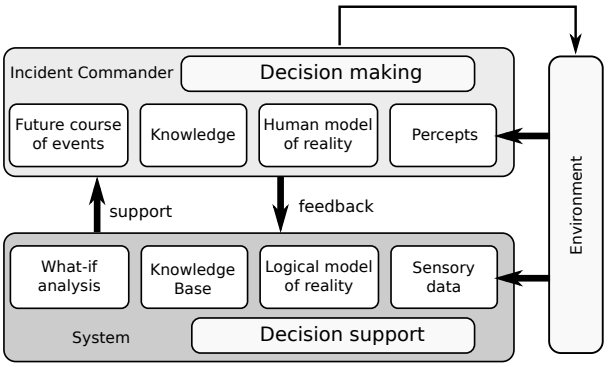

Fig. 1. Cooperation between the IC and the system.

So far there are no standalone computer systems that are able to support the IC at the emergency scene in the risk management activities. This is mainly caused by a) specificity of the decision making environment, b) problems of communicating the risk assessment to the IC. The issue of a) is caused by significant uncertainty and dynamically changing conditions of the objects and phenomena at the emergency scene. There is a problem with obtaining the information which satisfies the IC's *information triangle* rule [3]. It means that the information reported to the IC should be *relevant, accurate* and *timely*. The b) issue originates from the problem that the IC operates under time and mental pressure and has no time for longer analyses and more complex reports. The IC is very sensitive to information overload, simply not important from the intervention objectives point of view [4]. Moreover,

978-83-60810-58-3/$25.00

during the F&R action the IC reasons using the very abstract and vague concepts, such us safety, danger, threats, potential losses and others. Therefore, the system that supports and cooperates with the IC during the F&R actions should use the same concept's namespace as the IC. The system should gather information through the sensory layer and translate the concepts to be "compatible" with the model residing in the IC's mind. The accuracy of such an approximation is crucial in order to follow the IC's strategy and to provide help whenever any new risks arise. Figure 1 illustrates the correspondence of the IC and the software with respect to different aspects [5].

Creating the system which satisfies these constrains is a real challenge. There were a few attempts [6], [7] to build such systems. However, they depended strongly on a dense sensors networks which are not currently operating in the real world. Also, there was an issue with translating all these sensory data into whatever the IC could comprehend.

There are practical implementations that introduce the risk assessment in other countries' Fire Services. However, they are either complex and demand comprehending of large amount of information [3] by the IC or the are based on the IC experience [8]. Therefore, the safety of rescuers and the success of F&R actions depend again on the individuals. Implementing such approaches in the State Fire Service of Poland can only result in the advancement to the *specialist silos* [2] level in the risk maturity model (see Figure 2).

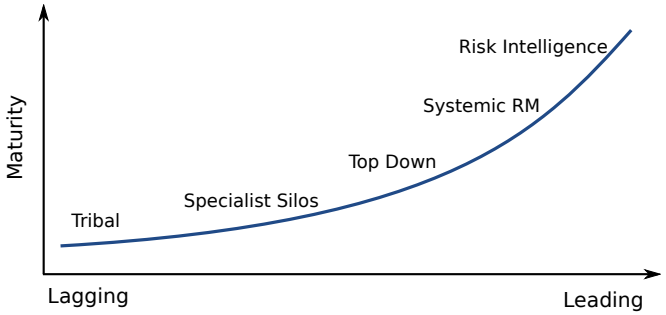

Fig. 2. Risk management maturity model chart.

In this article we present an approach which is able to transform the current *tribal* risk management model into *top down* (see Table I). The top down model is characterized by a) common framework, program statement and policy, b) routine risk assessment c) proper communication of strategic risks to the IC, d) knowledge sharing across risk functions e) awareness activities.

The rest of the article is structured as follows: in section II we present the context for risk management at the emergency scene, giving examples of applied risk assessment methodologies. Section III contains our proposition for the risk assessment. Section IV describes our methods for risk management at the emergency scene. The article is concluded with the evaluation of the approach and a discussion on the perspectives for the future work.

II. The Context

There are two leading approaches implemented for the risk assessment at the emergency scene. One of them is used by German Fire Service and is called *Threat Matrix* (in German – Gefahrenmatrix) [10], [8]. After arriving at the emergency scene German commanders have to recognise and evaluate the appearing risks. In order to do this systematically and not to miss any of the threats they have to fill the Threat Matrix. The Threat Matrix helps to identify both the threats emerging at the scene and the threatened objects (vulnerabilities). Having this information, the commanders can recognize the primary danger to deal with. The approach structures the problem of risk assessment, defining and limiting the set of threats and vulnerabilities to be recognized. However, the method strongly depends on individual experience and intuition. The definition of the consecutive threats are vague and there is no method of risks evaluation – the risks either exist or not. There is no evaluation of the likelihood of risk materialization and the consequences.

The more advanced approach — much more complicated as well — is one used by British Fire Brigade. The approach is composed from three risk assessment methods *Generic Risk Assessment (GRA) Dynamic Risk Assessment (DRA)* and *Analytical Risk Assessment (ARA)* [3].

GRA is a general framework for risk assessment in the Fire Service, regardless of the scope and nature of an incident. The approach takes under account the risks at every stage of duties – from the activities in the fire station via travel to the emergency scene up to the incident commanding. The approach links the risk with the conditions at the emergency scene and the tasks performed by the rescuers. "Generic" means that the values of the risks come from statistics based on the similar actions from the past. The results of the approach consist of a set of rules matching the given situation [11]. During the F&R action GRA allows the IC to operate under the standard procedures. GRA forms the foundations for DRA, operating procedures and training schemes. It also assists in the completion for ARA at incidents.

The second one, DRA, is used to describe the continuing assessment of the risks that is carried out in a rapidly changing environment at the emergency scene. DRA is defined in the initial phase and then reviewed continuously and updated. The outcome of DRA is a declaration of a tactical scheme for the IC, i.e. *offensive* or *defensive*. DRA is a continuous process and takes into account the continually and sometimes rapidly evolving nature of an incident. During DRA phase the IC refines the general rules defined by GRA [11] and fits them according to the state of the phenomenon, objects involved, equipment available and others. DRA must be reviewed continuously and updated as required. Having carried out the DRA and the tactical scheme established, the IC is aware of the immediate threats, vulnerabilities at risk and the control measures necessary to protect those vulnerabilities. This initial assessment of DRA further forms the basis of a more detailed risk assessment – ARA. ARA is introduced to analyse situation

TABLE I
THE RISK MANAGEMENT MATURITY MODEL [9]

Tribal and Hectic	**Specialist Silos**	**Top Down**	**Systemic**	**Risk Intelligence**
Ad-hoc/chaotic.	Independent risk management activities.	Common framework, program statement, policy.	Coordinated risk management activities.	Embedded in strategic planning, capital allocation, product development etc. across silos.
Depends primarily on individual heroics, capabilities, and verbal wisdom.	Limited focus on the linkage between risks.	Routine risk assessments.	Risk appetite is fully defined.	Early warning risk indicators.
	Limited alignment of risk to strategies.	Communication of too strategic risks to the Board.	Enterprise-wide risk monitoring, measuring and reporting.	Linkage to performance measurement/incentives.
	Disproportionate monitoring and reporting functions.	Executive /Steering committee.	Technology implementation.	Risk modelling/scenarios.
		Knowledge sharing across risk functions. Awareness activities.	Consistency plans and escalation procedures. Risk Management training.	Industry benchmarking.

in more detail on the basis of information obtained from the reconnaissance and from the rescuers. The special forms are defined and provided to the IC in order to help calculating and recording ARA [12]. The outcome of the review of ARA either confirms that the DRA and chosen tactical scheme was correct, or it results in a change of the scheme. This also provides the basis for the current and future DRA.

The discussed approaches enhance the risk assessment at the emergency scene and improve the safety of the rescuers. However, they have a major shortcoming: it is not easy to implement the risk assessment as a stand-alone, unsupervised computer process since they require a) a rich sensory infrastructure and b) a clever AI processing.

The issue with a) is continuously improving: the technology can deliver more precise, more modern and cheaper sensors each year which can produce lots of streams of data about various phenomena. The b) issue improves as well: there is a significant improvement in the fire and evacuation modelling [13], [14], the ontology modelling methodologies are being invented and evaluated, AI-based algorithms can support big data analytics and so on. We can therefore support the claim that the computer-driven Dynamic Analytical Risk Assessment, independent from IC is becoming more and more feasible.

III. DYNAMIC ANALYTICAL RISK ASSESSMENT

We propose an approach which allows for supporting the IC at the emergency scene in the managing of the risks. We called our approach Dynamic Analytical Risk Assessment due to the fact that the method reacts dynamically to the changing at the emergency scene and is detailed enough to be considered an analytical risk assessment. Our approach derives the foundations from the risk approaches presented in section II and uses the methods from AI to implement the ideas.

A. Scene Modelling

We start our process of creating the scene model from the review of the domain. We used a Use Case diagram for this purpose. The elaboration of the diagrams results also in a better mutual understanding between architect of the system, analytics and domain experts. The Use Case diagrams allow to extract the main objects, concepts and relation within the domain. Then, we used a set of documents called *incident analysis* in order to obtain the more detailed description of the domain. The documents study in detail the selected incidents and contain a comprehensive description of them, including the context, previous trainings at the objects involved, their recognition, the course of action minute after minute, decisions made and their background. It allows us for extracting (with support of domain experts) the complex objects, their hierarchy and spatio-temporal relation among them. The description was too complex to model it using Use Case diagrams. Therefore, we use the taxonomic hierarchies of classes defined by [15] in order to better represent the hierarchy and relationships between complex, plain objects at the emergency scene and their attributes.

In our approach we consider an emergency incident as a set of frames [16] from time t_s when the incident begins to the time t_e when the last crew come back to the fire station. A single frame F_n from the set represents the emergency scene at time t_n. The frame can be considered as a complex object which is composed by other complex objects such as buildings, equipments, rescuers, occupants and others. Figure 3 depicts the idea of the perception of the scene.

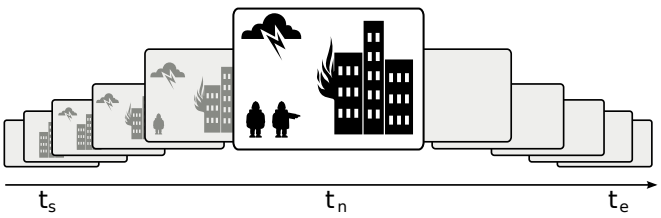

Fig. 3. The idea of frame-based scene modelling.

The complex objects within the frame may be composed from other complex objects or just by plain objects. Plain

objects are represented only using vectors of attributes values. We can create for each of the complex objects at the scene the hierarchy of sub-objects, attributes or both.

The attributes describing the objects can be static i.e. *nominal pressure* of the firefighting nozzle or dynamic when they reflect the current state of the object i.e. *a firefighter is exhausted*. The static attributes can be quite easily defined when the object is created. The values of dynamic attributes change continuously and are much more difficult to define. They depend on the situation at the scene and need communication with the sensory layer. For example, the level of the fatigue of the firefighter can be defined at the basis of breathing ratio and exhausted carbon dioxide concentration.

Modelling such aspects is challenging as it require to apply sophisticated methods. In order to face this problem we extend our ontology by the spatio-temporal perceptual concepts modelling defined by [17], [18]. The approach needs a domain ontology which is a core for reasoning processes. The creation of the domain ontology needs tight cooperation with domain experts. A cooperation with domain experts towards definitions of ontology is poorly studied. There are also no measures evaluating the correctness and completeness of the created ontology. Therefore a high attention should be paid in order to perform this correctly. First we created a draft of the ontology on the basis of domain literature [8], [19], [3]. Then we extended this draft with support of domain experts and contextual visualization [20] of the situation. In this process we involved not only the experts but also the software architects and psychologists. Figure 4 depicts the simplified snapshot of the created ontology.

B. Risk Assessing

The created ontology is only a carrier in our reasoning processes. It allows for structuring the problem and applying the method of *divide and conquer*. The evaluation of the value of the selected risk needs applying the hierarchical classification. This means that at the basis of lower layer concepts from our ontology we *approximate* a higher level concepts. We consider this process as an approximation because the concepts, objects or attributes from lower levels are not in such relation with higher level, which allows for its crisp definition.

The approximation of the higher level concepts by the lower level is a problem which in our case can be reduced to the classification problem. The standard classification uses the information system [21] for training the classifiers. The classifiers have to extract the features and their impact on decision class. However, in the hierarchical classification, where the decisions classes of lower level classifiers become the attributes for higher classes, the approach is insufficient due to the computing complexity. For example, in our case we have a sub-system for recognition of activities performed by rescuers [22]. The sub-system consists of a set of accelerometers and magnetometers placed in different body parts of the rescuers. In the purpose of the recognition of the activity of single rescuer the standard classification approach is good enough. However, if the recognition of some activity needs observing the group of rescuers (i.e. a tactic used to access the room on fire) the standard approach fails. This is caused by the necessity of consideration of a Cartesian product of each of the attributes values from the sensors.

In our approach, domain experts assist not only in the creation of ontology and categorization of objects/situations but also in learning the phase of classifiers. This recalls the human learning process when the tutor filters the information indicating features which plays the key role in the classification problem. In our case it is important that the higher level concepts (objects) are created as relational structures in which the points are represented by the vectors of attributes values from the lower hierarchical level and relations between them represent constrains. Over such objects the new attributes are defined with domain experts support. On the basis of this idea, the methods for ontology approximation were developed [23], [24].

We use the classifiers in order to induce the rules [25], [26]. Rules learnt from data can be used to support approximate reasoning about the concepts. Approximations can be considered both with respect to degrees of satisfaction of particular patterns in the observed data and the degrees of correspondence of previously unseen situations to already established ontology areas. It allows us for building the dynamic and spatio-temporal model of the emergency scene.

The presence, the state and the relations among complex objects at the scene define the concepts used by IC during the reasoning process. As was mentioned in the Introduction the concepts originate from the risk assessment field. Those are such concepts as: threats, vulnerabilities, risk, safety, danger and others. In order to approximate these concepts the across-hierarchy reasoning about objects within the frame is used, as well as spatio-temporal across-frames relations reasoning. For example, in order to evaluate, whether in a given moment the risk of explosion for rescuers exists, we have to consider the chances of *backdraft*[1] occurrence and recognition whether rescuers are currently entering the compartment on fire. Figure 4 depicts a simplified snapshot of the ontology created for recognition of the risk of an explosion for rescuers.

We present the methodology of risk assessment performed by the system, on the following example. The sub-systems for recognition of the activity of the rescuers and their position [22], [27] generate the stream of data. The set of classifiers uses these data to approximate the lower level concepts from our ontology (see Figure 4). These concepts are related to the navigation in the building, fire location as well as usage of rescue equipment. The decision classes from those classifiers constitute the attributes for higher level classifiers which recognize for example the usage of forcible entry tools. The usage of forcible entry tools simultaneous with the kneeling position of other rescuer approximate the concept of starting position of rescuers to enter the compartment on fire. The starting position of rescuers preceded by "gaining access to the fire" indicates that rescuers are already entering

[1] http://en.wikipedia.org/wiki/Backdraft

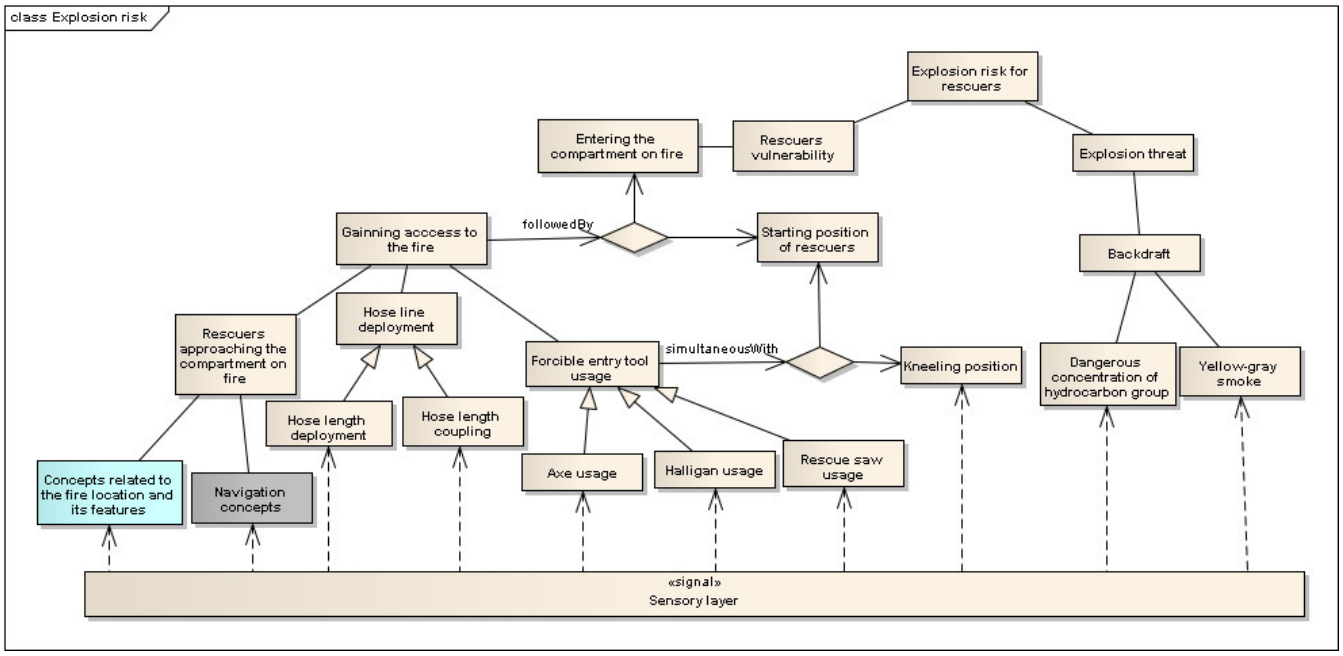

Fig. 4. The ontology for hierarchical spatio-temporal reasoning.

the compartment on fire creating vulnerability on the explosion threat caused by the backdraft phenomenon. The sensors from fire detector aspiration system and smoke observation provide the data for the classifiers which recognize the likelihood of explosion threat. All the concepts defined are introduced to evaluate the root concepts of *explosion risk for rescuers* (see Figure 4). The presented methods of feature extraction and filtering from lower level to upper level is supported by domain experts.

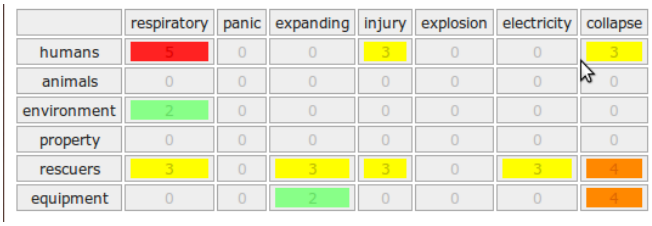

Fig. 5. An example Threat Matrix

C. Risk Communicating

As we mentioned in the Introduction, the IC is a very demanding subject to efficient risk reporting. Therefore, we introduce a hierarchical level of risk communication. We use the general indicator about the actual risk level at the top level of the hierarchy. Due to the fact that we use augmented reality glasses (characterized by low resolution) to communicate with intervention level commander, the highest level risk indicators are just two squares with colors: green, yellow or red indicating risk for human and rescuers. If the IC needs a more detailed information about the actual risks, the second level of risk communication is Threat Matrix. The Threat Matrix presents the threats at the emergency scene and the vulnerabilities which can be subjects to the threats. The example Threat Matrix is presented in Figure 5.

In most cases the matrix contains enough information for the IC to evaluate the emergency scene [8]. However, the less experienced ICs may need a more detailed explanation concerning the origins of the risks presented in the Threat Matrix. Therefore, we created the next level of information provided to the IC. We present the rules which were launched and served to calculate the given risks. Table II depicts the presentation of the rules.

TABLE II
THE PRESENTATION OF THE RULES THAT WERE USED TO CALCULATE RISKS IN THE THREAT MATRIX

Id	Situation description	L	S	Control
A1.1	farm site fires: presence of dust	2	1	use Personal Protection Equipment (PPE)
A1.3	hazardous atmospheres	1	4	Use PPE, Resuscitation equipment immediately available / monitoring of atmosphere
A1.7	asbestos on the roof (the hazard comes from breathing)	1	2	Use PPE, decontamination after intervention

The rules presented in the table contain also the control measures aimed at decreasing the severity if the risks do materialise. This is additional guide for less experienced ICs to help them in risk mitigation.

IV. Risk Management

The presented approach allows for the complete risk assessment at the emergency scene and for its presentation to the IC. However the risk assessment is only part of the process of risk management. The other important parts of this process are methods of risk mitigation and measurements of the effectiveness of the controls applied.

A. Risk Mitigating

The presented approach for risk assessment allows for reasoning under uncertainty about vague concepts at the emergency scene. This allows the IC for better assessing of the situation and keeping the operation safe. However, the better situational awareness is only part of the success of the incident risk management. Equally important is planning and operating. The good incident action plan (IAP) plays a key role in the successful incident management [19]. According to the [28] the IAP should contain the strategy of risk mitigation. A good mitigation plan predicts future course of events and proposes the adequate controls to mitigate the risks. Therefore, the risk management could be perceived as a game between the nature and the IC. In order to win the game IC has to recognize the "strategy of the nature". The recognition of the strategy and creating own strategy is a challenging task. We are not able to address the problem yet. Therefore we are going to face the problem in our future work aimed at transition of the system into *Risk Intelligence* (see Figure 2). At the current state of the research we are only able to hint the general recommendation and propose the control measures matching the rules from risk assessment (see example in Table II).

The system determines, on the basis of the risk assessment expressed by the Threat Matrix, whether the potential benefits (saved live or property) outweighs the undertaken risks. If this is the case, the system proposes the general recommendation – the tactics scheme – (*offensive* or *defensive*). The proposition of the scheme is based on the rules, taking mostly into account the chances that people are present inside the building and the building construction type. If this scheme is accepted by the IC, the system is trying to endeavour to reduce the risks to an acceptable level.

The second level in our *hierarchy of control measures* are the general strategies of applying the control measures. At every moment in the F&R action the system is trying to recognize whether any of the following strategies should be applied. *Eliminate* the risk or substitute it with something less dangerous. For example changing the scheme to defensive thus preventing rescuers access the danger zone. *Reduce* the risk by preventing or reducing the number of vulnerabilities that come into contact with the risk or reducing the time of the exposure to the risk. The strategy is calculated according the evaluation of the parameters of the fire [29] and the amount of resources needed to extinguish the fire or to rescue people. Ensuring that *discipline* is maintained throughout the exposure to the risk. This is performed by monitoring and visualization of activities performed by the rescuers [22].

The third level in hierarchy of control measures constitute the rules used for risk assessment. As it was mentioned in section III-B there were rules induced from ontology which approximate the concepts related to the risks. We asked the domain experts to define the controls which should be used if the given risks materialize. The number of rules, even limited to active at the moment, is significant. Moreover, the controls proposed are very detailed and need some attention while reading. Therefore, leaving the navigation across the rules to the IC would result in information overload. We tried to partially address the problem by introducing a tool called what-if analysis. The approach allows for keyword search, faced search or fast navigation across the rules. The IC or her/his assistant at the control room can quite quickly find, using the keywords, the rules matching the actual situation. This allows for fast review and implementation of proper control measures. The IC has access to the appropriate risk related information to assist with the identification of suitable control measures. This, in conjunction with other specific facts regarding the premises, for example information gained on risk visits, will assist the IC to formulate an effective plan.

B. Performance Indicators

The approach presented so far is designated to deal with the risk defined as a likelihood of threatening the vulnerabilities and the potential consequences [28]. However, during the rescue action there is also a risk related to the definition provided by ISO 31000 defined as an effect of uncertainty on intervention objectives [30]. This type of the risk is related to the tactics applied by the IC. Each of the activities of the rescuers committed by IC are characterized by uncertainty about the obtained outcome. This type of the risk should be measured by the defined performance indicator of applied strategy.

The performance should be measured against agreed standards to reveal when and where improvement is needed. Active self-monitoring of the system reveals how effectively the management system is functioning, looking at the equipment, processes and individual behaviour/performance.

Every incident has an objective that reflects the mission's objective – protect life, property and the environment from harm. An IC develops a strategy for accomplishing this mission, depending on the conditions that exist at the time. The rescuers execute the full mechanics of the tasks to complete each phase of the operation at the emergency scene. These tasks are based on fundamentals – ventilation; nozzle operation; water flow rates; secondary egress and emergency bailout by ladder.

Although each of the incidents is different there are common tactical phases of the incident management. There can be distinguished: arriving, reconnaissance, resource deployment, gaining access to the fire, search and rescue activities and extinguishing. Each of the phases has a set of activities and the outcome. The activities should be performed with accordance to the tactic and training processes, executing the rule "play as you train". Therefore, we can define in each tactical phase

the checklist which should be completed if the IC obeys to the procedures. There also should be observable, measurable effects for each of the tasks that is performed, which can be observed by the system, and the effects of completion of each step as the outcome.

If the set of activities at each phase is performed according to the checklist and the outcome is consistent with the expectations (trained) then we can state that the risk of the intervention objectives is low. If the IC is not well-trained, insubordinated and does not obey the defined checklist, then the risk related to the uncertainty on the intervention objectives rises. The analogous situation is when the conditions of the incident are changing in an unexpected way – then the risk also rises.

For example, the rescuers are in the phase of entering the compartment on fire. The checklist consists of: rescuers in full gear kneeling before the door, breathing apparatus in use, hose line wet, forcible entry tools ready to use, second squad ready for assistance, etc. The outcome of the phase are the jets cooling the ceiling and opened windows. Every task and tactical procedure completed is also reported as a "benchmark".

C. Call for Action

Apart from the organization of the scene where the risks are assessed, the main idea of this process is the *call for action*. Having the risks assessed we have to communicate them in such a way that forces the stockholders to the action of the risk mitigation. In our system the call for action is implemented by risk exposure and control activity level matrix. Figure 6 depicts the idea of the matrix.

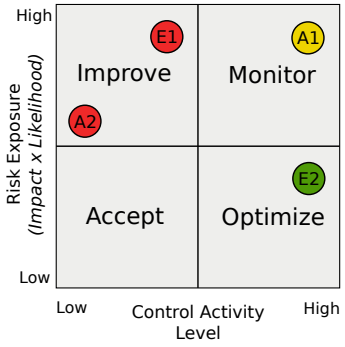

Fig. 6. Risk maps for presenting risk/control relationships.

There are four areas distinguished in the matrix. *Improve* is the area of high risk exposure with a low level of control. This area must be key priority for improvements in management and control activities. *Monitor* is the area of high risk exposure where controls are deemed adequate. This area should be monitored to provide the ongoing assurance of control effectiveness. *Accept* is the area of low risk exposure that also have a lower level of control. This area may be consciously accepted by the IC. *Optimize* is the area of low risk exposure with a high level of control. This area may generate opportunities for the IC to optimize the management and control activities.

Such a visualization of the risks and the controls illustrates clearly the areas where the current controls are not sufficient to operate in safe condition. This forces the IC to mitigate the risk in such areas or to lower the risks by it avoidance. The location of different risks within the given areas of risk maps is calculated according to the rules presented in Table II. The rules beside the calculation of the risks have also defined the control measures which help to mitigate the risks. If the selected rule is active and there is no adequate control applied then balance between the risk and the control is biased. The location of a given risk within the risk maps depends also on the risk level. Figure 6 illustrates that the risk caused by threats A2 and E1 should be handled by implementing the additional control measures; threat A1 creates a high risk, however it is properly controlled and some controls from E2 may be relaxed.

V. Conclusions

We present an approach allowing for the management of the risks at the emergency scene. The approach defines the framework for scene modelling, introduces the reasoning algorithms, risks mitigation methods, performance measuring and risk reporting and communicating. We implemented all the presented ideas into a standalone computer system. However, so far the system is not deployed in the State Fire Service of Poland. Our system is currently at the 4 level of Technology Readiness Level[2] It means that the main technological components of the system are integrated to establish that they will work together. This is relatively “low fidelity” compared with the eventual system. The system was tested in the laboratory with controlled parameter of the fire and many assumed simplifications. However, on the basis of the performed experiments we can support our claim that Dynamic Analytical Risk Assessment, independent from IC is becoming feasible.

We argue that it is possible to improve the quality of interventions and minimize the corresponding risks by providing IC with the support in the following areas: a) grouping and interpreting incoming information by means of higher level concepts and linking them with intervention objectives; b) filtering and ranking information; c) indicating which information is missing in order to make reliable decision; d) indicating where and how to acquire important information; e) monitoring situation and decisions made so far. We claim that such functionalities can be achieved through a combination of modern methods from the domain of Information System Security Risk Management, data organization with compliance to ontological approaches and interactive algorithms processing recommendations for IC. We pointed out that there is still a gap between analytical models and human abilities to benefit from them.

Data Cleansing of the Fire & Rescue Text Corpus.
The Case Study of Correction of the Misspellings and Segmentation into Sentences

***Abstract*—The article presents a case study of applying data cleansing methods and segmentation procedures in order to correct and enhance the structure of the domain corpus of fire service. During the study we present our approach and the results in the task of correcting the misspellings, as well as the method of segmenting the corpus into sentences.**

***Index Terms*—Fire Service, Data Cleansing, Text Corpus, Misspellings, Segmentation**

I. Introduction

OVER the years, the National Fire Service of Poland collected a large corpus of texts from about 6 million incidents. Unfortunately, there was little validation of the input which resulted not only in the (too much) free form of the texts which is difficult to automatically process, but also in lots of misspellings and lack of structure (sentences boundaries) which further impede computer analyses.

Our research was focused on finding the characteristics of the above problems and by using mostly regular expressions, n-gram analysis, spell checkers and databases of some entities (e.g. geographic locations) as well as reference domain texts (fire & rescue journal) we tried to cleanse the corpus.

The paper is structured as follows: In section II we introduce the fire & rescue text corpus named EWID. In section III we present our motivation and the context of our research. In sections IV and V we provide the details of how we corrected the corpus.

II. Characteristics of the EWID corpus

The national fire and rescue services (just like, e.g., police) are typically equipped with the incident data reporting systems (IDRS), which gather the information about conducted actions. Each of approximately 500 Fire and Rescue Units (JRG) of the State Fire Service of Poland (PSP) conducts around 3 fire & rescue actions per day. After every action a report is created in EWID – the internal computerized reporting system of PSP [1]. As of 2014, the total number of the reports in EWID is around 6 million, of which about 0.3 million records were available for the purposes of this research. Each record contains 560+ attributes (only a few dozens are usually set per record). Most of these attributes provide yes/no information about action parameters (binary), but there are also timestamps, quantities and short text entries. There is one attribute which we consider distinct: the natural language *description* of the action.

The collection of the 0.3 million EWID *descriptions* contains about 60 MB of texts, which is about 8 mln of words, written in semi-natural, technical language. Following is a sample passage from the corpus (awkward vocabulary and misspelled words are intentional):

"Affer arriving at the fire scene the undergrowth fire was observed. Two firefighting jets ware applied and suction line from the nearby lake was created. After putting out the fire, appliance crew came back to fire station".

The concern is that over the years this large corpus which contains valuable information has been collected with limited validation of the input. This situation is considered quite common in the real world data collections [2], [3]. The corpus in scope requires data cleansing followed by further processing in order to improve the semantics. This case study is focused on the data cleansing only. It may be beneficial for other text corpora, which are affected by typographic errors. We know of projects where data cleansing step was explicitly skipped, as the expected solution was no other than a laborious human work [4], [5]. In this work we propose a mostly automatic, iterative process supervised by domain experts. It is important to mention that we are more interested in having the entities in the text unified (disambiguated) rather than grammatically correct. We assume, that for the purpose of further operations on EWID corpus, such as clustering, statistical analysis, and so on, this unification may be beneficial.

III. Motivation

The motivation for the corpus reparation is to prepare the ground for further processing. In our particular case there was a need to have the data cleansed when working on a concept of a decision support system named CLEWID [6]. CLEWID is a proposition of a platform for fire & rescue data analyses. It is built of 4 layers, namely: 1) the raw data layer (EWID

978-83-60810-58-3/$25.00

and other sources), 2) the quality data layer, 3) the granular (semantic) layer, 4) the models layer. The scope of this article is to transform the raw data layer into the quality data layer to have the higher level layers operate on the more precise and strict data. The semantics are fixed on the granular layer, since granulation is about organising the data based on various aspects of their similarity.

IV. Details of corrections of the misspellings

The process was divided into stages. Each stage describes another approach and provides the information how much gain was achieved.

1) Removal of redundant characters: The lack of the validation for the *description section* in EWID database results in various characters being incorrectly inserted. This may result in creation of alternate forms of the same entities (e.g. GBA3 vs GBA-3). The selection of the characters which should be removed requires the input from the expert – this step can be done by searching for the words containing non-alphanumeric characters and deciding which of the characters should be dropped. In the case of EWID corpus most of non-alphanumeric characters were replaced by space. Additionally, digits at the beginning of a word boundary and hyphens within word boundaries after a letter and before a digit were removed.

2) Frequent words not recognized by the dictionary: At this stage there were 8,044,535 words including 309,036 words which were not recognized by the popular *aspell* spell checker [1] (3.8% error ratio). 500 most frequent (the reasonable number for a human to manually process) of the 309,036 not recognized words were extracted from the corpus. 200 of these entries proved to be valid words from domain vocabulary – it was reasonable that aspell didn't have them in its database. Automatic corrections by aspell were proposed for the remaining 300 and they were later manually adjusted by the expert. The knowledge from the domain expert was instrumental in achieving reasonable outcome, as some cases were not quite obvious. For example, aspell proposed 'dzielenie' (division) as the correction for the misspelled word 'dzialenie', which was overruled by expert's 'działanie' (action). The corrections were applied to the corpus and the spell checker was rerun. The error ratio dropped to 2.9%. This particular fix was an example of a huge gain with little effort.

3) The additional dictionaries: In order to extend the spell checker, we searched for collections of the domain vocabulary. There exist a number of texts collections which could serve as a reference in composing the domain vocabulary (domain knowledge). Ultimately, the expert decided that the domain journal "Przeglad Pozarniczy" (*PP*)[2] would contain the texts that are most relevant for the operational content of EWID corpus. PP publishes fire & rescue related articles, and by the fact that it is a journal it (hopefully) contains very small amount of misspellings. We spell checked the acquired PP corpus and all the misspellings reported by aspell (words not found in standard dictionary) were treated as candidates for domain vocabulary, thus domain dictionary was created. The extended spell checker reported error rate of 2.15%.

The idea to use a good quality domain corpus as an extension of a spell checker came after we already fixed the 500 most frequent words manually (as described in the previous section). The spell checker extended by journal-based domain vocabulary would likely have recognized most of the frequent words from EWID since they come from the same domain of fire & rescue. The lesson learned is that the domain vocabulary should be used as early as possible (if it is available).

By knowing the content of EWID the expert added more elements to dictionary. Geographical entities – streets, cities and districts were obtained from the external public sources (Polish governmental/administration organisations) and became another extension to the dictionary. The spell checker extended with the domain vocabulary and geographical entities was rerun and the error ratio dropped to 1.75%.

Another key step was the inclusion of surnames. Surnames in EWID are frequently reported as misspellings by aspell. Fortunately most first names are recognized by aspell. The public database of Polish surnames and first names was acquired and roughly checked for the completeness against our students surnames database (around 200 entries). 97% of the surnames were recognized, so the completeness of the surnames database was reasonable. However, this mechanism proved to be too greedy – too many actual misspellings were being forgiven as possible surnames. We needed to drop the surnames database. The spell checker extended with domain vocabulary, geographical entities and names reported 1.56% of errors.

4) The n-gram approach: The knowledge-based extensions of spell checker's dictionary exhausted the inventory of easy fixes. The remainder of the misspellings in the corpus required more extensive approach. The method that we have applied replaces (corrects) a misspelled words using their nearest correct neighbor. The neighbor(s) of a given word needs to be identified in a meaningful way. For this purpose, the list of all 3-grams (unique triplets of words in the corpus) was created. This list was spell checked with the use of the extended spell checker introduced above and, as a result, split in two. The `3-grams.correct` and `3-grams.errors` contain 3-grams recognized as correct and misspelled, respectively. Then the `3-grams.errors` list was iterated to find the nearest entry on the `3-grams.correct` list. The measure we use is the Levenshtein (editorial) distance [7]. The correction was applied if the distance between the misspelled trigram and correct trigram was less or equal 2. The threshold of 2 was set by the domain expert after his inspection of a sample of such corrections.

At this stage we faced a computational problem. The corpus is a collection of about 8 mln words. The building of the 3-grams.errors (about 0.3 mln entries) and 3-grams.correct (about 2 mln entries) databases proved to be unexpectedly quick. However, the performance of finding the closest match for each entry from 3-grams.errors in 3-grams.correct database

[1] GNU aspell, http://www.aspell.net/

[2] ISSN 0137-8910, http://www.ppoz.pl/

was very poor when choosing a simple approach: for each trigram in 3-grams.errors iterate over 3.grams.correct and calculate the Levenshtein distance between the two elements in each step. Database indexing of 3-grams.errors was not an options, since we didn't operate on exact matches, but needed to always calculate the difference.

Therefore we searched for a better method than scanning this large corpus and calculating the distance. The imaginary example below illustrates our solution:

Let us consider an example corpus of words

a-correct b-correct c-error d-correct e-error f-error.

For this corpus, there are 4 possible trigrams. Let us search for contexts contain the c-error:

(a) *a-correct b-correct c-error*

(b) *b-correct c-error d-correct*

(c) *c-error d-correct e-error*

A number of conclusions can be drawn from this observation: 1) the best context to fix the c-error is the (b)-trigram as it provides most likely the best (left and right) context for the misspelling, 2) the trigrams are redundant – it is enough to consider just one from the three above to have the c-error placed in the context, 3) the other two words in each trigram can be either correct or misspelled.

The third conclusion can be inspected further. At this stage the corpus contained around 2% of words with errors. The chances for two misspelled words occurring in one trigram seem low; assuming the misspellings are normally distributed across the corpus – there should be very few such trigrams. However, the assumption of normality proved to have a flaw, since in the population of humans, there are ones that tend to produce misspellings and others who do not. The result is that there occur trigrams with 2 misspelled words and less (but still) with all 3 words misspelled. Luckily, the prevailing majority of the trigrams were composed of one misspelling in the context of two correct words.

Considering the above, our approach proceeded as follows: the trigrams containing misspellings were split into two groups: i) a large group of trigrams with only one misspelled word, and ii) a small group of trigrams with two or three misspelled words.

Concerning the ii) group the plan was simple: the accepted Levenshtein distance was increased from 2 to $2 \cdot n$, where n is the number of misspelled words in the trigram. Then these trigrams were a subject to a linear scanning through the `3-grams.correct` database and because the small number of misspelled trigrams it proved not to be a computational issue.

In the group i) we started with our conclusion that trigrams are redundant. There are 3 setups for a misspelled word to be placed in the trigram, of which we choose the scenario (b) *b-correct c-error d-correct* (misspelling in the middle). The other two setups can be safely dropped since the goal of fixing the misspelled word can be achieved based on just a single context. The trigram was then reorganized into an associative array with the context as the key and the misspelled word as the value, i.e. *key="b-correct d-correct"* and *value="c-error"*. This structure later evolved: since between *b-correct* and *d-correct* more misspelled words may appear in the corpus, the value of the array should be a placeholder for more objects than just *c-error*. Therefore the final data structure has the form: *key="b-correct d-correct"*, *value="array('x1-error', 'x2-error', 'xN-error')"*. The same data structure was applied to the `3-grams.correct` database. The keys were hashed. The task has now become the searching for a hashed key of the misspelled trigram in the hashed keys of `3-grams.correct` database. Once the matching key is found, the Levenshtein distance between the given *xN-error* word and all the correct words (a small array) for the corresponding key in `3-grams.correct` database is calculated. This method proved to be very effective computationally and resolved the issue. The overall error rate dropped to under 1% after incorporating the ngrams method.

V. The Segmentation into Sentences and the Abbreviations

Another step in enhancing the nature of the date was the segmentation of corpus into sentences. It is important to note that the standard procedures of segmentation into sentences assume that the corpus is rather free from misspellings, that upper/lower case and other language rules are strictly obeyed – for such pure corpora the approaches like [8] could be more easily applied.

There is a couple of aspects related to sentences: 1) it is not proper to treat a dot as a terminator of a sentence since dots also appear in abbreviations 2) words which end with a dot may be not recognized by aspell either because they are misspelled or because they are correct domain abbreviations not known to aspell 3) for the n-grams analysis: trigrams should not cross the sentence boundaries 4) having the corpus segmented into sentences allows for enhanced further processing in more abstract layers. In many applications the sentences can be the smallest building blocks, e.g. in the Computer Aided Translation systems such as OmegaT [3] the sentences are atoms.

For the sake of simplifying our further considerations, let us introduce the terms *a sentence terminator* meaning *the last word of the sentence* and *a dotted word* meaning *word ending with a dot*.

We tried to automatically extract the abbreviations from the corpus. First we found all dotted words and sorted them by the number of the occurrences in the corpus. Table I is the header of the resulting list.

As this list extends there are less and less abbreviations, but we can not make any assumptions that after a certain position of this list there won't be any abbreviations. This is particularly true if we realize that the distribution of words in a text corpora is a Zipf distribution [9]:

"In human languages, word frequencies have a very heavy-tailed distribution, and can therefore be modeled reasonably well by a Zipf distribution (...)" [10].

[3] OmegaT, The free (GPL) translation memory tool, http://www.omegat.org

TABLE I
OCCURRENCES OF DOTTED WORDS

word	en translation	occurrences	abbreviation?
st.	fireman	54716	Y
ul.	street	40162	Y
C.	Celsius	39772	N
sprawny.	operating	26733	N
ok.	around	22184	Y
temp.	temperature	18295	Y
p.	floor	17087	Y
ůmieci.	garbage	13662	N
zdarzenia.	incident	12464	N
wody.	water	9706	N
budynku.	building	8097	N
lasu.	forest	7159	N
zach.	west	6368	Y
...			

The result from being a heavy-tailed distribution is that most words in the corpus (say 80%) appear relatively seldom (say 3 times). Taken the large number of the words, that means that we should be aware of the weakness of any manual action against the corpus, as we will only process a small portion of all the entities. Therefore, we look for a more automatic way of distinguishing the abbreviations from the sentence terminators.

We assumed that any sentence terminator may also appear in other position than at the end of the sentence, thus not end with a dot. Then we inspected the fraction: $f = w_d/(w_d+w)$, where w_d is *the frequency of occurrence a dotted word* and w is a *the frequency of occurrence of the same word without a dot*. f should return higher values for abbreviations. By inspecting the table II we can expect that the good threshold should be somewhere around 0.50 – higher values would be the abbreviations, lower values would be sentence terminators.

TABLE II
OCCURRENCES OF DOTTED WORDS AS A FRACTION OF $dotted/(dotted + notdotted)$. HIGH VALUES SHOULD INDICATE ABBREVIATIONS

word	en translation	fraction	abbreviation?
st.	fireman	0.99	Y
ul.	street	0.95	Y
C.	Celsius	0.10	N
sprawny.	operating	0.28	N
ok.	around	0.84	Y
temp.	temperature	0.89	Y
p.	floor	0.77	Y
ůmieci.	garbage	0.16	N
zdarzenia.	incident	0.09	N
wody.	water	0.14	N
budynku.	building	0.20	N
lasu.	forest	0.34	N
zach.	west	0.52	Y
...			

This method allows for pretty good results and abbreviations can be easily separated. However, a quick inspection of the full list reveals that false positives (not abbreviations) happen for values of above even 0.80. Therefore a few more features are added:

1. The number of characters in the word. Abbreviations should be short, that is an implicit part of their definition. The dotted words were getting benefit/penalty points for being short/long.

2. Position at the end of a paragraph indicates towards a sentence terminator. We added benefit points for each dotted word ending any paragraph.

3. Similarly, position directly before the beginning of a sentence indicates towards a sentence terminator. How to define the beginning of a sentence? The first idea was to treat any word beginning with an upper case as a likely beginning of a sentence. However, "kpt. John Snow" phrase quickly proves it is not entirely true. Instead, we built a list of bigrams starting with an upper case. Then we selected just the bigrams that occur often, more often than bigrams containing Names and Surnames – "John Snow" is not a frequent phrase in the corpus mentioning probably thousands of humans. Such frequent bigrams should very likely be the beginnings of the sentences. We added benefit points for the dotted word if it occurred before any beginning of a sentence (one occurrence is sufficient as it proves that such a word is a proper sentence terminator).

Finally we constructed the classifier based on the above features 1) the ratio of occurrence the dotted word with/without the trailing dot 2) the number of characters in the word 3) position at the end of a paragraph 4) position before the beginning of a sentence. The classifier was simply the sum of the 4 indicators, each of them normalized to <0,1> range. The list of sentence terminators was obtained and the corpus was segmented at each point were the sentence terminator with a trailing dot occurred. Manual browsing proved that this method was correct in about 97% cases, which seems a good score.

A. An example of the segmentation of a block of text into sentences

Let us illustrate our approach with the segmentation of an imaginary block of text: *Today temp. was 10 C. Strong wind from east. The fire was successfully put out.*

There are following dotted words to consider: temp, C, east, out. According to all of our considerations, the following would happen:

a) temp seldom appears without a dot in the EWID corpus. Some humans tend to write it without a dot (which is a mistake), but most write it properly and the statistics suggest it is an abbreviation. Our classifier correctly identified it as an abbreviation.

b) C is very short which suggest an abbreviation. Some firemen do follow C by a dot: "10 C." while it should be "10 °C". However, C is often spotted without the trailing dot, also spotted before the beginning of a sentence or even at the end of paragraphs which is a strong premise for a sentence terminator. Our classifier identified it as a sentence terminator.

c) east appears at the end of paragraphs and often without a dot. Our classifier identified it as a sentence terminator.

d) out appears at the end of paragraphs and often without a dot. Our classifier identified it as a sentence terminator.

The above block of text was therefore split into 3 sentences, which is correct.

B. Discussion

The knowledge-based data (text) correction method that we propose makes it possible to reduce error (typo) ratio from 4% down to below 1% (four-fold) in the EWID corpus. The cleansing/correction methods described above may also be tweaked for clearing the corpus from sensitive and private data. For example, there is an issue with sharing EWID corpus because it contains personal data (names, addresses, etc.) These sensitive data are not always easy to pinpoint, and the presented methods may help in this task, making anonymization of the text corpus feasible.

We also managed to quite successfully segment the corpus into sentences – the algorithm correctly proposed the endings of the sentences with about 97% accuracy. EWID system was hopefully carefully designed, but life often proves to find shortcomings in many designs, once these designs start to operate in the real world. The issue is that the designers seem to have lost their control over the content – there are difficulties in finding certain, fuzzy information (e.g. finding the information about all the accidents with the buses). Over the years EWID became the collection of lots of information in form of unstructured texts and it became a playground for researches like this one. One of our future ideas is to semantically inspect the content of EWID and sentences seem to be the proper building blocks for such an analysis. Once we have the sentences correctly defined we can cluster the whole corpus based on the sentences and then inspect the meaning (semantics) of each cluster. We believe that the system could improve the validation of the input by checking the input against it's knowledge base and then tag/correct/propose or otherwise interact with the human introducing the data.

What was learned from the experiment is a confirmation of [11]: "Usually the process of data cleansing cannot be performed without the involvement of a domain expert, because the detection and correction of anomalies requires detailed domain knowledge. Data cleansing is therefore described as semi-automatic but it should be as automatic as possible because of the large amount of data that usually is be processed and because of the time required for an expert to cleanse it manually. The ability for comprehensive and successful data cleansing is limited by the available knowledge and information necessary to detect and correct anomalies in data.".

The process of data cleansing has an iterative nature. Different aspects appear after the nature of data is better know, new thresholds must be checked, then parameters tweaked and then the whole process must be rerun. There is a difficulty with the order of the undertakings. On one hand we would like to start segmenting into sentences very early in the whole process of data cleansing. But at this time we would like to have the misspellings fixed already. In order to fix misspellings on the other hand, we use n-grams analysis which should not cross the sentences boundaries, but the sentences boundaries are not yet defined. We therefore need to run the analyses simultaneously and iteratively, as stated before. There is also the question whether bothering with data cleansing is worthwhile – the alternative is to accept that there is noise in the data (google and other search engines accept such noise after all). Answering the question of how much gain we achieve by cleansing the data would be possible after performing specific researches in higher level layers, e.g. the proposed CLEWID platform, where models operate on these lower level data. However, we didn't conduct such experiments.

***Abstract*—In this paper we describe an evacuation modeling framework based on a graph representation of the scene which is derived from its geometric description. Typically such graphs (geometric networks) are constructed using Medial Axis Transform (MAT) or Straight Medial Axis Transform (S-MAT). In our work we use Voronoi tessellation of a set of points approximating the scene (a single floor plan) along with the dual graph – Delaunay triangulation. Using these two graphs we extract not only the information about paths in the building, but also information about path widths and areas assigned to vertices. Typically only path lengths from MAT or S-MAT based geometric networks are used in evacuation modeling. Our approach enables us to include flow analysis and e.g. locate bottlenecks. We discuss a typical density-based evacuation model coupled with a partial behavioral evacuation model within proposed framework.**

I. Introduction

ICRA project (http://icra-project.org/) aims to provide modern engineering tools to support fire commanders during firefighting and rescue operations.

As a module in this project, we aim to build a framework which would provide the basis for implementation of density-based (flow-based) evacuation models. While density-based models only represent one approach to evacuation modeling [1], we nevertheless stress that they are very similar to hand calculations carried out using methods described in [2], [3] and thus are the easiest for experts to understand and assess. Advantages and limitations of different methodological approaches have been discussed in [4].

While the assumptions of specific models, their degree of complexity as well as their specifics may differ, all of these models will operate on the same underlying representation of the scene. On one hand, the scene is represented by a building model which describes geometric properties, on the other hand, it is represented by a graph that describes the topology of connections in the building. Such a graph is called a *geometric network* [5].

Vertices in a geometric network correspond to so-called transition points, whereas edges correspond to paths. Geometric networks are widely used in geographic information systems [5], and indoor navigation systems [6]. A computational geometry tool that has been often used in construction of geometric networks from planar plans is *Medial Axis Transform* (MAT) or *Topological Skeleton*, introduced by Blum [7].

Indoor navigation models for the purpose of emergency movement were previously studied in [8], [9], [10]. Building representations that supplement each other seem to be a common trend in the literature, see e.g. [11], [12], [13].

In this paper we describe an approximate process of constructing a geometric network that is further enriched: Vertices are assigned to areas in the building and edges are enriched by information about path lengths, widths, and stairs parameters that affect maximum flows. We also discuss an implementation of a typical density-based model [2] coupled with a partial behavioral model based on PD 7974-6 norm [3] within the proposed framework.

The outline of our paper is as follows: First we briefly describe the process of evacuation and the role of evacuation modeling in ICRA project. Afterwards we introduce two evacuation models: one includes a behavioral component, the other one is strictly a (density based) movement model. In the following sections we briefly discuss Building Information Modeling (BIM) and the process of geometric network calculation in our model.

Granularity announced in the title will become apparent when we discuss the duality of vertices in the graph and areas in the geometric description of a building.

II. Evacuation process

Evacuation models are typically implemented in the context of building safety analysis. In this usage scenario, which needs to address the worst-case usage pattern of a building, one is usually interested in comparison of available safe egress time (ASET) and required safe egress time (RSET). ASET is the period of time which permits safe escape from a building. RSET, on the other hand, is the time between ignition of fire and the completion of evacuation. Methods of ASET estimation are outside of the scope of actual evacuation modeling, although some models (e.g. buildingEXODUS [14] and FDS+EVAC [15]) enable joint fire and evacuation calculations or inclusion of fire simulation results in evacuation

This work was partially supported by the Polish National Centre for Research and Development (NCBiR) – grant O ROB/0010/03/001 under Defence and Security Programmes and Projects: "Modern engineering tools for decision support for commanders of the State Fire Service of Poland during Fire&Rescue operations in buildings", and by the Polish National Science Centre grants DEC-2011/01/B/ST6/03867 and DEC-2012/05/B/ST6/03215.

calculations [1]. In what follows, we remind the typical [3], [2] model of RSET calculation. Following [2] and [3] (from which we borrow the notation) we define:

$$RSET = \Delta t_{\text{det}} + \Delta t_a + \Delta t_{\text{evac}}$$

where Δt_{det} denotes the time between fire ignition and detection, Δt_a is the time of alarming, and t_{evac} is the actual evacuation time. Δt_{evac} is further decomposed as:

$$\Delta t_{\text{evac}} = \Delta t_{\text{pre}} + \Delta t_{\text{trav}}$$

where Δt_{pre} is pre-movement time and Δt_{trav} is travel time. Pre-movement time consists of recognition time (the time it takes an alarm aware occupant to take action) and response time (additional time it takes the occupant before he starts walking towards exit).

III. Evacuation model as a decision support system

There are important differences between typical usage of evacuation models and the usage scenarios considered in ICRA project: In building safety analysis, one typically aims to analyse potential worst-case scenarios, whereas during a Fire Rescue Action the placement of occupants may be known, and the model is used to assess this specific situation.

In ICRA project, the end user is the fire commander. Two primary use cases that we consider are direct assistance in Search and Rescue operations and providing a rough estimate of egress time along with bottleneck analysis. Usage scenarios differ mainly in assumptions of occupant localization. We cover these from the least to the most specific:

- In most situations, rough occupant density assumptions can be made based on domain knowledge. For example, if a fire alarm is triggered at a school at 9am, we can expect the highest overall density, with most classrooms utilized. Further assumptions about typical class size (e.g. 20 pupils) can lead to accurate evacuation time estimates. A uniform density in all rooms may be assumed without further clues.

The following two points are still an area of research, but we nevertheless stress them now as the current roadmap of our research:

- If technology permits, we may infer vague hints as to density placement of people in different parts of a building based e.g. on cellular traffic or information from other sources. Thus, we may rule out certain bottlenecks that would not be apparent if we assumed an overall uniform density of people in the building.
- We also consider a very specific scenario where only few occupants are left in the building, and their locations are (approximately) known. The module could provide hints for navigation of fire fighters and directly support Search and Rescue operation rather than provide egress time estimation.

In this paper we only consider the first usage scenario: we assume that occupants are uniformly placed in the building. We wish to estimate total egress time and determine possible bottlenecks in building structure. The model should also provide a plausible forecast for a given timestamp.

IV. Implementation of PD 7974-6 norm

PD 7974-6 norm by British Standards Institute [3] describes an algorithm of RSET calculation that encompasses two scenarios: a sparsely populated and a densely populated building. If the building is densely populated, first occupants will usually have shorter pre-movement times than in the other scenario [3], but a queue may form quickly afterwards, limiting the outgoing flow. If the building is sparsely populated, the movement is unobstructed, but pre-movement times of last occupants may be longer (e.g. there may be nobody around to notify them). Thus, the overall evacuation time for the first scenario may be calculated as:

$$\Delta t_{\text{trav}}^{\text{sparse}} = \Delta t_{\text{pre}(99)} + \Delta t_{\text{trav(walking)}}$$

and for the second scenario as:

$$\Delta t_{\text{trav}}^{\text{dense}} = \Delta t_{\text{pre}(1)} + \Delta t_{\text{trav(walking)}} + \Delta t_{\text{trav(flow)}}$$

where:

- $\Delta t_{\text{pre}(99)}$ is the pre-movement time of the 99th percentile of occupants in a sparsely populated building,
- $\Delta t_{\text{pre}(1)}$ is the pre-movement time of the first percentile of occupants in a densely populated building,
- $\Delta t_{\text{trav(walking)}}$ is the unimpeded evacuation time of an occupant with the longest path to the exit.
- $\Delta t_{\text{trav(flow)}}$ is the queuing time of occupants at the exits.

Usually $\Delta t_{\text{trav}}^{\text{sparse}} < \Delta t_{\text{trav}}^{\text{dense}}$, although in some situations the opposite may hold true, hence both scenarios are usually considered.

PD 7974-6 also describes the calculation procedure of pre-movement times for several behavioral scenarios and building types (characterized by their complexity, management level and alarm system). For the rest of this paper we assume that parameters required for calculation of pre-movement times (according to the discussed model) can be provided by an operator of Fire Command Center.

It is worth stressing that in this setting, alarm times and pre-movement times for certain scenarios are intervals, thus the output of the discussed evacuation model is not a single number, but a 2×4 matrix that describes the sparsely-populated and densely-populated scenarios, e.g.:

scenario	Δt_a	Δt_{pre}	$t_{\text{trav(walk)}}$	$t_{\text{trav(flow)}}$
sparse	$2-5$	>20	10	0
dense	$2-5$	>10	10	15

Fig. 1. The output of the model consists of time (in minutes) of alarming-time, pre-movement time and evacuation time (walking and queuing) for different scenarios. Pre-movement time in the sparse scenario corresponds to the last occupants (99th percentile), whereas in the dense scenario it corresponds to the first occupants (1st percentile).

In this setting, Δt_{pre} corresponds to inter-percentile range of pre-movement times of all occupants in the building. Pre-movement time of a single occupant in the building typically

follows approximately log-normal or normal distribution [3] (log-normal), [16] (log-normal or normal). It is worth stressing that other approaches to pre-movement time modeling are possible, see e.g. [16] for a discussion of a sampling-based approach, or overview of various other approaches in [1].

When hand calculations are used, $\Delta t_{trav(walk)}$ is usually approximated by the longest route to exit multiplied by a conservative estimate of human speed, whereas $\Delta t_{trav(flow)}$ is usually estimated by finding the dominating bottleneck in evacuation plan and performing calculations for this bottleneck alone.

V. Flow Model

The simplest model of $\Delta t_{\text{trav(flow)}}$ calculation hinted in the previous section requires determining the dominating bottleneck, which in turn requires analysis of the overall flow of people in the building. Since we are not hindered by time constraints that enforce simplicity (and approximations) of hand calculations, we describe a somewhat more general scheme. In what follows, we remind a flow model described in [2]. We begin by reminding an informal definition from the paper:

Consider a set of evacuation paths in a building. A *transition point* is any point where (i) a path becomes narrower or wider; or (ii) paths split, converge or join stairs.

From now on we consider a graph (V, E) such that vertices V represent transition points in a building and edges E represent evacuation paths. We will think of *flow* of people through edges $e \in E$, and thus for clarity we will assume that graph $G = (V, E)$ is directed. The unit of flow in this model is $\left[\frac{\text{persons}}{s \cdot m}\right]$ (flow denotes the number of people that pass through a corridor or a door of a given width in a time interval).

For each transition point $v \in V$:

$$\sum_{e=\langle v,w\rangle \in E} F_e W_e = 0$$

where F_e denotes flow departing (or arriving, if negative) from (or at) v through e and W_e is the minimum effective width of path $e \in E$. Furthermore, [2] defines maximum flow through e for horizontal travel and for stairs with different parameters (Riser and Tread) as a function of occupant density.

We remind that t_a, t_{pre} and $t_{\text{trav(walk)}}$ are calculated separately and the purpose of flow analysis is to determine $t_{\text{trav(flow)}}$ component only.

We may assume that queuing occurs and that a queue is already formed. For this reason, flow in this network can be approximated by optimization algorithms for flow networks ([17], [18]), by assuming fixed values of maximum flows through edges and iterating further calculations over vertices corresponding to consecutively depleted sources.

We stress that in the simple formulation above we make several gross simplifications, for example:

- we do not take into account the effects of fire or smoke,
- we assume that occupants act semi-rationally so as to reach (locally, at each moment) the maximum flow out of the building (in particular, no congestion points are formed at dominating bottlenecks),
- effective widths of corridors are estimated (using the floor plan) by actual corridor widths (i.e., we are ignoring potential obstacles not directly described on the floor plan),

However, all of these simplifications (and various other points) can be addressed within the same framework by extending the basic model.

VI. BIM and indoor navigation models

Afyouni et al. [11] presents a taxonomy of indoor spatial models proposed in the literature. The taxonomy is briefly summarized on Fig. 2. Authors of the paper further stress that hybrid spatial models that combine geometric and symbolic approaches may complement each other in various applications.

Building Information Modeling (BIM) is a general framework of representing, archiving and processing information about buildings in a structured digital format. One specific format which is widely used in practice is Industry Foundation Classes, and particularly IFC2x3 (IFC4 is published as ISO 16739, but IFC2x3 is still prevalent in practice today). Indoor navigation models for buildings represented in IFC were previously studied in e.g. [19], [20], [21]. IFC2x3 models combine the boundary-based geometric representation and an object-oriented (symbolic) model: typical objects in IFC2x3 files are storeys, walls or doors, along with information about their placement.

While IFC2x3 files may contain topological/graph-based representation of a building (described in terms of entities *IfcPath*, *IfcEdge* and other entities of supertype *IfcTopologicalRepresentationItem*), such graph-based representations are usually missing in IFC files exported by CAD tools.

Thus, in order to define the graph required for Flow Model calculations mentioned in the previous section, we transform the input BIM file to a geometric network, a structure that encompasses the geometric part defined in directly BIM and the topology which we infer from geometric representation. The topology is a graph whose vertices correspond to transition points.

From the perspective of evacuation modeling, a classification of the underlying grid or structure of the floor plan is discussed in [1] for various models. Authors discuss a fine network, a coarse network and a continuous network geometry. From the perspective of this ontology, the geometric network on which our model operates is a coarse network.

VII. Geometric Network Calculation

Usually Medial Axis Transform (MAT) or Straight-Medial Axis Transform (S-MAT) [5] is used to define a geometric network. See [6] for a discussion of other algorithms and [9] for an example of an alternative approach of indoor navigation that does not require topology construction. A Medial Axis of a set $F \subseteq V$ is the set of points $M \subseteq V$ that have at least two

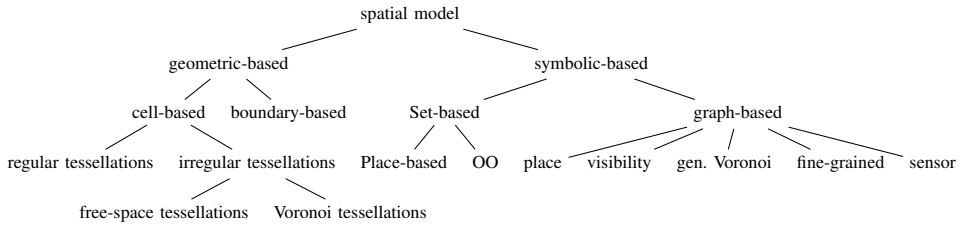

Fig. 2. Taxonomy of indoor spatial models presented by Afyouni et al. [11]

closest neighbours in F (see Fig. 3). If F is finite, Voronoi diagram [22] of F is the Medial Axis of F.

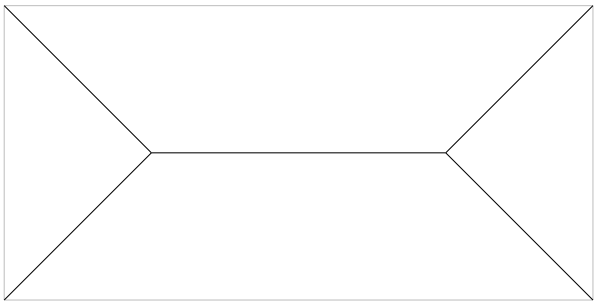

Fig. 3. Medial Axis Transform of the gray rectangle consists of five line segments shown on the picture.

Consider a plan of a floor in a building $F \subset R^2$ (Fig. 4). Instead of calculating MAT of F directly, we approximate F by a finite set of points S (Fig. 5) and calculate the Voronoi diagram of S, which consists of line segments. Denote by (V', E') the graph that consists of subset of line segments from Voronoi triangulation that do not intersect F (see Fig. 7). Edges in graph (V', E') describe permissible paths in our model.

Delaunay triangulation of S is the dual graph of the Voronoi diagram of S (Fig. 6). We utilize this triangulation in two ways: We use it to approximate the minimum width of a path ($e \in E$) by the shortest line segment in Delaunay triangulation that intersects e. Secondly, triangles in Delaunay triangulation are assigned to vertices $v \in V$ and provide a partitioning of the geometric view of the scene.

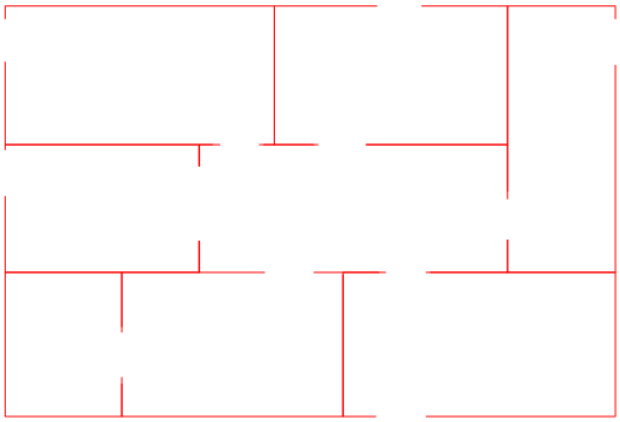

Fig. 4. A 2-dimensional slice of the building that represents a single floor (with doors removed).

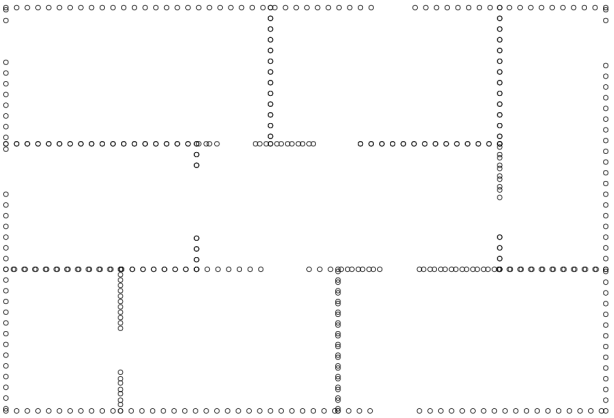

Fig. 5. Approximation of line segments by a set of points.

VIII. Conclusions and Future Work

In this paper we have discussed a framework for evacuation modeling based on building topology extraction from the building. We supplemented the typical graph representation of a floor plan derived from MAT by information obtained from Delaunay triangulation of the point set that approximates a single floor: path widths and areas assigned to vertices.

We have mentioned various areas of future research throughout our paper:

- Design of evacuation models based on different assumptions of occupant localization. Our current research focuses on localization of people within buildings.
- More refined models, e.g. taking into account effects of fire or smoke.
- Staircases are often bottlenecks during evacuations, which suggests a more detailed modeling of the effect of different types of staircases and their parameters on movement speeds of crowds.

Other possible areas of future research are:

- Specification of evacuation scenarios in a dialogue with the user (during the ride to fire scene). The dialogue necessarily needs to be very limited, but it could aid

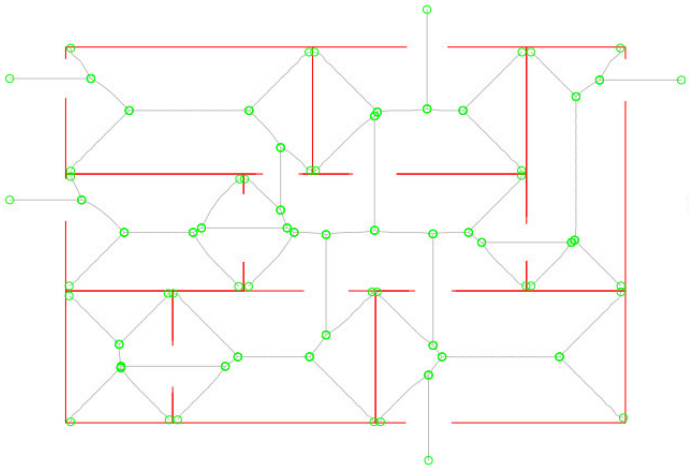

Fig. 8. A graph (V, E) resulting from contraction of edges of degree 2 in graph (V', E').

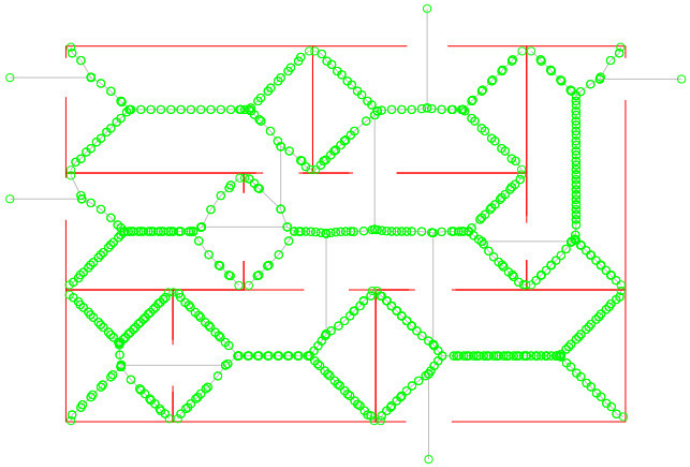

Fig. 7. A subset of line segments from Voronoi tessellation determines permissible paths. This is the initial graph (V', E').

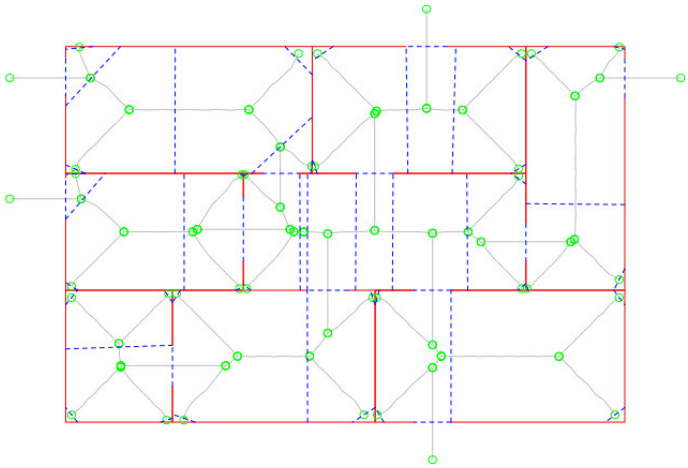

Fig. 9. Selected edges (dashed, blue) from Delaunay triangulation determine widths of paths described by edges in the graph. Delaunay triangulation also provides a mapping of points on the floor plan to corresponding vertices (though some triangles may contain a few vertices $v \in V$). Vertices in corners have very small areas assigned to them and the ratio of width to area size of such vertices is relatively high, thus they are not bottlenecks.

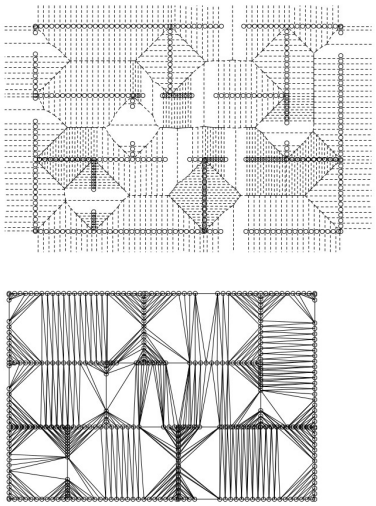

Fig. 6. Voronoi tessellation and Delaunay triangulation of a floor plan approximated by a set of points.

the commander in specifying initial plans of action better than passive information delivery. On rare occasions some hints may be also provided by the operator of Fire Command Center, e.g. unavailability of certain exits.

- We consider performing MAT or S-MAT calculations for floor plans consisting of line segments. In our preliminary experiments we have approximated the floor plan by a set of points so as to utilize the duality of Voronoi tessellation and Delaunay triangulation. The approximation by a discrete set may not be necessary.
- Addressing the problem of counter-flows, i.e. the interaction of fire-fighters getting into the building with the occupants trying to get out of the building.

AAIA'14 Data Mining Competition at the Knowledge Pit

KEY RISK factors for Polish State Fire Service is organized within the framework of the 9th International Symposium on Advances in Artificial Intelligence and Applications (AAIA'14), and is an integral part of the 1st Complex Events and Information Modelling workshop (CEIM'14) devoted to the fire protection engeneering. The task is related to the problem of extracting useful knowledge from incident reports obtained from The State Fire Service of Poland. Prizes worth over 3,000 USD will be awarded to the most successful teams. The contest is sponsored by Dituel Sp. z o.o. and F&K Consulting Engineers, with a support from The University of Warsaw and ICRA project.

Introduction

Incident Data Reporting Systems (IDRS) are used by public safety services across the globe to gather information about the incidents which required their actions. This information is used not only to simply document the events but it can also be incorporated into the training of new officers. Moreover, the knowledge extracted from such reports can help in better identification of threats and in planning of more effective procedures. An example of such a reporting system is EWID which is used by the State Fire Service of Poland. In the proposed competition, we would like to raise the problem of extracting useful knowledge from the reports generated in the EWID system, represented in a form of a data table. In particular, we would like to ask the participants to identify key factors influencing the risk of serious injuries among firefighters and people involved in various incidents. The contest will be hosted on a web platform called Knowledge Pit, designed especially for supporting organization of data mining competitions associated with scientific conferences.

Special session at CEIM'14 workshop

A special session devoted to the competition will be held at 1st Complex Events and Information Modelling workshop (CEIM'14) which is a part of 9th International Symposium on Advances in Artificial Intelligence and Applications (AAIA'14). We will invite authors of selected reports to extend them for publication in the conference proceedings (after reviews by Organizing Committee members) and presentation at the conference. The invited teams will be chosen based on their final rank, innovativeness of their approach and quality of the submitted report.

Awards

Authors of the top ranked solutions will be awarded with valuable prizes:

1. First Prize: computer hardware worth 2,000USD + one free FedCSIS'14 registration,
2. Second Prize: computer hardware worth 1,000USD + one free FedCSIS'14 registration,
3. Third Prize: one free FedCSIS'14 conference registration.

The award ceremony will take place during the FedCSIS'14 conference (September 7-10, Warsaw). Additionally, authors of all papers accepted for presentation at the CEIM'14 workshop, who decide to attend the conference will receive a diploma and a competition T-shirt.

***Abstract*—In this paper we summarize AAIA'14 Data Mining Competition: Key risk factors for Polish State Fire Service which was held between February 3, 2014 and May 5, 2014 at the Knowledge Pit platform http://challenge.mimuw.edu.pl/. We describe the scope and background of this competition and we explain in details the evaluation procedure. We also briefly overview the results of this analytical challenge, showing the way in which those results can be beneficial to one of our other projects which is related to the problem of improving firefighter safety at a fire scene. Finally, we reveal some technical details regarding the architecture and functionalities of the Knowledge Pit competition platform, which we are developing in order to facilitate solving of practical problems that require advanced data analytics.**

***Keywords*-data mining competition, risk factors, attribute selection, EWID system**

I. Introduction

INCIDENT DATA REPORTING SYSTEMS (IDRS) are used by public safety services across the globe to gather information about the incidents which required their actions. The information is gathered in order to calculate statistics within the groups of incidents, identify peculiar cases and to improve the procedures [1]. Results of a thorough analysis of incident reports can also be utilized by decision support systems to increase safety of firefighters at a fire scene [2].

EWID is an example of such a reporting system. It is used by the State Fire Service of Poland [3]. A report submitted to the system by Incident Commander (IC - a coordinating officer) after a fire and rescue action (F&R) consists of two parts: a quantitative description, where facts regarding the action are expressed by numerical or categorical characteristics and a description in a natural language. The first part is often called the attribute section and the second is the descriptive section.

The attribute section is represented in a form of structured and quantified characteristics. Among over 500 attributes, it contains information about incident type, its severity or size and resources involved in the response. The descriptive section can be treated as an extension to the attribute section. It contains a natural language description of probable causes, conditions at the event scene and the course of the action. Figure 1 depicts a chunk of a report submitted to the EWID system.

It is assumed that the descriptive section should contain all the relevant information which could not be expressed in the attribute section. However, due to the fact that there are no instructions regarding what information is relevant in a context of a particular incident type, the descriptive section sometimes contains irrelevant and useless fragments of text. A quality of the textual descriptions in the system also variates, depending on a personality and attitude of IC who writes the report. For instance, a content of the part devoted to the course of the action may range from very useful information concerning the consecutive decisions of IC, applied techniques and their consequences, to very cursory and ambiguous sentences such as: *rubbish lit*.

On the other hand, the attribute section is unable to reflect all information regarding a very large spectrum of possible incidents. All the above mentioned shortcomings make it challenging to extract useful information from the EWID reports, especially when this information is only indirectly related to the set of characteristics from the attribute section [4]. One example of a task that requires such information is the problem of recognition of risk factors which affect the possibility of a serious injury or death among firefighters and other people involved in various incidents. A similar problem, i.e. the identification of threats, has been already investigated by several researchers [3], [5], [6].

In the research presented in this paper we address the above mentioned challenge. We decided to ask the machine learning community to identify characteristics extracted from the EWID reports, which are useful for predicting whether any people were harmed during a given incident. For this

978-83-60810-58-3/$25.00

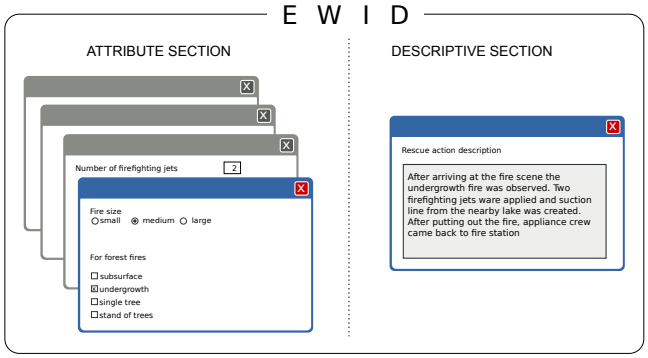

Fig. 1. The chunk of the EWID report.

purpose, we devised a data mining competition, titled *AAIA'14 Data Mining Competition: Key risk factors for Polish State Fire Service*. A form of this challenge was similar to the competitions which our team organized in the past [7], [8] on the TunedIT platform [9]. This time, however, we organized it on a novel web platform called Knowledge Pit (www.challenge.mimuw.edu.pl) hoping that the participants will be able to enrich our understanding of the EWID data and point at attributes that describe the most relevant information to the stated problem.

In the following sections we reveal details regarding the architecture of Knowledge Pit (Section II) and then, in Section III, we describe the proposed challenge. Next, in Sections IV and V, we present an overview of results obtained by participants of the competition and analyze those results with respect to the semantic types (i.e. the meaning) of attributes that were frequently appearing in the submitted solutions. Finally, we conclude the paper by drawing our plans for a continuation of this study.

II. The Knowledge Pit Platform

Knowledge Pit is a platform created to support organization of data mining challenges. It is designed in a modular way, on top of an open-source e-learning platform Moodle.org [10], to follow the best practices of a software development. Therefore, the platform with its current modules, including user accounts, challenges and resources management subsystems, time and calendar functionalities, communications features (i.e. forums and messaging subsystems), and a flexible interface for connecting automated judging services prepared to evaluate contestants' submissions, is conceptually ready to introduce new features or enhance the existing ones.

A more detailed architecture overview requires to describe two main parts of the system. All elements that are available to the users interested in participating in a data mining competition, together form a web user interface. To fulfill this requirement, Knowledge Pit utilizes a very popular solution stack Apache/MySQL/PHP – a set of software components that is sufficient to provide web solutions ranging from simple to complex ones [11], [12], [13]. The second part of the system concerns competition handling from the point of view of evaluating the submitted solutions. This functionality is separated from the remaining part of the platform to cope with the requirement for high flexibility (with regard to a programming language or a framework, parallelization of expensive calculations, etc.) of the judging software setup. The general architecture of the system is presented in Figure 2.

From the point of view of Knowledge Pit system there are several roles which can be assigned to a user – a guest, a contest participant or a contest organizer role. Therefore, the front-end engine consists of several modules which provide the functionalities to the users, depending on their role in a given moment. The main modules of the system are as follows:

- user management and user privileges
- challenge maintenance
- challenge Leaderboard
- challenge submissions manager
- calendar
- forum module
- internal messaging system
- chat
- private resources (files) repository

The above modules can be thought of as pieces of software that implement specific elements of the system. When combined, they constitute the higher-level features described below in this section.

A. User interface

Knowledge Pit implements users and user groups management, an advanced privileges support and an enhanced context handling, e.g. a user can be a guest in a given challenge, a participant in other and also a creator and manager of another one. The site administrators can manually promote or demote users access corresponding to any of the given contexts, e.g. a context of the page a user can browse. This means that the administrators can grant privileges in a local context (e.g. a forum of a specific contest, a chat, etc.) leaving the access privileges to the other parts of the site unchanged. Moreover, a special registry is used to administer the users and the user groups. If necessary, a new user type or users group can be created with selected privileges granted, thereby facilitating the task of managing large number of users in some particular contexts.

Each user is assigned to a set of assets such as a private file repository, a dedicated calendar with adjustable scope and event levels, a public profile shown to others in contexts of chats or forums, and a personalized site appearance – a set of settings that allows to adjust the way how the site looks, e.g. a user can hide or move specific parts of menus and navigation modules, or use predefined site themes, all accordingly to his own choice.

Each site visitor can view a calendar on which events are displayed accordingly to the access level and the site context. The calendar is fully customizable and has events ordered according to scopes:

- global

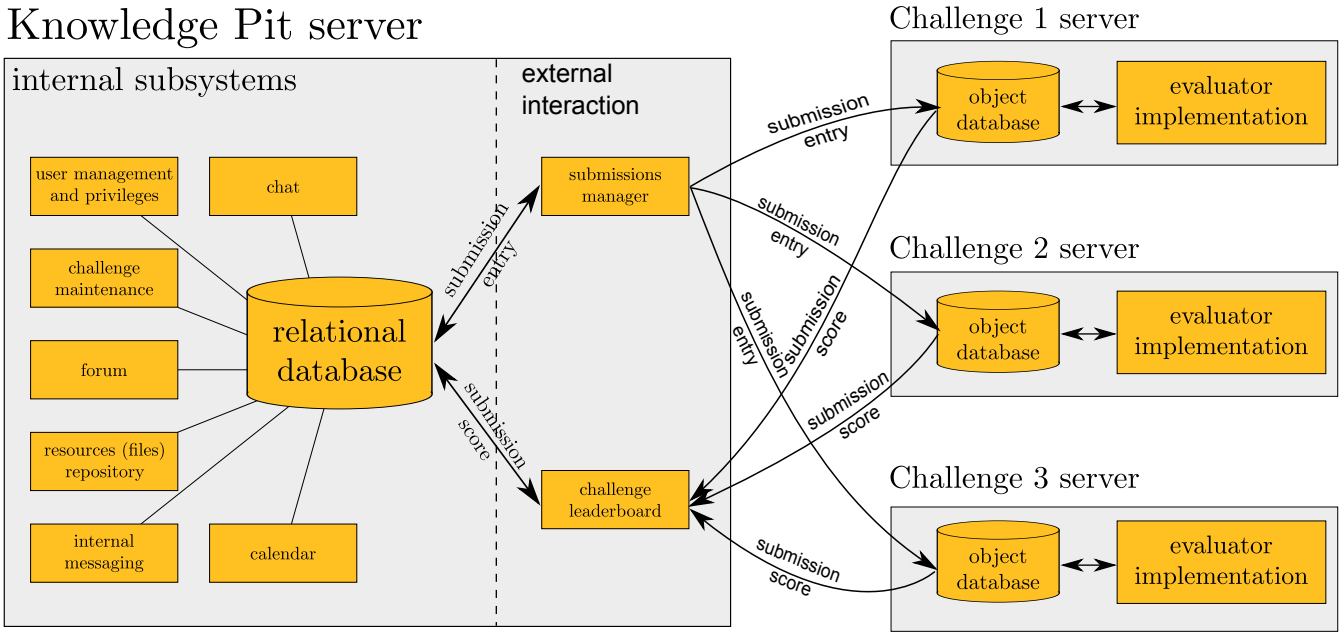

Fig. 2. A system architecture of the Knowledge Pit web platform.

- competition
- group
- user

Apart from events generated automatically with respect to each of the categories mentioned above, users can add their own events and bind them to the given levels. This functionality may facilitate cooperation between users of Knowledge Pit that decide to work in teams.

Calendars can be exported to standard exchange formats (to be imported into other calendar solutions) or can be subscribed to by RSS. This helps users to stay up to date and somehow automate their time management.

Each user has a dedicated storage space (or private resources repository) with an access and management abilities available via the web interface.

Users can communicate using the built-in chat and forum engines. They can exchange messages at various levels according to the context they are enrolled in. Each competition includes a dedicated internal chat and a forum. There are also global forums and chat rooms available to the site users, which can be enabled or disabled by the competition managers. This is yet another idea on how the Knowledge Pit platform can be useful – it may help scientists to get know new people with the same interests and stimulate their cooperation.

B. Definition and management of competitions

Data mining challenge support and maintenance are the main objectives of the site. Each contest is an individual entity in the system and it requires time and care to be well defined and created. There are two ways to achieve the goal of starting the competition. The site administrators create, run and hook a dedicated evaluator to a competition, due to theirs responsibility, knowledge and appropriate privileges, bypassing a standard acceptance procedure. The second (more common) way involves the operation of a regular user who prepares a project of the competition using the forms and tools available in Knowledge Pit. Then, a request to the site administrators is sent to revise the proposal of the contest. If it is accepted, a new hidden challenge is automatically created and the user obtains manager privileges to it. All standard modules are initialized by the default values of parameters. That includes data description pages, data files folder, news panel and submissions upload interface. Initially, a newly created challenge is hidden from other users until all necessary information is filled in and the dates are defined. After providing the necessary data (including a task description, input data files, etc.), the challenge may be published and becomes visible to anyone visiting the site.

C. A course of a competition

To each challenge there are associated three important dates:

1) a start date
2) a submissions end date
3) a contest end date

The first two dates define the actual time in which participants may compete by submitting their solutions to the challenge task. During this period the users are supposed to upload and manipulate their solution files using the available submission manager. The submitted files are automatically pre-evaluated by a dedicated service (e.g. a script or an external application that are compatible with a Knowledge Pit evaluator protocol), accordingly to the settings defined by the challenge authors. The users may upload multiple result data files among which they mark one as their target

solution that would take part in the final evaluation. The pre-evaluation is meant to generate scores that are placed on the competition's Leaderboard. The preliminary scores may serve as a rough estimation of how good the submitted solution is in comparison to results of the other users and therefore may stimulate the competitive spirit of the contest. The second period which ends the contest is the time needed to finally evaluate users' submissions (previously marked by the participants as their target solutions) and determine the winners. Each submission is scored and accordingly placed in a table called Final Leaderboard which is published within the challenge summary.

Organizers of a competition may require additional reports that describe solutions provided by the participants. In this case a competition manager may set a condition which restrains the final evaluation to the submissions with an attached report.

Each challenge, if it is already published and its visibility is not restricted by the organizers, is available to any site user. In that case, a guest has an access to the contest's general information, including a task description, a list of important dates, and the Leaderboard. Unless contest access restrictions are in effect, every user can enroll in a chosen challenge accessing all the contest's resources, including the provided data files.

D. Evaluation of the uploaded solutions

The above description refers only to the features available via the web user interface. It also presents the general flow of events starting from the contest organization, the users enrollment, the submission of solutions, their preliminary and final evaluation, ending on the publication of the challenge summary and announcement of the winners. However, not much was said about the method of defining the evaluators.

It would be very difficult to build and share a general evaluator for all possible types of data mining competitions. Usually, the stated data mining tasks are very different in many aspects, including:

- the category of performed data analysis (clustering, classification, multi-label classification, etc.)
- the solutions representation (a single file vs. multiple files placed together in one archive file) and their formats (multicolumn answers, the way of describing clusters, etc.)

Another important aspect of the data mining solution evaluation is that it often requires a lot of resources (memory, CPU time, disc I/O or database connections), e.g. when it is associated with a predictive model creation. This could result in malfunction of the competition platform due to its resources limitation. In Knowledge Pit the responsibility of the evaluation is delegated to the competition organizers. They need to provide an object database and a working evaluator. The responsibility of Knowledge Pit is limited to interaction with the object database where all the solutions are uploaded and stored. The submission scores are downloaded from it and propagated to internals of the system. The evaluator may be implemented in any suitable programming language, as a script, a stand alone compiled application or a utilization of available libraries. The only requirement is that it should maintain correct protocol of information exchange by means of changing the objects inside the database in a predefined way. The proposed flow of responsibilities frees Knowledge Pit from the things which it cannot cope with in a generic way. It also gives the organizers a very flexible method of expressing their data mining task in a form of a fully customizable evaluation procedures. For example, in AAIA'14 Data Mining Competition which is described in the following sections, MongoDB [14] was utilized as the object database and the evaluation system was implemented in the R programming language [15].

III. The Task Description

The Knowledge Pit was inaugurated with AAIA'14 Data Mining Competition which took place between February 3, 2014 and May 7, 2014. In this challenge the focus was on the feature selection problem and the data came from the public safety domain.

Our team obtained a data set containing nearly 260,000 reports from the EWID system. The reports corresponded to actions carried out by the Polish State Fire Service within the city of Warsaw and its surroundings (the Mazovia district) in years 1992 – 2011. We preprocessed a subset of this data and transformed it into a table in which each of the reports is described by nearly 12,000 attributes. Additionally, we distinguished three target attributes that correspond to information whether in the described incident there were casualties among firefighters, children or other involved people, respectively. The task in AAIA'14 Data Mining Competition was to identify attributes that can be used to robustly assign the reports to the corresponding decisions labels. We hoped that participants would come up with solutions which improve our understanding of the risk factors associated to various types of accidents.

The competition data set was provided to participants in two different formats. The first one was a traditional tabular representation of data as a comma-separated values file. Each row of this file represented a single EWID report and, in the consecutive columns, it contained values of its characteristics (the attributes). The attributes in this table could be divided into two groups. The first one contained the features extracted from the quantitative part of the report and the second group corresponded to a document-term matrix obtained from the natural language description sections. In total, the training data available to participants contained descriptions of 50,000 incident reports. Each report was characterized by 11,852 conditional attributes. All the attributes were discrete and only a few had more than two possible values. We thought about those attributes as indicators of the risk factors corresponding to the incidents.

The same data set was made available in a sparse matrix format as an EAV file [16]. In every row, the file contained exactly three integer numbers: an identifier of an object, an identifier of an attribute and the corresponding attribute value.

Since the EAV file stored exactly the same information as the traditional tabular representation of the data, this file was provided only for convenience of participants.

To each of the reports from the training data there were also assigned values of three binary decision attributes. The first decision attribute indicated incidents in which occurred a serious injury or death of one of the firefighters or members of the rescue team. The second decision attribute indicated cases for which there were children among the injured people. The third decision identified situations where any civilians were hurt. Values of those decision attributes were made available for all participants of the competition in a separate file.

It is worth noting that, by its nature, the provided data set was highly dimensional. The total number of conditional attributes corresponded to the number of distinct words in the textual part of the reports (after lemmatization), plus several hundreds of attributes from the quantitative part. Additionally, the data was sparse since only a small fraction of the attributes had a non-zero value for a particular report. On top of that, all three decision attributes were highly imbalanced – the positive classes corresponded to relatively rare events. The proportions of the positive cases for the rescuers, children and civilians were ≈ 0.004, ≈ 0.007 and ≈ 0.059, respectively. There was also a separate test data set which was used for the evaluation of submissions. It had similar characteristics to the training data but it was not available for the participants during the competition.

The competitors were asked to indicate sets of attributes that allow to accurately classify the incidents using an ensemble of Naive Bayes models [17], [18] and upload their solutions using the on-line submission system. We required that in each solution there were exactly ten attribute sets. The sets were ought to contain at least three integer numbers corresponding to indexes of attributes from the training data set. There was no upper limit for the number of attributes indicated in a single set, however, the evaluation system penalized solutions that use a large number of features.

The submitted solutions were evaluated on-line and the preliminary results were published on the competition Leaderboard. The preliminary score was computed for each submission on a random subset of the test set, which was fixed for all participants. This subset corresponded to approximately 10% of the test data. The final evaluation was performed after completion of the competition using the remaining part of the test data. Those results were also published on-line. In order to be considered for the final evaluation, each participating team had to provide a short report describing their approach.

Quality of the submissions was assessed by measuring performance of a classifier ensemble composed of Naive Bayes models. Those models were constructed using attribute sets indicated by the submitted solution, separately for each decision attribute. An output of the ensemble was computed by averaging probabilities of the positive classes returned by the individual Naive Bayes models. During the evaluation, all the training data was used for the construction of the models. The performance of a single ensemble was measured by taking Area Under the ROC Curve (AUC) [17], [18] of the probability predictions for the corresponding decision attribute and the result was averaged over all three decision attributes. Finally a penalty was applied for using a large number of conditional attributes.

In more details, if we denote by:

s	–	a submitted solution,
$\|s\|$	–	a total number of attributes used in the solution (counted with repetitions),
$AUC_i(s)$	–	Area Under the ROC Curve (AUC) of a classifier ensemble for the i-th decision attribute,

then the quality measure used for the assessment of submissions can be expressed as:

$$score(s) = F\left(\frac{1}{3}\sum_{i=1}^{3} AUC_i(s) - penalty(s)\right)$$

where the penalty is equal to:

$$penalty(s) = \left(\frac{|s| - 30}{1000}\right)^2$$

and the function F is defined as:

$$F(x) = \begin{cases} x & \text{for } x > 0 \\ 0 & otherwise \end{cases} .$$

All the data sets utilized in the competition, including the test set with the corresponding decision values, were made available after completion of the challenge at the competition web page: http://challenge.mimuw.edu.pl/contest/view.php?id=83. We are convinced that the public availability of the data will facilitate future research in this area by other members of the machine learning community.

IV. Results of the Competition

AAIA'14 Data Mining Competition attracted many skilled participants from around the world. In total there were 116 registered teams, from which 57 actively participated in the challenge by submitting at least one solution to the stated task. We received nearly 1,300 solutions and 290 of those submissions obtained a score higher than 0.94. Additionally, 46 teams provided a short report describing their approach.

The participants utilized diverse machine learning techniques in order to come up with their final attribute sets. A large share of the solutions was devised by combining the attribute filtering approach for reducing the initial feature subset with well known wrapper-based techniques. The final solutions were commonly tuned using evolutionary algorithms or the hill climbing method. The best results, however, were obtained by using algorithms optimized specifically for finding attribute sets that improve the AUC of Naive Bayes prediction models.

The wide spectrum of solutions submitted by the participants during the challenge makes it possible to perform a comprehensive study of the factors that have the biggest impact on predictions of the positive classes in the data. However, since

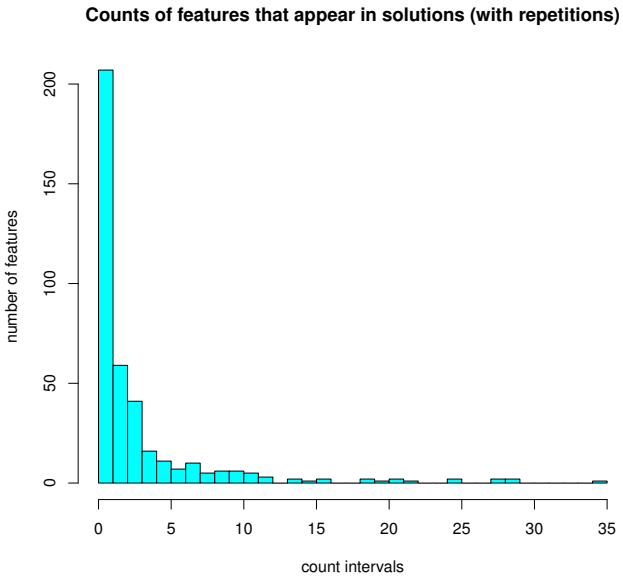

Fig. 3. Frequencies of individual attributes in the final solutions submitted by the twenty top-scored participants of AAIA'14 Data Mining Competition. The attributes were counted with every repetition. The most frequent attribute was present 35 times in the considered solutions. It corresponded to the term "during".

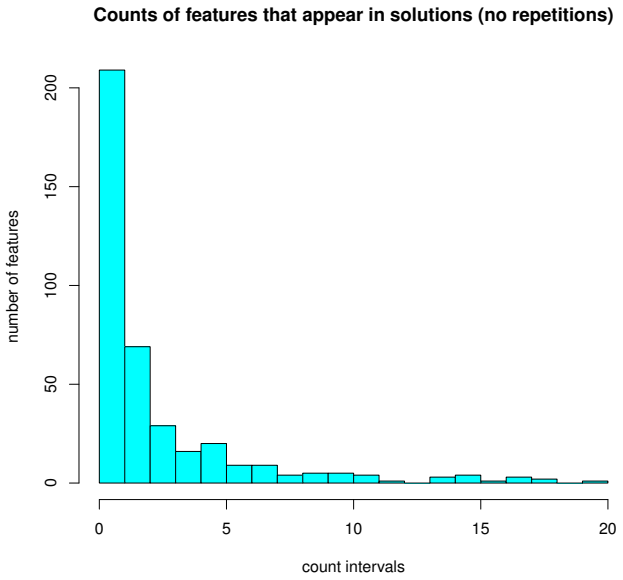

Fig. 4. Frequencies of individual attributes in the final solutions submitted by the twenty top-scored participants of AAIA'14 Data Mining Competition. The attributes were counted without repetitions (an attribute is counted once for every solution in which it appears). The most frequent attribute was present in all of the considered solutions. It corresponded to the term "during".

the considered phenomena are complex and diverse, and there was a short period between the submissions of the solutions and the preparation of this paper, the analysis described here is limited to a set of hypotheses. Those hypotheses try to explain some of the observed regularities, however, we need to stress that most of them require further investigation to be supported with strong statistical evidences. Therefore, all the explanations which we present in the following sections are just a starting point for a more detailed analysis leading to a better understanding of dangerous situations and the related threats faced by firefighters.

A. *Analysis of frequent features*

We start our analysis with reviewing the features which most commonly appeared in the top-scored solutions. Each of the features in question corresponds to a specific attribute from the attribute section, a word or a word-set (see Section III) from the descriptive section of the reports.

We analyzed the attributes indicated by the final solutions submitted by the twenty participants who obtained the highest ranks on the Final Leaderboard. In total (counted with repetitions) they constituted a set of 1,538 attributes. The number of different attributes in this set is 413. In most of the cases an attribute was used only in a single solution. However, there is a small subset of features that are more frequently used than the others. We focused our investigation on these attributes and verified their relation with the occurrence of serious injuries. Figures 3 and 4 depict the frequency of individual attributes, computed by considering every occurrence of attributes and by counting the solutions in which an attribute is present, respectively. In the second case, an attribute is counted only once for every solution in which it appears, regardless of the number of its appearances in that solution.

We analyzed the most frequent attributes with regard to their relation to the fire safety domain. We arranged them in several groups. Each of those groups defines a different type of relation to the cases of serious injuries or deaths in incidents.

The first group consists of features that correspond to nouns related to the injured parties. Incident Commanders who report the casualties tend to use a set of specific terms for describing the victims. Those terms are not used to refer to other people present at the emergency scene. In particular, examples of such nouns are: "a boy", "a kid", "a girl", "male", "female" or "a private". The usage of these words in a report indicates that something happened to the described person. There is also some interesting regularity in this group: the term "boy" appears nearly three times more often than the word "girl". The other interesting thing observed among the attributes in this group is that the terms referring to the common participants of the interventions change in situations when they get injured. For example, a firefighter who performs his/her activities according to the schedule, is usually anonymous (e.g. "two firefighters set the ladder"). However if something wrong happens, a full rank, the name and surname are reported in the descriptive section of the report. In the most of cases the injuries concern lower-ranked firefighters. Therefore, attributes represented by terms such as "str" (in Polish it is an abbreviation for "a private") were often selected as good predictive features.

TABLE I
THE FEATURE SETS SUBMITTED BY THE WINNERS OF AAIA'14 DATA MINING COMPETITION.

#Sub	First place	Second place	Third place
1	action_people_evacuation, to_sting, longitude, thought, ignition, action_people_release, losses_overall_dollars, hospital_name, private	local_threat_type_road_transport, kid, knee-joint, coal, head, to_transport, observation, bite	palm, during, head, action_people_evacuation, icicle, bar, man
2	road, observation, hand, man, hit, transport, rinse	private, action_people_evacuation, to_drive_away, passenger, warm, carbon_monoxide_poisoning, first_fire_engine_drove_km	thumb, withdraw, blast_off, losses_overall_dollars, grating, boy, observation
3	year, right, to_transport, leg, kid, during, used_equipment_chainsaw, to_go_somewhere, light, hospital_name, daughter, ankle	resources_fire_rescue_unit, person, ankle, condition, foot, action_used_extinguishing_aid_attack, hospital_name	girl, to_bite, carbon_monoxide_poisoning, to_lead, to_sting, action_people_release, to_hit_a_pedestrian, local_treat_medium
4	action_door_opening, decease, compartment, allotment garden, to_transport	light, used_equipment_chainsaw, to_faint, carbon_monoxide, to_sting, corpse, apply	kid, resources_fire_rescue_unit, hospital_name, driver, volume_of_incident_scene, finger, daughter
5	carbon_monoxide, oxygen_therapy, local_threat_cause_gas_device_fault, local_threat_medium, extinguishing_in_attack, burn, victim	kid_or_kids, eye, minibar, street_name, officer_name, latitude	work, apparatus, drive, hospital_name, deceased, light, action, delay
6	knee, head, rescuers_fire_rescue_unit_people, district	suffer, leg, grating, deceased, knee, extricate, palm	kid, make_of_a_car, injury, hospital_name, extract, hand, morning
7	action_smoke_extraction, palm, latitude, local_threat_type_road_transport, person, connector_or_a_switch, hospital_name, state_property, deceased	truck, to_set_fire, star_or_a_whistle, to_hit_or_run_over_someone, longitude, extract, compartment	truck_type, ankle, to_slip, private, hospital_name, to_swell, to_bite, corpse
8	resources_police_cars, team, technical, kid, water, to_drive_a_driver_or_a_steering_wheel, to_lead, cause_of_a_local_threat_act_of_terror, to_do_or_break	action_people_release, to_hit_or_crash, agricultural, immediately, department_branch_or_division, withdraw, boy	year, knee, passenger, suffer, personal_details, foot, firefighter
9	explosion_any_type, delay, face, homeless, grating, forearm	during, hand, to_fall_asleep, local_threat_medium, functioning, explosion_any_type, oxygen_therapy	leg, to_force, to_hit_or_crash, oxygen_therapy, coal, to_hit_or_run_over_someone, carbon_monoxide, to_wash, technical
10	corpse, girl, to_hit_or_run_over_someone, suffer, boy, burn_down	darkness, to_hit_or_knock_someone_off, ankle, to_twist, man, action_inside_chimneys, delay	team, local_threat_cause_careless_driving, orthopedic, face, to_carry_or_transport, mean_of_transport, compartment, person

The second group is related to descriptions of the injuries and mostly consists of names of human body parts. In this group, the most commonly used words are: "leg", "palm", "hand", "side", "body", "foot", "twinkle", etc.

The next group represents the attributes that describe activities undertaken by firefighters when they faced an injured person. This group consists of attributes from the attribute section such as: "action_people_evacuation", "localizing_people", "oxygen_therapy", etc. or words (mostly verbs) from the descriptive section such as: "to transfer" (to an ambulance), "to transport", "observation", "to cut", "to open", etc.

Another group represents features related to terms which describe a cause of the injuries or fatalities. In this group we find the following words: "intoxication", "to hit" (a pedestrian), "to get" (a stroke), "sprain", "to twist" (an ankle), "to slip", "bite", "bump", etc.

All the groups described above, are examples of attributes which were used by ICs in order to address matters related to an injury or death. They can be useful for a post-incident analysis of the causes, since the identification of such key phrases may boost performance of information retrieval systems that work on EWID data. However, those terms alone do not reveal any specific risk factors related to the fire safety domain. The knowledge resulting from the identification of those attributes does not have a direct impact on the safety of firefighters and incident victims. Moreover, it does not reveal interesting aspects of the rescue actions, apart from the words or phrases which are used in the reports in order to describe the casualties or fatalities.

There is, however, one group of features which are likely to correspond to important risk factors. By obtaining information regarding those factors during a real-life F&R action we may potentially improve the safety of involved people. This group consists of attributes corresponding to terms such as: "carbon monoxide", "darkness", "single-family terraced buildings", "mart", "electrocution", "bite off" and some specific geographical coordinates. A further analysis of a role and a context of these attributes in the reports may shed light on the factors that affect the possibility of serious incidents. Nevertheless, a thorough investigation is required in order to explain their role in the generation of the unwanted events.

B. Analysis of frequent attribute sets

Due to the fact that usefulness of knowledge obtained by the analysis of individual attributes was limited, we performed an additional investigation of frequent attribute sets. In this analysis we distinguish global and local sets of attributes.

As the first type we consider the whole attribute sets that correspond to individual models in the submitted solutions. The second type refers to subsets of attributes that commonly co-appear in the top-scored solutions.

In our first attempt, we analyzed the global feature sets, i.e., those which turned out to have the best predictive abilities for the whole data. These global feature sets were submitted by the winners of the competition. Table I gives the names of attributes from the sets submitted by the three best teams.

In those groups we indicated a few interesting types of sets that should undergo a further analysis. The first one can be summarized by terms or quantitative attributes such as: "activities_opening_doors", "decease", "compartment", "allotment", "garden", "to transport". Features from this set were often present in reports describing incidents caused by homeless or youngsters who illegally occupy cottage-gardens. This may indicate that there is a considerably large fraction of fatalities resulting from fires started in such conditions.

Another interesting type of attribute sets contains terms such as: "carbon monoxide", "oxygen therapy", "caused_by_heating_device_fault", "extinguishing", "fatality". This group may indicate that a large number of deaths is caused by carbon monoxide poisonings or fires started as a result of malfunctioning heating devices.

The next of the interesting feature set types can be characterized by terms: "explosion", "corps", "face", "homeless", "rate" and "forearm". It seems that there is a considerable number of incidents that involve homeless and some explosions. This set is very difficult to explain without a deeper analysis of the reports describing specific incidents.

A different attribute set type can be represented by the terms: "light", "used_equipment_chainsaw", "wood", "wane", "body", "to sting" and "girl". Combination of those terms often indicates a subset of incidents related to light injuries caused by an inappropriate usage of sharp tools, such as a chainsaw.

There is also a type of attribute sets which may be related to the incidents that happens after a nightfall, in a situation when somebody or something fell into a hole or a chimney. This set is represented by the attributes: "nightfall", "man", "cat", "twist", "shorten", "hit", "action_inside_chimneys".

The last of the identified types of interesting attribute sets is once again related to the problem of carbon monoxide poisonings. However, if the terms "oxygen therapy" or "carbon monoxide" appear along the terms such as "coal", "technical" or "functioning" it may indicate that the problem of poisoning is often related to malfunctioning coal furnaces.

C. Analysis of the local attribute sets

The analysis of the attribute sets submitted by the winning teams was an attempt to identify the most significant factors that have an impact on the occurrence of the cases from the positive decision classes. However, due to a large diversity of interventions of Fire Services – ranging from fires, through road traffic accidents, to natural disasters – finding the globally most affecting features is a very complex task. Therefore, we need to face a problem of finding attribute sets which have an impact on subclasses of incidents such as fires in residential buildings [3]. To accomplish this challenging task we applied a frequent item set mining technique, i.e. the *Apriori* algorithm [19].

We computed frequent attribute sets from the solutions submitted by the twenty top-scored participants (i.e. every line in the solution files was treated as a transaction) and we ranked them according to their support. The utilization of Apriori resulted in finding millions of frequent attribute sets. Due to our limited human processing abilities, we reduced the number of the sets for the analysis to the top 351 with the highest value of the support. Below we present a few examples of the interesting attribute sets which were revealed by this analysis.

As in the previous analysis, the most commonly appearing attribute sets are related to the expressions used by IC in order to report the injuries or fatalities. However, as in the previous cases, we were able to identify a few interesting attribute chunks. All of them should be further analyzed by experts from State Fire Service. Examples of such sets include: "used_equipment_chainsaw" and "light" – it indicates that there is a group of incidents related to an unfortunate use of a chainsaw by fire-fighters. Even though it seems reasonable that in the most of such cases the inflicted injuries are superficial, those results indicate that a proper handling of this type of tools should be better stressed during the firefighter training.

Another group consists of terms: "firefighter" and "sprain". It may indicate that there is a significant number of limb injuries during the rescue actions. The next of the interesting attribute sets is composed of terms: "firefighter", "releasing people" and "bite" which may indicate that there is a number of cases where firefighters are bitten by animals during a rescue activities. The last example of a common attribute set is "to slip" and "hand". It may be considered similar to the group of attributes related to limb injuries. It requires a further investigation in order to be associated with a specific type of firefighter actions.

D. Attribute cluster analysis

After the investigation of attributes and attribute subsets that frequently appear in the best solutions, we decided to check whether there is any redundancy among them. We were also interested in finding pairs of attributes that can be regarded semantically similar in the context of the fire safety. Successful identification of such pairs or groups would be beneficial for the further analysis of the EWID data. It would also be very useful for the risk assessment purposes, in situations when a part of information about an incident is unavailable or unreliable.

In order to find groups of closely related attributes we performed an attribute cluster analysis [20]. Intuitively, two attributes can be considered similar if they often co-occur in the solutions with the same groups of other attributes. However, if a pair of attributes commonly appears in the same sets submitted by the highest scored participants, it means that those features are complement in some way and they should

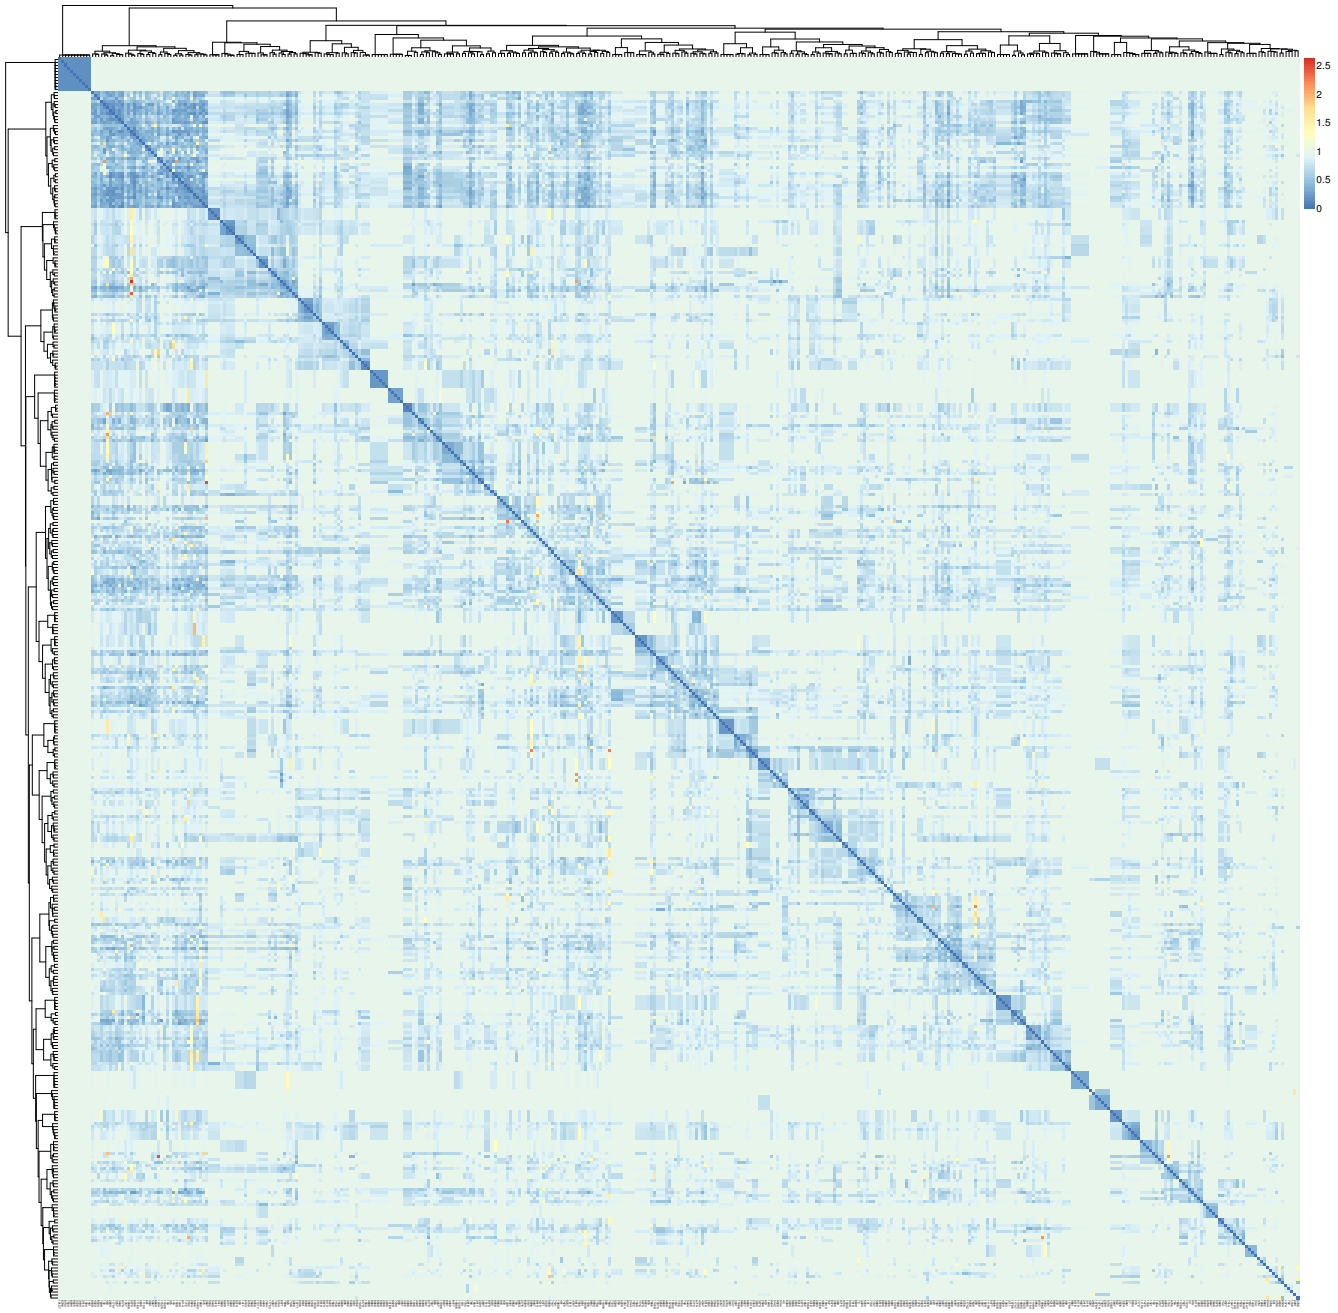

Fig. 5. A co-occurrence-based heat map of the attributes appearing in the top 20 solutions. Rows and columns of the matrix correspond to the attributes and the color of the spots symbolizes their dissimilarity. Additionally, on the top and the left side of the plot, a dendrogram of a hierarchical clustering of the selected attributes is given. The darker squares along the diagonal correspond to clusters of closely related (i.e., potentially exchangeable) attributes.

not be regarded similar. For this reason, we computed the dissimilarity between each attribute pair twofold.

First, we constructed a co-occurrence matrix whose rows and columns correspond to the 413 attributes from the solutions. For every attribute (a row of the matrix), we iterated over the attribute sets in which it was present and increased the matrix entries in the columns corresponding to the co-occurring features, by the inverse of the attribute set cardinality. In this way we constructed a new representation of the attributes. In the second step, we created a dissimilarity matrix taking the values from the co-occurrence matrix and subtracting from them the corresponding values of cosines between the new attribute representations.

Using the dissimilarity matrix we were able to perform the attribute cluster analysis. We did it using the hierarchical agglomerative approach with the Ward's linkage function [21]. The clustering results are depicted by the heat map in Figure 5. The darker spots correspond to pairs of similar

attributes. They are likely to be exchangeable in the context of classification and thus can be interpreted as semantically related. In the plot, potential clusters of attributes are represented by dark squares aligned along the diagonal of the matrix. For example, in the first cluster there were attributes such as "type_of_building_standalone_compartment", "one_story_high", "single_family_houses" and "action_inside_buildings_at_ground_floor".

In the future we plan to extend this analysis by considering decision rules which may be constructed from the frequent attribute sets. Such rules may compose a useful tool for supporting ICs at a fire ground, which is the main task of our ICRA project [2].

V. Summation

In this paper we focused on introducing a web platform, called Knowledge Pit, created in order to support organization of data mining competitions. On the one hand, this platform is appealing to members of the machine learning community for whom competitive challenges can be a source of new interesting research topics. Solving real-life complex problems can also be an attractive addition to academic courses for students who are interested in practical data mining. On the other hand, setting up a publicly available competition can be seen as a form of outsourcing the task to the community. This can be highly beneficial to the organizers who define the challenge, since it is an inexpensive way to solve the problem which they are investigating. Moreover, an open data mining competition can become a bridge between domain experts and data analysts. In a longer perspective, it may leverage a cooperation between industry and academic researchers.

We also described *AAIA'14 Data Mining Competition: Key risk factors for Polish State Fire Service* which was the first analytic challenge organized at Knowledge Pit. We presented the scope of this competition and briefly summarized its results. In addition, we discussed the results of our initial analysis of the best of the submitted solutions, highlighting their potential practical applications.

The conducted analysis is by no means complete. In future, the results of the competition will be thoroughly investigated by a team composed of experienced Incident Commanders and data mining experts. We hope that the results of this research, conducted as a part of a larger project ICRA [2], will have a noticeable impact on the fire safety domain. We also hope that our competition will revive a discussion on this topic among researchers with different backgrounds and expertise.

***Abstract*—We describe our submission to the AAIA'14 Data Mining Competition, where the objective was to reach good predictive performance on text mining classification problems while using a small number of variables. Our submission was ranked 6^{th}, less than 1% behind the winner. We also present an empirical study on the trade-off between parsimony of the representation and accuracy, and show how good performance can be obtained quickly and efficiently.**

I. Introduction

THE AAIA'14 Data Mining Competition[1] is related to a problem of text classification. A corpus of 50,000 texts coming from reports of the Polish State Fire Service is provided, with a representation consisting of 11,852 variables (mainly based on documents words). The objective is to classify the texts into three binary classes by the mean of an ensemble of ten Naive Bayes classifiers, using as few variables as possible. In this paper, we present the method we used at the AAIA'14 Data Mining Competition. It mainly exploits the results of a Selective Naive Bayes classifier (summarized in Section II), trained for each of the three challenge class variables. The best subset selections of variables are collected and grouped together to form our submission to the challenge (see Section III).

Interestingly, the challenge evaluation criterion combines the test performance and the number of selected variables in a single formula. Whereas feature selection [1] aims at improving interpretability, test accuracy and deployment time, most papers in the literature focus on test performance only. Still, a small number of selected variables is often a requirement in practical data mining studies. In Section III, the trade-off between test performance and number of selected variables is investigated, using the challenge dataset as a case study. Finally, Section IV summarizes the paper.

II. Selective Naive Bayes Classifier

We summarize the Selective Naive Bayes (SNB) classifier introduced in [2]. It extends the Naive Bayes classifier owing to an optimal estimation of the class conditional probabilities, a Bayesian variable selection and a Compression-based Model Averaging.

[1]http://challenge.mimuw.edu.pl/mod/page/view.php?id=565

A. Optimal discretization

The Naive Bayes (NB) classifier has proved to be very effective in many real data applications [3], [4]. It is based on the assumption that the variables are independent within each class, and solely relies on the estimation of univariate conditional probabilities. The evaluation of these probabilities for numerical variables has already been discussed in the literature [5], [6]. Experiments demonstrate that even a simple equal width discretization brings superior performance compared to the assumption using a Gaussian distribution per class. In the MODL approach [7], the discretization is turned into a model selection problem and solved in a Bayesian way. First, a space of discretization models is defined. The parameters of a specific discretization are the number of intervals, the bounds of the intervals and the class frequencies in each interval. Then, a prior distribution is proposed on this model space. This prior exploits the hierarchy of the parameters: the number of intervals is first chosen, then the bounds of the intervals and finally the class frequencies. The choice is uniform at each stage of the hierarchy. Finally, the multinomial distributions of the class values in each interval are assumed to be independent from each other. A Bayesian approach is applied to select the best discretization model, which is found by maximizing the probability $p(Model|Data)$ of the model given the data. Owing to the definition of the model space and its prior distribution, the Bayes formula is applicable to derive an exact analytical criterion to evaluate the posterior probability of a discretization model. Efficient search heuristics allow to find the most probable discretization given the data sample. Extensive comparative experiments report high performance.

The case of categorical variables is treated with the same approach in [8], using a family of conditional density estimators which partition the input values into groups of values.

B. Bayesian Approach for Variable Selection

The naive independence assumption can harm the performance when violated. In order to better deal with highly correlated variables, the Selective Naive Bayes approach [9] exploits a wrapper approach [10] to select the subset of variables which optimizes the classification accuracy. Although the Selective Naive Bayes approach performs quite well on datasets with a reasonable number of variables, it does not scale on very large datasets with hundreds of thousands of instances and thousands of variables, such as in marketing applications or text mining. The problem comes both from the

978-83-60810-58-3/$25.00

search algorithm, whose complexity is quadratic in the number of variables, and from the selection process which is prone to overfitting. In [2], the overfitting problem is tackled by relying on a Bayesian approach, where the best model is found by maximizing the probability of the model given the data. The parameters of a variable selection model are the number of selected variables and the subset of variables. A hierarchic prior is considered, by first choosing the number of selected variables and second choosing the subset of selected variables. The conditional likelihood of the models exploits the Naive Bayes assumption, which directly provides the conditional probability of each label. This allows an exact calculation of the posterior probability of the models. Efficient search heuristic with super-linear computation time are proposed, on the basis of greedy forward addition and backward elimination of variables. The classifier resulting from the best subset of variables is the MAP (maximum a posteriori) Naive Bayes, which we call MNB in the rest of the paper.

C. Compression-Based Model Averaging

Model averaging has been successfully exploited in bagging [11] using multiple classifiers trained from re-sampled datasets. In this approach, the averaged classifier uses a voting rule to classify new instances. Unlike this approach, where each classifier has the same weight, the Bayesian Model Averaging (BMA) approach [12] weights the classifiers according to their posterior probability. In the case of the Selective Naive Bayes classifier, an inspection of the optimized models reveals that their posterior distribution is so sharply peaked that averaging them according to the BMA approach almost reduces to the MAP model. In this situation, averaging is useless. In order to find a trade-off between equal weights as in bagging and extremely unbalanced weights as in the BMA approach, a logarithmic smoothing of the posterior distribution, called Compression-based Model Averaging (CMA), is introduced in [2]. The weighting scheme on the models reduces to a weighting scheme on the variables, and finally results in a single Naive Bayes classifier with weights per variable. Extensive experiments demonstrate that the resulting Compression-based Model Averaging scheme clearly outperforms the Bayesian Model Averaging scheme. In the rest of the paper, the classifier resulting from model averaging is called Selective Naive Bayes (SNB).

D. Training Time Complexity

The algorithm consists in three phase: data preprocessing using discretization or value grouping, variable selection and model averaging. The preprocessing phase is super-linear in time and requires $O(KN \log N)$ time, where K is the number of variables and N the number of instances. In the variable selection algorithm, the method alternates fast forward and backward variable selection steps based on randomized reorderings of the variables, and repeats the process several times in order to better explore the search space and reduce the variance caused by the dependence over the order of the variables. The number of repeats is fixed to $\log N + \log K$, so that the overall time complexity of this phase is $O(KN(\log K + \log N))$, which is comparable to that of the preprocessing phase. The model averaging algorithm consists in collecting all the models evaluated in the variable selection phase and averaging then according to a logarithmic smoothing of their posterior probability, with no overhead on the time complexity. Overall, the train algorithm has an $O(KN(\log K + \log N))$ time complexity and $O(KN)$ space complexity.

III. Challenge Submission

A. Preliminary experiments

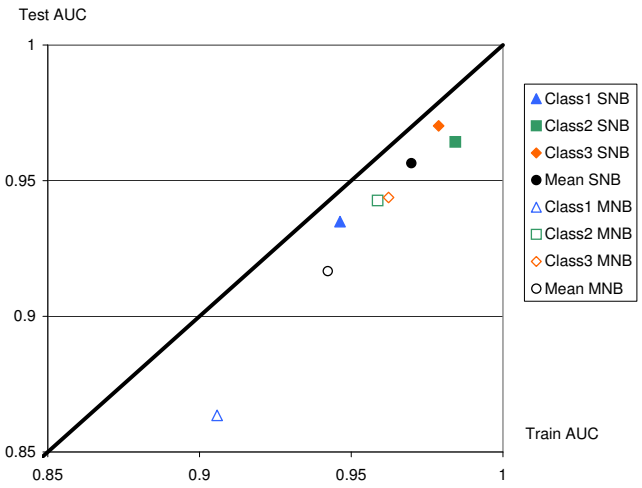

Fig. 1. Train versus test AUC for the MNB and SNB classifiers

The SNB classifier outputs several indicators for each variable:

- Level: evaluation of the predictive importance of the variable taken individually, based a normalized estimation of class conditional entropy. The level is between 0 (variable without predictive interest) and 1 (variable with optimal predictive importance).
- MAP: indicates that the variable belongs to best subset of variables, related to the MNB classifier.
- Weight: weight of the variable in the SNB classifier that exploits the model averaging method summarized in Section II.

We consider the standard NB classifier that exploits all the predictive variables; the non-informative variables with Level 0 are discarded. We also consider the 1NB classifier, which uses only one variable, the one with the highest Level. The MNB classifier is based on a subset of variables with fewer redundancy problems than the NB classifier. The SNB classifier exploits the same variables as the NB classifier, with weights per variable: it cannot be considered as a true Naive Bayes classifier.

As the challenge requires few variables, we focus on the MNB classifier which is very parsimonious compared to the SNB classifier, although it is both less accurate and less robust.

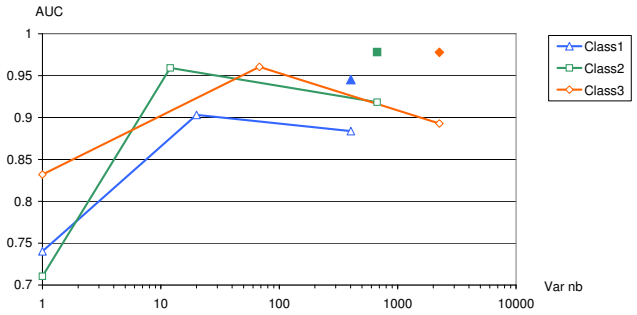

Fig. 2. AUC versus number of variables for the 1NB, MNB, NB and SNB classifiers

We trained the classifier [2] on a $70\% - 30\%$ split of the challenge dataset to evaluate its performance and robustness. We obtained a mean 96.9 train AUC and 95.6 test AUC for the SNB classifier, 94.0 train AUC and 91.6 test AUC for the MNB classifier, which confirms the usual behavior of both classifiers. This is illustrated in Figure 1, where the mean train and test AUC are presented as well as the detailed AUC per class.

We then trained the classifier using all the available data in order to reach better accuracy and robustness, with an expected decrease in accuracy on the challenge hidden dataset of about 1% for the SNB and 2% the MNB. In Figure 2, we report the AUC versus the number of variables for the 1NB, MNB, NB (empty shapes on the curves) and SNB (plain shapes) classifiers. As a reminder, the default AUC (with no variables) is 0.5. The results show that using one single variable, the 1NB classifier gets very good AUC, between 0.70 and 0.85. The MNB obtains 0.903 AUC with 20 variables for the first class, 0.959 AUC with 12 variables for the second class, 0.961 AUC with 68 variables for the third class. The NB classifier that keeps between 400 and 2000 informative variables out of the 11,852 input variables suffers from redundancy between the variables, which is harmful w.r.t. the independence assumption. All together, the NB uses far more variables than the MNB and gets a lower AUC. As expected, the SNB classifier obtains the higher accuracy using variable weights.

B. First submission

To get familiar with the challenge evaluation protocol, we grouped together the MAP variables of our three MNB classifiers (without removing the duplicates) and obtained a set of 100 variables. As the variable number is greater than that of each MNB, a better accuracy and robustness can be expected. The challenge rules states that the variable set is evaluated using and ensemble of ten Naive Bayes classifiers, each consisting of at least three variables. We chose to partition our set of 100 variables into ten random subsets of equal size, with the hope that the resulting ensemble classifier would behave similarly to a single Naive Bayes with 100 variables. This first submission was settled within a few hours after the download of the challenge data and got a score of 0.9468 on the leaderboard, second behind the leader (0.9476) on 2014-04-18.

[2] Available as a shareware at www.khiops.com

C. Additional experiments

As this first result was promising, we decided to proceed with further optimizations. The challenge evaluation criterion (score) is a mean AUC minus a penalty. The mean AUC should be above 0.5 (default performance). The penalty in the challenge is quadratic w.r.t the number of selected variables $|s|$ according to

$$penalty(s) = (\frac{|s| - 30}{1000})^2.$$

It is 0 with 30 variables and reaches 0.5 with 737 variables. With 100 variables, we got a penalty of 0.005 and therefore a leaderboard AUC of about 0.952, which is in line with our expectation. There might be room for some improvement, by optimizing directly the challenge evaluation criterion.

Algorithm 1 Bachward variable selection

Require: $X = (X_1, X_2, \dots X_K)$ {Set of input variables}
Ensure: S_{Best} {Best subset of variables}
$S = X, S_{Best} = X$ {Start with all the input variables}
{Backward selection}
while $|S| > 30$ **do**
  {Select best variable to remove}
  for $X_k \in S$ **do**
    if $(score(S - \{X_k\}) < score(S))$ **then**
      $X_{Remove} = X_k$
    end if
  end for
  {Update selection}
  $S = S - \{X_{Remove}\}$
  if $(score(S) < score(S_{Best}))$ **then**
    $S_{Best} = S$
  end if
end while

We then started from our subsets of MAP variables for each of the three classes, augmented with MAP variables resulting from the training of the three classes simultaneously ($AllClass = Concat(Class1, Class2, Class3)$). We obtained a starting set of 103 distinct variables. We then used a standard variable backward elimination algorithm based on a direct optimization of the challenge criterion on all the dataset. This variable selection method is summarized in Algorithm 1. At each step, it evaluates each variable elimination, then removes the variable that brings the best score. The algorithm returns the best subset of variables found during optimization.

In Figure 3, we report the AUC per class and the mean AUC obtained along the optimization path, from 103 variables down to 30 variables. The very few first optimization steps eliminate redundant variables, and improve the mean AUC from 0.953 to 0.957 with 95 variables. We then have a long plateau until getting 65 variables, and finally a slow decrease in

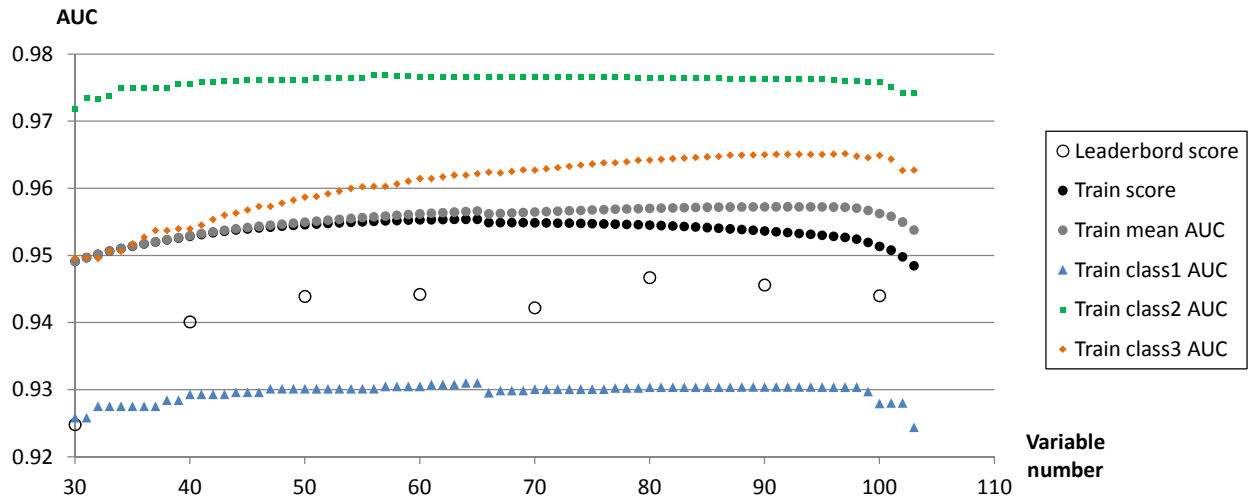

Fig. 3. Sensibility analysis: AUC versus number of selected variables

AUC, with a final AUC of 0.949 with 30 variables. The shape of the AUC curves is similar to that of Figure 2, which shows three AUC results with selections from one single variable to thousands of variables. The AUC increases quickly with very few variables (in Figure 2, one single variable is sufficient to goes from an AUC of 0.5 to around 0.75). Then, after a few tens of variables, a plateau is reached, and finally, for large numbers of variables, the performance decreases significantly down to the performance of the NB classifier (0.89 on average in Figure 2). In this bi-criterion problem, the beginning of the curve presented in Figure 3 can be interpreted as a Pareto curve, where each point corresponds to an optimal AUC given a max number of selected variables. In real data mining projects, this kind of curve might be helpful to find the best trade-off between accuracy and number of selected variables, according to the requirement and constraints of the project.

In the challenge, the score includes a penalty to choose the best trade-off. The challenge score is reported with black circles in Figure 3. The best score shown in Figure 3 gets a 0.5% improvement (up to a train score of 0.955 with 65 variables). This improvement is rather small and might be prone to overfitting, with an expected increased variance as the number of variables decreases. We got a score of 0.9452 on the leaderboard with this optimized solution. We tried other random partitions of the same variables into ten subsets (for the ten Naive Bayes ensemble classifier) and obtained score variations of about 0.3%. We also submitted a series of variable sets of increasing size along our optimization path, from 30 variables up to 100 variables by steps of ten. The resulting leaderboard scores (reported using white circles in Figure 3) shows that the improvements obtained during the train optimization vanish withing the variance of the results on the challenge leaderboard dataset. Furthermore, within a same set of selected variables, different random partitions in ten subsets produce a variance of the results of similar magnitude.

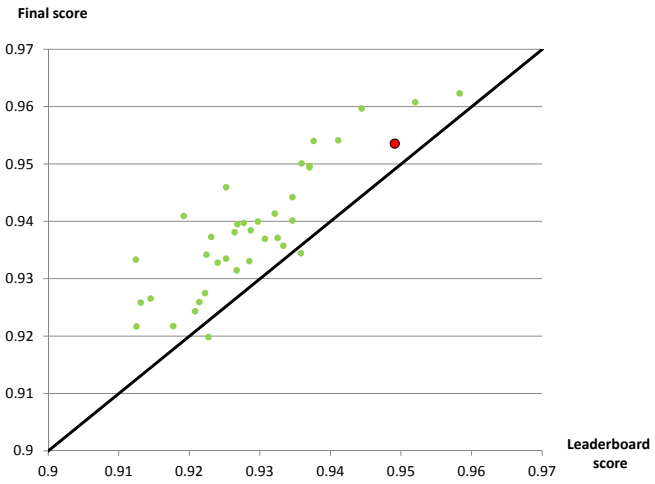

Fig. 4. Final challenge results

D. Final submission

The sensibility analysis of performance versus number of selected variables in Section III-C shows that the initial submission (see Section III-B) is competitive w.r.t. the objective of the challenge. Given the expected small and unreliable improvement in challenge score, the potential risk of using too few variables (larger expected variance) and the ignorance regarding the behavior of the ensemble classifier used in the challenge, we finally came back to the first submission. We removed the duplicate variables (keeping 97 variables), and obtained a challenge leaderboard score of 0.9491.

E. Challenge results

The last day of the challenge, our submission was ranked 3rd on the leaderboard. Usually, in data mining challenges, the participants tend to overfit the leaderboard score with many submissions, and we anticipated to get lower scores in the final results. Figure 4 shows the leaderboard versus final scores of all participants that obtained a score beyond that of the organizer's baseline; our score is represented by the red circle. Our final score (0.9536) was improved by 0.5% compared to the leaderboard score, which was a good surprise. Overall in this challenge, the final scores where improved on average by 1%. Participants ranked 4^{th} to 6^{th} on the leaderboard dataset got a 1.5% improvement of their final score and we finally got ranked 6^{th} in the final evaluation, 0.9% behind the winner.

IV. Conclusion

In most data mining projects, specific business requirements and constraints must be fulfilled. Several criterions must be taken into account, such as the time spend for the project, the training time, the deployment time, the intepretability of the models, the predictive accuracy. The AAIA'14 Data Mining Competition was an interesting challenge that focused on predictive accuracy versus number of selected variables. We have shown that using the Selective Naive Bayes classifier allows to quickly and efficiently obtain a competitive solution. We have also presented a sensitivity analysis between the two challenge criterions, that presents all possible trade-offs along a Pareto curve. This kind of analysis might be helpful to fulfill requirements in real world data mining projects.

***Abstract*—In this paper, we describe our solution in a competition that required performing data mining to identify key risk factors for the State Fire Service of Poland. The goal was to create an ensemble of Naive Bayes classifiers that could predict incidents involving firefighters, rescuers, children, or civilians. To this end, we first created a single Naive Bayes classifier and then partitioned the set of attributes used in that classifier. The attribute subsets were used to create new Naive Bayes classifiers that would form an ensemble, which generally performs better than both the single classifier and ensemble obtained by searching over all attributes considered when creating the single classifier. The application of our approach yielded a solution that ranked third in the competition.**

I. Introduction

THE main problem in our study is how to use data from incidence reports to identify key factors influencing the risk of serious injuries in actions carried out by the Polish State Fire Service. The dataset and the task description were provided by the organizers of the data mining competition hosted within the framework of the 9th International Symposium on Advances in Artificial Intelligence and Applications (AAIA'14), which is a part of the Federated Conference on Computer Science and Information Systems (FedCSIS) 2014. Additional information about the competition and its propositions is available in .

In accordance with the competition instructions, we performed data mining on the incidence reports. These reports are structured as a single table, in which each row represents one report and each column represents one attribute, i.e., a potential risk factor for injury during interventions and rescue operations. The result of this study is an ensemble of Naive Bayes classifiers that could be used to predict injuries of involved rescuers or civilians based on the most important risk factors.

We describe how we created such an ensemble and compare its performance to that of a single classifier and ensemble obtained by another method that searches over larger set of attributes. The utilized approach represents the main contribution of this paper.

The research presented in this paper was supported by the Ministry of Education, Science and Technological Development of the Republic of Serbia, Grant III-44010

In addition to Introduction and Conclusion, the paper features four sections. In Section II, we present the dataset and the task in the competition. In Section III, we present our approach to creating both a single Naive Bayes classifier and a Naive Bayes ensemble. In Section IV, we offer the comparison of performance of the single classifier and ensembles formed using the proposed approach. In Section V, we review work related to predicting fires and associated injuries.

II. Problem Description

In this section, we provide an overview of the dataset and outline the shared competition task.

A. Dataset

The provided dataset is extracted from 50,000 reports, which correspond to actions carried out by the Polish State Fire Service within the city of Warsaw and its surroundings between 1992 and 2011. The dataset is highly dimensional and given in form of a table, in which each report is described by 11,852 attributes. All of these attributes are discrete and only a few have more than two possible values. The data are also sparse, since only a small fraction of the attributes has a non-zero value for a particular report. There are three binary decision attributes that describe whether there were casualties among firefighters, children or other involved people, respectively. All three decision attributes are highly imbalanced, since the positive classes correspond to relatively rare events.

B. Task

The task is to identify attributes that could be used to robustly assign reports to corresponding decisions labels. As defined by the organizers, the quality of a solution is assessed by measuring performance of a classifier ensemble composed of Naive Bayes models. Those models are constructed using ten attribute sets, separately for each decision attribute. An output of the ensemble is computed by averaging probabilities of the positive classes returned by

978-83-60810-58-3/$25.00

individual Naive Bayes models. The performance of the ensemble is measured by taking an average Area Under the ROC Curve (AUC) over the probability predictions for each decision attribute, decreased by a penalty for using a large number of conditional attributes. Namely, if we denote the chosen set of attributes by s, the total number of attributes used (with repetitions) by $|s|$, and AUC of a classifier ensemble for the i-th decision attribute by $AUC_i(s)$, then the quality measure for the assessment of a chosen set can be expressed as:

$$score(s) = F\left(\frac{1}{3}\sum_{i=1}^{3} AUC_i(s) - penalty(s)\right) \quad (1)$$

$$penalty(s) = \left(\frac{|s| - 30}{1000}\right)^2 \quad (2)$$

$$F(x) = \begin{cases} x & \text{for } x > 0 \\ 0 & otherwise \end{cases} \quad (3)$$

C. Approach to building an ensemble

In this research, we base our work on the task defined in the previous subsection. However, we are also interested in finding a single classifier, using a similar evaluation function, which is calculated as an average of three AUC values decreased by the penalty. Then, we examine whether the single classifier could be divided so to obtain an ensemble yielding higher accuracy compared to the original classifier. We also try some other, more common method for creating an ensemble. Finally, all of these approaches are compared.

III. Methodology

Our approach to ensemble creation was motivated by the task defined in the previous section. We were first interested in finding a single classifier. Then, we examined how to obtain an ensemble. We used two approaches for creating an ensemble - a division of the single classifier and a search over the same attributes that were considered (searched) when creating the single classifier. In this section, we describe how we select attributes to train a single classifier and how an ensemble may be formed using a custom boosting-based algorithm.

A. Attribute ranking

As already mentioned, the used dataset is highly dimensional. Therefore, in order to find the best classifier (model), it is not practical to search over the entire set of attributes. Hence, we first ranked all attributes according to their relation to the decision attributes. Since the used dataset is large, in order to speed up the process of testing different ranking methods, we manually constructed a small dataset that had similar characteristics as the original dataset, i.e. it included discrete (usually binary) attributes and sparse data. Using this small dataset, we could analyze the results of different ranking methods. The chi-square test [3] gave very good results, so we chose it as our method for attribute ranking.

For each attribute, using the chi-square test, we calculated three weight coefficients, each representing a degree to which an attribute is related to one of the three decision attributes. Finally, for each decision attribute, we ranked all attributes according to their weight.

B. Creating a single classifier

After the ranking, we started a search for a single classifier. Once the search is finished, we should have an approximate accuracy degree that can be reached with one classifier, but also the approximate limit in the number of attributes for a classifier (single or ensemble), since we have a penalty for using a large number of attributes. In order to find the set of attributes that represents the best classifier we used algorithms based on forward and backward search [4].

First, for each of the three decision attributes, we selected the top 50 attributes with respect to their weight rank. The union of these three groups of attributes yielded a set of 121 attributes. We then executed forward search on this set in order to find the best subset, i.e. the one offering the highest accuracy when predicting the values of three decision attributes. The function responsible for evaluating these subsets uses 5-fold cross validation. For each fold, it creates three Naive Bayes models, one for each decision attribute. It calculates predictions using each model and assesses the individual model accuracy using the AUC value. We then calculated the average of these three AUC values and decreased it by the penalty. The overall accuracy is calculated by averaging these values over all five folds.

The forward search process narrowed down the set of 121 attributes to a starting set of 41 attributes, which yield a model whose overall accuracy is 0.950, as calculated by our evaluation function. To improve accuracy, we had to increase the number of attributes being searched. One option was to include more than 50 attributes for each decision attribute and start a forward search from the beginning. However, due to a lack of computing power, we had to gradually increase the number of attributes.

First, for each of the three decision attributes, we selected attributes that were initially ranked between 51 and 75. We created a union of the three sets of attributes with these rankings. This union was used in a forward search that started not from the empty set but from the starting set. This forward search led to the inclusion of new attributes. Next, we performed a backward search, which resulted in the removal of some attributes.

We repeated the whole process and gradually increased the number of attributes to 350. The latest iteration in attribute selection resulted in 72 attributes, which yield a model whose overall accuracy is about 0.965, as calculated by our evaluation function.

The forward search is an iterative process. In each iteration, all attributes that are not already in the model are tested to be included. The attribute that yields the biggest improvement in accuracy is added to the model. Usually, attributes that show improvement in one iteration showed improvement in the previous iteration too. Considering this, in order to speed up the process of searching, we implemented forward search so that in every new iteration it searches only over the attributes that showed improvement in the previous iteration. Also, backward search is implemented in the same manner, so that in every new iteration it only considers attributes whose potential removal showed improvement in accuracy in the previous iteration. In the rest of this paper, whenever we mention the terms forward or backward search, we refer to variants described in this subsection.

It is worth noting that we tried to include additional ranking to speed up the process of searching even more. We tried to select some large number of attributes from each ranking (based on the chi-square test), unite selected attributes and rank them according to the metric that measures how good predictors they are. The metric measures the predictive quality of a single attribute as the accuracy of the model formed using just that one attribute. This additional ranking did not lead to any improvement, i.e. the forward search process did not include attributes with higher weight (according to this metric) as often to justify this method.

C. Creating an ensemble

The main idea behind ensemble systems is to create many classifiers and combine them so that the combination improves upon the performance of a single classifier. Generally, good ensembles should demonstrate diversity, i.e. each classifier should make errors on different examples, so that in combination these classifiers could reduce the total error. Algorithm that we used in order to create a diverse set of classifiers is based on the idea of boosting method, more concretely on the idea behind the AdaBoost algorithm [5].

We want to examine two approaches when creating ensembles. The first one is to try to use one strong single classifier that may be constructed after searching over a set of attributes and to split it into a set of classifiers. The other is to search through that entire set of attributes in order to find a different ensemble. Finally, we may observe differences between two ensembles. In order to make a comparison, these ensembles will have similar structure, i.e. they will include the same number of attributes and the cardinalities of the corresponding classifiers will be the same.

The advantage of the first approach is that it consumes less time, because it searches over a smaller set of attributes. Even if we take into consideration the time needed to find a single classifier, this method is still faster, since our search algorithm needs less time to find one big classifier than ten smaller classifiers where for each of them the search starts from the beginning. We can expect the first method to yield lower accuracy, because it searches over a limited set of attributes. However, it may be less prone to overfitting since it uses only significant attributes selected for a single classifier, but this could be the subject of further analysis.

In this research, we will only consider ensembles in which classifiers have balanced cardinality. Moreover, we will not examine cases when different classifiers in an ensemble may include the same attributes. These two constraints may be part of future research.

D. Boosting-based algorithm for ensemble creation

Our algorithm for ensemble creation follows the general idea of the well-known AdaBoost algorithm. It is an iterative method, where in each iteration we construct one classifier that focuses on examples that are misclassified by previous classifiers.

The algorithm uses ten iterations, as we need ten classifiers. At the beginning of each iteration we construct a training set, by sampling with replacement 50,000 examples from the original training set. Every example has the assigned probability to be sampled. The probability depends on the accuracy with which the example was classified by the previous classifiers (constructed in previous iterations). The more misclassified an example, the higher is its probability to be sampled for the next iteration. Therefore, each new classifier focuses on examples that were misclassified. Initially, the probabilities (p) have uniform distribution, so that in the first iteration every example has the same probability of being sampled.

In each iteration, we search for a classifier that maximizes accuracy, which is calculated as average AUC value for three decision attributes. The selection process is based on the same forward and backward search algorithms that we used when building a single classifier. Once the classifier is found, the probability for each example is updated in accordance with the classification error (err). When classifying, the Naive Bayes method calculates probabilities, so for each example it yields probabilities for three decision attributes. The average of these three probabilities indicates accuracy, and the classification error is calculated as a complement. Classification error is in the interval [0,1]. Here, we introduce a small constant c, which is close to 0, so that probabilities are multiplied with value from interval [c,1]. This constant is used because we do not want the probability of an example classified with error 0 to be multiplied by 0. All the steps executed in one iteration are as follows:

1. Create a training set, using the probabilities p.
2. Using this training set, find the most accurate classifier.
3. Update the probabilities according to the formula: $p = p * (c + (1 - c) * err)$
4. Normalize the probabilities so their sum is 1.

TABLE I
NUMBER OF USED ATTRIBUTES AND RESULTS FOR EACH STEP OF MODEL SELECTION

Number of attributes from rankings	Total number of attributes	Number of attributes in the model	Number of inserted + removed attributes	Overall accuracy of the model
50	121	41	41	0.9500514
75	175	53	14 + 2	0.9561488
100	233	59	6 + 0	0.9571192
150	335	66	9 + 2	0.9586754
200	430	67	7 + 6	0.9605470
250	540	69	6 + 4	0.9630121
300	628	70	2 + 1	0.9638735
350	727	72	4 + 2	0.9648648

If the repetition of attributes among classifiers is not allowed, this algorithm may yield imbalanced classifiers, i.e. classifiers that have very different accuracies. For instance, the first classifier could contain the most significant attributes, because it is created using the uniform distribution of probabilities. Ensembles usually demonstrate better performance if the classifiers are more balanced. Hence, if necessary, we may try to balance these classifiers to improve the overall accuracy.

IV. RESULTS AND DISCUSSION

In this section, we provide an overview of the performance of the single classifier, and ensembles formed by dividing the single classifier and searching over all attributes considered when creating the single classifier. Finally, all of these approaches are compared with respect to the predictive quality of models obtained.

A. Creating a single classifier

As discussed above, in every step of the (model) selection process, we increased the number of attributes being searched. In Table 1, we present the results obtained in each of these steps. Each row contains data about one step in the process. In the first column, we show the number of attributes from each of the three rankings considered in the search process. The second column indicates the total number of attributes considered in the search process, i.e. the union of all attributes obtained from the three rankings. The cardinality and accuracy of the obtained model are presented in the third and fifth column, respectively. Furthermore, the fourth column indicates the number of attributes inserted and removed from the model during one step.

We stopped at the step that included 350 attributes from each of the rankings. Certainly, we could include additional steps in order to improve our model. Each step terminates after a relatively short period. In the future, we can execute further steps, and we expect further improvement in accuracy. We do not expect the cardinality of the model to change very much because of the penalty for using a large number of attributes.

B. Creating an ensemble

Since some of the described methods for creating ensembles are time-consuming, we decided to first test our methods on the initial set used in the process of creating a single classifier (the first row in the Table 1). Later, chosen methods are applied on the final set (the last row in Table 1). The initial set has 121 attributes and yields a classifier that includes 41 of these attributes.

In the first approach, we want to use the classifier and try to split it into ten smaller ones, which are further combined into an ensemble. The cardinalities of these classifiers will be balanced, so there will be nine classifiers with 4 attributes and one with 5.

In order to check the probability that this kind of split yields an ensemble that is more accurate than the single classifier, we made 100 random splits (each split yielding nine subsets with 4 attributes and one with 5). For each of these 100 ensembles, we observed the value that represents accuracy, calculated by the formula defined in the task and using 5-fold cross validation. In the next table (Table 2) we give some quantitative measures regarding these values for all of the 100 ensembles (minimum, maximum, quartiles and mean). The histogram (Fig. 1) shows how the values are distributed.

The accuracy of a single classifier of 41 attributes is 0.9500514. From Table 2 and the accompanying histogram, we may see that there is a large proportion of ensembles whose accuracy is higher than that of the single classifier.

We aim to find a method that yields an ensemble with high accuracy, ideally higher than all of the ensembles obtained after random splits. Here, we test our boosting algorithm to split the classifier (41 attributes). We executed this algorithm with different values of constant c. We present these results in Table 3.

TABLE II
QUANTITATIVE MEASURES FOR ACCURACY OF 100 GENERATED ENSEMBLES

Min.	1st Qu	Median	Mean	3rd Qu	Max.
0.9477	0.9490	0.9496	0.9496	0.9501	0.9515

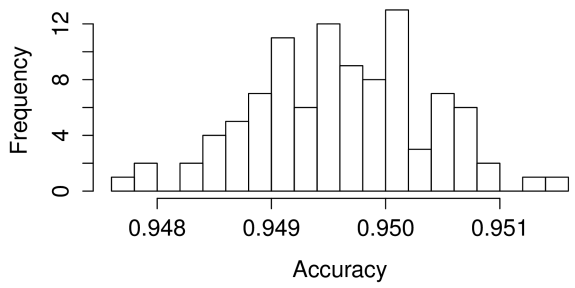

Fig. 1 Accuracy of generated ensembles

TABLE III
ACCURACY OF ENSEMBLES OBTAINED FOR DIFFERENT VALUES OF CONSTANT C

c value	Ensemble accuracy
0.01	0.9494519
0.001	0.9495294
0.0001	0.9498423

As expected, lower values of *c* yield higher accuracy. When we decrease this constant, the examples, with error whose order of magnitude is same as for *c*, have more accurate probabilities. It is possible to decrease the constant further. However, we do not expect this to offer significant improvement, since the number of examples with error lower than 0.0001 is small. We tried to modify our algorithm so that for sampling we use squared (and normalized) probabilities to additionally emphasize differences in probabilities, but this did not produce an ensemble with higher accuracy.

It is important to mention that, when executing our algorithm, we also tried to calculate probabilities according to the original AdaBoost algorithm, but this gave lower accuracy. Most probably, this is because the calculated values used for updating probabilities do not emphasize differences between correctly classified examples and misclassified examples, as much as our algorithm does.

We may see that, when *c* is 0.0001, our algorithm produced an ensemble only slightly more accurate than half of the ensembles obtained by random splits. This does not present a satisfactory result.

One of the reasons why the ensemble produced by the boosting algorithm has low accuracy could be that the classifiers from the ensemble are imbalanced with respect to accuracy. The analysis indicates that the first classifier contains the most significant attributes, because it was created using the uniform distribution of probabilities for sampling. Every subsequent classifier usually has lower accuracy when compared to the previous one.

Among ensembles obtained by random splitting, when we compare those with high accuracy to those with low accuracy, ensembles with higher accuracy usually contain more balanced classifiers. For each ensemble, we may observe the values of accuracy for its ten classifiers and determine standard deviation for these ten values. Lower standard deviation means having more balanced classifiers. In the next Table 4, we show standard deviations for five most accurate and five least accurate ensembles.

From Table 4, it is clear that ensembles with higher accuracy have lower standard deviation. However, this is a characteristic that should be considered, but it is not a rule. When we calculate standard deviation for an ensemble obtained by our boosting algorithm with constant 0.0001, we get a value of 0.1259726. This is much higher deviation when compared to all ensembles from Table 4, and probably from all other ensembles obtained by random splitting. However, the accuracy of this ensemble is better than that of one half of the ensembles obtained by random splitting, as we showed earlier.

Therefore, we will try to balance classifiers in the ensemble obtained by boosting algorithm, with respect to their accuracy. Balancing will be done in iterations. In each iteration, we select classifiers with maximum and minimum accuracy. Then, we try to swap two attributes from those classifiers. We examine each pair of attributes, until the swap yields an improvement greater than some threshold value we set. When the swap is executed, we continue to the next iteration. This process improves accuracy and usually decreases standard deviation. Also, it usually stops after a few iterations. When this method is executed on an ensemble obtained by the boosting algorithm, it stopped after three iterations and improved accuracy to 0.9512469. A small number of iterations is favorable since we do not want to change our ten classifiers too much, considering that boosting algorithms grouped attributes so that each classifier is focused on different set of examples. Accuracy yielded after balancing is high, and only two ensembles from those obtained from random splits have better accuracy.

TABLE IV
STANDARD DEVIATION FOR TEN ENSEMBLES WITH HIGHEST AND LOWEST ACCURACY

ensemble (rank)	standard deviation	ensemble accuracy
1st	0.06989024	0.9515106
2nd	0.07783254	0.9513274
3rd	0.08413265	0.9509978
4th	0.07679123	0.9508524
5th	0.08046396	0.9507565
96th	0.1000637	0.9482818
97th	0.09956434	0.9482052
98th	0.1126992	0.9479637
99th	0.08952922	0.9479142
100th	0.09684023	0.9477181

We also executed balancing on other ensembles that have similar accuracy as ensemble obtained by the boosting algorithm, but none yielded as high improvement. This could indicate that the way in which attributes are grouped by boosting is important, i.e. that the diversity of ensembles is important, and that it may not be easily compensated by balancing. However, we would need to do more testing to confirm that. We also experimented with executing the boosting method on the same set of 41 attributes, where we allowed repetition of attributes among classifiers, but this yielded ten similar classifiers and much lower accuracy.

In our second approach, we executed our boosting algorithm on the set of all 121 attributes. As we aim to compare this approach to the first one, we constructed an ensemble with the same characteristics. That ensemble included classifiers with same cardinalities (nine classifiers with cardinality 4, and one with cardinality 5), with no attribute repetitions. The set of attributes included in this ensemble was much different when compared to the set of 41 attributes from the single classifier. The accuracy of the obtained ensemble is 0.9379888. This accuracy is much lower compared to all ensembles constructed by random splitting.

Finally, considering results presented above, we chose only to test our first approach on the single classifier obtained in the final step. This classifier contains 72 attributes, hence we constructed ensemble containing eight classifiers of seven and two of eight attributes. We tried both boosting with balancing and random splitting. Again, some of the ensembles obtained by random splitting outperformed both the single classifier and the ensemble obtained by boosting and balancing. Our final result was an ensemble yielding the highest accuracy.

V. Related Work

There are many attempts to use fire related data for predicting, managing and reducing injuries caused by fire outbreaks. One group of such studies estimates future wildfire activities in order to reduce negative effects and facilitate its management, limiting the most destructive aspects of fire. Beckage and Platt [6] explored potential of a time series model that considers the area burned in previous years and the Southern Oscillation Index (SOI) condition to predict the area burned in the current years. However, the authors raise attention that their prediction is not true for "out of sample" predictions since model selection, parameter estimation, and the modeling process itself used the data that were to be predicted. Furthermore, Yue, et al. [7] managed to improve their regression and parameterization models for predicting wildfire activity by combining them with an ensemble of climate model projections for 2050 conditions. Moreover, they observed importance of considering meteorological attributes other than temperature in predicting changes in area burned.

The second group of research focuses on predicting injuries and identifying key factors influencing the risk of injuries in various incidents. One such analysis of data from population-based case-control study in King County, Washington [8] showed that there is association between smoking and residential fire injuries. By using relative risk estimation as a uniform method of comparison Warda, et al. [9] summarized house fire injury risk factor data retrieved from fifteen relevant articles. The authors stress that the research is relevant for developing, targeting, and evaluating preventive strategies. In their study, Burgess, et al. [10] compared injury rates among various fire departments and observed that the rates vary substantially. Variations in work practice and risk management regulations as well as in reporting practices were proposed as a potential explanation for the study findings.

Selection of significant attributes is deemed a prerequisite for constructing an accurate prediction model. In this sense, Shai [11] examined social and demographic predictive factors using multiple regression. Besides identifying significant attributes in predicting fire injuries for the civilian population, the author observed interaction effect between age of housing and income. The results of such research showed that older housing, low income, the prevalence of vacant houses, and ability to speak English (native language for area of Philadelphia) have significant effects on fire injury rates. In this research, we also aimed to find features that make accurate predictions regarding injuries in fire incidents. As opposed to Shai, we used Naive Bayes (NB) models, feature ranking and feature subset selection methods. The combination of multiple feature selection methods allowed us to capture complex feature interactions and select the model with the highest predictive capacity. Moreover, we used these methods to create both a single classifier and classifier ensemble, and to compare the two approaches. It was shown that ensemble models can yield higher accuracy than single models [12].

VI. Conclusion

In this paper, we present an approach for creating an ensemble of Naive Bayes classifiers from a single classifier. The creation of this approach was motivated by the need to identify key risk factors for the Polish State Fire Service as part of a data mining competition. The use of the proposed approach yielded an ensemble that generally performs better than both a single classifier and ensemble obtained by searching over all attributes that were considered when creating the single classifier. Moreover, the trained ensemble ranked third in the competition.

The advantage of this approach is that the model can be incrementally improved relatively quickly. We can include more steps in the process of selection of a single classifier in order to improve the classifier. Every step requires relatively small amount of time to finish. After executing these steps, we can make a division of the single classifier in order to obtain a new ensemble. The process of division does not consume much time.

In the future research, we would like to improve our methodology. As our results suggest, one single classifier can be divided into smaller ones which in combination yield higher accuracy. Our goal is to find a method for classifier division that would give a good ensemble, i.e., an ensemble that would outperform all of the ensembles generated by random divisions. Our method did not give completely satisfactory solution, but it is on the line of achieving the goal. So far, we tested only an algorithm based on boosting. It was used for division and when constructing an ensemble by searching (all attributes considered when creating the single classifier). We could try to improve this algorithm, but also to try other different algorithms for creating ensembles, since there are many others known in literature. Later, we should make further comparisons between approaches where we construct an ensemble from a single classifier and by searching. Finally, we could experiment with the possibility of attribute repetitions and different cardinalities among classifiers in an ensemble in order to obtain higher accuracy.

***Abstract*—The Polish State Fire Service gathers information about incidents which require their intervention. This information is stored to document the events. However, it can be very useful for new officers training, better identification of threats and planning of more effective procedures. The identification of key risk factors for casualties among firefighters, children or other involved people was a topic of data mining competition organized as a part of 1st Complex Events and Information Modelling workshop devoted to the fire protection engineering. The task of the competition was to find ten subsets of features for ten Naive Bayes classifiers. The ensemble output was used to predict occurence of casualities. Herein, the solution description that took 5th place is presented. The proposed method used cascade step forward feature selection procedure to find features subsets.**

***Index Terms*—key risk factors, fire service, Naive Bayes, feature selection, cascade step forward**

I. Introduction

THE POLISH EWID [2] reporting system is the Incident Data Reporting System (IDRS) used by Polish State Fire Service to gather information of their interventions in incidents. This data documents historical events. However, useful knowledge could be extracted from them, which can be later used for new officers training, preparation of safer and more effective procedures, and better understanding of danger factors in incidents [5], [4], [8]. The identification of key risk factors for casualties among firefighters, children and other people involved was a topic of data mining competition organized within the 9th International Symposium on Advances in Artificial Intelligence and Applications (AAIA) and was an integral part of the 1st Complex Events and Information Modelling workshop devoted to fire protection engineering. The competition results will bring data-driven insights into key risk factors in incidents and contribute to safety improvement, which is important for Fire Service supporting systems [6],[7].

The competition dataset comes from reports of the EWID system, which documents actions carried out by the Polish State Fire Service within the city of Warsaw and its surroundings in years 1992–2011. Each report obtains a feature vector descriptor after preprocessing [4], [5]. The competitors task was to find ten subset of features among over 11,000 discrete attributes describing 50,000 reports, which are relevant to the safety of people in incidents. Based on selected features, the ensemble of ten Naive Bayes classfiers [3] was created for each of three decisions variables:

1) injured firefighter in the action,
2) injured children in the incident,
3) other injured people involved.

They were used to evaluate the competition score metric, which considered the performance of the classfiers on each of the decision variable and penalizes large feature subsets. It is worth to note, that the same ten subsets of features were used in Naive Bayes construction for all decisions variables. The additional obstacle in analysis was sparsity of training data and rare occurance of positive values in decision variables.

The task of the competition can not be simplified to a sole feature selection problem. It is a problem of feature selection for ensemble of classifiers which should have the highest average accuracy in predicting three various dependent variables simultaneously with the smallest possible number of features. The proposed method used a cascade step forward selection of features that maximize the competition score metric on cross validation (CV) on training dataset. In each selection step, previously chosen features subsets were considered, therefore the proposed method is called 'Cascade Step Forward' (CSF) feature selection. The CSF procedure was speeded-up by initial features filtering and storing information about values occurences in CV folds.

The atricle is organized as follows: firstly detailed description of competition dataset, task and score metric are desribed; secondly, the proposed method is presented; then, obtained results are shown; finally, the conclusions and directions for future research are presented.

II. Methods

A. Data description

The training dataset available for participants consists of 50,000 incident reports. Each report was described using 11,852 discrete features. The majority of features were binary, with only few features with more distinct values (up to 5 values). The details of number of discrete values in features are

978-83-60810-58-3/$25.00

presented in Table I. The major values in the training dataset were zeros. From all 592,600,000 available values in training dataset only 5,217,892 have non zero values, which is only 0.8805% of all values. The sparsity and high dimensionality of data was implied by the nature of considered problem. The features correspond to the number of distinct words in the textual part of the reports (after lemmatization) and to several hundreds of features from the quantitative part of the reports [4], [5].

TABLE I
NUMBER OF DISCRETE VALUES IN FEATURES.

Discrete values	2	3	4	5
# of features	11826	9	7	10

For each report there were associated three binary decision varibles. The first decision attribute indicates incidents resulting in injury or death of a firefighter or a member of rescue team. The second decision variable indicates cases in which there were children among injured people and the third attribute identifies situations where civilians were hurt. All three decision attributes are highly imbalanced, since the positive classes correspond to relatively rare events. The details of positive values occurence in decision variables are presented in Table II

TABLE II
NUMBER OF POSITIVE VALUES IN DECISION VARIABLES.

Decision variable	# of positive values	Percentage
1	199	0.40%
2	366	0.73%
3	2955	5.91%

Let's denote dataset as $D = \{X_1, X_2, ..., X_N, Y_1, Y_2, Y_3\}$, where $N = 11,852$ is a feature number, X_i is a i-th feature vector and Y_1, Y_2, Y_3 stand for three decision variables, injury of firefighter, children, other involved people, respectively.

B. Task description

The competition task was to select ten subsets of features. They were used to build an ensemble of ten Naive Bayes classifiers for each decision variable. The sum of the output of classifiers ensemble was used to predict the occurence of positive values in each of decision variables. The accuracy of the selected features was computed with competition metric described below. It is worth to note, that there was a lower bound limit equal 3 for number of features in each subset.

C. Evaluation metric

The competition score metric can be expressed as:

$$score(s) = F\left(\frac{1}{3}\sum_{1}^{3} AUC_i(s) - \left(\frac{|s| - 30}{1000}\right)^2\right), \quad (1)$$

where

- $s = \{s_1, s_2, ..., s_{10}\}$ is a selected ten subsets of features,
- $|s|$ is a total number of selected features with repetitions,
- AUC_i is Area Under the Curve (AUC) of Receiver Operating Characteristic (ROC) [3] computed for i-th decision variable,
- $F(x) = \begin{cases} x, & \text{if } x \geq 0 \\ 0, & \text{otherwise.} \end{cases}$

The first term of eq.1 computes the average performance of classifier ensemble on all decision variables, whereas the second term penalizes the solutions with large number of selected features. It is worth to note, that penalization term vanishes when exactly three features are selected in each subset.

D. Proposed Method

The competition used a Naive Bayes classifier (NBC) [3] to evaluate the metric. The NBC is a classification method, which for a given sample $\mathbf{x} = \{x_1, ..., x_K\}$, with K features, calculates the posterior probability for all $y \in Y$, $p(Y = y|X_1 = x_1, ..., X_K = x_K)$, and assigns the class with the highest posterior probability. This can be expressed as:

$$y = \operatorname*{argmax}_{y \in Y} p(Y = y|X_1 = x_1, ..., X_K = x_K). \quad (2)$$

The posterior probability can be rewritten with Byes rule, the eq.2 becomes:

$$y = \operatorname*{argmax}_{y \in Y} \frac{p(Y = y)p(X_1 = x_1, ..., X_K = x_K|Y = y)}{p(X_1 = x_1, ..., X_K = x_K)}. \quad (3)$$

The evidence probability in denominator is the same for all classes and what is more, the NBC assumes that all features are conditionally independent given decision, thus the eq.4 can be written as:

$$y = \operatorname*{argmax}_{y \in Y} p(Y = y) \prod_{i=1}^{K} p(X_i = x_i|Y = y). \quad (4)$$

For discrete features the prior and likelihood can be computed as follows:

$$p(Y = y) = \frac{M_y}{M}, \quad (5)$$

and

$$p(X_i = x_i|Y = y) = \frac{M_{x_i,y}}{M_y}, \quad (6)$$

where

- M is total number of samples,
- M_y is number of samples with class label equal y,
- $M_{x_i,y}$ is number of samples with class label equal y and X_i feature equal to x_i.

The feature selection for single NBC can be done with greedy step forward (SF) procedure [3] with maximization of score with CV. The SF algorithm starts selection with empty subset of features $S_0 = \{\}$. Afterwards it checks the performance of the classifier with addition of each of the available features. The performance is computed on repeated (R_{cv} times) CV with drawing training and testing split for each repetition. The feature X_j which maximizes the quality metric is added to the subset, $S_1 = S_0 \cup X_j$. The whole procedure is

repeated till the required number of features L is selected or the required score value is achieved. The pseudocode of SF selection for single classifier is described in the Algorithm 1 listing.

Algorithm 1: The step forward feature selection procedure for single classifier.

input : $D = \{X_1, X_2, ..., X_N, Y_1, Y_2, Y_3\}$,
N number of available features,
L number of features to select,
R_{cv} repeats in cross validation.
output: The selected optimal subset S of features.
begin
  Set $S_0 = \{\}$
  for l *in 1 .. L* **do**
    for i *in 1 .. N* **do**
      Build a classifier H_i using as a feature subset $S_{l-1} \cup X_i$
      for c *in 1..* R_{cv} **do**
        Draw training and testing split of data
        Compute perfomance of classifier H_i on testing subset;
    Select classifier H_j with the highest average accuracy
    Set $S_l = S_{l-1} \cup X_j$

The SF procedure is applicable for selecting features for single classifier. It is inefficient for selecting features for ensemble of classifiers because for every classifier the similar subset of features will be assigned. The classifier ensemble requires a diverse subset of features for each classifier to obtain high accuracy [9]. To overcome this obstacle the 'Cascade Step Forward' feature selection procedure is proposed. The CSF algorithm, contrary to SF, searches for subsets of features for each classifier in the ensemble. It applies the SF procedure to find a subset of features for each classifier. However, in candidate feature scoring the performance is computed for ensemble instead of single classifier. The CSF procedure returns a set of feature subsets $S_{all} = \{S^1, ..., S^J\}$, where J is a number of classfiers in the ensemble. The pseudocode for CSF procedure is presented in Algorithm 2 listing.

E. Implementation Details

The greedy feature selection procedure has high computational cost. However, it can be decreased with filtering the features with low likelihood values. In feature selection only attributes with likelihood values greater than threshold value t for at least one decision variable were considered. The filtering condition can be expressed as:

$$p(X_i|Y_1) > t \vee p(X_i|Y_2) > t \vee p(X_i|Y_3) > t. \qquad (7)$$

The threshold value used was $t = 0.02$. After applying the eq.7 from inintial 11852 there remained 2333 features. The CSF procedure run only on remaining features.

Algorithm 2: The cascade step forward feature selection procedure for ensemble of classifiers.

input : $D = \{X_1, X_2, ..., X_N, Y_1, Y_2, Y_3\}$,
J number of classifiers in ensemble,
N number of available features,
L number of features to select,
R_{cv} repeats in cross validation.

          Draw training and testing split of data
          Compute perfomance of ensemble of classifiers $\{H^1, .., H^{j-1}, H_i^j\}$ on testing subset
      Select classifier H_i^j with the highest average accuracy
      Set $S_l^j = S_{l-1}^j \cup X_i$
    Set $S_{all} = S_{all} \cup S^j$

In the proposed solution splitting dataset into training and testing subsets was performed many times during cross validation. Therefore, the counts of values occurences were stored in each fold to speed-up process of computing priors and likelihoods. The available dataset was splitted into $F = 500$ equally sized folds, from which $F_{tr} = 50$ and $F_{te} = 450$ were drawn for the training and testing respectively. Such uncommon partition provides a quite good matching between local CV scoring and public leaderboard score. The CV scoring was repeated $R_{cv} = 20$ times for each new feature testing. The i-th fold stores information M_y^i about samples number with class label equal y, and $M_{x_i,y}^i$ about number of samples with values equal x_i and class label y for all of considered features. Therefore, the probabilites needed for NBC construction can be computed as:

$$p(Y = y) = \frac{\sum_{i=1}^{F_{tr}} M_y^i}{F_{tr}\frac{M}{F}}, \qquad (8)$$

and

$$p(X_i = x_i|Y = y) = \frac{\sum_{i=1}^{F_{tr}} M_{x_i,y}^i}{\sum_{i=1}^{F_{tr}} M_y^i}. \qquad (9)$$

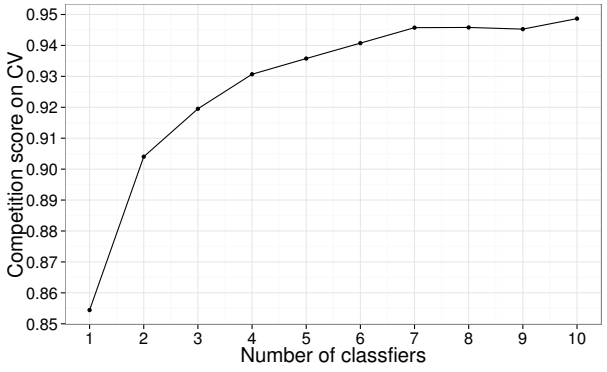

Fig. 1. The local CV score obtained for classifier ensemble in CSF feature selection.

The CSF feature selection was implemented in C++ to achieve high speed of computations.

III. Results

To omit the penalization term in the score metric (eq.1) there were selected exactly three features for each classifier. The selected features for each classfier are presented in Table III. It is worth to note, that selected features are only 0.25% of all available features. The obtained local CV scores during CSF selection for ensemble with different number of classifiers are presented in the Fig.1. It can be observed that the score is increasing when adding up to 7 classifiers into ensemble. For greater number of classifiers in the ensemble the score is stable. The local CV score was 0.9487, the public leaderboard score computed on approximately 10% of testing data was 0.9376, whereas score computed on full testing set was 0.9540. The solution that scored the 1st place achieved 0.9623 on full testing dataset, so there is only 0.0083 difference between proposed solution and the best one. The dependency between scores computed on public leaderboard and full testing dataset for solutions of all participants, with score on full testing dataset greater than 0.9, are presented in the Fig.2. It can be observed that for almost all solutions the score on public leaderboard was lowered with respect to score on the full testing dataset.

TABLE III
SELECTED ATTRIBUTES FOR EACH CLASSIFIER.

Classifier	Attribute 1	Attribute 2	Attribute 3
1	11701	5270	675
2	143	142	2182
3	691	5909	3735

IV. Conclusion

The solution description that took 5th place in AAIA'14 Data Mining Competition: "Key risk factors for Polish State Fire Service" was presented. The proposed solution used a cascade step forward feature selection to select feature subsets for classifiers in the ensemble. The CSF maximize the competition score on cross validated training dataset in each step. To speed-up the selection process the initial filtering out of features with low likelihood were performed and number of occurence of feature values and class labels were stored in folds of training dataset. The identified key risk factors can be useful for Polish State Fire Service in new officers training, preparation of safer and more effective procedures and awareness of threats in actions.

The proposed CSF method can be applied for feature selection for other domains, for example in neuroimaging data analysis where data sets are highly dimensional and only small fraction of features are usable [10]. The performance of CSF procedure can be improved by cosidering several best features in each step instead of just one.

***Abstract*—The explosive growth of big data poses a processing challenge for predictive systems in terms of both data size and its dimensionality. Generating features from text often leads to many thousands of sparse features rarely taking non-zero values. In this work we propose a very fast and robust feature selection method that is optimised with the Naive Bayes classifier. The method takes advantage of the sparse feature representation and uses diversified backward-forward greedy search to arrive with the highly competitive solution at the minimum processing time. It promotes the paradigm of shifting the complexity of predictive systems away from the model algorithm, but towards careful data preprocessing and filtering that allows to accomplish predictive big data tasks on a single processor despite billions of data examples nominally exposed for processing. This method was applied to the AAIA Data Mining Competition 2014 concerned with predicting human injuries as a result of fire incidents based on nearly 12000 risk factors extracted from thousands of fire incident reports and scored the second place with the predictive accuracy of 96%.**

I. Introduction

The unmanageable scale of big data comes in many forms symbolically paraphrased by *5Vs*: Volume, Velocity, Variety, Veracity and Value [1]. Huge volume defined by both the size or dimensionality of big data is one such "V" that particularly adversely affects computational complexity of the process of learning from data. The hype about big data may be therefore elusive while its possible value very difficult to extract. There are many examples reported in the literature that demonstrate both very powerful and very ineffective exploitations of large data sets for predictive tasks [4], [1], [1], [3].

Inspired by the pioneering work in [4], however, there is a widespread belief that the more data the better and the inability of exploiting it all is just a reflection of the predictor's weakness [3]. We argue, however, that a blind admission of all big data into the predictive modelling may be wrong or at least inefficient approach for some class of problems. Although certain cognitive tasks may indeed require billions of data points to reveal the full explanative power of the data [4], [5], our experience indicates that the majority of data problems can be explained by the relatively small data sample, which might be buried under the masses of big data. For these problems the availability of big data for predictive analytics widens the choice and the opportunity for both novel data exploitations and the improvement of predictive performance of the existing models.

As a result, the emerging paradigm of working with big data appears to be centred around careful data filtering, preprocessing, features generation and selection. Very often these procedures eliminate most of the original data leaving only essential evidence that retains almost complete explanative power [3]. What is more, the evidence reported in the machine learning literature indicates that given a typical supervised learning problem the key drivers for performance lie predominantly in the discriminative power and the choice of the data features rather than in the complexity of the predictive model [6], [7], [8], [9], [10]. All these points lead to a conclusion that when faced with the problem of learning from big data the main challenge and effort should be directed towards extracting or generating the key explanative data features while the actual learning and predictive performance could be delivered with relatively simple and robust learning model [10].

In line with this approach we have entered AAIA'2014 data mining competition with the intend to demonstrate how effective could be feature selection for supervised learning problems with very high dimensional data. We proposed a relatively easy and fast, greedy feature selection method that works particularly well with the large number of sparse features. In the competitive environment we will demonstrate that it delivers very high performance with a very simple predictor like Naive Bayes. We also propose much faster yet nearly equally robust feature selection method that eliminates completely the need of predictor application, and for that as we argue it is a very strong contender for real-time applications of predictive analytics on big data.

II. Task Description

AAIA Data Mining Competition 2014 was concerned with extracting the risk factors and attributes of fire incidents that would allow the most accurate prediction of human injuries or casualties as a result of these incidents. The total of 11852 features extracted from 50000 fire incident reports were presented as input data and the objective of the competition was to select a subset of features that would achieve the best predictive accuracy of detecting simultaneously the following 3 binary class target outputs with the Naive Bayes model:

- serious injury or death of one of the firefighters or members of the rescue team
- children were among injured people
- civilians were among hurt/injured people

978-83-60810-58-3/$25.00

Additional constraint enforced by the competition was the format of the solution and its assessment. The format of the solution was enforced to be organised within 10 feature subsets of at least 3 features each and the performance metric was set to be the area under the curve (AUC) of the receiver-operator curve (ROC) obtained from averaging the outputs from Naive Bayes classifier ensembles across all 3 target variables. The performance metric additionally incudes the penalty term that penalises for using many features in the solution as in the following:

$$score(s) = max\left\{0, \frac{1}{3}\sum_{i=1}^{3} AUC_i(s) - \left(\frac{|s|-30}{1000}\right)^2\right\} \quad (1)$$

Note that the size penalty term reduces to 0 when all 10 selected feature subsets have exactly 3 features. The problem is challenging due to the fact that the input data is huge, high dimensional and sparse in nature, while the class target values are highly imbalanced. Further difficulty is that the evaluation considers the average performance of de-facto 3 distinct classification problems sharing the same features. A successful feature selection method needs to find the compromise in maximising the average performance of all the 3 models at the same time.

III. Feature Elimination

Given the very large feature dimensionality and the sparse nature of the input data the first natural step is to eliminate redundant features that have no chance of contributing to the performance of the target prediction. The approach taken was that given the feature sparsity and huge imbalance of the target class variables, the features which have all non-zero values occurring only at negative class outputs have completely zero predictive power in isolation or in combination with other features. Denoting by $X^{[N\times M]}$ the matrix of input data and by $Y^{[N\times 3]}$ the matrix of corresponding class outputs we can safely eliminate redundant features by applying the following simple filtering expressed in Matlab formulation:

```
F = find(sum(X(any(Y, 2), :))>0);    (2)
```

This simple filtering resulted in elimination of 1931 (16.3%) redundant features. An interesting observation is that if the three target class variables were to be predicted and assessed separately, the above filtering would have resulted in much deeper reductions of: 6418 (54.1%), 6174 (52.1%), and 2146 (18.1%), respectively. What is more, separating predictive tasks would further allow to identify feature redundancy through containment. Namely, we can further eliminate a feature *A* whose non-zero intersection with the positive target class (true positives) is fully contained by other feature *B*, while its non-zero intersection with the negative class (false positives) fully contains feature *B*. What it means is that prediction with feature *A* would always be less accurate than with feature B which is guaranteed to make more positive predictions (true positives) at a lower costs (false positives). Such further elimination through feature containment would achieve the reductions of 9754 (82.3%), 9313 (78.6%), and 5005 (42.2%) respectively. It suggests that it might be much more efficient to model all three predictive tasks independently rather than force them to share the same feature subset of input data.

Constrained by the evaluation criterion defined by eq. 1 the feature set to work with had to be left with the only lightly reduced size - down to 9921 features, to avoid the loss of information.

IV. Naive Bayes Classifier

Naive Bayes (NB) is a simple yet very effective and fast probabilistic classification method that naively assumes that features are conditionally independent given the class value [11]. Given a binary classification problem with n features F_i the NB model tries to give the estimate of the posterior class probability given feature observations: $p(C, F_1, ..., F_n)$. From the chain rule applied to conditional probability definition the searched likelihood becomes:

$$p(C, F_1, ..., F_n) = p(C)p(F_1|C)p(F_2|C, F_1)... \\ ...p(F_n|C, F_1, F_2, ..., F_{n-1}) \quad (3)$$

which after applying the naive assumption of conditional feature independence simplifies to:

$$p(C, F_1, ..., F_n) = \frac{1}{Z}p(C)\prod_{i=1}^{n} p(F_i|C) \quad (4)$$

where Z is a constant scaling factor that is fixed for known feature variables.

Since most of the features are binary or categorical we are dealing with the multinomial distribution here, and constructing a posterior class likelihood is just a matter of calculating a product of class conditional probabilities of specific feature values observed for every input data instance. This process is critical and most often repeated when evaluating classification performance hence it is reasonable to speed it up by precalculating the class conditional likelihoods of all feature values empirically from the training data. Calculating the posterior would be then reduced to taking the relevant class conditional feature probabilities from the lookup table and multiplying them together or adding log likelihoods in odder to avoid the precision loss for small numbers.

Since the competition performance metric was an AUC of the ROC curve, the class posteriors are all that is required for the score calculation.

V. Sparse Feature Selection Strategies

Given the training input data of 50000 examples composed of nearly 10000 sparse features (after filtering) and a well defined and fast predictive performance metric defined in eq. 1 the objective was to extract 10 subsets of features that would maximise the expected predictive performance on the unseen testing set. Our preliminary investigations revealed that separating a validation set out of training data appears to be a good method for comparing the generalisation robustness of the strategies. On the other hand setting any data aside for the validation reduces the evidence that the predictive model is learnt on and hence may not give the best performance on the testing set. The approach that was finally taken was to use the actual performance feedback to decide whether a validation set improves the predictive performance on the testing set.

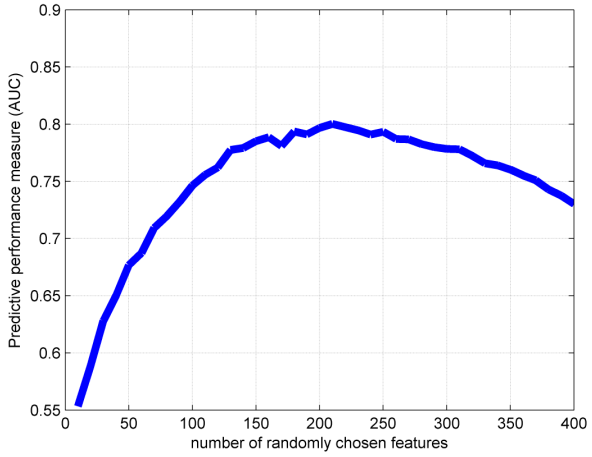

Fig. 1. Random subset method performance curve

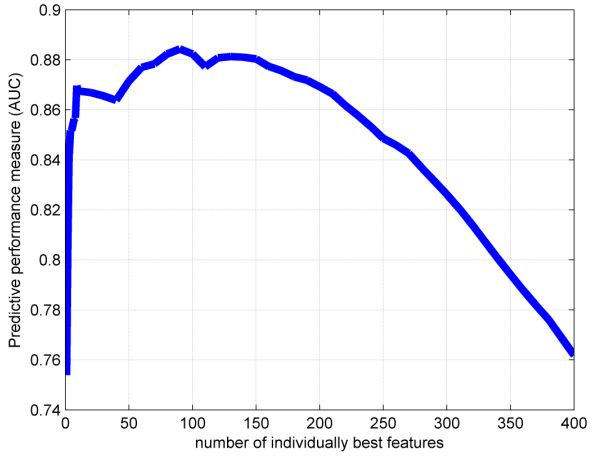

Fig. 2. Incremental single best performance curve

A. Random Feature Subsets (RFS)

Random feature subset method appears very naive for large feature space problems, however it was quickly developed to provide some intuition around the predictive value of the data and to set some baseline predictive performance levels. It was also useful for establishing the impact of the performance metric penalty term provided by eq. 1 and through some experiments draw an estimate of what might be the optimal size of the feature set that would maximise the competition performance criterion.

The performance of random feature subset selection method was evaluated using random features set sizes increasing from 10 to 500 at a step of 10 and obtaining corresponding performance measure inline with eq. 1. It has been repeated 50 times and the results averaged to build stable performance estimates for increasing number of random features included in the model. The resulting performance curve is presented in fig. 1.

As it can be seen from the figure, the performance of the random feature subset method is expectedly quite poor and peaks for roughly 200 features included in the model.

B. Incremental Single Best (ISB)

The random feature subset method performs quite poorly but it does not require any computation effort related to feature selection. Incremental single best method presented here goes a step further and shifts the balance towards improving the predictive performance at the relatively small prior computational cost of evaluating all individual features performance. Since each feature is evaluated in isolation, no conditional feature dependencies are considered, and the model build simply follows the greedy strategy of sequentially adding individually best available features until their combined predictive performance stops increasing. Fig. 2 illustrates the performance curve of such incremental single best selection strategy for the feature set sizes set from 1 to 500. Clearly the performance curve very quickly climbs to a much higher levels above 0.88 comparing to the random subset method and

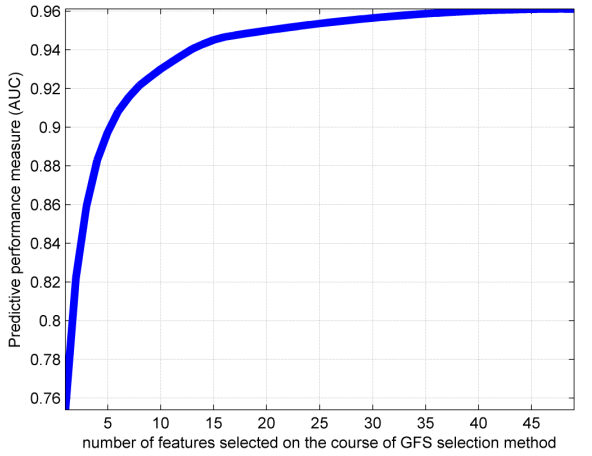

Fig. 3. Greedy forward search performance curve

it peaks for about 90 individually best features included in the model.

C. Greedy Forward Search (GFS)

The next feature selection strategy to consider is a traditional greedy forward search. This method would start from the same individually best feature. At each round it then checks the performance change of adding all remaining features one at the time to finally add a feature that results in maximum possible improvement of predictive performance. This search already introduces a significant processing cost as its computational complexity based in the number of performance evaluations is $O(N \times n)$ where N is the total number of available features and n stands for the number of features selected for the model.

The performance curve of the GFS is presented in fig. 4.

It might be surprising that it beats the performance of all previously presented selection methods with just 4 first features. The performance curve peaks with 49 features. The reported validation performance in excess of 0.96 was com-

parable to the training performance and on its own climbs to a competitive level. The advantage of GFS method is a rapid performance growth with just a few features yet the computational complexity heading towards quadratic order becomes a real issue here and caused the complete search to take few days on the standard PC. Further drawback of this method is that beyond few features the risk of falling into local shallow maxima grows really fast and affects the method ability to find robust solutions.

D. Diversified Greedy Backward-Forward Search (DGBFS)

Greedy forward search introduced in the previous section demonstrated really good potential for high predictive performance that is however hindered by the problem of local maxima trap. The proposed diversified DGBFS method tries to exploit the strengths of the forward search method while improving its flexibility to get out of local maxima traps, increasing the exposure to the diversity of the whole feature set and significantly improving the speed of the search.

The method starts from the same greedy forward search but rather than adding only the single feature that maximally improves the performance for every feature set scanning round it keeps adding all the features that improve the currently best performance. As a result a single forward scanning round could add hundreds of features instead of just one. What happens then is a backward search, in a sense that all features selected so far are attempted to be removed from the set and such removal is granted if it causes the performance improvement. Such backward search adds vital ability of the method to refine its earlier greedy choices by exploring latter additions that do not maximise the performance gain but lead to better longer term solutions.

The forward and backward scanning rounds follow each other in a sequence until for both not a single addition or removal is able to improve the performance. Since this method is dependent on the order of features presented for the scanning, feature indices are randomly permutated before each scanning round such that the whole feature space is equally exposed to the chances of being selected.

The complete performance curve across many rounds of additions and removals is visualised in fig. 4.

Forward moving sections represent the performance progression during forward search and backward sections reflect the corresponding performance gains during backward search. Notable is a big overshoot of the size of the selected feature set during the first forward search. This was the effect of the initial ease of improving the performance through additions. In fact most of the newly added features were later removed in the subsequent backward search since they were added not because they were very robust but because they were just better than random features initially populating the selected feature set.

The presented DGBFS feature selection method achieved the top expected performance of over 0.97 and was selected to generate solutions for the AAIA'14 Data Mining Competition. Both the initial feedback and the final assessment positioned its solution on a second place in the competition trailing just a fraction of a per cent behind the top wining solution.

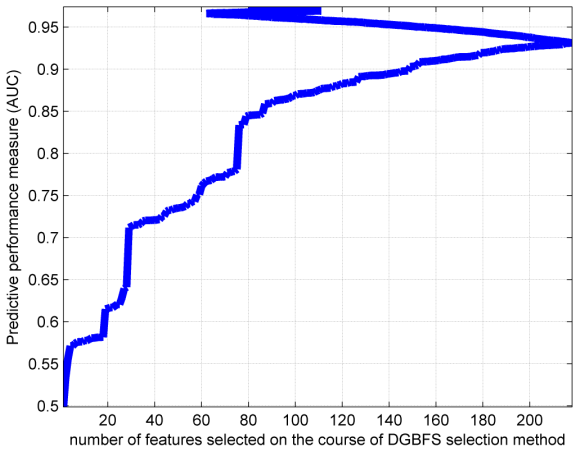

Fig. 4. Diversified greedy backward forward search performance curve

E. Fast Cumulative Sparse Feature Count Search (FCSFCS)

The greedy feature selection method presented in the previous section results in the best predictive performance as defined by eq. 1 that uses optimised Naive Bayes classifier to generate posterior class likelihoods. However, even such simple classifier additionally optimised for processing speed still absorbs non-negligible processing time and, due to the nature of Naive Bayes implementation, may require temporary expansion from the sparse to full representation making it impossible to evaluate the predictive performance with very many features. These issues significantly adversely affect the model scalability and might render its application impossible for larger scale problems, especially in the real-time operation.

To address this issue a further significant simplification is introduced which models the Naive Bayes posterior by just a simple sum of binarised features. We assumed that all the sparse features can be converted into a binary representation that indicate simply a presence of non-zero value. In case of the opposite enumeration of the features, binarisation should be preceded by the value conversion such that binarised "1/true" is always assigned to the sparse class i.e. unlikely set of feature values that has the highest joint probability with the positive target class. Once such binarisation is completed the posterior probability of the positive target class given the features can be simply modelled by the sum of positive binarised feature values which is equivalent to the voting count of true features for each input example. Such sum on binary features is extremely fast to calculate, is fully compliant with sparse feature representation and can swiftly evaluate the models with extremely large feature subsets. What is more it is actually performing very well as a classification method just slightly trailing the Naive Bayes classifier.

The performance of such method has been explored due to its very attractive properties of scalability and speed crucial for applications of huge high-dimensional data for predictive analytics purposes. Using this method allowed to explore normally prohibitive search strategies of greedy backward search (starting from the whole set) and multiple greedy ensemble search that now we managed to carry out in a matter of minutes

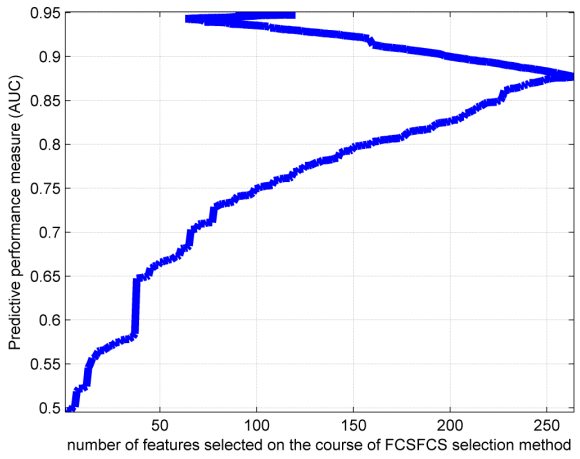

Fig. 5. Fast cumulative sparse feature count performance curve

on a standard PC.

Fig. 5 presents the performance curve achieved by the FCSFCS method using the same penalised AUC of ROC performance measure defined in eq. 1. Although it is just over 1% behind the top DGBFS method, given its simplicity and swift processing taking just minutes it really is a very good and fast feature selection proposition method or in fact a complete very shallow yet robust predictor.

F. Individual vs Ensemble Models

For the evaluation purposes a clarification is required as to the way feature subsets were evaluated. The competition performance criterion defined in eq. 1 clearly enforces the construction of the ensemble of 10 feature subsets with at least 3 features in each subset. The question of whether to construct the ensemble of the subsets of features or use just a single flat subset in fact reflects a long standing dilemma of individual vs ensemble learning. One motivation for ensemble learning is that it is much more efficient and faster to build multiple models with different parts of the feature subset if the computational complexity of the learning process exceeds linear order. This is however not the case for Naive Bayes classifier that given N examples of M-dimensional features is linearly complex in both $O(NM)$. There are also many examples reported in the literature, how a combination of weak learners each built on a small subset of evidence outperforms the single predictor trained on the complete evidence [12]. This effect of ensemble robustness through synergic complementarity is well known and reported on in ensemble learning methods like boosting [13], [12], where the performance gain through combination of weak learners is probably the most exposed.

What we have seen in the context of predominantly greedy feature selection methods is that building the ensemble of feature subsets is much more prone to overfitting. In fact we have built the ensemble versions of the DGBFS and FCSFCS methods where greedy additions or removals were done in turns for all ensemble subsets and the methods terminated when it was not possible to improve the performance for neither addition nor removal from any of the ensemble feature subsets. For all such experiments we have observed a consistent pattern of training performance improved by more than 1% but the validation and testing consistently down by almost 2%. We have also observed a pattern of about 10% to 20% increase in the total number of features selected with the ensemble evaluation method. A possible explanation is that with 10 different feature subsets the ensemble search has many more degrees of freedom and appears to find many new ways to better fit the training data with more features despite the penalty term. In the validation or testing phase, those many unstable coincidences of feature values turn out to be just random noise while the penalty term hits back with the guaranteed decrease of predictive performance.

Therefore throughout the competition the single flat feature subset representation was used and then to meet the solution requirement of being represented in a form of exactly 10 feature subsets a simple yet robust feature distribution method was used. This method exploited the property of the greedy search models which tend to provide the solution in a form of items ordered inline with their quality or contribution to the group performance. What it means is that the features added first and "surviving" in the solution subset tend to be the best while items added last are likely to be individually the worst. To distribute the predictive power of features evenly among the ensemble subsets taking from the top (best) to bottom (worst) the ensemble subsets were appended in turns until all selected features were distributed. As a result the ensemble was composed of different feature subsets that shared similar predictive power and the size difference between the least and most populous subset was at most 1 feature.

VI. Summary of Experiments

The experiments followed the typical competition journey of trying initially simple models, reflecting on the results, and gradually adding more and more complexity in a search for performance improvement. There were many more feature selection methods tested beyond the one reported above. Among the most significant were feature selection with decision trees reported in [10] and the acclaimed fast binary feature selection with conditional mutual information reported in [8]. None of these alternatives came close to the performance achieved by our top DGBFS method.

Fig. 6 illustrates the comparison of performance curves corresponding to different feature selection methods investigated in the paper.

What is striking is how efficient greedy forward search initially was. With just a few features it achieved really impressive performance. However this effect is achieved at the price of really slow processing and in the longer run suboptimal performance caused by the traps of falling into local maximum. The sparse feature voting method was by far the fastest as it effectively eliminated the Naive Bayes classifier, yet still managed to deliver very high predictive performance. The diversified greedy backward forward method performed relatively fast as it absorbed many suboptimal but good features and stabilised with a very robust solution after just few forward and backward rounds. It had reported the best predictive performance and was submitted as proposed solution to the AAIA'14 data mining competition.

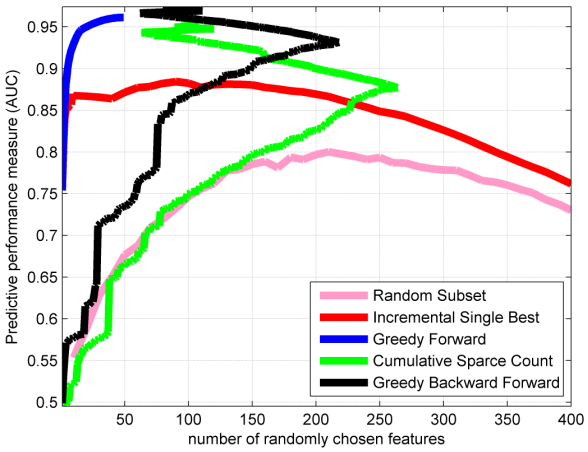

Fig. 6. Feature selection performance curves comparisons

VII. Conclusions

In this work we illustrated relatively simple yet very robust and generic feature selection method that appears to be particularly suitable for handling very large data sets of high-dimensional sparse features. The method employs highly diversified backward-forward search that is relatively fast yet allows to achieve deep features complementarity and very high and stable predictive performance. We have drafted the journey leading to the development of the top model and included informative and comparative examples of other feature selection models some of which could be good candidates for specific predictive requirements. Specifically we have shown that greedy forward search could be a very good model for a very limited number of features, while the binarised features voting method due to its extremely high speed looks to be particularly suitable for live, dynamic predictive system applications with the real-time requirement.

All of the presented feature selection models were considered for an entry in the AAIA'2014 Data Mining competition. Since the predictive performance is the only metric for the competition, the top performing model of diversified greedy backward-forward search has been applied to the data and its solution submitted as our entry in the competition. This solution scored the second place with the tested predictive performance in excess of 96%, just a quarter of the per cent behind the top scored solution. This achievement proves how important is the feature selection step and how much it can reduce the useful input data to provide huge improvements in predictive performance. In the end the model selected only 79 features from the total pool of nearly 12000 thereby elimination more than 99% of data.

The presented model could be used to better understand and prevent various accidents and complex hazardous situations. It really is a good example of how predictive analytics turned big data into small data to potentially save many lives.

***Abstract*—This document describes the winning method for the AAIA'14 Data Mining Competition: Key risk factors for Polish State Fire Service. The competition challenge was a feature selection problem for a set of three classifiers, each of them in a form of ensemble of naive Bayes classifiers. The method described in this paper uses a genetic algorithm approach to identify an optimal set of variables used by the classifiers. The optimal set of variables is found through a three-stage procedure that involves different settings for the genetic algorithm. The first step leads to reduction of attribute set under consideration from 11,582 to 200 attributes. The following two steps focus on finding an optimal solution by first exploring the solution space and then refining the best solution found in an earlier step.**

I. Introduction

THIS paper describes the winning method for the AAIA'14 Data Mining Competition: Key risk factors for Polish State Fire Service. The challenge was a feature selection problem for a set of three classifiers, each of them defined as ensemble of ten naive Bayes (NB) classifiers sharing the same set of features. The description of the competition and the task can be found at: http://challenge.mimuw.edu.pl/contest/view.php?id=83.

The method described here is based on genetic algorithm (GA) approach. I treated the challenge task as an optimisation problem, where the task was to find an optimal set of variables (it was divided into 10 sets of variables by the competition rules). The set was to optimise the objective function that was based on the score function defined for the competition. In my solutions, the objective function was slightly modified in order to avoid the overfitting phenomenon by using n-fold cross-validation (CV) in the process (with varying n).

The method described in this paper consisted of three different steps. For each step a different GA setup was used. The three steps can be summarised as follows:

- In the first step a small subset of *informative* variables from the original 11,852 variables was identified. For this task a single NB classifier was used rather than an ensemble of NBs.
- In the second step, solutions based on ensemble of NBs were identified, using only the informative variables subset identified in the first step.
- In the third step, the GA was used to improve the best solution obtained in the second step.

II. Genetic Algorithms

Genetic algorithms (GAs) introduced by Holland [1] are a category of evolutionary computation. Evolutionary computation is used to solve mathematical optimisation problems by means of heuristics, and therefore it can be viewed as a meta-heuristic optimisation algorithm. Evolutionary computation is concerned about developing algorithms and techniques that are inspired by the natural evolution. Concepts borrowed from the nature include generations, individuals and populations, genes, mating, natural selection, survival of the fittest, etc.

GAs are the most popular class of evolutionary algorithms [2] that uses *genes* and *chromosomes* to represent the individuals (which correspond to solutions). Genes are basically encoding of the solution by means of a string of numbers (typically binary, with possible other representations). New solutions are generated by means of combining typically pairs of individuals (existing solutions) form the population (working set of solutions). The combination mimics generic crossover with possible additional mutations. It has been believed that suitable chromosome representation can be critical to achieving satisfactory performance of the GA for the given problem. This premise was used in defining approach that I used in the competition.

III. The Challenge

The challenge was to predict three binary decision attributes based on a subset of 11,852 attributes. The challenge imposed a classifier model – for each of the three decision variables an ensemble of exactly 10 naive Bayes (NB) classifiers was to be used, with each NB having at least 3 attribute variables. The same set of NB classifiers was to be used for the three decision attributes.

The performance of the classifiers was determined by means of the receiver operating characteristic (ROC) curve. The goal was to maximise the average area under the ROC curve for the three classifiers. Additionally, a penalty for using a large number of attributes (beyond 30) was introduced. The penalty term p was defined as:

$$p = (\frac{n-30}{1000})^2$$

where n is the number of attributes in the solution. Fig. 1 visualises the effect of penalty as the function of the number

978-83-60810-58-3/$25.00

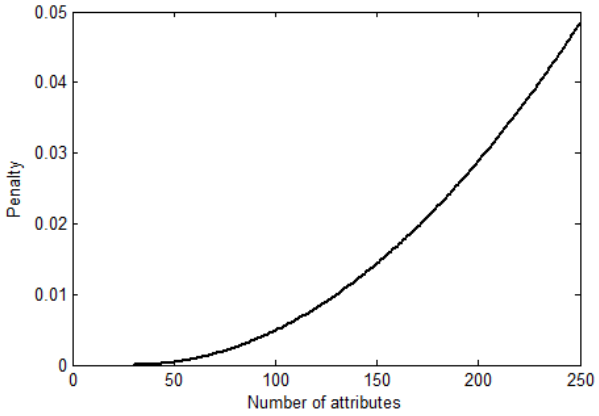

Fig. 1. Penalty as a function of the number of attributes included in the model

of attributes included in the ensemble. Taking into account that the area under the ROC curve should range between 0.5 and 1 and that the baseline solution provided by the competition organisers achieved the score of approximately 0.91, one should conclude that the number of attributes in the ensemble should not be greater than 200 to 300.

The data provided for competition was comprised of 11,582 variables and approximately 50,000 records. For each record a complete set of attributes is available. The distributions of values for the most of variables are heavily unbalanced and that applies to the decision variables as well.

IV. Cross-Validation

One of the basic challenges in data mining is overfitting [3]. To account for overfitting, I used k-fold cross-validation (CV) [4] embodied in the objective function. I used a simple k-fold CV schema, where data records were assigned to appropriate folds using modulo k operator and the original order of the records in the dataset. I used k-1 folds as a training set and the remaining fold as the test set, repeating it for each fold (round robin). The objective function was calculated based on the average of results for k folds.

I experimented with different values for k, as generally there is no widely accepted way to determine a *good* value of k. It is believed, that *good* values depend on the problem and particular dataset. In fact, I varied values for k for different steps. For the first step I used k=10, for the second step I used k=5, while for the third step I used k=3. While the change for the change between the first and second step was dictated just by the desire to avoid artefacts coming from the k selection, the reason for the change to k=3 was a result of simple investigation I decided to do after the second step: I evaluated performance of the same algorithm run with different CV settings: n=3,4,5,7, and 13 using the competition submission website that allowed to get feedback based on the evaluation set. I noticed that the results for n=3 and n=4 produced the same solution that scored better on the competition leaderboard than the solutions achieved using greater values of n. Therefore, for the final step I decided to use n=3.

V. The Method

In this section I will describe the method to find solutions to the competition challenge. The approach taken consisted of three steps that varied in the details of the experimental setup. The idea was to in the first step to identify attributes that can lead to good solutions. For the following steps I decided to use only a subset of attributes to improve the performance of the search heuristic.

My approach was dictated by two observations: (1) initial data analysis indicated that there are many variables that are in *present* state very rarely (and therefore arguably are not contributing much information or leading to overfitting) and (2) that initial experiments suggested that the *good* solutions quite consistently preferred certain variables over others. Based on those observations I decided first to narrow a subset of candidate attributes to 200.

In the three steps the same simple GA was used. However the chromosome and operator definitions, method of constructing initial population and the population size, and other parameters were varied throughout the steps. Below I provide the details of the algorithm for each step.

VI. The First Step – Identifying Informative Attributes

In the first step, the goal was to reduce an attribute set by identifying a subset of attributes that was *most informative*. In order to do that, I used a GA that would identify a NB (note: a single NB, not an ensemble of ten NBs) that otherwise would be optimising the problem as stated in the competition.

A. Chromosome Definition

Chromosome was defined as a list of integer values that were allowed to take values from 1 to 11,852. The length of chromosome was constrained to be at least 30, with upper limit set to 250 (but effectively solutions never exceeded 200 attributes anyway).

B. Crossover

As the crossover operator I used the uniform crossover method with mixing probability 0.5.

C. Mutation

Mutation had two operators, each of them applied with 0.5 probability:

- Remove – in that case the attribute would be removed from the list of attributes for that NB
- Replace – it would replace an attribute with a random attribute sampled from the uniform distribution. The addition of attributes was achieved by replacing an *empty* (denoted as 0) gene with a value related to one of the attributes (denoted as an integer 1 to 11,852).

The probability of mutation was set initially to the value 0.01 and was designed to decline after each generation. After

each iteration (generation), the probability of mutation was multiplied by a constant delta equal to 0.999. The parameters were set in such a way that a mutation would occur for a new individual with probability over 0.9.

D. Initial Population

Initial population consisted of 200 individuals. The initial number of attributes for individuals from the initial population was sampled from the uniform distribution with lower and upper limit 30 and 130 correspondingly. The attributes were sampled from the complete set of 11,582 attributes using the uniform distribution. The size of the initial population of 200 individuals was determined based on the size of the problem. The total number of possible attributes in the population (200 multiplied by 80, where 80 is an average chromosome size in the initial population) would exceed the total number of attributes in the data (11,852).

E. Simulations

In order to identify the *informative* attributes I run 200 independent simulations and collected the best result (an individual with the highest score at the end of simulations) for each of the 200 simulations. Each simulation terminated after 2500 generations. For each generation I generated 50 new individuals (25%) and subsequently rejected 50 individuals with the lowest score.

To perform simulations I used my own implementation of the algorithm written in C++ programming language. The implementation was intended to provide optimised code for the task. Rather than using the raw data, I used pre-calculated conditional probability tables for each attribute (given decision attribute and CV fold).

F. Result

As the result of simulations I obtained a set of 200 solutions. Please note that those solutions assumed a single NB model, rather than an ensemble of 10 NB models. To evaluate those solutions using the competition leaderboard I used a simple technique: I assumed that the first 27 attributes will be assigned for the 9 NBs in the ensemble with each contacting only 3 attributes (the minimum required). The remaining attributes were assumed to belong to the last NB in the ensemble. Additionally I sorted the attributes for the evaluation purpose. Solutions obtained using this method resulted in scores in the range of 0.93 to 0.945 on the competition leaderboard.

But the most valuable result for this step was the set of *informative* variables. It turned out that the 200 solutions shared a lot of common attributes, suggesting that there were clearly attributes that were more informative than the others.

The attributes regarded *informative* as were (sorted according to the ranking): 5270, 143, 2887, 8179, 10062, 460, 2924, 8914, 258, 2182, 7187, 7980, 5306, 1880, 7999, 11266, 1509, 11463, 7299, 5909, 3273, 5835, 1244, 72, 142, 8985, 6961, 10114, 6660, 2835, 7055, 8959, 304, 7148, 8039, 8107, 6779, 10880, 5446, 11359, 3294, 3492, 3951, 4323, 11459, 1335, 2684, 401, 4347, 3257, 7755, 8990, 675, 5519, 1772, 6949, 2883, 6196, 766, 6238, 9846, 6534, 5990, 5996, 7425, 10446, 1111, 3598, 3735, 8110, 8114, 9873, 691, 759, 10902, 2380, 3324, 4415, 8249, 40, 2971, 4959, 9926, 8972, 2635, 4962, 11802, 8772, 3290, 5572, 6163, 8529, 3402, 9715, 10019, 27, 6430, 7172, 8216, 8794, 9657, 9771, 1161, 7243, 7520, 10771, 271, 1540, 4153, 4469, 5655, 8034, 8853, 11196, 3166, 5229, 5350, 8159, 9848, 11701, 73, 799, 3890, 5861, 6474, 6653, 480, 2966, 3706, 6388, 11217, 11231, 327, 896, 3479, 5393, 5778, 9725, 8397, 648, 840, 1954, 2538, 7158, 10300, 11604, 833, 2697, 4594, 7046, 8314, 10740, 11088, 2273, 2402, 2868, 4137, 6162, 7304, 8553, 10014, 11483, 2539, 5262, 6750, 10638, 11421, 135, 220, 1307, 3751, 4443, 6222, 6498, 6507, 7103, 7414, 8093, 8663, 9055, 11594, 282, 1289, 1767, 2568, 4198, 5041, 5143, 5859, 6579, 6602, 7069, 7356, 8807, 11587, 11636, 364, 426, 958, 2218. I arbitrarily decided to use 200 attributes for the further experiments. The 200th attribute was close to 0.05 probability of occurring in the solution.

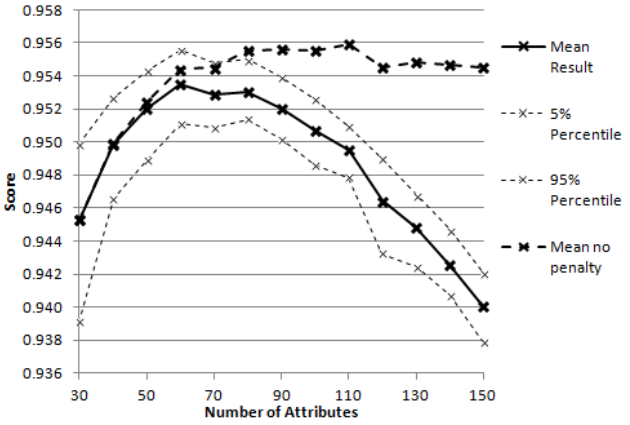

Fig. 2. Performance as a function of the number of attributes

As well, at this step I determined that the optimal number of parameters ranged between 60 and 80 (assuming single NB, not an ensemble). It should be noted that the definition of the chromosome and the simulation allowed the algorithm for adjusting the number of attributes in the solution, and therefore I did not need to be concerned about specifying the right number of the attributes in the solution.

In fact I run the experiments for which I used constant chromosome size, in order to ensure that the results I get are consistent with the fixed chromosome size experiments. Those experiments shed some light on the problem of the optimal number of attributes in the solution. The results are shown in Fig. 2. This analysis conformed that the optimal number of attributes should be approximately in range of 60 to 80 attributes if the penalty term is included.

VII. The Second Step – Finding Optimal Ensemble

In the second step, the task was to come up with a *good* solution for NB ensemble.

A. Chromosome Definition

For this step, the chromosome encoded the structure of the classifier ensemble, as stated in the competition requirements. The chromosome was defined as a vector of 10 lists of integers, where each list corresponded to one NB in the ensemble. The list was constrained to have at least three elements, with no upper limit on the number of elements.

B. Crossover

For both crossover and mutation, I treated each list of 10 chromosomes as individual chromosomes, applying crossover to i-th chromosome from the first individual with the i-th chromosome form the other individual. I indeed tried to crossover i-th chromosome from the first individual with j-th chromosome from the second individual, but performance of such algorithm was inferior to the one used, therefore I rejected the idea.

This time I used single point cross-over with the point randomly generated from the uniform distribution.

C. Mutation

The probability of mutation for a single NB classifier definition (repeated for each list in the vector) was set initially to be 0.05, and it was decreased at each generation with factor of 0.999. The mutation algorithm used one of three mutation operators applied with different probabilities:

- Add – adding a new element to the list (sampled from 200 attributes using uniform distribution), applied with probability 25%
- Remove – remove an attribute from the list (if there are more than 3 attributes in the list), applied with probability 25%
- Replace – replace an existing attribute with a randomly selected attribute (sampled from 200 attributes using uniform distribution), applied with probability 50%

D. Initial Population

Initial population consisted of 100 individuals. This time the chromosomes were randomly initialised using 200 attributes identified in the first step. The initial chromosome size was assumed to be 3 for all individual lists within a chromosome (hence started with 30 attributes in each solution).

E. Simulations

Each simulation included 5000 generations. For each generation I generated 25 new individuals (25%) and rejected 25 individuals with the lowest score. I run over 50 of simulations and collected the final best results for each of the simulation runs.

F. Results

The best solution identified at this step allowed me to achieve a score of 0.9512 at the competition leaderboard.

VIII. Step Three – Improving the Score

The final step was inspired by the idea of using evolutionary algorithms that alter the initial solution in order to improve it. But rather than using any specific approach, I decided to us the same GA framework I used previously, with the only difference that I decided to focus on the mutation operator as the search driving mechanism. The basic setup was the same as the algorithm in the second step, with some changes described below.

A. Chromosome Definition and Corssover

Chromosome definition and crossover operators were exactly the same as in the second step.

B. Mutation

The mutation operator was exactly the same as in the second step. The only difference was that the initial probability of mutation for each list element (individual NB in an ensemble) was increased to 0.15 to induce more mutations.

C. Initial Population

The key change was the initial population – this time I used seeding. I decided to use initial population that comprised of 50 copies of the same individual – the one that was achieving the highest score in the second step.

D. Simulations

Each simulation had 5000 generations, but in fact I used several simulations:

- I terminated the first simulation at around 500 generations, and I achieved the leaderboard score of 0.9522.
- I used the best result achieved so far as the seed for the initial population, and this time I allowed to run the complete 5000 generations. That allowed me to achieve the leaderboard result of 0.9561.
- Consequently, I used the best result so far to repeat the procedure. This time I decided to use several parallel runs with the same seeding. Most of the results were inferior to the initial (seeding) solution (0.9561) with most of leaderboard submissions ranging between 0.954 and 0.946. One outlier was the solution with the leaderboard result 0.9583 that I used at the final submission.

The solution that I used for the final submission was as follows:

- 11463, 11088, 8179, 6498, 2883, 460, 143, 6388, 2924
- 10880, 4415, 1880, 258, 2966, 5926, 6491
- 10446, 9771, 8249, 7980, 7187, 5270, 401, 5990, 8039, 8959, 8093, 3890
- 833, 72, 3751, 1266
- 8914, 7999, 6474, 5041, 4962, 10019, 947
- 10902, 5996, 2835, 748
- 8034, 7055, 6961, 5909, 1244, 27, 3324, 7172, 270
- 11701, 8110, 7356, 7187, 6222, 6162, 7158, 9873, 7560
- 11266, 10062, 220, 11231, 2971, 7521
- 11459, 7148, 7755, 3951, 2887, 766.

IX. Conclusion

In this paper I presented the description of the method used to optimise the set of variables used for classifiers based on ensembles of NB. I used the same GA framework, however in three different ways to address the challenge problem:

- First, I used GA to reduce the number of attributes in the problem in order to improve performance of the consequent simulations
- Then I used GA to find a set of optimal solutions to the competition problem,
- Finally, I used GA with focus on mutation to refine the solutions obtained from the previous step.

I would like to emphasise that I strongly believe that the winning solution I obtained can be improved. Similar applies to the algorithms used – they can be refined and improved in terms of convergence efficiency, chromosome encoding, etc.

Acknowledgment

I would like to thank my wife, Katarzyna Holownia, for encouragement and support during the competition.

***Abstract*—Feature selection is important phase in machine learning and in the case of multi-label classification, it can be considerably challenging. In like manner, finding the best subset of good features is involved and difficult when the dataset has significantly large number of features (more than a thousand). In this paper we address the problem of feature selection for multi-label classification with large number of features. The proposed method is a hybrid of two phases - preliminary feature selection based on the information value and additional correlation-based selection. We show how with the first phase we can do preliminary selection of features from tens of thousands to couple of hundred, and then with the second phase we can make fine-grained feature selection with more sophisticated but computationally intensive methods. Finally, we analyze the ways of allocating the selected features to diverse subsets, which are suitable for training of ensembles of classifiers.**

I. Introduction

MACHINE LEARNING provide means to automatically analyze enormous quantities of data and consequently to: derive various conclusions, make predictions for unseen data, find patterns within the data etc. As learning relies on the available data, its preprocessing is very important to such extent that most of the time of the project might be spent for this phase. During data processing various issues of the data can be addressed: feature modeling and construction [1] [2], outliers removal [3], noise detection and reduction [4], missing values imputation [5] [6], data normalization [7] [8], and data transformation [9] [10].

Many learning algorithms such as neural networks [11], Naive Bayes [12] [13], decision trees [14] notably experience degrading performance when the datasets contain redundant or irrelevant features. This phenomenon is confirmed with theoretical and empirical evidence in plenty of research papers, some of which are [15] [16] and [17]. The problem of feature selection [18] [16] [19] can be defined as the task of selection of subset features that describe the hypothesis at least as well as the original set. The representation of data instances is optimized with feature selection, which in turn can lead to:

- Improving the performance of learning algorithms.
- Reducing the training and execution times of algorithms.
- Improving the memory requirements and allow application of more algorithms.
- Improved robustness to over-fitting.
- Better understanding and visualization of the data.

Different methods for feature selection focus on various aspects of the above goals, or achieve the same goals but in different ways. In [20] are given guidelines for feature selection and are introduced the most widely used methods. It is important to note that finding the most useful and relevant features is not always the same task, as it is shown in [16] and [21].

II. Related work

There are two approaches for feature selection: filter and wrapper approach. The filtering approaches rank the features based on some metric. These methods are generally characterized by simplicity, scalability and solid empirical background. Because they rely on relatively simple metrics, they are memory and computationally efficient and can be applied on datasets with tens or even hundreds of thousands of features. Such application of these methods, as well as their empirical analysis, is further elaborated in [22], [23] and [24]. Filter methods are independent of the machine learning algorithm that is going to be applied later on.

Filter approaches for feature selection can further be categorized into two groups. The first group consists of methods that rank the features based on some measure of their individual predictive power: information value [25] [26] [27], information gain [28] [29], information gain ratio [28] [29], RELIEF [30] [31], entropy [32] etc. In [33] and [34] are described some filtering methods based on posterior probability. The common problem of all methods in this group is that they take into consideration only the individual usefulness of attributes in relation to the target classification and can not discover

This work was partially financed by the Faculty of Computer Science and Engineering at the Ss.Cyril and Methodius University, Skopje, Macedonia

redundancy, multicollinearity or interdependence between the chosen features.

The second type of filter approaches consists of methods which analyze the subset of features based on some metric that describes the performance of the whole subset and not only the individual features [1]. Namely, the correlation-based approaches described in [35] and [36] fall into this type of methods. Important to realize is that they search for subsets of features that have low inter-correlation between them and high correlation to the target classification [37]. Likewise, [38] proposes an approach for detecting stable clusters of features based on principal component analysis.

The wrapper approaches search for subsets of features that are useful for the classification or regression task at hand. They are based on evaluating the performance of different subsets of features using a machine learning algorithm [21] [17] [39]. When applying these methods the individual contribution of features is not being evaluated. In contrast, the contribution of the subset of features is taken into consideration and the whole process is black-box like. In other words, the method does not give exact information why that specific subset of features was selected. In order to apply a particular wrapper method, one has to define: how will be the space of all possible feature subsets traversed; how will be the performance of the learning algorithm evaluated in order to guide the search; and which learning algorithm to be used. If the number of features is small, then all combination of features can be evaluated, but this is rarely the case. The main problem of these methods is their computational complexity. Be that as it may, there are a lot of search techniques that mitigate this problem [19]. On the other hand, the main advantages of these methods is their universality and independence of the domain of the data and task. The research community has proposed various ways of making hybrid methods that combine filter and wrapper and [40] reviews them.

Our research presented in this paper focuses on feature selection in areas of application where datasets have tens or hundreds of thousands of variables. These areas include text processing, gene expression array analysis, and combinatorial chemistry. This paper is organized as follows: Section III describes the problem at hand and section IV gives overview to the proposed solution. In subsections IV-A and IV-B we describe the proposed hybrid approach for feature selection. Subsection IV-C presents various schemes for constructing diverse subsets of features that are suitable for ensembles of classifiers. In Section V we summarize our work.

III. Problem definition

This paper originated from our research during and after the AAIA'14 Data Mining Competition "Key risk factors for Polish State Fire Service". This competition is organized within the framework of the 9th International Symposium on Advances in Artificial Intelligence and Applications [41], and is an integral part of the 1st Complex Events and Information Modeling workshop devoted to the fire protection engineering. The task is related to the problem of extracting useful knowledge from incident reports obtained from The State Fire Service of Poland. With this in mind, our research goals were mainly guided within the task goals and requirements. Under those circumstances, during the following sections we will occasionally relate to some specifics for this task. Nevertheless, the proposed methods are not specific for this task and they can be applied to a variety of problems.

The organizers obtained a data set containing nearly 260000 reports describing the actions carried out by the Polish State Fire Service within the city of Warsaw and its surroundings in years 1992 - 2011. Each report consists of two parts. The first one contains a summary of resources utilized during the action in a form of structured and quantified characteristics. The second part contains a natural language description of the reported events, which is entered by the officer coordinating the action. They have preprocessed a subset of the reports and transformed it into a table in which each of the reports is described by almost 12000 attributes. The training dataset contains about 50000 instances. Additionally, they have distinguished 3 target attributes that correspond to information whether in the described incident there were casualties among firefighters, children or other involved people, respectively. The goal of the competition is participants to come up with solutions which will improve the understanding of the risk factors associated various types of accidents. Given these points, it seems that the problem is actually multi-label classification. As a matter of fact, after careful review of the training data we have observed that some instances (i.e. reports) are indeed classified to the positive classes in more than 1 of the decision attributes. The organizers have modeled the decision attributes in a way that actually transforms the multi-label problem into 3 binary classification problems. Such approach for tackling multi-label problems is, in essence, problem transformation method and is described in [42].

The task in this competition was to identify attributes that can be used to robustly assign the reports to the corresponding decisions labels. In particular, organizers decided to use ensemble of 10 Naive Bayes classifiers for each of the target classifications. Having 3 decision attributes, means that the selected features should be divided into 10 subsets and each subset should be used to train 3 individual Naive Bayes models. Every model assigns scores (i.e. probabilities) to test cases representing if that the case should be classified to the positive decision class or not. In this way, for every decision attribute and every test case there are 10 scores. The ensemble of predictions is constructed by taking the sum of the scores of the individual models.

The metric used to evaluate the performance of the selected attributes was the average AUC of the prediction ensemble for different decision attributes, decreased by a penalty for using a large number of attributes. We assume that the choice of metric is because the data is highly imbalanced and many papers confirm that this metric is best suitable for such cases [43] [44] [45].

Namely, if we denote by: s - submitted solution; $|s|$ a total number of attributes used in the solution (with repetitions); and

$AUC_i(s)$ Area Under the ROC Curve (AUC) of a classifier ensemble for the i-th decision attribute, then the quality measure used for the assessment of submissions can be expressed as:

$$score(s) = F\left(\frac{1}{3}\sum_{i=1}^{3} AUC_i(s) - penalty(s)\right)$$

where the penalty is equal to:

$$penalty(s) = \left(\frac{|s| - 30}{1000}\right)^2$$

and the function F:

$$F(x) = \begin{cases} x, \text{ for } x > 0 \\ 0, \text{ othewise} \end{cases}$$

From all the given task description and stated requirements the following challenges should be acknowledged:

- Evaluation of the usefulness of features in relation to the 3 target classifications.
- Selecting a small subset of features that will be contributing to all 3 target classifications.
- Optimal arrangement of the selected features in N subsets (N=10 in this case) in order to train ensemble of classifiers.

In order to overcome those challenges we propose a hybrid method which is described in the following section.

IV. Proposed method

Selecting the best subsets of features for this dataset is a challenging task because most of the feature selection algorithms cannot be applied due to the large number of features. Additionally some of the methods for feature selection are applicable only on binary classification problems. With this in mind and given that the task at hand has 3 decision attributes, the selection of features that are contributing to the 3 classification tasks at the same time gets even more difficult.

We propose a hybrid approach for feature selection consisting of three phases. The *first phase* performs preliminary feature selection in order to discard the features that are unlikely to contribute to any of the decision classes. The *second phase* applies more sophisticated feature selection algorithms on the dataset that after the first phase has significantly smaller number of features. As a result from the second phase the set of selected features is very concise and all of them contribute to the 3 classification tasks. If the goal was to create 1 model for each of the classification tasks, then we would use the selected features and we use some learning algorithm to build the models. In such case the feature selection would end here. Be that as it may, the contest rules described in III state that the goal is to train an ensemble of Naive Bayes classifiers. Having this in mind, we need a *third phase* that would optimally arrange the chosen features into subsets that will be later used by each individual classifier. We realize that it was not specifically forbidden to use one feature in more than 1 subset. Although this may be allowed, we believe that such approach is problem-specific and would require a significant effort for fine tuning, to the extent that the scientific contribution of the approach would diminish. For this reason we have decided to use diverse subsets of features for each individual classifier. In other words, each selected feature belongs to only 1 subset. The following subsections describe each of the phases in our approach.

A. Preliminary feature selection

The large number of feature in the original dataset presents a difficult task for most methods. The reason for this is because of the memory and/or computational complexity it imposes. The goal of this task is to overcome that problem by reducing the features to a significantly smaller number using some simple algorithm. Being able to do this clears the way for more sophisticated feature selection methods. As it was explained in section I, the prime candidates for a fast preliminary (i.e. coarse-grained) feature selection are the filter methods that assess that individual contribution of features. The following metrics can be used for feature selection are less demanding in terms of memory and computational power: information gain, information gain ratio [28] [29] and information value [25] [26] [27]. In spite of the slight differences between them in terms of computational complexity time, all of them can be computed in linear time ($O(mn)$) with 1 pass of the training dataset. We were not able to obtain results with the RELIEF method [30] [31] in reasonable time due to its higher complexity - $O(mnp)$. Here where m is number of training instances, n is the number of attributes and p is the number of randomly selected instances used for the RELIEF algorithm. We acknowledge that with proper tuning of the p parameter we might have been able to obtain results with it too, but since this phase performs only preliminary selection we believe that this is not worth the effort.

We have decided to use the information value for estimation of the predictive power of each of the features in relation to each of the decision attributes. It is widely adopted in industry especially for credit scoring problems [25] [26] [27]. The reason for this is because there are some widely adopted rules of thumb in terms that give simple guidelines of whether the feature is strong or weak predictor based on the information value. However, note that weak features may provide value in combination with others; or have individual values that could provide predictive power as dummy variables. As it has been suggested in [46], the following guidelines for evaluating the strength a predictor based on the information value can be used:

- Less than 0.02: unpredictive
- 0.02 to 0.1: weak
- 0.1 to 0.3: medium
- Greater than 0.3: strong

Although they are firmly grounded in good practice, how these guidelines be related to other metrics is discussed in [47]. At the same time, there are some drawbacks of this metric related to the some border cases that prevent using its original

definition (2). In [10] are proposed some enhancements of the weight of evidence (WoE) parameter, which in turn overcome the computational obstacles for the information value. With (1) is defined WoE, and it is further used for calculation of the information value (2). Here N_i^j and P_i^j represents the number of negative and positive instances labeled with the i-th value of the j-th feature, respectively. Also SN and SP denote the total number of negative instances and the total number of positive instances in the training dataset, respectively.

$$WoE_i^j = ln\left(\frac{N_i^j}{P_i^j}\right) - ln\left(\frac{SN}{SP}\right) \quad (1)$$

$$IV^j = \sum_{i=1}^{n}\left[\left(\frac{N_i^j}{SN} - ln\frac{P_i^j}{SP}\right) \times WoE_i^j\right] \quad (2)$$

From (2) it is obvious that the information value is applicable only to binary classification problems. When having multi-label classification with k possible positive labels, one needs to compute k information values for each of the features. For this specific task, having 3 decision attributes and almost 12000 features, means that we had to compute nearly 36000 information values. The computation for all of them takes less than 15 minutes on a regular laptop. As it turns out, some of the features are strong or medium predictors for one decision attribute, but are very weak predictors for the other one or two target attributes. The next challenge was how to aggregate the 3 information values of each feature into 1 value, so we can use it for feature selection. The following subsections describe the results of each aggregation type.

1) Average information value: When having multi-label classification with k positive classes we can average the k information values of each feature to get estimate of the its information value in relation to all positive classes. For this case in particular, we have tried averaging the 3 information values of each feature in order to use it for feature selection. We have examined various subsets containing 50 to 120 of the best features based on their average information value. By training ensembles of Naive Bayes classifiers as described in III we have obtained AUC performance on the leader-board dataset varying from 0.886 to 0.9, based on the number of features and the scheme of arrangement of them into diverse subsets. As a reference, the best results of the same test dataset were up to 0.94. The experiments showed that the performance of the ensembles build on the these selected features were fairly stable. However, they were worse than what we hoped to be achieved with more sophisticated methods. Nevertheless, it was notable that the average information value can be safely used for preliminary feature selection.

2) Maximum information value: The next obvious idea for aggregating the individual information values of a feature is to calculate their maximum. When we applied this logic on the current dataset and we selected the best different subsets containing 50 to 120 features based on their maximum information value, the performance of the ensembles was worse than with the approach in IV-A2. In fact, the AUC performance on the leader-board dataset was less than 0.8, regardless of the arrangement of the features in subsets. By looking into the selected features and their maximum information values we can explain this phenomenon. As it can be observed on Fig. 1, some features might have high information value for one of the decision attributes, but low for the other decision attributes. This in turn, translates to high maximum but low average information value.

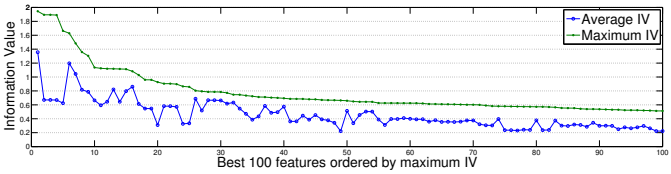

Fig. 1. Maximum vs. average information value of best 100 features

To conclude, this aggregation might be bad-performing for final feature selection, but one should not rush to avoid it. In fact, this aggregation may identify features for training models for each of the decision attributes separately and may also identify features that in combination with others might be very useful. The maximum information value is very useful for discarding features because it guarantees that the discarded ones are bad or week predictors for all decision attributes (positive labels).

3) Weighted average information value: Another approach for aggregating the individual information values of a feature is to calculate their weighted arithmetic average. The weight can be calculated based on the number of positive instances in the training dataset for each decision attribute (i.e. label). This idea has been applied for weighting averages of other statistics [48] [49]. However, for final feature selection wighted average type of aggregation does not seem to be suited, mostly because the most common positive label is always preferred. On the leader-board dataset the AUC of different subsets varying from 50 to 120 features was about 0.86. Maybe with a different weighting scheme, the performance would be improved. However, as this phase should not select final subset of features, we did not investigate other weighting schemes.

4) Dependent features: It has been extensively proved that features with high correlation have negative impact on performance for many machine-learning algorithms, among which is the Naive Bayes classifier. Some such papers are mentioned in section I. In order to address this issue, we have calculated the correlation coefficients and p values [50] between all features and used this information to find dependent features. By discarding a feature if we have already selected a dependent feature with higher aggregate information value, we were able to slightly improve the performance of the maximum and weighted average aggregations. In those cases, the performance was similar to the average aggregation. Despite that, the obtained results were not satisfactory for final feature selection.

5) Coarse-grained selection of features: We have applied the three aggregation methods for the information values and

then we selected sets of the best N features (where N is 400, 500, 600, 800, 1000, and 1500). By analyzing the sets obtained for different values for N we have concluded that for the same value of N but different aggregation methods most of the features (i.e. 70-90 %) are overlapping. That indicated the aggregation type will not have significant impact on the coarse-grained selection of features, except for their ranking. In order to decide how many features to select during this phase we have analyzed the max-aggregated information values and have noticed that after the best 500 features the maximum information value drops bellow 0.1, meaning that the discarded features are week predictors for all decision labels. The maximum information value is very useful for discarding features because it guarantees that the discarded ones are bad or week predictors for all decision attributes (positive labels).

Finally, as a result from this phase we have selected the best 500 features based on the maximum information value and we continued with the next phase to apply more sophisticated feature selection algorithms on the significantly simplified training dataset.

B. Fine-grained feature selection

After phase 1, the training dataset is significantly simplified. More specifically for the current dataset, we have 50000 instances and 500 features. It is significantly reduced than the original, so more intelligent feature selections algorithms can now be applied.

The number of features in a dataset should indicate whether it is possible to use wrapper methods for fine-grained feature selection. The experiments performed in [51] show that wrapper methods can be applied to relatively smaller datasets (containing less than 200 features and few thousand instances). In spite of the continued improvement in processing power during the recent years, trying out many combination of features especially with more complex learning algorithms is a very hard task. In this case, the reduced size of dataset is still quite large in order to be able to apply a wrapper method for feature selection on it. This fact limited the use of wrapper method to very simple internal learning algorithms. Again, having too many combinations of feature subsets still makes wrapper methods not adequate for this task.

One of the best performing methods for evaluation of subsets of features is the correlation-based feature subset selection [35]. It evaluates the worth of a subset of attributes by considering the individual predictive ability of each feature along with the degree of redundancy between them. Subsets of features that are highly correlated with the class while having low inter-correlation are preferred.

If we were to apply this method on the 3 decision attributes separately, we would still need to aggregate the 3 selected subsets of features. As it was shown in subsection IV-A, this task can be very involved. Instead of doing that, we have decided to transform the problem space. The original task is multi-label classification which was transformed by the organizers to 3 separate binary classification problems. In cases like this, we propose to merge the separate binary classification problems into 1 multi-class problem. To summarize, starting with a multi-label problem transformed as several separate binary problems we merge it to a multi-class problem. By doing this we can apply feature selection methods that select the best features in relation to all positive classes. More particularly, with the proposed transformation we obtained 8-class classification problem by using the following Eq. (3) to map each instance to a new artificial class. Here, AL_i denotes the artificial label of the multi-class problem instance i, where as L_i^1,L_i^2 and L_i^3 are the classes in the binary classifications of the same instance.

$$AL_i = 1 \times L_i^1 + 2 \times L_i^2 + 4 \times L_i^3 \tag{3}$$

In general, multi-label classification tasks where the number of positive labels is N, can be transformed to N binary classification problems [42]. Let the label of the i-th instance in the $j-th$ binary problem is L_i^j, where for L_i^j is 0 for negative instances and 1 for positive instances. With this transformation to multi-class problem the same instance will be labeled with AL_i as defined in Eq. (4):

$$AL_i = \sum_{j=1}^{N} 2^{j-1} \times L_i^j \tag{4}$$

After performing this transformation, the correlation-based feature subset selection can be applied. Depending on how many features are in the training dataset and how they are chosen (i.e. which aggregation was used), this method selects from 40 to 70 features. Considering the obtained attributes we have observed that one particular subset of 53 features was very common, henceforth the next phase was performed using that subset (shown on Table I).

C. Allocation of features into diverse subsets

After end of phase 2 we have a very concise dataset which, in this case, is described with 53 features. The correlation-based method for feature selection [35] does not rank the features, but we can rank them computed based on the information value calculated during phase 1. They can be ranked based on their maximum or average information value.

The goal of this phase is to optimally allocate the selected features into diverse subsets. For this task the number of subsets is set at 10, but in general, one can try various number of individual classifiers for the ensemble. Each subset should contain approximately equal number of features. The following subsections describe the schemes for allocation of features into subsets. Before we continue, let us define an *iteration* as allocating 1 feature to each subset (e.g. in this case choosing 10 features, 1 for each subset). The different schemes explained bellow, have different logic of choosing the next feature to allocate to a subset. If we consider the subsets as items that are ordered, we can decide which of them will get processed first. By being processed we mean allocating a feature to it. Likewise, the features are ordered by their maximum information value.

1) FIFO scheme: The First-In-First-Out (i.e. First-Come-First-Served) term has been widely used in data structures literature and queue theory. During 1 iteration the FIFO scheme would allocate the next best feature to the next subset. The following iteration will allocate features starting from the first subset and so on until there are no more features. Obviously, this scheme mostly favors the first subset and least favors the last. Using the leader-board dataset, we have obtained AUC of 0.9292. To summarize, this approach uses the maximum information values for ranking the features. When we used the average information value for ranking, the performance was slightly worse. The simple explanation for this is because the average information value is more consistent than the maximum, hence the FIFO scheme favors the first subsets more.

2) FIFO-independence scheme: In order to improve the FIFO scheme, we can dependent features in order to optimally allocate the features into subsets. The idea is to have independent features within 1 subset. The algorithm used during phase 2 is correlation based which ensures that the selected features have very low inter-correlation among them. However, if we use a more strict test for independence (p value = 0.01), then we can still find some pairs of dependent features. This improved FIFO scheme selects the next best feature that is independent to all features that are already in the subset. As it turns out, when using the leader-board dataset, this scheme slightly improved the performance to AUC of 0.9293.

3) Interchanging FIFO-FILO scheme: With this scheme in each iteration we change the logic from FIFO to FILO and vice versa. So, when assigning the first attribute to the first subset we choose the best feature, then for the second subset we choose the next best feature and so on, until the last subset has 1 feature. Then when assigning a second feature to all subsets, we start with the last subset and assign the best available feature to it. In like manner, we continue assigning the next best feature until the first subset has 2 features. In the next iteration the first subset will have priority, and so on until we run out of features. With this scheme the AUC ROC performance on the leader-board dataset was 0.9298, which was an additional improvement.

4) Monte Carlo scheme: This scheme randomly scatters the features to subsets. It is the simplest scheme and produced results ranging from 0.926 to 0.9321. We have analyzed the final distributions to subsets that produced better and the ones that produced worse results. When looking at the information values for all three target attributes of the features in each subset it was notable that the better performing arrangements of subsets had features that are medium or strong predictors in relation to 1 or 2 target attributes and weak predictors for the other target attribute.

We have concluded that this scheme might produce very good results, but in order to be consistent it needs to be improved. One way of doing this is to use this scheme as a starting point and later to make rearrangements by swapping some features between the subsets. Choosing which features to swap is based on the following logic:

- We first find a bad performing subset of features and determine which target attribute has least weak features in relation to it.
- Then find a subset where a lot of features are medium or strong predictors for the same target attribute.
- Swap the features from the 2 subsets.
- Repeat the process until no swaps can be made.

This algorithm generally helps both subsets. The first subset will get a stronger feature for the class that has bad performance. The second subset is also improved because the possibility of over-fitting because of too many strong predictors for it for particular target attribute is reduced. Using this technique we have finally arrived at the feature arrangement shown on Table I on the following page.

V. Conclusion

In this paper we have proposed a three-phase hybrid feature selection method that is able to extract features from datasets with thousands of features. This method is especially useful for datasets that originate from text processing areas of application. Additionally we have analyzed the different ways to aggregate information values of one feature in the case of multi-label classification. As a consequence we have pointed out the advantages and shortcomings of the aggregation types. Also we have proposed and analyzed different schemes of allocation of the selected features to diverse subsets that are suitable for training ensembles of classifiers. Equally important was the proposed method of transforming multi-label classification problems into multi-class in order to be able to apply some feature selection algorithms. We have tested the proposed methods on the AAIA'14 data mining competition dataset [41] and our solution has been recognized as one of the top 5.

7th Workshop on Computational Optimization

Many real world problems arising in engineering, economics, medicine and other domains can be formulated as optimization tasks. These problems are frequently characterized by non-convex, non-differentiable, discontinuous, noisy or dynamic objective functions and constraints which ask for adequate computational methods.

The aim of this workshop is to stimulate the communication between researchers working on different fields of optimization and practitioners who need reliable and efficient computational optimization methods.

We invite original contributions related to both theoretical and practical aspects of optimization methods.

Topics

The list of topics includes, but is not limited to:

- unconstrained and constrained optimization
- combinatorial optimization
- global optimization
- multiobjective optimization
- optimization in dynamic and/or noisy environments
- large scale optimization
- parallel and distributed approaches in optimization
- random search algorithms, simulated annealing, tabu search and other derivative free optimization methods
- nature inspired optimization methods (evolutionary algorithms, ant colony optimization, particle swarm optimization, immune artificial systems etc)
- hybrid optimization algorithms involving natural computing techniques and other global and local optimization methods
- optimization methods for learning processes and data mining
- computational optimization methods in statistics, econometrics, finance, physics, medicine, biology, engineering etc

A Look-Forward Heuristic for Packing Spheres into a Three-Dimensional Bin

Hakim Akeb
ISC Paris Business School
22 boulevard du Fort de Vaux
75017 Paris, France
Email: hakeb@iscparis.com

***Abstract*—In this paper a look-forward heuristic is proposed in order to solve the problem of packing spheres into a three-dimensional bin of fixed height and depth but variable length. The objective is to pack all the spheres into the bin of minimum length. This problem is also known under the name of three-dimensional strip packing problem. The computational investigation, conducted on a set of benchmark instances taken from the literature, shows that the method is effective since it improves most of the best known results.**

I. Introduction

PACKING spheres can be used to model many solid state systems. Indeed, the association of different-sized spheres for example can approximate a given solid form. Packing (non-)identical spheres is for example used in the domain of stereotactic radio surgery radiation therapy (see for example the works of Gavriliouk [3], Sutou and Dai [13], and Wang [15]) where the target areas are delimited by spheres of different sizes.

The problem of packing spheres into a container was studied by several authors in the literature. The spheres can be of identical or different sizes (radii). The problem of packing non-identical spheres into a given 3D container was for example considered by Li and Ji [8] where a dynamics-based collective method for random sphere packing was proposed as well as an application to the problem of packing spheres into a cylinder container. The authors studied also the stability of the method and the convergence of their algorithm. Sutou and Dai [13] used a global optimization approach (including Linear Programming relaxation and branch-and-bound) in order to place unequal spheres inside a three-dimensional container. More precisely, the objective is to maximize the volume of the container (of fixed size) occupied by the placed spheres. This is also called the *Knapsack* version of the problem, i.e., the objective is not to place all the objects but those maximizing the obtained profit. The profit used often corresponds to the volume of the corresponding object placed. Stoyan, Yaskov, and Scheithauer [12] developed a mathematical model in order to place different-sized spheres inside a parallelepiped of fixed length and width but with variable height. The objective is then to minimize the height of the container. The proposed method uses different tools including extreme points and neighborhood search. Solutions are given for a set containing eight instances (designed by the authors) where the number of spheres varies from 20 to 60.

For the case of identical spheres, M'Hallah, Alkandari, and Mladenović [9] for example studied the problem of packing spheres of the same radius into the smallest containing sphere by using Variable Neighborhood Search (VNS) and Non-Linear Programming (NLP). VNS here consists to move some spheres situated in the neighborhood of a given placed sphere, then a NLP procedure is called in order to remove overlapping between spheres. M'Hallah and Alkandari [10] applied the same principle (VNS and NLP) as in [9] to solve the problem of packing unit spheres into the smallest cube. Soontrapa and Chen [11] considered the problem of packing identical spheres into a cube by using a random search technique based on the Monte Carlo method. The problem concerns actually the development of a fuel catalyst layer.

Finally Birgin and Sobral [2] studied the problem of packing identical and non-identical spheres into different three-dimensional containers. The objective is to minimize the dimension of the container. The method proposed by the authors is based on twice-differentiable models as well as non-linear programming.

The problem to solve in this paper is the Three-Dimensional Strip Packing Problem (3DSPP) which is known to be NP-Hard [6]. Given a set S containing n spheres $s_i, 1 \leq i \leq n$ where each sphere has radius r_i and is placed with its center at coordinates (x_i, y_i, z_i) in the Euclidean space. Let also $\mathbb{B}$ be a three-dimensional bin (rectangular cuboid or parallelepiped) of fixed height and depth (H, D) respectively but of unconstrained length L. The objective is then to place the n spheres inside the parallelepiped of minimum length such that no sphere overlaps another sphere and no sphere exceeds the container boundaries. The method presented is based on the use of several tools including the *Maximum Hole Degree* (MHD) heuristic, a modified look-forward strategy, and an interval search.

II. Problem formulation

The three-dimensional bin $\mathbb{B}$ has six faces $\mathbb{F} = \{\text{left}, \text{top}, \text{right}, \text{bottom}, \text{back}, \text{front}\}$ and is placed such that its bottom-left-back corner corresponds to the origin $O(0,0,0)$ of the axes in the Euclidean space as shown in Fig. 1. The length L, the height H, and the depth D of the container are associated with the $\overrightarrow{Ox}$, $\overrightarrow{Oy}$, and $\overrightarrow{Oz}$ axes respectively. Moreover, each

978-83-60810-58-3/$25.00

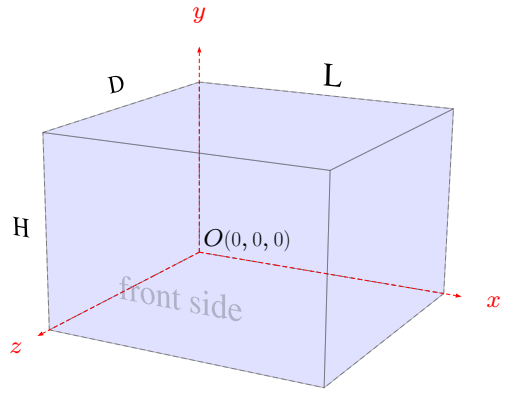

Fig. 1. The three-dimensional bin container placed with its bottom-left-back corner at the origin of the axes in the Euclidean space.

sphere $s_i \in S$ has radius r_i and its center's coordinates are (x_i, y_i, z_i). The 3DSPP can then be formulated as follows:

$$\min L \tag{1}$$

$$(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2 \geq (r_i + r_j)^2 \quad \text{for } 1 \leq i < j \leq n \tag{2}$$

$$x_i \geq r_i \qquad \forall i \in [1, \ldots, n] \tag{3}$$

$$x_i \leq L - r_i \qquad \forall i \in [1, \ldots, n] \tag{4}$$

$$y_i \geq r_i \qquad \forall i \in [1, \ldots, n] \tag{5}$$

$$y_i \leq H - r_i \qquad \forall i \in [1, \ldots, n] \tag{6}$$

$$z_i \geq r_i \qquad \forall i \in [1, \ldots, n] \tag{7}$$

$$z_i \leq D - r_i \qquad \forall i \in [1, \ldots, n] \tag{8}$$

Equation 1 indicates the objective (value) to minimize (the length L of the bin). Equation 2 is the non-overlapping constraint that verifies that any pair of distinct spheres $(s_i, s_j) \in S^2$ do not overlap each other. Equations 3–8 mean that each sphere must not exceed the boundaries of the container.

The distance between the edges of two distinct spheres s_i and s_j, denoted by $d_{i,j}$, is defined as follows:

$$d_{i,j} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2} - r_i - r_j \quad \text{for } i \neq j \tag{9}$$

III. The 3DMHD heuristic for packing spheres into a three-dimensional bin

In this section, a greedy heuristic, denoted by 3DMHD (Three-Dimensional Maximum Hole Degree), for packing spheres into a three-dimensional bin is described. This is in fact the adaptation of the Maximum Hole Degree (MHD) heuristic [4], designed for packing circles, to the three-dimensional case.

Note that a simple way to pack the spheres inside the container consists for example to place the first sphere s_1 at the bottom-left-back corner, i.e., at coordinates (r_1, r_1, r_1). After that, at each step $i, (1 < i \leq n)$ a new sphere is chosen and is placed at the *best* position (that has the maximum hole degree). More precisely, let:

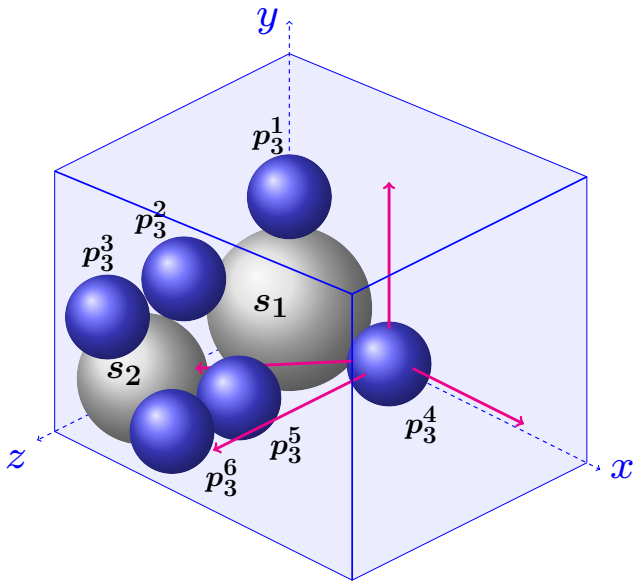

Fig. 2. The 3DMHD heuristic for packing spheres into a three-dimensional bin.

- S_{in} define the set of spheres already placed inside the container.
- S_{out} is the complementary set containing the spheres that are not yet placed (outside). Note that $S_{\text{in}} \cup S_{\text{out}} = S$.
- P denotes the set of possible positions (called *corner positions*) for the spheres of set S_{out}.

Fig. 2 shows an example where two spheres s_1 and s_2 (the two greatest ones) are already placed inside the container $\mathbb{B}$, i.e., $S_{\text{in}} = \{s_1, s_2\}$. The figure also indicates six possible corner positions for packing another sphere s_3. These positions are denoted by $\{p_3^1, \ldots, p_3^6\}$. Each position p_3^k is computed by using three objects, an object may be a sphere already placed or one of the six faces of the parallelepiped. These three objects denote set $\mathscr{T}(p_3^k)$ associated to this position. For example, position p_3^1 is computed by using sphere s_1, the left-edge and the back-face of the container, then $\mathscr{T}(p_3^1) = \{s_1, \text{left}, \text{back}\}$. Similarly, $\mathscr{T}(p_3^2) = \{s_1, s_2, \text{left}\}$.

Generally, let position $p_{i+1}^k \in P$, associated to a sphere of radius r_{i+1}^k, be one of the possible corner positions for the next sphere s_{i+1} to place. Then, the 3DMHD value for position p_{i+1}^k is defined as follows:

$$\lambda(p_{i+1}^k) = \max_{j \in S_{\text{in}} \cup \mathbb{F} \setminus \mathscr{T}(p_{i+1}^k)} 1 - \frac{d_{i+1,j}^k}{r_{i+1}^k} \tag{10}$$

Equation 10 means that the hole degree $\lambda(p_{i+1}^k)$ is computed for each position in the set of positions P (associated with set S_{out}) for the next sphere to place. This value uses the distance $d_{i+1,j}^k$ between the edge of position p_{i+1}^k and the nearest object j in the set $S_{\text{in}} \cup \mathbb{F} \setminus \mathscr{T}(p_{i+1}^k)$ that contains the spheres already placed, the six faces $(\mathbb{F})$ of the container but

Algorithm 1 The 3DMHD greedy heuristic

Require: Set S_{in} containing spheres already placed, S_{out} containing the remaining spheres to place, set P indicating the possible positions for spheres in S_{out} and the current length L of the container.

Ensure: TRUE if all the spheres are packed into the container, FALSE otherwise.

1: $i \leftarrow |S_{\text{in}}|$;
2: **while** $(P \neq \emptyset)$ **do**
3: Compute/update the 3DMHD value for each corner position $p \in P$;
4: Place the next sphere s_{i+1} at position p^* that has the maximum hole degree as shown in equation 11.
5: Move sphere s_{i+1} from S_{out} to S_{in};
6: Remove from set P the positions that overlap the new inserted sphere;
7: Compute new positions by using the new inserted sphere and the other objects already placed;
8: $i \leftarrow i+1$;
9: **end while**
10: **if** $(i = n)$ **then**
11: Set $L \leftarrow \max(x_i + r_i)$;
12: Update the best known length if L is smaller than this value;
13: **return** TRUE;
14: **else**
15: **return** FALSE;
16: **end if**

excluding set $\mathscr{T}(p^k_{i+1})$. The distance is divided by the radius r^k_{i+1} of the sphere corresponding to position p^k_{i+1}. Note that if a given position touches more than three objects, then $\lambda = 1$, meaning that this positions has a high probability to be chosen for placing the next sphere.

For example, Fig. 2 indicates the distance between position p^4_3 and four other objects: sphere s_2, the front face, the top face, and finally the right face of the container.

Then, the 3DMHD heuristic places the next sphere at position $p^* \in P$ that corresponds to the maximum value of $\lambda(p^k_{i+1})$ as indicated in equation 11.

$$p^* = \arg\max_{p^k_{i+1}} \lambda(p^k_{i+1}) \tag{11}$$

Algorithm 1 explains how the 3DMHD heuristic proceeds in order to place a set of spheres inside the container $\mathbb{B}$ of dimensions $(L \times H \times D)$. Procedure 3DMHD receives a partial solution $\{S_{\text{in}}, S_{\text{out}}, P\}$ indicating the spheres already packed into the container, the remaining spheres, and the set of corner positions for spheres in S_{out} respectively. The current length L of the container is also transmitted to the procedure. The heuristic's output is a boolean value indicating whether yes or no all the spheres were successfully packed into the container. So procedure 3DMHD is able to start with any partial solution were the number of spheres already packed is greater than or equal to zero.

At line 1 in algorithm 1 counter i indicating the number of spheres already packed is set to the number of spheres inside S_{in}. After that, in the **while** loop, the 3DMHD value is computed for each position $p \in P$ (line 3), this is done by using the formula of equation 10. At line 4, the best position p^* is chosen in order to place the next sphere s_{i+1}. After that, the new sphere moves from set S_{out} to set S_{in} (line 5) and the set of positions P is updated by removing those overlapping the new inserted sphere (line 6) and by computing new positions by using the new inserted sphere (line 7). Counter i is then incremented at line 8. The **while** loop ends when the set of positions P becomes empty meaning that no additional sphere can be packed. Then two cases can be distinguished: if $i = n$ then all the n spheres were successfully packed into the container. In this case the procedure computes at line 11 the exact value for L which is equal to $\max(x_i + r_i)$, i.e, using the most right placed sphere $s_i \in S_{\text{in}}$. If the obtained value L is smaller than the best known length then this value is updated (line 12) and the procedure returns TRUE (line 13). If $i < n$ then a feasible packing was not obtained and the procedure returns FALSE (line 15), this means that the current length L of the container has to be changed.

Note that one can test several values for the length L of the bin in order to try to compute a feasible solution with the 3DMHD heuristic (not necessarily a binary search but other more efficient strategies). This can be done for example by decreasing the length from an upper bound to a lower bound. Indeed, this strategy may escape from local optima (see Section IV below).

A. A Multi-Level Look-Forward strategy for the 3DSPP

This section describes a look-forward algorithm designed for the three-dimensional strip packing problem.

Look-forward (LF) strategies (see for example [7], [4], [1]) are often used in order to improve the results obtained by different algorithms. Its objective is to evaluate the future behavior of a decision (choice) made at a given step of the problem solving process. For example, in a greedy algorithm, the *best* decision among all the possible decisions is made at step i in order to move to the next step $i+1$. The look-ahead strategy tries several (or all) choices at step i and see what will be obtained when executing the greedy algorithm few steps ahead of until the end (this is often executed on a copy of the partial solution). After that, the decision actually made at step i is the one that had the best behavior or led to the best outcome.

In packing problems, the look-forward strategy often uses a parameter called *density* of a solution. The density of a solution S_{in}, denoted by $density(S_{\text{in}})$ is equal to the sum of the volumes of spheres in S_{in} divided by the volume of the container as indicated in Equation 12. The look-forward strategy selects then the decision that will obtain the highest density.

$$density(S_{\text{in}}) = \frac{4 \times \pi \times \sum_{i=1}^{|S_{\text{in}}|}(r_i^3)}{3 \times L \times H \times D} \tag{12}$$

Algorithm 2 LF-3DMHD

Require: Sets S_{in}, S_{out}, P, and the current length L of the container.
Ensure: TRUE if all the spheres are packed into the container, FALSE otherwise.

1: $i \leftarrow |S_{\text{in}}|$;
2: found $\leftarrow$ FALSE;
3: **while** ($P \neq \emptyset$ and found=FALSE) **do**
4: Sort the positions of set P in decreasing order of their hole degree (λ) value;
5: **for each** of the first $\psi_1 \times |P|$ positions $p \in P$ **do**
6: Let $S'_{\text{in}} \leftarrow S_{\text{in}}$, $S'_{\text{out}} \leftarrow S_{\text{out}}$ and $P' \leftarrow P$;
7: Insert the next sphere s'_{i+1} into S'_{in} at position p and update sets $S'_{\text{in}}, S'_{\text{out}}$, and P';
8: $density^* \leftarrow 0$;
9: Sort the positions of set P' in decreasing order of their hole degree (λ) value;
10: **for each** of the first $\psi_2 \times |P'|$ positions $p' \in P'$ **do**
11: Let $S''_{\text{in}} \leftarrow S'_{\text{in}}$, $S''_{\text{out}} \leftarrow S'_{\text{out}}$ and $P'' \leftarrow P'$;
12: Insert the next sphere s''_{i+2} into S''_{in} at position p' and update sets $S''_{\text{in}}, S''_{\text{out}}$, and P'';
13: found $\leftarrow$ 3DMHD($S''_{\text{in}}, S''_{\text{out}}, P'', L$);
14: **if** (found=TRUE) **then**
15: Set L equal to the length computed by 3DMHD;
16: **return** TRUE;
17: **else**
18: **if** ($density(S''_{\text{in}}) > density^*$) **then**
19: $density^* \leftarrow density(S''_{\text{in}})$;
20: **end if**
21: **end if**
22: **end for**
23: Assign to position $p \in P$ the density $density^*$ obtained after calling 3DMHD;
24: **end for**
25: Let $p^* \in P$ be the position that has obtained the highest density $density^*$;
26: Place the next sphere s_{i+1} at position p^* and move sphere s_{i+1} from S_{out} to S_{in};
27: Remove from set P the positions that overlap the new inserted sphere;
28: Compute new positions by using the new inserted sphere;
29: $i \leftarrow i+1$;
30: **end while**
31: **if** ($i = n$) **then**
32: Set $L \leftarrow \max(x_i + r_i)$ where x_i and r_i are the $x-$coordinate and the radius of sphere $s_i \in S_{\text{in}}$;
33: Update the best known length if L is smaller than this value;
34: **return** TRUE;
35: **else**
36: **return** FALSE;
37: **end if**

The algorithm that implements the look-forward strategy, denoted by LF-3DMHD, is described in algorithm 2. It receives as input parameters a partial solution $\{S_{\text{in}}, S_{\text{out}}, P\}$ where $|S_{\text{in}}|$ spheres are already packed, set S_{out} denotes the spheres that remain to pack and P contains the corner positions for spheres of set S_{out}. The algorithm receives also the current length (L) of the container. Algorithm LF-3DMHD returns TRUE if it succeeds to compute a feasible solution, FALSE otherwise.

Instruction at line 1 of algorithm 2 sets the counter i indicating the number of spheres already packed. At line 2, a boolean value (found) is set to FALSE (this indicator is set to TRUE if a feasible solution is obtained).

The difference between the look-forward strategy and the 3DMHD heuristic (described in algorithm 1) is that the look-forward tries (evaluates) several positions at each step of the packing process while the greedy heuristic 3DMHD selects, at each step, only one position (the best one) in order to pack the next sphere. Moreover, the look-forward used here contains two levels, i.e., it places the two next spheres and continues the placement of the remaining spheres by using the greedy heuristic 3DMHD (algorithm 1). This is implemented by using two nested **for** loops that begin at lines 5 and 10 respectively. In addition, the first **for** loop considers only the best $\psi_1 \times |P|$ positions with $0 < \psi_1 \leq 1$ and P is the set of corner positions in the first level. In the second **for** loop the algorithm considers only the best $\psi_2 \times |P'|$ with $0 < \psi_2 \leq 1$ and P' is the set of corner positions in the second level. So if for example $\psi_1 =$

0.5, then only the half best positions in the list of positions are considered in the first level of the look-forward strategy, and if $\psi_1 = 1$, then this means that all the positions will be considered. Using a value of ψ_1 and ψ_2 lower than 1 will of course decrease the computation time of the algorithm.

More precisely, the positions in set P are sorted in decreasing order of their hole degree value (λ). This is done at line 4. In the first **for** loop, the algorithm expends the current solution $\{S_{\text{in}}, S_{\text{out}}, P\}$ by choosing at each time a position $p \in P$ by creating a copy of the current solution denoted by $\{S'_{\text{in}}, S'_{\text{out}}, P'\}$ (line 6) and inserts the next sphere s'_{i+1} at that position (line 7). At line 8, a variable called $density^*$ is set to 0. This parameter is used in order to store the best density obtained in the second level of the look-forward. The corner positions of set P' are after that sorted in decreasing order of their λ value (line 9). The second **for** loop starts at line 10, after placing sphere s'_{i+1}. Like in the first level, only a proportion $\psi_2 \times |P'|$ of the best corner positions are taken into account in set P'. Then for each selected position $p' \in P'$, the procedure creates a copy, denoted by $\{S''_{\text{in}}, S''_{\text{out}}, P''\}$, for the current partial solution $\{S'_{\text{in}}, S'_{\text{out}}, P'\}$ (line 11). After that, the next sphere s''_{i+2} is placed at position p' (line 12). Then, the partial solution is evaluated by calling the 3DMHD heuristic (algorithm 1) at line 13 in order to try to pack the remaining $n-i-2$ spheres. If 3DMHD succeeded to pack all the remaining spheres, then it returns TRUE (line 14), the current length of the container is then set to the length computed by 3DMHD (line 15). The algorithm then exits at line 16 since it has succeeded to pack all the spheres (it returns TRUE). Otherwise (found=FALSE), this means that 3DMHD did not succeed to place all the remaining spheres, then the density of the obtained solution $density(S''_{\text{in}})$ is assigned to the best known density $density^*$ if a better value is obtained (line 19). The second **for** loop ends when all the selected positions $p' \in P'$ are evaluated and the best obtained density $(density^*)$ is assigned to position $p \in P$ that is currently considered in the first **for** loop.

At the output of the two **for** loops, the next sphere s_{i+1} is placed at position p^* (line 26) that has obtained the best density after calling 3DMHD. The set P of positions is then updated at line 27 by removing those that overlap the new inserted sphere and new positions are computed at line 28. The number of placed spheres (i) is incremented at line 29.

Instructions of the **while** loop (lines 3–30) are executed until a feasible solution is obtained (found=TRUE) or the set of positions P becomes empty. So if $i = n$ (line 31), this means that a feasible solution is reached, then the true length of the container is computed at line 32 and the best known length is updated if a better one is obtained (line 33). The algorithm returns TRUE (line 34). If $(i < n)$, then this means that algorithm LF-3DMHD did not succeed to compute a feasible solution and returns FALSE (line 36).

Finally, algorithm 2 can for example be called by an interval-search procedure that modifies the value of the length L of the container at each call as described in section III-B below.

Algorithm 3 (LF2)

Require: Instance S containing n spheres, the height H, and the depth D of the three-dimensional bin $\mathbb{B}$;

Ensure: The best length L^* obtained and the corresponding density $density^*$;

1: Set $L_{\min} \leftarrow \max\left(\frac{4\times\pi\times\sum_{i=1}^{n}(r_i^3)}{3\times H\times D}, 2\times r_{\max}\right)$ be the lower bound of the interval search;
2: Set $L_{\max} \leftarrow 3 \times L_{\min}$;
3: Set $\Delta L \leftarrow 0.01$;
4: $L \leftarrow L_{\max}$;
5: $L^* \leftarrow L$;
6: $density^* \leftarrow 0$;
7: **while** $(L \geq L_{\min})$ **do**
8: $S_{\text{in}} \leftarrow \emptyset$;
9: $S_{\text{out}} \leftarrow S$;
10: Create set P of positions corresponding to the placement of each sphere $s_i \in S$ of radius r_i at position (r_i, r_i, r_i) in the bin of dimensions $L \times H \times D$;
11: found $\leftarrow$ LF-3DMHD$(S_{\text{in}}, S_{\text{out}}, P, L)$;
12: **if** (found = TRUE) **then**
13: Update L if a lower value was obtained by LF-3DMHD;
14: $L^* \leftarrow L$;
15: Update the best density $density^*$;
16: **end if**
17: $L \leftarrow L - \Delta L$;
18: **end while**

B. Interval Search for Computing the Best Packing

This section describes the interval search, denoted by LF2 and described in algorithm 3, used in order to compute the best feasible packing. The search principle consists to decrease the value of the bin length L from an upper bound $L_{\max}$ by a given step ΔL until matching the lower bound $L_{\min}$. The search may also stop if the computation time limit is reached.

Algorithm 3 (LF2) explains how the heuristic proceeds in order to compute the best packing of the n spheres into the three-dimensional bin of minimum length. Procedure LF2 receives as input parameters the instance $S = \{s_1, ..., s_n\}$ containing n spheres of radii $r_1, ..., r_n$ respectively as well as the height H and the depth D of the three-dimensional bin $\mathbb{B}$. The output of the algorithm is the best length found L^* and the corresponding density $(density^*)$ that is equal to the sum of the volumes of the spheres divided by the volume of the bin $(L^* \times H \times D)$.

The continuous lower bound for the length of the container is used as the minimum value $(L_{\min})$ of the interval search (line 1). Note that if this value is lower than the diameter of the greatest sphere, then this diameter $(2 \times r_{\max})$ is used as the lower bound. The upper bound $L_{\max}$ of the interval search is set equal to $3 \times L_{\min}$. The step ΔL with which the length is decreased at each step is defined at line 3, this value is set to 0.01. The length of the container is then set equal to the upper bound $L \leftarrow L_{\max}$ (line 4) and the best length L^* is set equal to

L at line 5. The next instruction serves to initialize the value of the best known density ($density^*$) associated with the best length L^* (line 6).

After that, at each step in the **while** loop (lines 7–18) a starting configuration is created where the set S_{in} of spheres already packed is set equal to the empty set (line 8) and the set of the remaining spheres to pack (S_{out}) is set equal to the instance S. List P of positions for spheres in set S_{out} is then computed (line 10) so that each position is placed at (r_i, r_i, r_i). This is a novel method because most of the greedy heuristics start by placing one or several objects, here only the list of positions is computed and no object is placed.

Algorithm LF-3DMHD is then called at line 11 in order to try to compute a feasible solution (packing the n spheres into the bin of dimensions $L \times H \times D$.) If procedure LF-3DMHD succeeded to pack the n spheres (found=TRUE) then the value of L is updated if a lower value was computed by LF-3DMHD (line 13) and the best length L^* is set equal to L (line 14). The best density $density^*$, corresponding to L^* is then updated at line 15. The value of the length L is after that deceased (line 17), even if a feasible solution was not obtained by procedure LF-3DMHD. Indeed, this method is, to our opinion, preferable to a basic dichotomous search where the dimensions of the container are increased when a feasible solution was not obtained. This is not always a good strategy because, in our case for example, if a feasible solution is not obtained by using a given value of the length L, it may be obtained by using a lower value $L - \Delta L$. In fact, decreasing the value of the length L is a good strategy to escape from local optima in order to increase the solution quality.

Algorithm LF2 stops when the value of L becomes lower than the lower bound L_{min} or when the computation time limit is reached.

IV. Computational Results

In order to evaluate the performance of the proposed algorithm LF2 (algorithm 3), two sets of instances were considered:

- Six instances, denoted by SYS, proposed by Stoyan, Yaskov, and Scheithauer [12]. The number of spheres varies from 25 to 60. All the spheres have different radii in each instance (strongly heterogeneous instances).
- Twelve instances, denoted by KBG1,...,KBG12, proposed by Kubach, Bortfeldt, Tilli, and Gehring [5]. Here, the number of spheres is equal to 30 for the first six instances and 50 spheres for the six last ones. Moreover, instances KBG1–KBG3 and KBG7–KBG9 are strongly heterogeneous since all the radii are different. The other six instances KBG4–KBG6 and KBG10–KBG12 are weakly heterogeneous because there are only $n/10$ different radii in each instance, each radius is duplicated 10 times.

The different procedures and algorithms are coded in C++ language and executed under Linux environment on a computer with a 2.4 GHz processor. The results obtained are compared to those given the B1.6 algorithm [5] that is mainly based on a look-forward strategy and starting configurations, the results taken from [5] were also obtained on a 2.4 GHz processor. Algorithm B1.6 is in fact the adaptation of algorithm B1.5 [4] for placing circles inside a rectangular container to the three-dimensional case. Algorithm B16 however tries more starting configurations than B1.5 does. In addition, B1.6 uses a parameter denoted by τ $(0 < \tau \leq 1)$ that serves to indicate the proportion of corner positions evaluated at each step of the look-forward process. The authors in [5] tried two values: $\tau = 0.8$ and $\tau = 1$. The first case means that only 80% of positions are evaluated by the look-forward while the second case means that all positions are evaluated. So in fact, algorithm B1.6 is executed two times (60 minutes for each value of τ). It is to note that the proposed algorithm LF2 is executed only once during 60 minutes on each instance.

In algorithm LF2, the number of positions evaluated by the look-forward is set to 50% in the two levels ($\psi_1 = \psi_2 = 0.5$). So at each time the corner positions are sorted in decreasing order of their hole degree λ and only the first half ones are evaluated. The objective is of course to save computation time.

Table I shows the results obtained by the different algorithms. Column 1 indicates the instance's name and column 2 its size. The two next columns indicate the height H and the depth D of the container. Column 5 (SYS) indicates the results (best length) obtained by the SYS method [12] on instances SYS1–SYS6. Columns 6 and 7 contain the best results (the best length L and the corresponding density respectively) obtained by algorithm B1.6 on the 18 instances (SYS and KBG) when parameter τ is set equal to 0.8 (80% of positions are evaluated by the look-forward). The next two columns display the same results as the two previous columns but when parameter τ is set equal to 1 (all the positions are evaluated in the look-forward). Columns 10–14 contain the results obtained by the proposed algorithm LF2 on all the considered instances. Column 10 (L) gives the best length obtained and column 11 the corresponding density. Column 12 (t^*) indicates the time needed by algorithm LF2 for computing the best solution. The two last columns of table I indicate the percentage of improvement obtained by the proposed algorithm LF2 on algorithm B1.6. Column "Imp. 0.8" shows the improvement obtained when considering B1.6 with $\tau = 0.8$ and the last column "Imp. 1" is the percentage of improvement when B1.6 with $\tau = 1$ is considered. Note that the percentage of improvement is computed as follows: Imp. $= \frac{Density(\text{LF2}) - Density(\text{B1.6})}{Density(\text{LF2})}$. Finally, note that some solutions for KBG instances are optimal, this is the case for instances KBG2, KBG4, and KBG10. This is why there is an "*" before each value in the three columns that contain the corresponding density in table I.

The results of table I indicate that the proposed algorithm LF2 improves all the results obtained by the SYS method on the first six instances (the results of the SYS method are not known for instances KBG). Algorithm LF2 improves B1.6 with $\tau = 0.8$ in 11 cases out of 18 and the two algorithms reach the optimal value of the container length for instances KBG2, KBG4, and KBG10 since the computed length is equal to the greatest diameter in the instance. Algorithm B1.6 with $\tau = 0.8$ remain better than LF2 on instances KBTG5, KBTG6,

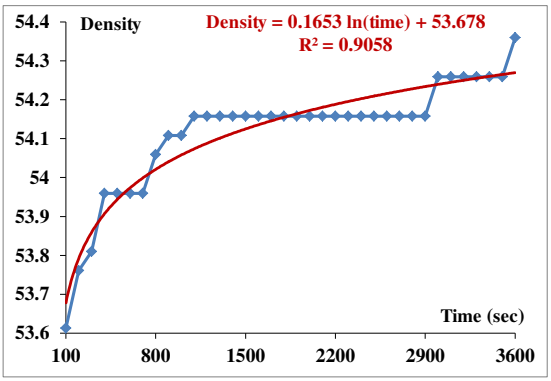

Fig. 3. Estimation of the evolution of the best density obtained with the time by algorithm LF2 on instance SYS4 ($n = 45$) spheres. The regression is based on a logarithmic function, $R^2 = 90.58\%$.

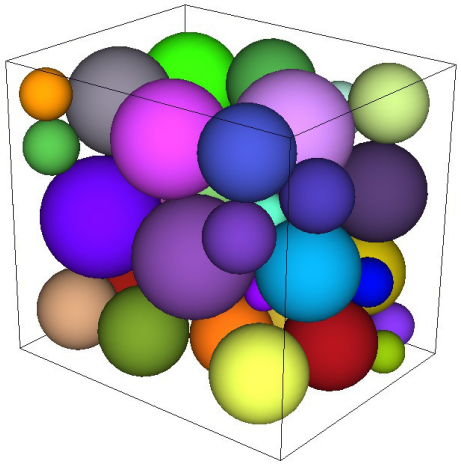

Fig. 4. Solution obtained by algorithm LF2 on instance SYS4 ($n = 45$, $L = 10.7653$ ($Density = 54.410\%$)).

KBTG9, and KBG12). Finally, the last row of the table (column "Imp. 0.8") indicates that algorithm LF2 improves B1.6 with 1.09% in average.

Table I indicates also that algorithm LF2 improves B1.6 with $\tau = 1$ in 12 cases. The two algorithm reach the optimal solution on instances KBG2, KBG4, and KBG10. And algorithm B1.6 with $\tau = 1$ is better than LF2 on instances KBTG5, KBTG9, and KBG11) but the percentage of improvement has decreased to 0.61%.

Fig. 3 indicates the evolution of the density of the solution according to the computation time on instance SYS4 (n=45 spheres). The evolution follows a logarithmic function with a coefficient of determination $R^2 > 90\%$. This means that the density of the obtained solution begins by increasing quickly since the length is near to the upper bound $L_{\max}$ and it is then easier to compute a feasible solution. The improvement of the density slows down when the length approaches the lower bound $L_{\min}$.

Fig. 4 gives the solution obtained by the proposed algorithm LF2 on instance SYS4 that has 35 spheres. The best length obtained is equal to 10.7653 (the best value obtained by B1.6 was 10.8760), this corresponds to an improvement of 1.02%.

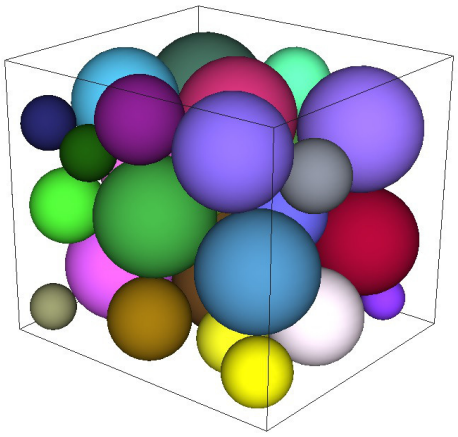

Fig. 5. Solution obtained by algorithm LF2 on instance KBG1 ($n = 30$, $Density = 54.494\%$).

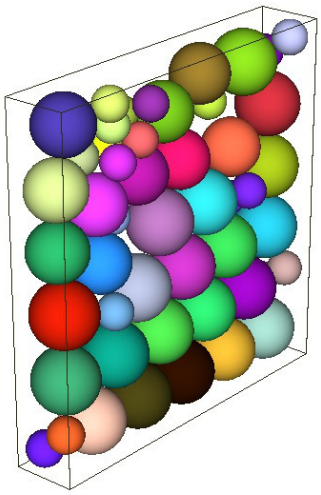

Fig. 6. Optimal solution obtained by algorithm LF2 on instance KBG10 ($n = 50$, $Density = 51.866\%$).

Fig. 5 displays the solution obtained by algorithm LF2 on instance KBG1 that contains 30 spheres. The density obtained is equal to 54.494% (the best value obtained by B1.6 was 54.096%), so the improvement obtained is equal to 0.73%.

Finally, Fig. 6 displays the optimal solution obtained by algorithm LF2 on instance KBG10 that contains 50 spheres but where the number of different radii is only 5. The optimal density is in this case equal to 51.866% and the corresponding optimal length is equal to $2 \times r_{\max}$, i.e., $L = 1.810$, where $r_{\max} = 0.905$ is the greatest radius in the instance.

V. Conclusion

In this paper, a look-forward heuristic was proposed in order to solve the problem of packing spheres into a three-dimensional bin. The first novelty is that method starts with an empty configuration instead of placing one or several pieces inside the container. The second difference is that the interval search proceeds by decreasing the value of the length of the bin instead of using a dichotomous search, the objective is to escape from local optima. Finally the look-forward procedure uses a double search (two levels) instead of one level.

The obtained results on the tested instances showed that the proposed method is effective since it has succeeded to improve or reach almost all the best known results published in the literature. As a future work, it will be interesting to design a new heuristic for packing weakly heterogeneous spheres because it is well-known that the MHD heuristic was designed for packing strongly heterogeneous circles and spheres.

***Abstract*—In the article a 3-dimensional filter method for solving optimal control problems of differential-algebraic equations (DAEs) was presented. Direct multiple shooting method, which is appropriate for the control problems of the multistage DAE systems, leads to the large-scale nonlinear programming problems. In the proposed approach the extended Fletcher's filter with three inputs was used. The filter method promotes global convergence without the need to use a penalty function. The first input of the filter denotes the value of the cost function. The second and third inputs come from two types of equality constraints - consistent initial conditions of the DAE system and continuity constraints on the state trajectories. The new algorithm was tested on the optimal control problem of a fed-batch fermentor for penicillin production. The numerical simulations were executed in MATLAB environment using Wroclaw Center for Networking and Supercomputing.**

***Keywords*—optimal control, DAE systems, inconsistent initial conditions, filter algorithm, nonlinear programming.**

I. Introduction

CONTROL and optimization of the complex and multistage differential-algebraic systems (DAEs) play a key role in a lot of technological systems. The dynamical behavior of the processes can be described by the differential equations. But conservation laws, balance equations, boundary conditions as well as interface with the environmental signals are modeled using the algebraic equations. Today, the differential-algebraic equations are one of the most elegant and simple ways to model a physical system, because they allow the creation of separate models for subcomponents that can then be pasted together [3], [4].

After some elimination processes, DAE systems can be rewritten in the form of ordinary differential equations, which can not present the nature of the process in the same manner like DAEs. A few advantages of a DAE formulation are the following: (1) it may be difficult to reformulate the problem as an ODE when nonlinearities are present, (2) the algebraic equations typically describe conservation laws or explicit equality constraints and they should be kept invariant, (3) it is easier to vary design parameters in an implicit model, (4) the implicit model does not require the modeling simplifications often necessary to get an ODE, (5) the variable keep their original physical interpretation, (6) the system structure can be exploited by problem-specific solvers, (7) less specialized mathematical expertise is required on the part of the designer [5].

One group of the approaches to the optimal control of complex dynamical processes are direct methods, which reformulate the original infinite dimensional optimization problem as a finite dimensional nonlinear programming (NLP) problem. In direct methods, the control and both differential and algebraic states are parametrized. Direct multiple shooting is one of the most popular direct methods. It enables using the efficient DAE solvers to calculate the function values and derivatives accurately. Since the integrations are decoupled on different multiple shooting intervals, this method is well suited for parallel computing. In this manner the control and optimization of the unstable dynamical modes can be considered. The approach allows an effective treatment of control and state path constraints [7]. Using the multiple shooting methods results in a large-scale NLP problem.

In this paper a tri-dimensional filter method based on the line search technique is considered. The filter method to solve nonlinear programming problem can be seen as an alternative to the traditional merit function approach. In this method, compared to the traditional penalty function methods, in which adjustment of the penalty parameter can be problematic, may make the trial steps accepted more easily.

The first idea of the filter method was to interpret the NLP problem as a bi-objective optimization problem with two conflicting purposes. The objective function had to be minimized, but the constraint violation should be minimized too. In the method presented in [10], all the constraints violations were added together and only one constraint violation was defined.

However, each constraint may have its own behavior. Some constraints can be highly nonlinear, while some others are linear or nearly linear [17]. There is the other situation, when the constraints can be grouped depending on the role in the mathematical model.

In the article the constraints were splited into equality constraints for consistent initial conditions for DAE model and equality constraints, which measure the discontinuity of the differential state trajectories. Thus the filter consists of three values: value of the objective function, equality constraints,

978-83-60810-58-3/$25.00

which measure inconsistency of the initial conditions of DAE model, and equality constraints for continuity of the differential state trajectories.

The article is constructed as follows. In the 2nd section the multistage optimal control problem of differential-algebraic systems was presented. Then, in 3rd section, the 3-D filter algorithm was presented. The results of the numerical simulations were discussed in the 4th section.

In the article was used the same notation as in [7] and [20].

II. Problem statement

Let us consider the problem of optimal control of the process with the performance cost function

$$\min_{(u(t),x(t),z(t),p)} \int_{t_0}^{t_f} L\big(x(t),z(t),u(t),p\big)dt + E\big(x(t_f)\big), \quad (1)$$

subject to a system of the index-one differential-algebraic equations (DAE) [6]

$$\begin{aligned} B(\cdot)\dot{x}(t) = &\quad f\big(x(t),z(t),u(t),p\big) \\ 0 = &\quad g\big(x(t),z(t),u(t),p\big), \end{aligned} \quad (2)$$

where x and z denote the differential and algebraic state variables, respectively, u is the vector valued control function, whereas p is a vector of system parameters, which does not depend on the time. Matrix $B\big(x(t),z(t),u(t),p\big)$ is assumed to be invertible. Then the DAE is in a semi-explicit form.

The initial values for the differential and algebraic states and values for the system parameters are prescribed

$$x(t_0) = x_0, \quad (3)$$

$$p(t_0) = p_0. \quad (4)$$

In addition, the terminal constraints

$$r_1\big(x(t_f),p\big) = 0, \quad r_2\big(x(t_f),p\big) \geq 0, \quad (5)$$

as well as the state and control inequality constraints

$$h(x(t),z(t),u(t),p) \geq 0 \quad (6)$$

have to be satisfied.

There is a quite other situation, when the multistage DAE system is considered, because each stage can be described by other set of the differential-algebraic equations.

Let us assume, that there are N stages in the complex industrial process and there is an independent variable t, for example time or length of the chemical reactor.

For a suitable partition of the time horizon $[t_0,t_f]$ into N subintervals $[t_i,t_{i+1}]$ with

$$t_0 < t_1 < \cdots < t_N = t_f, \quad (7)$$

the control function $u(t)$ is discretized. It could be represented by a piecewise constant, piecewise linear or a polynomial approximation [19]. If the control function is parametrized as a piecewise constant vector function, then

$$u(t) = u^l \quad (8)$$

for $t \in [t_{l-1},t_l], \qquad l = 1,\cdots,N.$

By the multiple shooting method, the DAE is parametrized in some sense too. The solution of the DAE system is decoupled on the N intervals $[t_l,t_{l+1}]$. In this manner it introduces the initial values s_x^l and s_z^l of the differential and algebraic states at times t_i as the additional optimization variables.

The trajectories $x(t)$ and $z(t)$ are obtained as a sum of trajectories $x^l(t)$ and $z^l(t)$ on each interval $[t_{l-1},t_l]$. The trajectories $x^l(t)$ and $z^l(t)$ are the solutions of an initial value problem

$$\begin{aligned} B^l(\cdot)\dot{x}(t) = &\quad f^l\big(x^l(t),z^l(t),u^l(t),p\big) \\ 0 = &\quad g^l\big(x^l(t),z^l(t),u^l(t),p\big) + \alpha^l(t_l)g^l\big(s_x^l,s_z^l,u^l,p\big) \\ t \in &\quad [t_{l-1},t_l], \qquad l = 1,\cdots,N. \end{aligned} \quad (9)$$

The relaxation parameter $\alpha^l(t_l)$ was introduced to allow an efficient DAE solution for the initial values and controls s_x^l, s_z^l, u^l, that may temporarily violate the consistency conditions. In this manner, the trajectories $x^l(t)$ and $z^l(t)$ on the interval $[t_{l-1},t_l]$ are functions of the initial values, controls and parameters s_x^l, s_z^l, u^l, p.

The integral part of the cost function is evaluated on each interval independently

$$\begin{aligned} &\min_{\substack{s_x^l,s_z^l,u^l,p \\ l=1,\cdots,N}} \int_{t_0}^{t_1} L^1\big(x^1(t),z^1(t),u^1(t),p\big)dt + \cdots + \\ &+ \int_{t_{N-1}}^{t_N} L^N\big(x^N(t),z^N(t),u^N(t),p\big)dt + E\big(x(t_N)\big) = \\ &= \min_{\substack{s_x^l,s_z^l,u^l,p \\ l=1,\cdots,N}} \sum_{l=1}^{N} \int_{t_{l-1}}^{t_l} L^l\big(x^l(t),z^l(t),u^l(t),p\big)dt + \\ &+ E\big(x(t_N)\big). \end{aligned} \quad (10)$$

The parametrization of the optimal control problem of the multistage DAE systems using the multiple shooting approach and a piecewise constant control representation leads to the following nonlinear programming problem

$$\begin{aligned} &\min_{\substack{s_x^l,s_z^l,u^l,p \\ l=1,\cdots,N}} \sum_{l=1}^{N} \int_{t_{l-1}}^{t_l} L^l\big(x^l(t),z^l(t),u^l(t),p\big)dt + \\ &+ E\big(x(t_N)\big) = \min_{\chi} \Phi(\chi), \end{aligned} \quad (11)$$

subject to the continuity conditions

$$s_x^l = x^{l-1}(t_{l-1}), \qquad l = 2,\cdots,N, \quad (12)$$

the consistency conditions

$$0 = g^l(s_x^l,s_z^l,u^l,p), \qquad l = 1,\cdots,N, \quad (13)$$

control and path constraints imposed pointwise at the multiple shooting nodes

$$h^l(s_x^l,s_z^l,u^l,p) \geq 0, \qquad l = 1,\cdots,N, \quad (14)$$

the terminal constraints

$$r_1(s_x^l,s_z^l,p) = 0, \quad r_2(s_x^l,s_z^l,p) \geq 0, \quad (15)$$

lower and upper bounds on the decision variables

$$\chi_L \leq \chi \leq \chi_U, \tag{16}$$

$$\chi = [s_x^1, \cdots, s_x^N, s_z^1, \cdots, s_z^N, u^1, \cdots, u^N, p]^T, \tag{17}$$

$$\chi_L = [s_{x,L}^1, \cdots, s_{x,L}^N, s_{z,L}^1, \cdots, s_{z,L}^N, u_L^1, \cdots, u_L^N, p_L]^T, \tag{18}$$

$$\chi_U = [s_{x,U}^1, \cdots, s_{x,U}^N, s_{z,U}^1, \cdots, s_{z,U}^N, u_U^1, \cdots, u_U^N, p_U]^T, \tag{19}$$

and with the DAE system in each interval

$$\begin{aligned} B^l(\cdot)\dot{x}(t) = &\quad f^l\big(x^l(t), z^l(t), u^l(t), p\big) \\ 0 = &\quad g^l\big(x^l(t), z^l(t), u^l(t), p\big) + \alpha^l(t_l) g^l(s_x^l, s_z^l, u^l, p), \\ t \in &\quad [t_{l-1}, t_l], \qquad l = 1, \cdots, N. \end{aligned} \tag{20}$$

III. The filter method

About 10 years ago, Fletcher and Leyffer proposed the filter methods to solve nonlinear programming (NLP) as an alternative to the traditional merit function approach. The underlying concept of filter is quite simple, being based on the multi-objective optimization, that is, the trial point is accepted provided there is a sufficient decrease of the objective function or the constraint violation function. In addition, the computational results presented in [10] were also very encouraging. The trust region filter sequential quadratic programming (SQP) methods have been studied in [9], [11]. On the other hand, the filters approach has been used also in conjunction with the line search strategy [20], [21], with interior point methods [18] and with the pattern search method [1]. Finally, the multidimensional filters have been employed to solve least squares problems, nonlinear equations and unconstrained optimization problems [12], [13].

In this paper, a tri-dimensional filter method based on the line search strategy, was proposed. The main idea of a filter is to interpret the NLP problem as a bi-objective optimization problem with two conflicting purposes: minimizing the objective function and the constraints violation. So, the formal filter in [10] consisted of two parts: the value of the objective function and the constraint violation. It means, that all the constraints are considered together and only one constraint violation is defined. However, each constraint may have its own behavior. For example, some constraints may be highly nonlinear, while some others are linear or nearly linear. In this work only equality constraints are considered. But they are two kinds of constraints, which have definitely a different meaning and applications. Thus, the new filter consists of three inputs: objective function value, inconsistency of the initial conditions for differential-algebraic equations and continuity of the differential state trajectories.

A. A line search filter approach

As it was assumed, the considered problem is stated as

$$\min_{\chi \in \mathcal{R}^n} f(\chi) \tag{21}$$

subject to

$$c(\chi) = 0, \tag{22}$$

where the objective function $f : \mathcal{R}^n \to \mathcal{R}$ and the equality constraints $c : \mathcal{R}^n \to \mathcal{R}^m$ with $m < n$ are sufficiently smooth.

The Karush-Kuhn-Tucker (KKT) for the nonlinear programming problem (21)-(22) are

$$g(\chi) + A(\chi)\lambda = 0, \tag{23}$$

$$c(\chi) = 0, \tag{24}$$

where $A(\chi) = \nabla c^T(\chi)$ denotes the transpose of the Jacobian of the constraints $c(\chi)$ and $g(\chi) = \nabla f(\chi)$ denotes the gradient of the objective function. The vector λ corresponds to the Lagrange multipliers for the equality constraints. Under constraint qualifications assumption, the KKT conditions are the first order optimality conditions for (21)-(22) [15].

Given an initial estimate χ_0, the line search algorithm generates a sequence of improved estimates χ_k of the solution for the NLP. For this purposes in each iteration k a search direction d_k is computed from the linearization at χ_k of the KKT conditions

$$\begin{bmatrix} H_k & A_k \\ A_k^T & 0 \end{bmatrix} \begin{pmatrix} d_k \\ \delta\lambda_k \end{pmatrix} = - \begin{pmatrix} g_k \\ c_k \end{pmatrix}, \tag{25}$$

where $A_k = A(\chi_k)$, $g_k = g(\chi_k)$ and $c_k = c(\chi_k)$.

The symmetric matrix H_k denotes the Hessian $\nabla^2_{\chi\chi}\mathcal{L}(\chi_k, \lambda_k)$ of the Lagrangian

$$\mathcal{L}(\chi, \lambda) = f(\chi) + c^T(\chi)\lambda \tag{26}$$

of the nonlinear programming problem or an approximation of the Hessian.

The vector λ_k is some estimate of the optimal multipliers corresponding to the equality constraints, and $\delta\lambda_k$ in (25) can be used to determine a new estimate λ_{k+1} for the next iteration.

After a search direction d_k has been computed, a step size $\alpha_k \in (0, 1]$ is determined in order to obtain the next iterate

$$\chi_{k+1} = \chi_k + \alpha_k d_k. \tag{27}$$

It would be ideally to guarantee, that the sequence χ_k of iterates converges to a solution of the NLP. So, for this purposes, a backtracking procedure was proposed.

In the backtracking line search procedure a decreasing sequence of step size $\alpha_{k,l} \in (0, 1] \quad (l = 0, 1, 2, \cdots)$ is tried until some acceptance criterion is satisfied. Traditionally, a trial step size $\alpha_{k,l}$ is accepted if the corresponding trial point

$$\chi_k(\alpha_{k,l}) = \chi_k + \alpha_{k,l} d_k \tag{28}$$

provides sufficient reduction of a merit function, such as the exact penalty function

$$\phi_\rho(\chi) = f(\chi) + \rho\theta(\chi), \tag{29}$$

where the infeasibility measure $\theta(\chi)$ was defined as

$$\theta(\chi) = \|c(\chi)\|. \tag{30}$$

Under certain regularity assumptions it can be shown that a feasible strict local minimum of the exact penalty function coincides with a local solution of the NLP if the value of the penalty parameter $\rho > 0$ is chosen sufficiently large.

The overall algorithm for solving the equality constrained NLP problem is as follows.

ALGORITHM 1. The filter line search SQP algorithm [20]

Given: Starting point χ_0; constants $\theta_{\max} \in (\theta(\chi_0), \infty)$; γ_θ, $\gamma_f \in (0,1)$; $\delta > 0$; $\gamma_\alpha \in (0,1]$; $s_\theta > 1$; $s_f \geq 1$; $\eta_f \in (0, \frac{1}{2})$; $0 < \tau_1 < \tau_2 < 1$.

1. Initialize.
   Initialize the filter $\mathcal{F}_0 = \{(\theta, f) \in \mathcal{R}^2 : \theta \geq \ \theta_{max}\}$ and the iteration counter $k \leftarrow 0$.
2. Check convergence.
   Stop if χ_k is a stationary point of the NLP (21)-(22), i.e. if it satisfies the KKT conditions (23)-(24) for some $\lambda \in \mathcal{R}^m$.
3. Compute search direction
   Compute the search direction d_k from the linear system (25). If this system is detected to be ill-conditioned, go to the feasibility restoration phase in step 8.
4. Backtracking line search.
   4.1 Initialize line search.
   Set $\alpha_{k,0} = 1$ and $l \leftarrow 0$.
   4.2 Compute new trial point.
   If the trail step size becomes too small, i.e., $\alpha_{k,l} < \alpha_k^{\min}$, go to the feasibility restoration phase in step 8. Otherwise, compute the new trail point $\chi_k(\alpha_{k,l}) = \chi_k + \alpha_{k,l} d_k$.
   4.3 Check acceptability to the filter.
   If $\chi_k(\alpha_{k,l}) \in \mathcal{F}_k$, reject the trial step size and go to step 4.5.
   4.4 Check sufficient decrease with respect to current iterate.
   4.5 Choose new trial step size
   Choose $\alpha_{k,l+1} \in [\tau_1 \alpha_{k,l}, \tau_2 \alpha_{k,l}]$, set $l \leftarrow l + 1$, and go back to step 4.2.
5. Accept trial point.
   Set $\alpha_k = \alpha_{k,l}$ and $\chi_{k+1} = \chi_k(\alpha_k)$.
6. Augment filter if necessary.
7. Continue with next iteration.
   Increase the iteration counter $k \leftarrow k + 1$ and go back to step 2.
8. Feasibility restoration phase.
   Compute a new iterate χ_{k+1} by decreasing the infeasibility measure θ so that χ_{k+1} satisfies the sufficient decrease conditions (31)-(32) and is acceptable to the filter, i.e., $(\theta(\chi_{k+1}), f(\chi_{k+1})) \notin \mathcal{F}_k$.
   Augment the filter and continue with the regular iteration in step 7.

Line search methods that use a merit function ensure sufficient progress toward the solution. Hence, here it is required that the next iterate provides at least as much progress in one of the measures θ or f that corresponds to a small fraction of the current constraint violation, $\theta(\chi_k)$. It means, that for fixed constants $\gamma_\theta, \gamma_f \in (0,1)$ a trial step size $\alpha_{k,l}$ provides sufficient reduction with respect to the current iterate χ_k if

$$\theta(\chi_k(\alpha_{k,l})) \leq (1 - \gamma_\theta)\theta(\chi_k) \tag{31}$$

or

$$f(\chi_k(\alpha_{k,l})) \leq f(\chi_k) - \gamma_f \theta(\chi_k). \tag{32}$$

In a practical implementation, the constants γ_θ, γ_f typically are chosen to be small.

B. A multidimensional filter

The multidimensional filter algorithm was stated by Gould, Leyffer and Toint in the article [12]. It was used for solving nonlinear equations and nonlinear least-squares.

The following system of nonlinear equations is considered

$$c(\chi) = 0, \tag{33}$$

where c is twice continously differentiable function from $\mathcal{R}^n$ into $\mathcal{R}^m$. In the next step, the equation (33) is partitioned into p sets $\{c_i(\chi)\}_{i \in \mathcal{I}_j}$ for $j = 1, \cdots, p$, with $\{1, \cdots, n\} = \mathcal{I}_1 \bigcup \mathcal{I}_2 \bigcup \cdots \mathcal{I}_p$ and

$$\theta_j(\chi) = \|c_{\mathcal{I}_j}\| \tag{34}$$

for $j = 1, \cdots, p$, where $\|\cdot\|$ is the Euclidean norm and $c_{\mathcal{I}_j}$ is the vector whose components are the components of c indexed by $\mathcal{I}_j$.

The point is therefore a solution of (33) if and only if

$$\theta_j(\chi) = 0 \tag{35}$$

for $j = 1, \cdots, p$. The quantity $\theta_j(\chi)$ may be interpreted as the size of the residual of the jth set of equations at the point χ.

The classical approach for solving (33) is to minimize a merit function involving some norm of the residual

$$\min_{\chi \in \mathcal{R}^n} f(\chi) = \frac{1}{2}\|\theta(\chi)\|^2. \tag{36}$$

The main idea of filter algorithms for constrained optimization is that new iterates of the underlying iterative algorithm can be accepted if they do not perform, compared to past iterates kept in the filter, worse on both important and typically conflicting accounts for this type of problem: feasibility and low objective function value.

In the context of nonlinear equations, one may consider driving each of the $\{\theta_i(\chi)\}_{i=1}^p$ to zero as an independent task.

A point χ_1 dominates a point χ_2 whenever

$$\forall j = 1, \cdots, p \qquad \theta_j(\chi_1) \leq \theta_j(\chi_2). \tag{37}$$

Thus, if iterate χ_{k_1} dominates iterate χ_{k_2}, the latter is of no real interest, since χ_{k_1} is at least as good as χ_{k_2} for each of the equation sets. All, what is needed to do now, is to remember iterates that are not dominated by other iterates using a structure called a filter.

A filter is a list $\mathcal{F}$ of p-tuples of the form $(\theta_{1,k}, \cdots, \theta_{p,k})$ such that

$$\theta_{j,k} < \theta_{j,l} \tag{38}$$

for at least one $j \in \{1, \cdots, p\}$ and $k \neq l$.

Filter methods propose to accept a new trial iterate χ_k^+ if it is not dominated by any other iterate in the filter and χ_k.

Additionally, it is inappropriate to accept a new point χ_k^+ if $\theta(\chi_k)$ is arbitraily close to being dominated by another point

already in the filter [16]. To avoid this situation, the acceptability condition should be more strength. More formally, one can say that a new trial point χ_k^+ is acceptable for the filter $\mathcal{F}$ if and only if

$$\forall \theta_l \in \mathcal{F} \quad \exists j \in \{1, \cdots, p\} \quad \theta_j(\chi_k^+) < \theta_{j,l} - \gamma_\theta \delta(\|\theta_l\|, \|\theta_k^+\|), \tag{39}$$

where $\gamma_\theta \in (0, 1/\sqrt{p})$ is a small positive constant and where $\delta(\cdot,\cdot)$ is one of the following

$$\delta(\|\theta_l\|, \|\theta_k^+\|) = \|\theta_l\| \tag{40}$$

$$\delta(\|\theta_l\|, \|\theta_k^+\|) = \|\theta_k^+\| \tag{41}$$

or

$$\delta(\|\theta_l\|, \|\theta_k^+\|) = \min(\|\theta_l\|, \|\theta_k^+\|). \tag{42}$$

C. A tri-dimensional filter SQP algorithm

The groups of constraints violations for NLP problem (21)-(22) are defined as follows

$$\mathcal{S}_I = \frac{1}{2} \sum_{i=1}^{p} c_i^2(\chi) \tag{43}$$

for continuity of the differential state trajectories and

$$\mathcal{S}_{II} = \frac{1}{2} \sum_{i=p+1}^{m} c_i^2(\chi), \tag{44}$$

which represents inconsistency of the initial conditions.

These two groups of constraints are defined similarly, but they have definitely different meanings and play another role in the optimization process.

In a filter $\mathcal{F}$, triples of values $(\mathcal{S}_I(\chi), \mathcal{S}_{II}(\chi), f(\chi))$ are considered.

Definition 1. The iterate χ_k dominates the iterate χ_l if and only if $\mathcal{S}_I(\chi_k) \leq \mathcal{S}_I(\chi_l)$, $\mathcal{S}_{II}(\chi_k) \leq \mathcal{S}_{II}(\chi_l)$ and $f(\chi_k) \leq f(\chi_l)$. It is denoted by $\chi_k \preceq \chi_l$.

Thus, if $\chi_k \preceq \chi_l$, the latter is of no real interest, since χ_k is at least as good as χ_l with respect to three violations. Furthermore, if $\chi_k \preceq \chi_l$, one can say that the triple $(\mathcal{S}_I(\chi_k), \mathcal{S}_{II}(\chi_k), f(\chi_k))$ dominates the triple $(\mathcal{S}_I(\chi_l), \mathcal{S}_{II}(\chi_l), f(\chi_l))$.

Definition 2. The kth filter is a list of triples $\{\mathcal{S}_I(\chi_l), \mathcal{S}_{II}(\chi_l), f(\chi_l))\}_{l<k}$, such that no triple dominates any other.

Let $\mathcal{F}_k$ denote the indices in the kth filter

$$\mathcal{F}_k = \{l < k : \chi_j \not\preceq \chi_l \quad \forall j \in \{0, 1, 2, \cdots, k-1\} \backslash \{l\}\} \tag{45}$$

Filter methods accept a trial point $\chi_{k+1} = \chi_k + \alpha d_k$ if its corresponding triple $(\mathcal{S}_I(\chi_{k+1}), \mathcal{S}_{II}(\chi_{k+1}), f(\chi_{k+1}))$ is not dominated by any other triple in the kth filter, neither the triple corresponding to χ_k, i.e. $(\mathcal{S}_I(\chi_k), \mathcal{S}_{II}(\chi_k), f(\chi_k))$

Definition 3. A new trial point χ_{k+1} is said to be "acceptable to the kth filter" if χ_{k+1} is acceptable to χ_l for all $l \in \mathcal{F}_k$.

In this manner defined 3-dimensional line search-SQP filter was tested on optimal control problem of nonlinear differential-algebraic system with inconsistent initial conditions.

IV. Case study: optimal control of a fed-batch fermentor for penicillin production

This problem considers a fed-batch reactor for the production of penicillin [2]. We consider here the free terminal time version where the objective is to maximize the amount of penicillin using the feed rate as the control variable. The mathematical statement of the free terminal time problem is as follows.

Find $u(t)$ and t_f over $t \in [t_0, t_f]$ to maximize

$$J = x_2(t_f) \cdot x_4(t_f) \tag{46}$$

subject to differential-algebraic system

$$\frac{dx_1}{dt} = h_1 x_1 - u\left(\frac{x_1}{500 x_4}\right), \tag{47}$$

$$\frac{dx_2}{dt} = h_2 x_1 - 0.01 x_2 - u\left(\frac{x_2}{500 x_4}\right), \tag{48}$$

$$\frac{dx_3}{dt} = -h_1 \frac{x_1}{0.47} - h_2 \frac{x_1}{1.2} - x_1 \frac{0.029 x_3}{0.0001 + x_3} + \frac{u}{x_4}\left(1 - \frac{x_3}{500}\right), \tag{49}$$

$$\frac{dx_4}{dt} = \frac{u}{500}, \tag{50}$$

$$h_1 = 0.11\left(\frac{x_3}{0.006 x_1 + x_3}\right), \tag{51}$$

$$h_2 = 0.0055\left(\frac{x_3}{0.0001 + x_3(1 + 10 x_3)}\right), \tag{52}$$

where x_1, x_2 and x_3 are the biomass, penicillin and substrate concentration (g/L), and x_4 is the volume (L). The initial conditions are

$$x(t_0) = [1.5 \quad 0 \quad 0 \quad 7]^T. \tag{53}$$

There are several path constraints for state variables

$$0 \leq x_1 \leq 40, \tag{54}$$

$$0 \leq x_2 \leq 25, \tag{55}$$

$$0 \leq x_3 \leq 10. \tag{56}$$

The upper and lower bounds on the only control variable (feed rate of substrate) are

$$0 \leq u \leq 50. \tag{57}$$

The control problem of a fed-batch fermentor for penicillin production was solved with the proposed 3-D SQP filter algorithm combined with multiple shooting method.

At first, the overall time domain was divided into 20 equidistant intervals. It results in 20 differential-algebraic submodels, each of them consists of 4 differential equations and 2 algebraic equations. Initial conditions only for the first stage are known. So, there are 76 decision variables connected with initial values for differential variables and 40 variables, which represent pointwise values of algebraic states. The last decision variable was the duration time of the process.

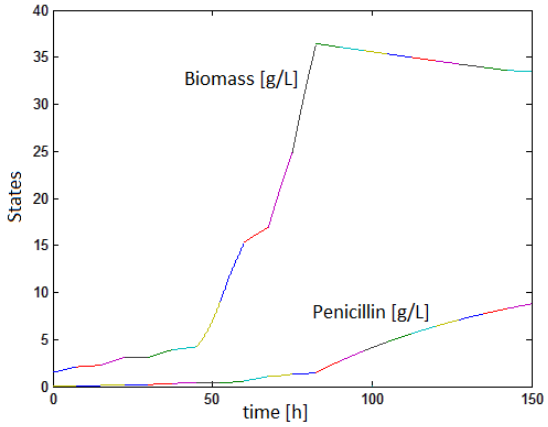

Fig. 1. The optimal trajectories of the both biomass and penicillin concentrations

Backward Differentiation Formula of order 1 was used to solve DAE systems at each stage.

The initial values for decision variables were as follows

$$\chi_{1,x_{1,2}}, \cdots, \chi_{19,x_{1,20}} = 1.5, \tag{58}$$

$$\chi_{20,x_{2,2}}, \cdots, \chi_{38,x_{2,20}} = 0.0, \tag{59}$$

$$\chi_{39,x_{3,2}}, \cdots, \chi_{57,x_{3,20}} = 0.0, \tag{60}$$

$$\chi_{58,x_{4,2}}, \cdots, \chi_{76,x_{4,20}} = 7.0, \tag{61}$$

$$\chi_{77,h_{1,1}}, \cdots, \chi_{96,h_{1,20}} = 10.0, \tag{62}$$

$$\chi_{97,h_{2,1}}, \cdots, \chi_{116,h_{2,20}} = 10.0, \tag{63}$$

$$\chi_{117,u_1}, \cdots, \chi_{136,u_{20}} = 10.0, \tag{64}$$

$$\chi_{137,t_f} = 110.0[h]. \tag{65}$$

The solution, with the accuracy 10^{-6} for each input of the filter, was obtained after 6 hours. The final value of the objective function is $89.5473[g]$. The duration of the whole process is 150 hours. There are the optimal trajectories of the both biomass and penicillin concentrations in Fig. 1.

V. Conclusion

In the article optimal control problem of complex systems with differential-algebraic constraints was considered. One of the most important question in optimization and control of DAE systems concerns on consistent initial conditions. For these purposes the 3-dimensional line search-SQP filter was designed. It enables simultaneous optimization of objective function and treatment of constraints.

The filter algorithm, which consists of three inputs, was tested on the optimal control problem of a fed-batch fermentor for penicillin production. The encouraging results were obtained.

In real-life applications, very often multistage technological processes are under considerations. The multiple shooting method, which enables efficient treatment of such processes, incorporates additional equality constraints and decision variables to the NLP problem, connected with continuity of the differential state trajectories.

The most important advantage of the multiple shooting method is a possibility of control and optimization of highly nonlinear differential-algebraic systems in an open-loop. Application in this field is currently also an important challenge for the presented 3-dimensional SQP filter algorithm [8], [14].

***Abstract*—In this paper, a hybrid scheme, to solve optimization problems, using a Genetic Algorithm (GA) and an Ant Colony Optimization (ACO) is introduced. In the hybrid GA-ACO approach, the GA is used to find a feasible solutions to the considered optimization problem. Next, the ACO exploits the information gathered by the GA. This process obtains a solution, which is at least as good as—but usually better than—the best solution devised by the GA. To demonstrate the usefulness of the presented approach, the hybrid scheme is applied to the parameter identification problem in the *E. coli* MC4110 fed-batch fermentation process model. Moreover, a comparison with both the conventional GA and the stand-alone ACO is presented. The results show that the hybrid GA-ACO takes the advantages of both the GA and the ACO, thus enhancing the overall search ability and computational efficiency of the solution method.**

***Index Terms*—Genetic Algorithm; Genetic algorithms; Ant Colony Optimization; hybrid; model parameter identification; *E. coli*; fed-batch fermentation process**

I. Introduction

TO SOLVE different optimization problems we can apply various techniques and approaches, namely exact algorithms (Branch-and-Bound, Dynamic Programming, local search techniques) [1], [2], [3], heuristics [5], [6], and meta-heuristics (Genetic Algorithms, Ant Colony Optimization, Particle Swarm Optimization, Simulated Annealin, Tabu Search, etc.) [4], [7], [8]. Today, the use of meta-heuristics has received more and more attention. These methods offer good solutions, even global optima, within reasonable computing time [9]. An even more efficient behavior, and a higher flexibility when dealing with real-world and large-scale problems, can be achieved through a combination of a meta-heuristic with other optimization techniques, the so-called hybrid metaheuristic [7], [13], [12], [14], [20], [21], [19].

The main goal of all hybrid algorithms is to exploit the advantages of different optimization strategies, while avoiding their disadvantages. Choosing an adequate combination of metaheuristic techniques one can achieve a better algorithm performance in solving hard optimization problems. Developing such effective hybrid algorithm requires expertise from different areas of optimization. There are many hybridization techniques that have shown to be successful for different applications [10], [11].

In this paper, we investigate a hybrid metaheuristic method that combines the Genetic Algorithms (GA) and the Ant Colony Optimization (ACO), named GA-ACO. There already exist some applications of the ACO-GA hybrid for several optimization problems. In [15], [16] a hybrid metaheuristic ACO-GA, for the problem of sports competition scheduling is presented. In the proposed algorithm first, the GA generates activity lists, thus providing the initial population for the ACO. Next, the ACO is executed. In the next step, the GA, based on the crossover and mutation operations, generates a new population. Authors of [17] presented a hybrid algorithm in which the ACO and the GA search alternately and cooperatively in the solution space. Test examples show that the hybrid algorithm can be more efficient and robust than the traditional population based heuristic methods. In [18], the problem of medical data classification is discussed. Authors propose a hybrid GA-ACO and show the usefulness of the proposed approach on a number of benchmark real-world medical datasets. For solving NP-hard combinatorial optimization problems, in [22], a novel hybrid algorithm combining the search capabilities of the ACO and the GA is introduced. As a result a faster and better search algorithm capabilities is achieved.

Provoked by the promising results obtained from the use of hybrid GA-ACO algorithms, we propose a hybrid algorithm, i.e. collaborative combination of the GA and the ACO methods for the model parameters optimization of the *E. coli* fermentation process. The effectiveness of the GA and the ACO have already been demonstrated for model parameter optimization considering fed-batch fermentation processes (see, [24]). Moreover, parameter identification of cellular dynamics models has especially become a research field of great interest. Robust and efficient methods for parameter identification are thus of key importance.

The paper is organized as follows. The problem formulation is given in Section 2. The proposed hybrid GA-ACO technique is described in Section 3. The numerical results and a discussion are presented in Section 4. Conclusion remarks are done in Section 5.

II. Problem Formulation

A. *E. coli* Fed-batch Fermentation Model

The mathematical model of the fed-batch fermentation process of the *E. coli* is presented by the following non-linear differential equation system [28]:

$$\frac{dX}{dt} = \mu X - \frac{F_{in}}{V} X \tag{1}$$

$$\frac{dS}{dt} = -q_S X + \frac{F_{in}}{V}(S_{in} - S) \tag{2}$$

$$\frac{dV}{dt} = F_{in} \tag{3}$$

where

$$\mu = \mu_{max} \frac{S}{k_S + S} \tag{4}$$

$$q_S = \frac{1}{Y_{S/X}} \mu \tag{5}$$

- X is the biomass concentration, [g/l];
- S is the substrate concentration, [g/l];
- F_{in} is the feeding rate, [l/h];
- V is the bioreactor volume, [l];
- S_{in} is the substrate concentration in the feeding solution, [g/l];
- μ and q_S are the specific rate functions, [1/h];
- μ_{max} is the maximum value of the specific growth rate, [1/h];
- k_S is the saturation constant, [g/l];
- $Y_{S/X}$ is the yield coefficient, [-].

For the model parameters identification, experimental data of an *E. coli* MC4110 fed-batch fermentation process can be used. The experiments providing the real-world data were performed in the Institute of Technical Chemistry, University of Hannover, Germany. The detailed description of the fermentation condition and experimental data can be found in [23], [27].

The fed-batch process starts at time t = 6.68 h, after batch phase. The initial liquid volume is 1350 ml. Before inoculation a glucose concentration of 2.5 g/l was established in the medium. Glucose concentration, in the feeding solution is 100 g/l. The temperature was controlled at 35 °C, the pH at 6.9. The stirrer speed was initially set to 900 rpm and later was increased to 1800 rpm, so that the dissolved oxygen concentration was never below 30%. The aeration rate was kept at 275 l/h and the carbon dioxide was measured in the exhaust gas. The process was stopped at time t = 11.54 h.

The bioreactor, as well as the FIA measurement system is shown in Figure 1. The feed rate profile and the dynamics of the measured substrate concentration are presented, respectively in Fgure 2 and Figure 3.

For the considered non-linear mathematical model of the *E. coli* fed-batch fermentation process (Eq. (1) - Eq. (5)) the parameters that should be identified are:

Fig. 1. *E. coli* MC4110 fed-batch fermentation process: bioreactor and FIA measurement system

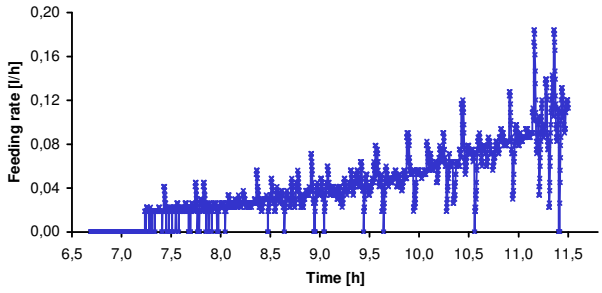

Fig. 2. *E. coli* MC4110 fed-batch fermentation process: feed rate profile

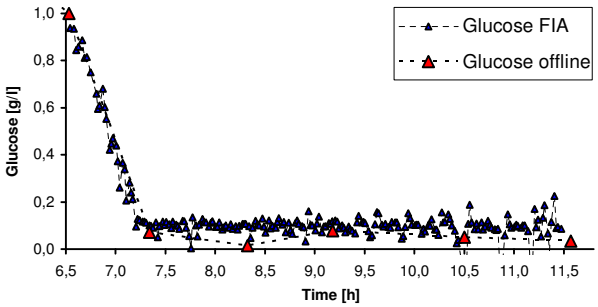

Fig. 3. *E. coli* MC4110 fed-batch fermentation process: measured substrate concentration

- maximum specific growth rate (μ_{max}),
- saturation constant (k_S),
- yield coefficient ($Y_{S/X}$).

The following upper and lower bounds of the model parameters are considered [24]:

$$0 < \mu_{max} < 0.7,$$

$$0 < k_S < 1,$$

$$0 < 1/Y_{S/X} < 30.$$

In the model identification procedures, measurements of main process variables (biomass and glucose concentration) are used. For the on-line glucose determination the FIA system has been employed. For the biomass, an off-line analysis was performed [27].

B. Optimization Criterion

The objective of the optimization consists of adjusting the parameters (μ_{max}, k_S and $Y_{S/X}$) of the non-linear mathematical model function (Eq. (1) - Eq. (5)) to best fit a data set. The objective function is presented as a minimization of a distance measure J between the experimental and the model predicted values of the main state variables (biomass X and substrate S):

$$J = \sum_{i=1}^{m} \left(X_{\exp}(i) - X_{\,\mathrm{mod}}\,(i)\right)^2 + \\ + \sum_{i=1}^{m} \left(S_{\exp}(i) - S_{\,\mathrm{mod}}\,(i)\right)^2 \rightarrow \min \tag{6}$$

where m is the number of experimental data; $X_{\exp}$ and $S_{\exp}$ is the known experimental data for biomass and substrate; $X_{\,\mathrm{mod}}$ and $S_{\,\mathrm{mod}}$ are the model predictions for the biomass and the substrate with a given set of parameters (μ_{max}, k_S and $Y_{S/X}$).

III. Methodology

A. Genetic Algorithm

Genetic Algorithm is a metaheuristic technique based on an analogy with the genetic structure and behaviour of chromosomes within a population of individuals using the following foundations [33]:

- chromosomes in a population compete for resources and mates;
- those chromosomes most successful in each "competition" will produce more off-spring than those chromosomes that perform poorly;
- genes from "good" chromosomes propagate throughout the population so that the two good parents will sometimes produce offspring that are better than either parent;
- thus, each successive generation will become more suited to their environment (will move closer to an optimal solution).

The structure of the GA, shown by the pseudocode, is presented in Figure 4).

Genetic Algorithm
$i = 0$
Initial population $Pop(0)$
Evaluate $Pop(0)$
while (not done) **do** (test for termination criterion)
  $i = i + 1$
  Select $Pop(i)$ from $Pop(i-1)$
  Recombine $Pop(i)$
  Mutate $Pop(i)$
  Evaluate $Pop(i)$
end while
Final solution

Fig. 4. Pseudocode for GA

The GA, mainly operates on binary strings and using a recombination operator with mutation. It is based on a population of chromosomes, $Pop(t) = x_1^t, ..., x_n^t$ for generation t. Each chromosome introduces a potential solution to the problem and is implemented as some data structure S. Each solution is evaluated according its "fitness." Fitness of a chromosome is assigned proportionally to the value of the objective function of the chromosomes. Then, a new population (generation $t + 1$) is formed by selecting better chromosomes (the selection step).

A roulette wheel, developed by Holland [30] is the most often used selection method. The probability, P_i, for each chromosome to be selected is defined by:

$$P[\text{Individual } i \text{ is chosen}] = \frac{F_i}{\sum_{j=1}^{PopSize} F_j}, \tag{7}$$

where F_i equals the fitness of the chromosome i and $PopSize$ is the population size.

Selected members of the new population have been subjected to transformations by means of "genetic" operators to form a new solution. There are unary transformations m_i (mutation type), which create new chromosomes by a small change in a single chromosome ($m_i : S \rightarrow S$), and higher order transformations c_j (crossover type), which create new chromosomes by combining parts from several chromosomes ($c_j : S \times \ldots \times S \rightarrow S$). The combined effect of selection, crossover and mutation gives so-called reproductive scheme growth equation (the schema theorem) [29]:

$$\xi\,(S, t+1) \geq \\ \xi\,(S,t) \cdot eval\,(S,t)\,/\bar{F}\,(t) \left[1 - p_c \cdot \frac{\delta\,(S)}{m-1} - o\,(S) \cdot p_m\right].$$

A good schemata receives an exponentially increasing number of reproductive trials in successive generations.

B. Ant Colony Optimization

The ACO is a stochastic optimization method that mimics the social behavior of real ants colonies, which try to find shortest rout to feeding sources and back. Real ants lay down quantities of pheromone (chemical substance) marking the path that they follow. An isolated ant moves essentially at random but an ant encountering a previously laid pheromone will detect it and decide to follow it with high probability and reinforce it with a further quantity of pheromone. The repetition of the above mechanism represents the auto-catalytic behavior of a real ant colony, where the more ants follow a given trail, the more attractive that trail becomes. Hence, the overall idea of the optimization approach comes from observing such behavior, in which ants are collectively able to find the shortest path to the food.

The ACO is implemented by instantiating a team of software agents, which simulate the ants behavior, walking around the graph representing the problem to solve. The requirements of the ACO algorithm are as follows [25], [26]:

- The problem needs to be represented appropriately, to allow the ants to incrementally update the solutions through the use of a probabilistic transition rules, based on the amount of pheromone on the trail and other problem specific knowledge.
- Existence of a problem-dependent heuristic function that measures the quality of components that can be added to the current partial solution.
- Explication of a set of rules for pheromone updates, which specify how to modify the pheromone value in specific situations.
- A probabilistic transition rule, based on the value of the heuristic function and the pheromone value, that is used to iteratively construct a solution needs to be provided.

The structure of the ACO algorithm, represented as a pseudocode, is depicted in Figure 5. The transition probability $p_{i,j}$, to choose the node j, when the current node is i, is based on the heuristic information $\eta_{i,j}$ and the pheromone trail level $\tau_{i,j}$ of the move, where $i, j = 1, \ldots, n$.

$$p_{i,j} = \frac{\tau_{i,j}^a \eta_{i,j}^b}{\sum\limits_{k \in Unused} \tau_{i,k}^a \eta_{i,k}^b}, \tag{8}$$

where $Unused$ is the set of unused nodes of the graph.

The higher the value of the pheromone and the heuristic information, the more profitable it is to select this move and to continue the search. In the beginning, the initial pheromone level (across the graph) is set to a small positive constant value τ_0; later, the ants update this value after completing the solution construction stage. Different ACO algorithms adopt different criteria to update the pheromone level.

The pheromone trail update rule is given by:

$$\tau_{i,j} \leftarrow \rho \tau_{i,j} + \Delta\tau_{i,j}, \tag{9}$$

where ρ models pheromone evaporation (a process that takes place in the nature) and $\Delta\tau_{i,j}$ is a new added pheromone, which is proportional to the quality of the solution. Thus better solutions will receive more pheromone than others and will be more desirable in a next iteration.

IV. Hybrid GA-ACO Algorithm

We propose to combine two metaheuristics, namely the GA [29], [30] and the ACO [31]. The GA is a population-based method where initial population is randomly generated. Thus the randomly generated initial solutions are further genetically evaluated. As seen above, the ACO algorithm is a population-based as well. The difference, as compared with the GA, is that the ACO does not need initial population. The ACO is a constructive method, in which the ants look for good solutions guided by the parameter called the pheromone. At the beginning the initial pheromone is the same for the all arcs of the graph representing the problem. After every iteration, the pheromone levels are updated (in all arcs; in arcs traveled by the ant the pheromone level is increasing, while in abandoned arcs it it evaporating). As the result, the elements representing better solutions receive more pheromone than others and become more desirable in a next iteration. In our hybrid algorithm the solutions constructed (proposed) by the GA are treated as solutions achieved by the ACO in some previous iteration, and we use them to specify the initial pheromone level in the solution graph. After that we search for the solution using the ACO algorithm. The structure of the proposed hybrid GA-ACO algorithm is shown by the pseudo-code in Figure 6.

V. Numerical Results and Discussion

The theoretical background of the GA and the ACO is presented in details[24]. For the considered here model problem of parameter identification, we used real-value coded GA instead binary encoding. Therefore the basic operators in the applied GA are as follows:

- encoding – real-value,
- fitness function – linear ranking,
- selection function – roulette wheel selection,
- crossover function – extended intermediate recombination,
- mutation function – real-value mutation,

Final solution

Fig. 6. Pseudocode for Hybrid GA-ACO

- reinsertion – fitness-based.

In the applied ACO algorithm, the problem is represented by graph and the artificial ants try to construct the shortest path (under specified conditions). In our case the graph of the problem is represented by three partity graph. There are not arcs inside a level and there are arcs between (three) levels. Every level corresponds to one of the model parameters we identify (μ_{max}, k_S and $Y_{S/X}$). Every level consists of 1000 vertexes, which corresponds to 1000 uniformly distributed points in the domain (interval) of every one of the considered model parameters. The pheromone is positioned on the arcs. The ants create a solution starting from random node from the first level. They chose nodes from other levels applying the probabilistic rule. In this application the probabilistic rule uses only the pheromone value. We can think that the heuristic information is constant. Thus the ants will prefer the nodes with maximal quantity of the pheromone.

To set the optimal settings of the GA and the ACO algorithms parameters, we performed several runs of the algorithms with varying parameters, according to the considered here optimization problem. The resulting optimal settings of the GA and the ACO parameters are summarized in Table I and in Table II.

The computer, used to run all identification procedures, was an Intel Core i5-2329 3.0 GHz, with 8 GB Memory, Windows 7 (64bit) operating system and Matlab 7.5 environment.

We performed 30 independent runs of the hybrid GA-ACO. The hybrid algorithm started with population of 20 chromosomes. We used 40 generations to find the initial solution. Next, we took the achieved best GA solution to specify the ACO initial pheromones. Next, the ACO was used to obtain the best model parameters vector using 20 ants for 100 generations (see, Table III).

For comparison of performance of the hybrid algorithm we used the pure GA and the pure ACO. They were run (30 times) with (optimized) parameters shown in Table I and in Table II.

The main numerical results, obtained when solving the parameter identification problem, are summarized in Table IV. In this table we show the best, worst and average values of the objective function achieved by the pure ACO, the pure GA and the hybrid GA-ACO algorithms after 30 run of every one of them, as well as their running times. The obtained average values of the model parameters (μ_{max}, k_S and $Y_{S/X}$) are summarized in Table V.

As it can be seen, from Table IV, the hybrid GA-ACO achieves values of the objective function that are similar to these obtained by the pure GA and the pure ACO algorithms. In the same time, the running time of the proposed hybrid algorithm is about two times shorter. The pure ACO algorithm starts with an equal initial pheromone distribution for all problem elements. In the case of the hybrid GA-ACO we use the best solution found by the GA to specify the initial distribution of the pheromone (used by the ACO). Thus our ACO algorithm uses the GA "experience" and starts from a "better" pheromone distribution. This strategy helps the ants

	ACO	69.5379	5.5903
	GA-ACO	39.4620	4.5706

to find "good solutions" using less computational resources (e.g. like computer time and memory). As a matter of fact, our hybrid algorithm uses more than three times less memory than the pure ACO and the pure GA algorithms.

In Table VI we compare results achieved in current work with results obtained in our earlier work [32]. There, we had run the ACO algorithm for several iterations and used it to generate an initial populations for the GA algorithm. Thus the GA started from a population that was closer to the good (optimal) solution than a randomly generated population. We observe that the ACO-GA and the GA-ACO algorithms achieve very similar results, and in a similar running time. We run the ANOVA test to measure the relative difference between the two algorithms. The two hybrid algorithms achieves statistically equivalent results, but the GA-ACO algorithm uses 30% less memory. Thus we can conclude that hybrid GA-ACO algorithm performs better than the ACO-GA hybrid algorithm.

best	35.5212	4.4903
worst	41.4495	4.6865
average	36.1313	4.5765

In Figure 7, the comparison of the dynamics of measured and modeled biomass concentration is shown. With a solid line we show the modeled biomass during the fermentation process, while with stars we show the measured biomass concentration. We put only several stars because the two line are almost overlapped. In Figure 8 the comparison between the time profiles of measured and modeled substrate concentration, during the fermentation process, is shown. On both figures we observe how close are the modeled and the measured data. Thus we illustrate the quality of our hybrid GA-ACO algorithm.

VI. CONCLUSION

In this paper we propose a hybrid GA-ACO algorithm for parameter identification of the *E. coli* fed-batch fermentation process. In the proposed approach, first, we start the GA for several generations with a small population. Next, we use the best solution found by the GA, to instantiate the initial pheromone distribution for the ACO algorithm. We observe that our hybrid GA-ACO algorithm achieves results similar to the pure GA and the pure ACO algorithms, but it is using less computational resources (time and memory). The used time is two times smaller while the used memory is three times smaller. With this algorithm we understand how important is the pheromone distribution for good performance of the ACO algorithm. We compare our hybrid GA-ACO approach, with a hybrid ACO-GA algorithm. Both hybrid algorithms

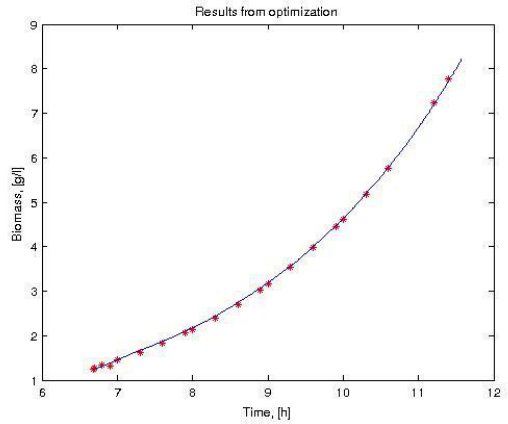

Fig. 7. *E. coli* fed-batch fermentation process: comparison between measured and modeled biomass concentration

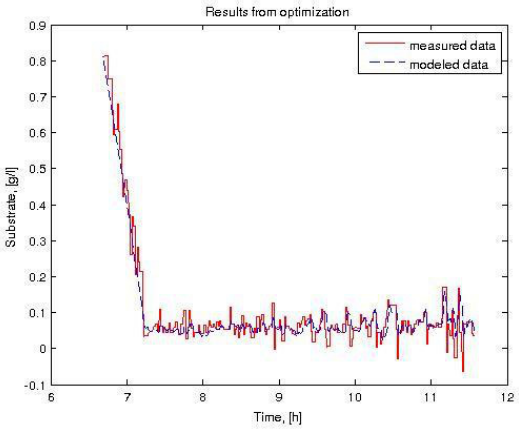

Fig. 8. *E. coli* fed-batch fermentation process: comparison between measured and modeled substrate concentration

achieve statistically similar results for a similar running time, but GA-ACO algorithm uses about 30% less memory, which is important when one is to solve large problems.

***Abstract*—In this paper we propose to enhance a width-beam search in order to solve the three-dimensional sphere packing problem. The goal of the problem is to determine the minimum length of the container having fixed width and height, that packs *n* predefined unequal spheres. The width-beam search uses a greedy selection phase which determines a subset of eligible positions for packing the predefined items in the target object and selects a subset of nodes for exploring some promising paths. We propose to handle lower bounds in the tree and apply a hill-climbing strategy in order to diversify the search process. The performance of the proposed method is evaluated on benchmark instances taken from the literature. The obtained results are compared to those reached by some recent methods available in the literature. Encouraging results have been obtained.**

***Index Terms*—Beam; Heuristic; Hill-Climbing; Optimization; Packing.**

I. Introduction

THIS paper deals with the *Three-Dimensional Sphere Packing Problem* (noted 3DSPP), where an instance of such a problem is defined by a set I of n unequal items and an object $\mathcal{P}$ having fixed width W and height H and, unlimited length (another representation for similar problems can be found in Wascher *et al*. [20]). In this case, each item $i \in I = \{1, \ldots, n\}$ is characterized by its radius r_i and the goal of the problem is to minimize the length, denoted L, of the object $\mathcal{P}$ such that all items of I are packed in the target object, without overlapping. The 3DSPP may be formulated as follows:

$$\min \quad L \tag{1}$$
$$(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2 \geq (r_i + r_j)^2 \tag{2}$$
$$\forall (i,j) \in I \times I,\ i < j$$
$$r_i \leq x_i \leq L - r_i, \forall i \in I \tag{3}$$
$$r_i \leq y_i \leq H - r_i, \forall i \in I \tag{4}$$
$$r_i \leq z_i \leq W - r_i, \forall i \in I \tag{5}$$
$$\underline{L} \leq L \leq \overline{L} \tag{6}$$
$$(x_i, y_i, z_i) \in \mathbb{R}^3_+, \forall i \in I \tag{7}$$

where the objective function (1) minimizes the length of the object $\mathcal{P}$ containing all the items of I, Eq. (2) ensures the non-overlap constraint of any pair of distinct items *(i, j)* of $I \times I$; that is, the distance between the centers of both items which must be greater than or equal to the sum of their radii and Eqs (3)-(5) ensure that all items of I belong to the target object $\mathcal{P}$ of dimensions *(L, W, H)* and Eq. (7) ensures that all items are placed in the object $\mathcal{P}$. Also, it is easy to start any approach by a trivial value representing the sum of the spheres' area affected to $\underline{L}$ (Eq. (6)) and a feasible solution value, that can be obtained by applying a simple greedy procedure, affected to $\overline{L}$.

In this paper, we propose new strategies in order to enhance a width-beam search based algorithm already proposed in Hifi and Yousef [8]. First, we introduce a new greedy strategy in order to generate some eligible nodes. Second, we propose to curtail the search process by estimating a global lower bound. Third ans last, a hill-climbing strategy is used in order to correct the global lower bound and to select some nodes realizing highest potentials able to reach better solutions.

The remainder of the paper is organized as follows. Section II gives a literature review for the 3DSPP and some of its variants. The problem representation is discussed in Section III-A. The greedy selection phase, which serves to determining a subset of eligible positions for predefined items to pack, is detailed in Section III-B. A modified version of the algorithm is described in Section III-D, where a lower bound is used for exploring better paths that diversify the search. Moreover, because of the huge number of feasible positions that a predefined item may generate, both beam width and hill-climbing strategies cooperate for selecting the best promising nodes at the same level of the developed tree. Section IV evaluates the performance of the proposed algorithm and compares its produced results to those reached by the original width-beam search and recent methods available in the literature. Finally, Section V concludes by summarizing the contribution of this paper.

II. Related works

The 3DSPP belongs to the well-known family of Cutting and Packing (CP) that represents a natural combinatorial optimization problems. Problems of CP family admit numerous real-world applications in the domain of industrial engineering, logistics, manufacturing, production process, automated planning, etc. One of the more recent paper addressing an optimization with a packing problem is due to Sutou and Dai [18], where the unequal sphere problem has been used for tackling an application of the automated radio-surgical treatment planning. Wang [19] has also considered sphere packing problems as an optimization tool for the radio-surgical

treatment planning. Other problems of the CP family have been described and redefined in Wascher *et al.* [20] where an instance of these problems can be defined by a set of predetermined items to be packed in one or many larger containers (objects) so as to minimize the unused area / space or in some cases to maximize a utility function. Furthermore, the items are bounded by their dimensions (rectangular, circular, or irregular) and the objects can be bounded (rectangular, circular, ...) or unbounded (strips / parallelepipeds, ...).

Among existing papers addressing sphere packing problems, Lochmann *et al*. [12] proposed a statistical analysis for packing random spheres with variable radius distribution. Li and Ji [11] discussed a dynamics-based collective method for random sphere packing and they tried to apply it to the problem of packing sphere into a cylinder container. In this paper, the stability of the method and its convergence were tackled. Farr [3] studied the problem of random close packing fractions of log-normal distributions of hard spheres. The author tailored a one-directional approach in order to predict a close packing of spheres of log-normal distributions of sphere sizes.

Packing spheres into a container has been addressed by Sutou and Dai [18] who proposed a global optimization approach. Stoyan *et al.* [17] designed a mathematical model in order to pack spheres into an open container, where both height and widths are fixed whereas the length is unfixed. They use a neighboring search based upon extremum points in order to construct and improve a series of solutions. M'Hallah *et al.* [13] proposed a heuristic based on combining VNS with nonlinear programming solver. The method iterates some moves of the current configuration and complete the partial configuration with a solver dedicated for nonlinear programmes. M'Hallah and Alkandari [14] considered the principle used in [13] to solve the problem of packing identical spheres into the smallest containing sphere. Soontrapa and Chen [16] tackled the problem of packing identical spheres into a smallest containing sphere by using a random search according to Monte Carlo's method. Birgin and Sobral [1] proposed twice-differentiable non-linear programming models for the problem of packing both circles and spheres into different containers where the containers may be circular, rectangular, etc. In order to find a global solution for their proposed models, ALGENCAN solver was used for generating a multiple starts solutions. Finally, Hifi and Yousef [8] investigated the use of a dichotomous search for solving the three-dimensional sphere packing problem (an extensive efficient models and methods for packing both circular and sphere problems were reviewed in Hifi and M'Hallah [4]).

In this paper, we propose to enhance the algorithm proposed in Hifi and Yousef [8] by considering three modifications: (i) considering a modified greedy strategy in order to generate eligible nodes, (ii) an estimation of the global lower bound for curtailing the search process and, (iii) the hill-climbing used for correcting the global lower bound and selecting only some nodes with highest potentials.

III. A WIDTH-BEAM SEARCH FOR 3DSPP

In this part, the problem representation and strategies used are first described in Secsion III-A. Second, Section III-B describes the greedy procedure in order to build feasible packings containing all items of I. Third, Section III-C discusses the principle of the proposed algorithm and its main steps. Fourth and last, Section III-D presents the modifications used for enhancing the algorithm.

A. Representation of the problem

The local strategy is based on the simple Greedy Principle (called GP) where the minimum distance position is favored for packing a series of predefined items. GP is then used as the first evaluation operator for finding a subset of possible positions of the next item to pack. Such a procedure uses the following notations:

- The bottom-left-depth corner of $\mathcal{P}$ is positioned at $(0, 0, 0)$ and $\mathcal{P}$ is characterized by a set formed with six labels (namely faces): $\mathbb{F} = \{\text{left}, \text{top}, \text{right}, \text{bottom}, \text{depth}, \text{front}\}$. Then, $\mathcal{P}$ is represented in the Euclidean space, as illustrated in Figure 1.
- The center of the i-th item belonging to I is positioned at (x_i, y_i, z_i).
- The distance $\delta_{i,j}$ between two items i and j is computed as follows: $\forall (i, j) \in I^2$,

$$\delta_{i,j} = \sqrt{(x_i - x_j)^2 + (y_i - y_j)^2 + (z_i - z_j)^2} - (r_i + r_j).$$

Note that assigning an item $i \in I$ to a possible position of $\mathcal{P}$ while respecting non-overlapping between this item and the left-face of $\mathcal{P}$ requires to satisfy the following distance: $\delta_{i,\text{left}} = x_i - r_i$. For more general cases, Table I reports the distance to be satisfied whenever an item i is assigned to a selected position of $\mathcal{P}$.

TABLE I
THE DISTANCE BETWEEN AN ITEM i AND A FACE f

f	$\delta_{i,f} \mid i \in I,\ f \in \mathbb{F}$
left	$x_i - r_i$
bottom	$y_i - r_i$
depth	$z_i - r_i$
right	$L - x_i - r_i$
top	$H - y_i - r_i$
front	$W - z_i - r_i$

B. Defining eligible positions

It is well-known that tailored heuristics are mainly based on the strategies which are able to guide well the search process. These strategies may be use some selection criteria in order to provide either partial or final solutions for the problem to solve. Herein, we consider a simple greedy principle (GP) which is based on searching the position realizing the minimum distance position between items and feces. In fact, GP is used as a selection criterion for defining a set of eligible positions to assign to the predefined item i (not

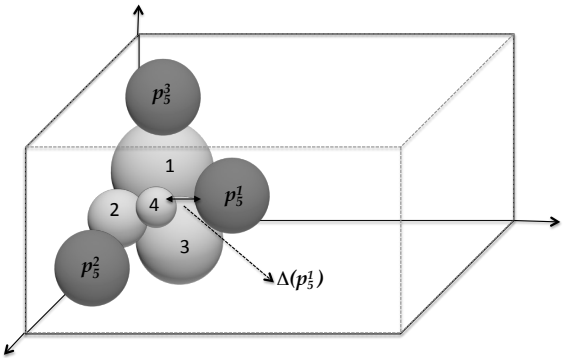

Fig. 1. Illustration of the mechanism used for computing eligible positions considered by GP.

already positioned) among all eligible positions representing the set P_{I_i}.

In what follows, we assume that the (center of the) first item $i = 1$ of I is positioned at the position (r_1, r_1, r_1) and $\forall i \in I,\ i \geq 2$, the following notations are considered:

- I_i denotes the set of items of I already positioned in the current object $\mathcal{P}$.
- $\overline{I_i}$ contains the items of I which are not yet assigned to $\mathcal{P}$.
- P_{I_i} denotes the set of distinct eligible positions for the next item i to pack given the set of packed items I_i.
- An eligible position $p_{i+1} \in P_{I_i}$ (for the item i) is determined by using three elements $e_1,\ e_2$ and e_3 where an element is either an item of I already positioned (representing the set I_i) or one of the six faces belonging to $\mathbb{F}$.
- $\mathcal{T}_{p_{i+1}}$ represents the set composed of the three elements $e_1,\ e_2$ and e_3.

Figure 1 illustrates GP's mechanism on a small example. For this example, assume that the first four items are already positioned in the object $\mathcal{P}$; then, there are three eligible positions that emerge for the next item 5 to pack. Following the above notations, $I_4 = \{1, 2, 3, 4\}$ and $P_{I_4} = \{p_5^j,\ j = 1, \ldots, 3\}$. First, the position p_5^1 touches both items 1 and 3 and, the "bottom" face of $\mathcal{P}$. Second, the position p_5^2 is obtained by using the item 2 and both faces "left" and "bottom" of $\mathcal{P}$. Third and last, the position p_5^3 is computed by using the item 1 and both faces "left" and "depth" of $\mathcal{P}$. Finally, it follows that $\mathcal{T}_{p_5^1} = \{1, 2, \text{bottom}\}$, $\mathcal{T}_{p_5^2} = \{2, \text{left}, \text{bottom}\}$ and $\mathcal{T}_{p_5^3} = \{1, \text{left}, \text{depth}\}$. Further, item 4 is positioned around the three items 1, 2 and 3 that means $\mathcal{T}_4 = \{1, 2, 3\}$. For the next item 5 to pack, its coordinates are computed by using both items 1 and 3 and one of the faces (the "bottom" in this case) of $\mathcal{P}$ that gives $\mathcal{T}_5 = \{1, 3, \text{bottom}\}$. We recall that the objective of the problem is to minimize the length of the target object $\mathcal{P}$. It means that the right face of $\mathcal{P}$ can be omitted and only the five faces can be considered when optimizing the length of the target $\mathcal{P}$. Hence, all eligible positions may be obtained by using the fifth faces, the positioned items and the current item to pack.

Then, the value corresponding to the $(i+1)$-th item to pack, when positioned at the eligible position $p_{i+1}^k \in P_{I_i}$ by GP, is computed as follows

$$\Delta(p_{i+1}^k) = \min_{j \in I_i \cup \mathbb{F}''} \delta_{(i+1,j)} \tag{1}$$

where $\mathbb{F}' = \mathbb{F} \setminus \{\text{right}\}$ and $\mathbb{F}'' = \mathbb{F}' \setminus \mathcal{T}_{p_{i+1}^k}$.

Finally, when GP is used, it starts by positioning the first item $i = 1$ at the bottom-left-depth position, i.e., at the position (r_1, r_1, r_1), while the remaining $n - 1$ items are successively positioned according to the minimum distance rule (cf., Eq. (1)). As illustrated in Figure 1, the item 5 will be placed at position p_5^1 because its corresponding distance realizes the minimum value.

C. A width-beam search heuristic for the 3DSPP

Beam Search (BS) has been first proposed in [15] for tackling the scheduling problem and it has since been successfully applied to many other combinatorial optimization problems (some adaptations can be found in Della Croce *et al.* [2], Hifi *et al.* [5], [6], [7] and, Yavuza [21]). Such an approach can be viewed as a truncated tree search procedure where its objective is to avoid exhaustive search by performing a partial enumeration of the solution space.

1) Packing all items on the target object: At each level of the developed tree, only a subset of nodes (called the *set of elite nodes*) are selected for further branching and the other nodes are discarded, where no backtracking is performed. For each level, the cardinality of the elite nodes to be investigated is fixed to ω that is called the *beam width*. Generally, these selected ω nodes represent those having a high potential to lead the best solutions for the treated problem. Furthermore, each node is assessed via an *evaluation function* whose role is to provide a promising separation mechanism of the nodes of each level of the developed tree.

As observed in Hifi and Yousef [8], applying BS to 3DSPP required to define the nodes of the tree and the branching mechanism out of the nodes of B. Herein, a node η_i is represented by the pair of subsets:

1) The first subset I_i containing all items assigned to the target object $\mathcal{P}$ and,
2) The complementary subset $\overline{I}_i$ containing the unassigned items.

Moreover, branching out of a node η_i is equivalent to create at most $|P_{I_i}|$ branches emanating out of the current node (related to the eligible positions as described in Section III-B). Each resulting node corresponds to packing the subset of items I_i and assigning to the current item i a favorite eligible position. Moreover, each of these created nodes will be represented by a pair of two complementary subsets of items of I. Further, in order to explore a reasonable number of nodes, a width-beam search almost of the standard beam search has been

used in Hifi and Yousef [8]. Therefore, all nodes emanating from the same level are simultaneously evaluated following an estimator operator and only the best ones are selected for the rest of the search.

Such a process is described by the main steps of Algorithm 1, where it works according to a given node, namely η^ℓ. This node is the one taken at the level ℓ of the developed tree. Thereafter, the initialization step is applied for starting the set B containing the best provided nodes regarding the starting node η^ℓ (lines 1 to 3), the initialization of the variable `feasible` to false (line 4) and, fixing the runtime limit $t_{\max}$ (line 5) for which the algorithm stops when that time is performed (in this case, the control parameter t_{iter}, for the limit $t_{\max}$, is initialized to zero). Note that the variable `feasible` is used for controlling the (un)feasibility of the series of the solutions builded. The main loop (line 7) starts by choosing the best eligible positions for each node belonging to B. These positions are computed by using GP's selection (cf., Section III-B). Second, all created nodes are stored in a provisional set B_ω where the potential of each of these nodes are evaluated according to the final solution provided by iteratively applying GP as a heuristic (cf. as discussed in the last paragraph of Section III-B). Thereafter, for each final solution (either feasible or unfeasible for the target object $\mathcal{P}$), the potential of a node $\eta \in B_\omega$ is represented by the *density of the positioned items* in $\mathcal{P}$. Whenever one of these constructed solutions provides a feasible solution (line 11), i.e., all items are positioned in the target object $\mathcal{P}$, then the algorithm stops with a feasible solution (i.e., setting the variable `feasible` to true). Otherwise, the set B of the best nodes is updated (line 12) by the ω nodes which realizing the highest densities and the current level of the developed tree is incremented. The internal runtime t_{iter} is then incremented and the process is iterated until either B is reduced to an empty set or when $t_{\max}$, the limited runtime, is performed, i.e., $t_{\text{iter}} \geq t_{\max}$.

Algorithm 1 . Beam Search for the 3DSPP: BS

Input. A node η^ℓ.
Output.`feasible` // setting equal to `true` whenever a feasible packing is reached, `false` otherwise

1: **Initialization Step.**
2: Let ω be a predefined beam width.
3: Set $B = \{\eta^\ell\}$, where η^ℓ denotes the input node associated to the ℓ-th level.
4: Set the variable `feasible` to `false` /* no feasible solution at hand */
5: Let $t_{\max}$ be a maximum fixed runtime and t_{iter} (initialized to 0) be a counter which serves to control the time spent for exploration the space search.
6: **Iterative Step.**
7: **while** $\Big((B \neq \emptyset)$ and $(t_{\text{iter}} < t_{\max})\Big)$ **do**
8: Branch from the current level ℓ by selecting the ω eligible positions for each node $\eta_{\ell_i} \in B$;
9: Insert all obtained nodes into B_ω;
10: Evaluate the potential of each node belonging to B_ω using GP for completing the path.
11: If a feasible solution is given by GP, then set `feasible` to `true` and **exit**;
12: Replace B by the best ω nodes of B_ω realizing highest densities and, increment the level ℓ.
13: Update the current runtime t_{iter}.
14: **end while**

Algorithm 2 . A Dichotomous Search Based Heuristic: DSBH

Input. An instance of 3DSPP.
Output.An object $\mathcal{P}$ of dimensions (L_{best}, W, H) and the coordinates of all items of I.

1: **Initialization step**
2: Call an iterative GP on the open strip (∞, W, H) and let $\overline{L}$ be the starting length reached.
3: Set $\underline{L} \leftarrow \frac{4\pi}{3\times W\times H}\sum_{i\in N}(r_i^3)$ and $L^\star = \overline{L}$.
4: Set ω to a predefined minimum value.
5: **Iterative step**
6: **while** $\Big($the runtime limit is not performed$\Big)$ **do**
7: **repeat**
8: $L^\star = (\overline{L} + \underline{L})/2$
9: Generate the starting node η^1 with its three sets I_i, $\overline{I}_i$ and P_I^1.
10: Set `feasible` $\longleftarrow$ BS(η^1), where BS is called with $(L^\star, W, H)$
11: **If** $\Big($`feasible=true`$\Big)$ **then** set $\overline{L} = L^\star$; $\underline{L} = L^\star$ otherwise
12: **until** $(\overline{L} - \underline{L} \geq \alpha)$
13: Set $\underline{L} \leftarrow \frac{4\pi}{3\times W\times H}\sum_{i\in N}(r_i^3)$ and increment ω.
14: **end while**

2) Using a dichotomous search: Because Algorithm 1 is applied on the target container $\mathcal{P}$, then one can repeat the same principle on a series of target containers $\mathcal{P}_1, \ldots, \mathcal{P}_r$, where $r \geq 1$. Indeed, one can starts the search with the initial interval $[\underline{L}, \overline{L}]$, where $\underline{L}$ denotes a lower bound for the 3DSPP and $\overline{L}$ its upper bound (in the case of a feasible solution exists, its objective value is assigned to $\overline{L}$). Then, for each fixed interval, Algorithm 1 tries to construct the best feasible solution by packing all the items into the current target object; that is, $(L^\star, W, H)$, where $L^\star \in [\underline{L}, \overline{L}]$.

The main steps of the dichotomous search are summarized in Algorithm 2. First, it starts by defining the initial interval $[\underline{L}, \overline{L}]$ where the upper bound $\overline{L}$ is obtained by applying GP as a heuristic on the open object, i.e., (∞, W, H). The main loop "repeat ... until" (cf., lines 7 - 12) of the dichotomous procedure serves to explore a series of neighborhoods depending on the values of ω. At line 8, a new target upper bound is computed, namely $L^\star = (\overline{L}+\underline{L})/2$. Line 9 generates the initial node positioned at the bottom-left-depth corner (in the position (r_1, r_1, r_1)) and creates its corresponding sets I_i, $\overline{I}_i$ and P_I^1 (as discussed in Section III-B). At line 10, BS is called with the target value of the object $(L^\star, W, H)$ and the created sets reached at the next step. Line 11 serves to update the interval search where its upper bound is updated whenever a feasible solution is obtained, the lower bound is updated otherwise. Thereafter, the process is iterated untill the gap between both lower and upper bounds becomes closest to a certain tolerance, namely α. Finally, the aforementioned process is iterated a certain number of times following the values of ω (line 13) and according to the runtime limit fixed.

D. A modified version of the width-beam search for 3DSPP

We first describe the modified GP that tries to generate some interesting eligible positions. Second and last, we introduce the lower bound in order to curtail the search; this upper bound cooperates with both hill-climbing strategy and beam width strategies in order to select future nodes for branching.

1) A modified GP: The Modified GP (MGP) provides other eligible positions able to homogeneously concentrate a subset of items on the target object. Return now to Figure 1 and observe the candidate positions of item p_5: any eligible position induces a packing concentrated on the bottom-left-depth position. By applying this principle to the instance SYS1 (one of the instances tested in Section IV), one can observe that all packed items are focused on the starting position that leaves the other parts of the object sufficiently empty.

Herein, we first propose to modify such a placement by adding three corner positions whenever all eligible positions for a selected item to pack; that are $\mathcal{T}_{p_2^4} = \{\text{top}, \text{depth}, \text{left}\}$, $\mathcal{T}_{p_2^5} = \{\text{top}, \text{left}, \text{front}\}$ and $\mathcal{T}_{p_2^6} = \{\text{bottom}, \text{left}, \text{front}\}$.

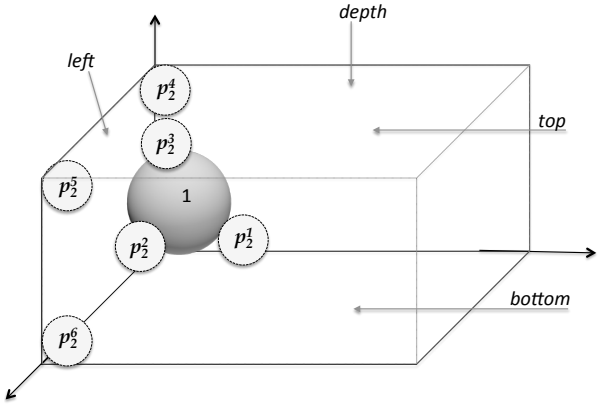

Fig. 2. Illustration of MGP's eligible positions.

Figure 2, where we assume that the first item is already positioned in the object $\mathcal{P}$, shows six eligible positions that emerge for the next item 2 to pack. According to the representation described above, $I_1 = \{1\}$ and $P_{I_2} = \{p_2^j,\ j = 1, \ldots, 6\}$. First, the position p_2^1 touches the item 1 and both faces "depth" and "bottom" of $\mathcal{P}$. Second, the position p_1^2 is obtained by using the item 1 and both faces "left" and "bottom" of $\mathcal{P}$. Third, the position p_1^3 is computed by using the item 1 and both faces "left" and "depth" of $\mathcal{P}$. Finally, all other positions touch three faces of $\mathcal{P}$. It follows that $\mathcal{T}_{p_2^1} = \{1, \text{depth}, \text{bottom}\}$, $\mathcal{T}_{p_2^2} = \{1, \text{left}, \text{bottom}\}$, $\mathcal{T}_{p_2^3} = \{1, \text{left}, \text{depth}\}$, $\mathcal{T}_{p_2^4} = \{\text{top}, \text{left}, \text{depth}\}$, $\mathcal{T}_{p_2^5} = \{\text{top}, \text{left}, \text{front}\}$ and $\mathcal{T}_{p_2^6} = \{\text{bottom}, \text{left}, \text{front}\}$.

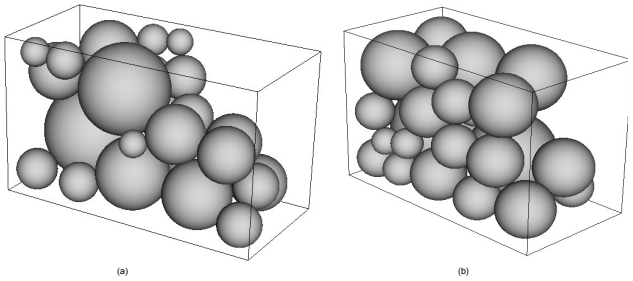

Fig. 3. Illustration of (a) GP's behavior and (b) its modified version MGP's on SYS1 instance.

On the one hand, as illustrated in Figure 2, the item 2 can be packed at one of the six positions $p_2^j,\ j = 1, \ldots, 6$, and if the smallest distance to the left side of $\mathcal{P}$ is favored, then five positions remains favorable (cf., Figure 3.(a)). In this case GP provides an object of length equal to 11.51. On the other hand, If such a principle is applied, from Figure 3.(b) and for the same instance, one can observe the improvement made on the packing which at the same time produces a better length (10.49 in this case) for the target object.

E. Using the hill-climbing strategy

Hill-Climbing (HC) can be used as a curtailing strategy for avoiding exhaustive search. In this case, the search process may perform a partial enumeration of the solution space, where in term of tree, only a subset of paths are taken for further branchings and the other nodes are discarded. Further, each selected node is assessed via its evaluation function whose role is to provide a promising separation mechanism of the nodes. In our study, we introduce the HC strategy that is used for avoiding exhaustive search that is equivalent to an augmented beam search (Hifi *et al.* [7] and Yavuza [21])), where a subset of paths are taken for further branchings and the other nodes are discarded. At each step of the search procedure, a node η is selected and after evaluating all its successors, only the best ω nodes are chosen for further branchings. Each selected node is assessed via its evaluation function whose role is to provide a promising separation mechanism of the nodes.

Algorithm 3 describes a modified BS (noted MBS) where MBS replaces BS in the dichotomous search DSBH (cf., Algorithm 2, which also noted MDSBH for the modified DSBH). We recall that a node corresponds to a partial solution at level $\ell \leq n-1$ and the set B of current nodes contains initially the starting nodes of the root node B_0, whereas B_ω containing the offspring nodes is initialized to the empty set.

Algorithm 3 . A Modified BS (MBS)

Input. A set of items I and a predefined length l_{best}.
Output. `feasible`..

1: **Initialization Step.**
2: Let ω and ϵ be two predefined values.
3: Set $B = B_0$, where B_0 denotes the starting eligible nodes according to the first packed item $i = 1$.
4: Set the level $\ell = 1$ and $B\ell = \emptyset$.
5: Set the variable `feasible` to `false` /* no feasible solution at hand */
6: **Iterative Step.**
7: **while** $\Big((B \neq \emptyset)$ and (the runtime limit is not performed) and $(\ell < n)\Big)$ **do**
8: **for** each $\eta \in B$ **do**
9: Let $B_\eta = \{\gamma_1, \ldots, \gamma_{|P_{I_\eta}|}\}$ be the successors of η.
10: Evaluate the potential of each node γ belonging to B_η by computing $g(\gamma)$ and $h'(\gamma)$.
11: For each $\gamma \in B_\eta$ apply ISBH$(\gamma, L^\star)$ and update $L^\star$ if necessary with the incumbent solution.
12: Set $B_\ell = B_\ell \cup B_\eta$;
13: **end for**
14: Filter B_ℓ by keeping the ω best nodes realizing the smallest values of $L^\star / \big(g(\gamma) + h'(\gamma)\big)$.
15: Replace all the nodes of B by those of B_ℓ, increment ℓ and set $B_\ell = \emptyset$.
16: **end while**

On the one hand, a selected node η taken from B (step 7), whose evaluation is z_η, creates a subset of nodes $B_\eta =$

$\{\gamma_1, \ldots, \gamma_{|P_{I_\eta}|}\}$, where each resulting node is evaluated according to its *cost operator*; that is,

$$z_\eta = g(\eta) + h(\eta).$$

On the other hand, because $|P_{I_\eta}|$ is large, only some nodes are chosen for further branchings. Indeed (line 9), if a node γ of B_η packs at most $n-1$ items, then it remains in B_η when $z'(\gamma) < z^\star$, such that

$$z'(\gamma) = g(\eta) + h'(\eta) \quad (2)$$

where $h'(\eta) = (1+\epsilon)h(\eta)$ and ϵ is considered as a small predefined value that is used for making a correction on the complementary lower bound $h(\eta)$. Whenever Eq. (2) is not satisfied, then γ is removed from B_η.

Further, since we try to diversify the search that allows for exploring new solutions, we apply BGP on all selected nodes (line 10). Then, $L^\star$ is updated whenever BGP produces a better length; in this case, its corresponding incumbent solution is also updated. The rest of the nodes belonging to B_η (line 11) are reordered in nondecreasing order of their estimated lower bound $z'(\gamma)$ and only the best ω nodes are selected and becomes the new nodes of B for further branchings. This process is iterated until no further branching is possible, i.e., until $B = \emptyset$, or the last level is equal to n, or when the fixed runtime limit is performed. Note also that, at lines 9 and 10, if a node γ of B_η is a leaf (i.e, no further branching is possible out of γ), then its objective function value z_γ is computed and compared to $z^\star$. If $z_\gamma < z^\star$, then the incumbent solution is set to a leaf node; $z^\star$ is then updated: $z^\star = z_\gamma$; and γ is removed from B_η.

IV. Computational results

In this section we investigate the effectiveness of the modified width beam search-based heuristic (noted MDSBH) on two sets of benchmark instances: Set1 and Set2. The proposed algorithm was coded in C++ and tested on an Intel Core 2 Duo (2.53 Ghz and with 4 Gb of RAM) and the runtime limit was fixed to one hour.

The first set "Set1" contains six instances (SYS1, ..., SYS6) extracted from Stoyan *et al.* [17], where the number of the predefined items varies from 25 to 60. These instances have been already tested using Stoyan *et al.*'s [17], Birgin and Sobral's [1] and Kubach *et al.*'s [10] approaches.

The second set "Set2" contains six instances (KBTG1, KBTG2, KBTG3, KBTG7, KBTG8, and KBTG9) taken from Kubach *et al.* [10]. For each instance, both dimensions W and H of the object are fixed to 10 whereas the number of the predefined items is fixed to 30 (resp. 50) for the first (resp. last) three instances. Moreover, these six instances have been already tested in Kubach *et al.* [10] where they represent the six instances with unequal spheres.

A. Performance of MDSBH vs five heuristics: Set1

Generally, when using approximate algorithms to solve optimization problems, it is well-known that different parameter settings for the approach lead to results of variable quality. As discussed in Section III-D, MDSBH considers three parameters: the beam width ω, the value of ϵ used for correcting the value of the global lower bound and the maximum runtime limit to fix. Our computational study was conducted by varying ω in the discrete interval $\{5, 6, 7, \ldots\}$, the maximum runtime limit was fixed to 3600 seconds (which can be considered as a standard runtime limit considered by algorithms of the literature) and ϵ which takes one of the following values: $0.1,\ 0.2$ and 0.3. Of course, the upper value of ω depends on the limited runtime and the size of the instance.

In order to show the effect of these parameters, we first discuss the quality of the solutions obtained by MDSBH when varying the value of ϵ. Table II shows MDSBH's objective values when varying ϵ from 0.1 to 0.3. From Table II, we observe that MDSBH with $\epsilon = 0.2$ provides better average results since it realizes a value of 9.939 compared to both values 9.957 and 9.961, which corresponds to $\epsilon = 0.1$ and $\epsilon = 0.3$, respectively.

	MDSBSs' solutions when varying ϵ

TABLE II
Behavior of MDSBH, when varying ϵ, on the instances of Set1.

Figure 4 illustrates the configurations realized by MDSBH for instance SYS1. Hence, for the rest of the paper, $\epsilon = 0.2$ is chosen for evaluating the performance of MDSBH on all benchmark instances of the literature.

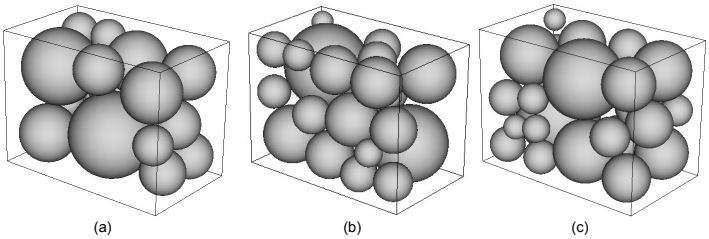

Fig. 4. SYS1 solutions (with MDSBH) when varying ϵ: (a) $\epsilon = 0.1$ with length $L^\star = 9.1946$, (b) $\epsilon = 0.2$ with length $L^\star = 9.1796$, and, (c) $\epsilon = 0.3$ with length $L^\star = 10.9001$.

Second, for the instances of Set1, Table III compares the results of MDSBH to those reached by five algorithms: SYS (Stoyan *et al.* [17]), BSA (Birgin and Sobral [1]), KBTG$_s$ (Kubach *et al.* [10]), its parallel version noted KBTG$_p$ (proposed in Kubach *et al.* [9]), where the known solutions of the literature are taken from Kubach *et al.* [9], [10] and HY (Hifi and Yousef [8]).
Column 1 of Table III shows the instance label, Column 2 displays the objective value $L^\star_{\rm SYS}$ realized by STS whereas column 3 displays BSA's objective value (noted $L^\star_{\rm BSA}$).

TABLE IV
PERCENTAGE IMPROVEMENTS BETWEEN ALL TESTED HEURISTICS: MDSBH, HY, SYS, BSA AND BOTH KBTG$_s$ AND KBTG$_p$ ON INSTANCES OF SET1.

The analysis of the results of both Tables III and IV follows:

1) First, MDSBH outperforms the five algorithms SYS, BSA, KBTG$_s$, KBTG$_p$ and HY. Indeed, it is able to reach the best solutions for all instances of Set1.
2) Second, when comparing MDSBHs' results to those reached by SYS, one can observe that the percentage of the improvement varies from 6.45% (instance SYS5) to 8.47% (instance SYS3). This percentage improvement remains interesting when comparing MDSBHs' results to those reached by BSA: in this case, such improvement varies from 6.24% (instance SYS5) to 8.07% (instance SYS4).
3) Third, the improvement remains positive when comparing MDSBH's results to those provided by the sequential (resp. parallel) KBTG algorithm. Indeed, the improvement when compared to the sequential version varies from 1.16% (instance SYS1) to 6.20% (SYS4) whereas it varies from 0.39 (instance SYS6) to 1.95% (instance SYS4) when compared to the parallel version.
4) Fourth and last, MDSBH realizes better results than those reached by HY; in this case, the percentage improvement varies from 0.20% (instance SYS6) to 0.69% (instance SYS1).

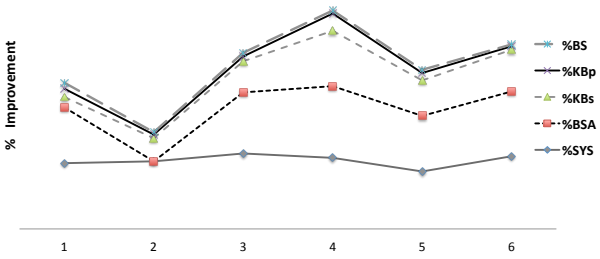

Fig. 5. Variation of the percentage improvement realized by MDSBH when compared to the results of the five heuristics (SYS, BSA, KBTG$_s$, KBTG$_p$ and HY) on the instances of Set1.

Figure 5 shows the behavior of MDSBH on the instances of Set1 where each curve represents the improvement variation realized according to the algorithm SYS, BSA and both KBTG$_s$, KBTG$_p$ and HY, respectively.

B. Performance of MDSBH versus KBTG and HY heuristics: Set2

In this section, we compare the results reached by MDSBH to those reached by KBTG$_s$ and HY (note that, for this type of instances, both KBTG$_s$ and HY realize the best objective values of the literature). This comparison is performed on the instances of the second group Set2 taken from Kubach *et al.* [10]. Herein, instead of determining the minimum length $L^\star$ of the target container $\mathcal{P}$, Kubach *et al.* [10] computed the density of all packed items in the final object $\mathcal{P}$. Therefore, we also report the best length $L^\star$ of the final object $\mathcal{P}$ as in Hifi and Yousef [8], since it corresponds to the dual problem that maximizes the density of the occupied area (or equivalently to minimizing the unused area).

#Inst. Label	$d^\star_{KBTG_s}$	HY $L^\star$	HY $d^\star$	MDSBH	MDSBH %HY	MDSBH
KBTG1	54.096	10.9031	56.0092	10.8076	23	0.884
KBTG2	30.071	1.9900	30.071	1.9900	23	0.000
KBTG3	51.387	18.2415	53.6243	18.1936	24	0.263
KBTG7	55.372	13.0997	57.5662	12.9653	14	1.037
KBTG8	45.060	2.5825	47.004	2.5820	13	0.019
KBTG9	52.732	27.8033	55.3203	27.7152	26	0.318
Av.	48.120		49.932			0.420

TABLE V
PERFORMANCE OF BSBH VERSUS KBTG$_s$ ON INSTANCES OF SET2.

The results realized by the three tested methods (MDSBH, KBTG$_s$ and HY, respectively) are reported in Table V. Column 1 displays the instance label, column 2 reports the solution value (expressed in term of density) realized by KBTG$_s$'s algorithm (extracted from Kubach *et al.* [9], [10]), columns 3 and 4 display both HY's length and its density whereas columns 5 and 6 report the best length realized by

MDSBH and the value of ω for which the best solution is reached. Finally, the last column displays the percentage of improvement realized by MDSBH according to the solution values reached by both $KBTG_s$ and HY, respectively. The analysis of the results of Table V follows.

1) HY outperforms KBTGs since it provides an average density of 49.932% whereas KBTGs realizes a percentage value of 48.120%.
2) MDSBH remains competitive since it improves most solutions reached by both KBTGs and HY. Indeed, it is able to improve five out of six best solutions while it matches the other solution (instance KBTG2) when compared to the results reached by HY.
3) For the improved solutions (except for the instance KBTG2 where all algorithms reach the optimal solution), MDSBH realizes an improvement varying from 0.019% (instance KBTG8) to 1.037% (instance KBTG7).
4) Globally, the average improvement over all instances is equal to 0.420%, as displayed by the last line of Table V.

V. Conclusion

In this paper the three-dimensional sphere packing problem is solved by using a modified dichotomous search-based heuristic. The proposed method is based upon three complementary phases: (i) a modified greedy selection phase which tries to select more eligible positions to iteratively pack all predefined items into the target object, (ii) a width beam search combined with hill-climbing strategies for exploring promising paths and (iii) a dichotomous search for providing a best target object, that is able to pack all items without overlapping. The performance of the modified algorithm was evaluated on benchmark instances available in the literature. The provided results were compared to those reached by the original version of the algorithm, as well as to the results given by some recently proposed heuristics. The new version of the method remains competitive and succeeded in yielding new solutions for many instances.

***Abstract*—The damage identification problem is one of crucial problems during operation of machines' elements made of polymeric composites. Therefore the appropriate non-destructive techniques should be developed in order to detect and identify the damages with the best possible accuracy. Moreover, such methods should be applicable in various testing conditions. One of the intensively developed directions in non-destructive damage assessment is a class of methods based on wavelet analysis of modal shapes of vibration applied for a tested structure. The effectiveness of an algorithm is strongly dependent on the type of applied wavelet and its parameters. The proposed approach uses a combination of the wavelet-based damage identification algorithm with multi-objective meta-optimization in order to select optimal parameters of applied wavelets and determine a front of optimal non-dominated solutions. Based on these solutions the operator can choose the desired accuracy of damage identification with respect to the suitable computation time.**

I. Introduction

SINCE the polymeric composites are more and more applicable as constructional materials in various industrial branches (e.g. automotive, aircraft and aerospace industries) and the manufactured elements are often subjected to critical loads during their operation, the development of appropriate damage identification methods, which will be able to detect and identify the damages specific for these materials, seems to be a necessity. From the majority of recently developed and applied non-destructive methods and techniques one could select a group of methods, which are based on analysis of vibration data of a tested structure. These methods have several advantages with respect to others, e.g. the possibility of carrying out on-field diagnostics, simplicity of measurements and concluding about the damage presence, a possibility of performing the measurements without unmounting the tested element from the machine, etc. However, for increasing the accuracy of detection and identification of damages the advanced signal processing methods are usually used.

One of the intensively developed approaches in the damage assessment problems is a wavelet-based analysis. Since the most of these problems are referred to the structural diagnostics of spatial domains the wavelet-based algorithms were extended for application on two-dimensional data. Numerous studies, both theoretical and experimental, were based on various wavelet transforms and various wavelets in order to obtain relevant information about damage state of a tested structure. A number of researchers developed their algorithms based on continuous wavelet transform (CWT) [1], [2], [3], [4] or stationary wavelet transform (SWT) [5]. The analysis of the applied wavelet-based algorithms was presented in [6]. The previous comparison studies of various wavelet transforms and various wavelets applied in the damage identification algorithm [7] show that the most accurate and computationally efficient algorithm is provided by application of the discrete wavelet transform (DWT) together with B-spline wavelets.

Following the recent advances in the field of improvement of wavelet-based damage identification methods one can notice that they are generally based on hybridization of the mentioned algorithm with various soft computing methods. There are numerous hybridizations of wavelet-based algorithm with artificial neural networks [8], [9], [10] as well as optimization algorithms: Krawczuk et al. [11] use genetic algorithms for improvement of cracks detection in beams, while the authors of [12] applied particle swarm optimization for improvement of detectibility of damages.

Further studies [14] of the first author allow developing a more efficient algorithm, which was based on fractional discrete wavelet transform (FrDWT) introduced in [15] with application of fractional B-spline wavelets. Based on the application of extended (two-dimensional) version of the fractional B-spline wavelets proposed in [16] it was possible to select the wavelet parameters suitable for the investigated problem in order to achieve the most accurate results of damage identification, which constitutes an improvement of accuracy with respect to integer-valued order of B-spline wavelets used previously [7], [17]. In order to select optimal parameters of the applied 2D fractional B-spline wavelets the authors hybridized a wavelet-based damage identification algorithm with various optimization algorithms (evolutionary algorithm, direct search algorithm, simulated annealing algorithm and particle swarm optimization) [18], which allowed for the further improvement of the damage identification effectiveness. The method was validated on numerical models and on experimental data achieved from vibrometric measurements of artificially damaged composite structures. Moreover, in the same paper, the authors surveyed the literature regarding the optimization problem of the wavelets' parameters mainly for

The research project was financed by the National Science Centre (Poland) granted according the decision no. DEC-2011/03/N/ST8/06205.

the damage identification purposes. It was noted that, the optimization approaches might be included into two groups: classic methods and soft computing and heuristic ones. One of the main conclusions from this review was that there was the lack of sufficient methods to tune behavioural parameters of optimization algorithms in order to have a much more practical algorithm for damage identification, which could be implemented in the embedded system of the end-user device. In order to improve application abilities of the wavelet-based damage identification algorithm and evaluate the effectiveness of optimized wavelet parameters (and thus the effectiveness of damage detection and identification) with respect to the computational time the problem could be formulated as multi-objective meta-optimization one.

The meta-optimization is a quite novel approach, which found numerous applications in the engineering problems. One of the earliest attempts to meta-optimization can be found in [19], where the genetic algorithm was used in order to find best mutation and crossover rates for another lower-level genetic algorithm. In the next years, there were similar trials to this problem by many authors, e.g. see [20], [21], [22]. Also in this subject, the authors of the paper [23] discussed the most important issues related to tuning evolutionary algorithm parameters by means of various meta-optimization methods. Their main conclusion was that it was no matter what kind of tuner algorithms to be used in this task, because for each case, it was possible to get a much better result from evolutionary computations with meta-optimization than relying on own intuition and the usual parameter setting conventions. The similar strategy as in the case of evolutionary algorithms can be observed for other soft computing method. For example in [24], the authors proposed the concept in which a superordinate swarm ('superswarm') can be used to optimize the parameters of subordinate swarms ('subswarms'). Subordinate swarms were used for neural network training. Another point of the view is given in [25]. Branke and Elomari in their work proposed the method that could be used, in a single run, to identify the best parameter settings for all possible computational budgets. Their approach allows to save a lot of time. In the best of authors' knowledge the only application of meta-optimization in non-destructive testing with use of wavelet-based algorithm was presented in [26], where the authors performed electromagnetic measurements with appropriate post-processing in order to detect and identify cracks in walls of nuclear fission reactors.

In this study the authors developed an existing hybridized algorithm based on the results of the previous study [18]. The application of meta-optimization to the wavelet-based damage identification algorithm has several goals. In spite of the computational procedure implemented in [18] the authors determined common wavelets' parameters for all types of investigated damages. The parent optimization sub-algorithm in the meta-optimization algorithm was based on a double criterion problem, which allows to obtain a front of optimal non-dominated solutions dependent on the accuracy of damage identification vs. the computation time. Thus, one may decide which strategy should be applied, for instance, the worse solution with quick data processing or the best solution with long-time data processing.

II. Damage identification

A. Wavelet-based algorithm

The algorithm of damage detection and identification was based on spatial FrDWT, which uses the two-dimensional Mallat's multi-resolution analysis, where B-spline scaling functions of fractional order $\beta_\tau^\alpha(x)$ constitute a space of the square-integrable subspaces $L^2\left(\mathbb{R}^2\right)$ and form a sequence of functional spaces V_i in the form:

$$\{0\} \subset \ldots \subset V_{-2} \subset V_{-1} \subset V_0 \subset V_1 \subset V_2 \subset \ldots \subset L^2\left(\mathbb{R}^2\right). \tag{1}$$

The form of a scaling function of fractional order $\beta_\tau^\alpha(x)$ is defined by two parameters [15]: $\alpha \in \mathbb{R}$, which is an order of scaling function, and $\tau \in \mathbb{R}$, which is a shift parameter, and is as follows:

$$\beta_\tau^\alpha(x) = \sum_{k=0}^{\infty}(-1)^k \left| \begin{array}{c} \alpha+1 \\ k-\tau \end{array} \right| \rho_\tau^\alpha(x-k), \tag{2}$$

where

$$\rho_\tau^\alpha(x) = -\frac{\cos\pi\tau}{2\Gamma\left(\alpha+1\right)\sin\left(\pi\alpha/2\right)}\left|x\right|^\alpha - \frac{\sin\pi\tau}{2\Gamma\left(\alpha+1\right)\cos\left(\pi\alpha/2\right)}\left|x\right|^\alpha \operatorname{sgn}(x), \tag{3}$$

$\Gamma\left(\alpha+1\right)$ is the Euler γ-function, which allows for fractional factorization. The scaling $\beta_\tau^\alpha(x)$ and wavelet $\psi_\tau^\alpha(x)$ functions hold two-scale relations [15], [16]. For the cases when $\alpha \notin \mathbb{Z}$ and $\tau = \left(\alpha+1\right)/2$ the integer-valued B-spline wavelets can be obtained.

Following the method of complexification of B-spline wavelets of fractional order based on generation of Hilbert transform pairs of them proposed in [16] it is possible to obtained direction-oriented 2D complex wavelets. The complexification is based on a combination of wavelets with the same order α, but different shift parameters τ in the form:

$$\psi_\tau^\alpha(x) = \psi_\tau^\alpha(x) + j\psi_{\tau+1/2}^\alpha(x), j^2 = -1. \tag{4}$$

Considering that the analytic wavelet has a form [16]:

$$\psi^\alpha(x) = \psi + j\mathcal{H}\left\{\psi\right\}, \tag{5}$$

where $\mathcal{H}$ denotes a Hilbert transform, the 2D complex wavelets have the following form [16]:

$$\begin{aligned}
\psi_1\left(\mathbf{X}\right) &= \psi(x)\phi(y) + j\mathcal{H}\psi(x)\phi(y),\\
\psi_2\left(\mathbf{X}\right) &= \psi(x)\mathcal{H}\phi(y) + j\mathcal{H}\psi(x)\mathcal{H}\phi(y),\\
\psi_3\left(\mathbf{X}\right) &= \phi(x)\psi(y) + j\phi(x)\mathcal{H}\psi(y),\\
\psi_4\left(\mathbf{X}\right) &= \mathcal{H}\phi(x)\psi(y) + j\mathcal{H}\phi(x)\mathcal{H}\psi(y),\\
\psi_5\left(\mathbf{X}\right) &= 2^{-1/2}\left(\psi(x)\psi(y) - \mathcal{H}\psi(x)\mathcal{H}\psi(y)\right)\\
&\quad +2^{-1/2}j\left(\psi(x)\mathcal{H}\psi(y) + \mathcal{H}\psi(x)\psi(y)\right),\\
\psi_6\left(\mathbf{X}\right) &= 2^{-1/2}\left(\psi(x)\psi(y) + \mathcal{H}\psi(x)\mathcal{H}\psi(y)\right)\\
&\quad +2^{-1/2}j\left(\psi(x)\mathcal{H}\psi(y) - \mathcal{H}\psi(x)\psi(y)\right),
\end{aligned} \tag{6}$$

where $\mathbf{X} = (x, y)$ denotes 2D signal and $2^{-1/2}$ is used for scaling the wavelets. The wavelets (6) are oriented along the primal direcrions: $\theta_1 = \theta_2 = 0$, $\theta_3 = \theta_4 = \pi/2$, $\theta_5 = \pi/4$ and $\theta_6 = 3\pi/4$, which allows for increasing detectability of damages located in these directions. The decomposition graphical example can be found in [18].

Considering that discrete-type wavelet transforms could be expressed as a set of high-pass and low-pass filters, the decomposition procedure could be presented in the form of pairs of filters along the specific directions of a signal $\mathbf{X}$. Considering (4) and (6) one can obtain six complex subbands $\mathbf{w}^P$, $P = 1, \ldots, 6$, after the decomposition (see [16], [18] for details).

In order to ensure sensitivity of an algorithm to all possible orientations of spatial damages the real parts of $\mathbf{w}^P$ are normalized according to the Euclidean metric. Moreover, considering the strong dependence between magnitudes of displacements of modal shapes and obtained coefficients after decomposition it is suitable to consider multiple modal shapes during the analysis. The resulted post-processing expression with respect to M considered modes takes a form:

$$\mathbf{W} = \sum_{M} \left| \sum_{P} \Re \left(\mathbf{w}_M^P \right)^2 \right|. \tag{7}$$

Based on the above-presented algorithm the damage identification procedure was performed. As was mentioned earlier, the wavelets were defined by α and τ, thus these parameters were selected for the optimization procedure. The goal of optimization is to find suitable values for α and τ, which allow for obtaining of best results in detection and localization of damages.

B. Optimization procedure for searching values of α and τ

The main goal of the optimization procedure is to adjust the fractional order α and the shift factor τ in order to obtain the best properties of the damage identification algorithm. In the previous paper [18], the authors proved that the single optimization method could be successfully applied in this kind of tasks. Hence, the optimization problem can be written as follows:

$$\begin{array}{ll} \text{Minimize} & U(\alpha, \tau) \\ \text{subject to} & \alpha^{(L)} \le \alpha \le \alpha^{(U)}, \tau^{(L)} \le \tau \le \tau^{(U)} \end{array} \tag{8}$$

where $\alpha^{(L)}, \alpha^{(U)}, \tau^{(L)}, \tau^{(U)}$ are the lower and upper values of the boundary constraints that should be chosen taking into account the properties of the wavelet. The global criterion method [27] is used to create a single objective function $U(\alpha, \tau)$. In this way, an indirect utility function can be expressed in its simplest form as the weighted exponential sum:

$$U(\alpha, \tau) = c_1 \left[1 + \sum_{i=1}^{T(p)} \max(\mathbf{W}_i) \right]^{-\lambda} + c_2 \left[\sum_{i=1}^{n} \sum_{j=1}^{n} w_{i,j}^* \right]^{\lambda} \tag{9}$$

where c_i are weights indicating the relative significance of elements in the sum, the exponent λ determines the extent to which a method is able to capture all of the Pareto-optimal points for either convex or non-convex criterion spaces, detail coefficients in the matrix $\mathbf{W}_i$ are computed using the recurrence relation proposed in [18], $w_{i,j}^*$ is an element of the matrix $\mathbf{W}_{T(p)}$. The function $T(p)$ can be defined using the following expression:

$$T(p) = \text{card}\left\{ w_{i,j} : \forall i, j \in \{1, 2, \ldots, n\} \;\; w_{i,j} \ge p \max(\mathbf{W}) \right\} \tag{10}$$

where n is the size of the matrix $\mathbf{W}$, whereas p is the ratio between the greatest magnitudes and the other detail coefficients in the matrix $\mathbf{W}$. The value of this parameter should be chosen arbitrarily from the range $[0, 1]$.

It is very important to have the physical interpretation of the formulated objectives. The first component of the weighted exponential sum (9) describes the values of detail coefficients that have the greatest magnitudes. This criterion can be interpreted as follows. If the damage occurred somewhere in the composite plate then the result of this would be locally affected on the values of displacements of modal shapes. The second component of the sum is correlated with the blurring of the regular form or forms which indicate the damage. It can be stated that the values of $w_{i,j}^*$ in the matrix represent the blurring of the regular form.

The authors showed in their previous paper [18] that the problem, which has been formulated in the form of (9) could be solved using heuristic optimization algorithms. As it was presented in their work, an evolutionary algorithm, a direct search algorithm, a simulated annealing algorithm and a particle swarm optimization algorithm could be adopted. The main problem in this kind of approaches is to find the compromise between the time computational complexity of an algorithm and the accuracy of a solution. These factors are strongly dependent on properties and values of the relevant parameters (behavioural parameters) of these algorithms.

III. META-OPTIMIZATION METHOD

The idea of meta-optimization which is also known in the literature as super-optimization or hyper-heuristic is to apply one optimization technique to adjust another optimization technique. In this paper, the meta-optimization strategy corresponding to the data flow diagram presented in Fig. 1 is used in order to search the space of behavioural parameters. As it can be seen, the meta-optimization algorithm (MAC) evaluates a meta-objective function whereas the main optimization algorithm (OAE) computes the cost function in order to find an optimal solution with the minimum time complexity and maximum accuracy.

Meta-optimization concept can be realized in different ways, however one of the most promising approaches employs the multi-objective optimization algorithm. Consequently, the main purpose of the meta-optimization process is to tune values of behavioural parameters of the main optimization

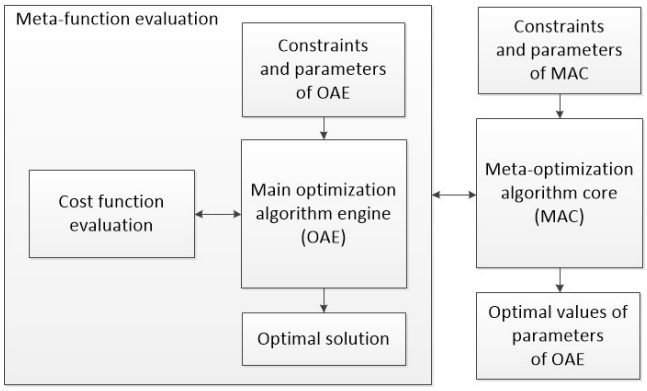

Fig. 1: A data flow diagram of the meta-optimization method

algorithm in order to minimize a multiple objective function $\mathbf{U}$. This function can be formulated taking into account two fundamental criteria. The first criterion (MBF) corresponds to the estimation of the accuracy of a solution, whereas the second one (FES) represents the time computational complexity of the main optimization algorithm. When one assumes that both objectives are not conflicted then the multi-objective meta-optimization problem can be stated as follows:

$$\begin{array}{ll} \text{Minimize} & \mathbf{U}(\xi) = [\text{MBF}(\xi)\ \ \text{FES}(\xi)] \\ \text{subject to} & \Omega(\xi) \end{array} \tag{11}$$

where ξ is the set of properties of the main algorithm, Ω represents boundaries and constraints in the meta-optimization process. The accuracy of the solution that is found by the main optimization algorithm, can be computed as the mean value of best scores of the cost function evaluations. On the other hand, the time complexity is approximated using the total number of cost function evaluations in the same algorithm.

Generally, multi-objective optimization problems do not have single global solution, and therefore there is the need to investigate a set of points, each of which satisfies the objectives. Due to this, in the present study, predominant Pareto optimality concept is mainly used. A solution is Pareto optimal if there is no other solution that improves at least one objective function without detriment another function [27]. It is often viewed the same as a non-dominated solution.

It is reasonable to expect that each of multi-objective versions of soft computing methods indicated in the previous section to be applicable in the task of meta-optimization. Nevertheless, the authors propose to use a much less complicated algorithm in the main optimization engine, while a more advanced approach in the meta-optimization core. In such manner, it is possible to obtain general values of relevant parameters of the main algorithm that can easily be implemented in the embedded system of the end-user device.

IV. Research results

The advantages and limitations of the proposed meta-optimization method were attempted in two separate experiments. The aim of the first case study was to validate the performance of the meta-optimization approach over a set of well-practised test functions. The second experiment dealt with the useful application of the elaborated method for wavelet-based damage identification in composite structures. It was decided that, the engine of the main optimization algorithm was prepared using the particle swarm optimization algorithm (PSO-OAE), while the core of the meta-optimization process was implemented by means of the multi-objective evolutionary algorithm (MOEA-MAC). MOEAs are known in the literature as the heuristic methods for solving optimization problems, which are based on the natural selection process that mimics biological evolution. The MOEA recommended in [28] is utilized herein to solve the meta-optimization problem defined as (11). Well-known and often practised genetic operators for multi-objective optimization are applied to obtain the convergence of a solution. In such manner, the problem of finding values of behavioural parameters is solved by computing the Pareto front, hence the set of evenly distributed non-dominated optimal solutions are determined. PSO is also classified into heuristic approaches, however this is a population-based stochastic optimization technique, which is inspired by simulation of social behaviour. In this paper, PSO proposed by [29] is adopted and applied to search for the optimal values of α and τ. The both optimization algorithms were implemented in the MATLAB® environment using Genetic Algorithm and Particle Swarm Optimization Toolboxes.

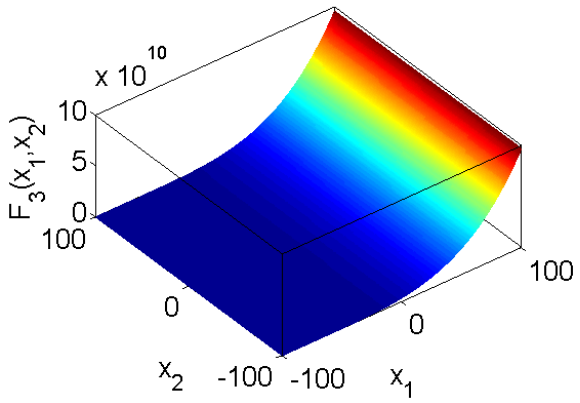
A. Benchmark tests

In the first step, the proposed method was verified using selected benchmark functions proposed in the CEC'2008 Special Session and Competition on Large Scale Global Optimization [30]. Due to the nature of the main problem formulated in this study, the authors decided to select the following test functions:

- F_3 : Shifted Rosenbrock's function

$$F_3(\mathbf{x}) = \sum_{i=1}^{D-1} \left(100\left(z_i^2 - z_{i+1}\right)^2\right) \tag{12}$$

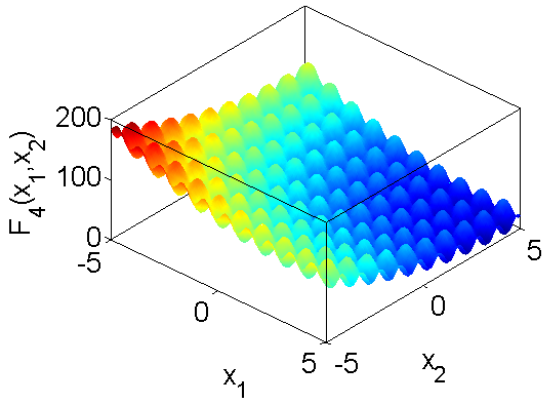
where $\mathbf{z} = \mathbf{x} - \mathbf{o} + \mathbf{1}, \mathbf{x} = [x_1, x_2, \ldots, x_D]$, $\mathbf{x} \in [-100, 100]^D$, $\mathbf{o} = [o_1, o_2, \ldots, o_D]$ is the shifted global optimum $\mathbf{x}^* = \mathbf{o}, F_3(\mathbf{x}^*) = 0$.



- F_4 : Shifted Rastrigin's function

$$F_4(\mathbf{x}) = \sum_{i=1}^{D} \left(z_i^2 - 10\cos(2\pi z_i) + 10\right) \qquad (13)$$

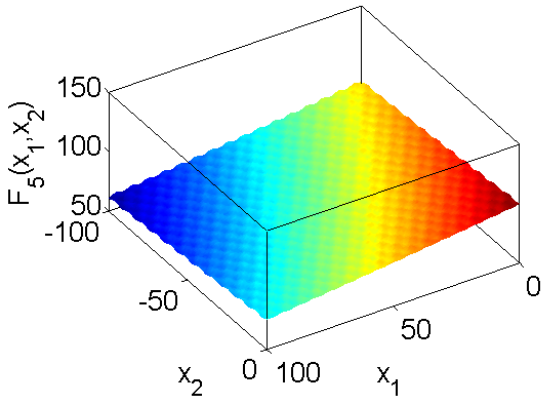
where $\mathbf{x} \in [-5,5]^D$, $\mathbf{z}$ is the same as in the previous function, the shifted global optimum $\mathbf{x}^* = \mathbf{o}, F_4(\mathbf{x}^*) = 0$.



- F_5 : Shifted Griewank's function

$$F_5(\mathbf{x}) = \sum_{i=1}^{D} \frac{z_i^2}{4000} - \prod_{i=1}^{D} \cos\left(\frac{z_i}{\sqrt{i}}\right) + 1 \qquad (14)$$

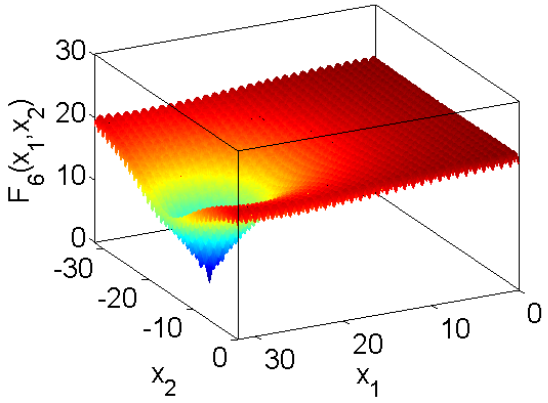
where $\mathbf{z} = (\mathbf{x} - \mathbf{o})$, $\mathbf{x} \in [-600,600]^D$, the shifted global optimum $\mathbf{x}^* = \mathbf{o}, F_4(\mathbf{x}^*) = 0$.



- F_6 : Shifted Ackley's function

$$F_6(\mathbf{x}) = -20\exp\left(-0.2\sqrt{\frac{1}{D}\sum_{i=1}^{D} z_i^2}\right) - \exp\left(\frac{1}{D}\sum_{i=1}^{D}\cos(2\pi z_i)\right) + 20 + e \qquad (15)$$

where $\mathbf{x} \in [-32,32]^D$, $\mathbf{z}$ is the same as in F_5 function, the shifted global optimum $\mathbf{x}^* = \mathbf{o}, F_6(\mathbf{x}^*) = 0$.



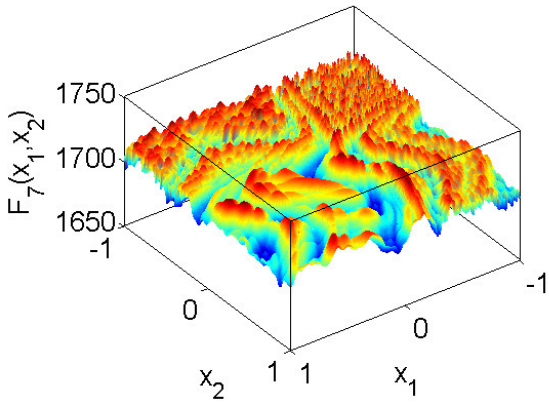
- F_7 : FastFractal 'DoubleDip' function

$$F_7(\mathbf{x}) = \sum_{i=1}^{D} \lambda_1\left(x_i + \lambda_2\left(x_{(i \bmod D)+1}\right)\right) + 1720 \qquad (16)$$

where
$\lambda_1(x) \approx \sum_{k=1}^{3}\sum_{1}^{2^{k-1}}\sum_{1}^{\hat{o}_2}\lambda_3\left(x, \hat{o}_1, \frac{1}{2^{k-1}(2-\hat{o}_1)}\right)$,
$\lambda_2(y) = 4\left(y^4 - 2y^3 + y^2\right)$,

$$\lambda_3(x,c,s) = \begin{cases} \left(-6144(x-c)^6 + 3088(x-c)^4 \right. \\ \left. -392(x-c)^2 + 1\right)s, x \in (-0.5, 0.5) \\ 0, \text{otherwise} \end{cases},$$

and $\mathbf{x} \in [-1,1]^D$, the global optimum is unknown, $F_7(\mathbf{x}^*)$ is also unknown, $\hat{o}_1$ is a double precision variable, pseudo-randomly chosen, with seed o_1, with equal probability from the interval [0,1], $\hat{o}_2$ is an integer variable, pseudo-randomly chosen, with seed o_2, with equal probability from the set $\{0,1,2\}$.



The task of the main optimization was defined as a continuous minimization problem. As it was mentioned above, the extreme was found with the help of the PSO-OAE. The cost function in the PSO-OAE was computed using one of the benchmark functions (12-16). In this algorithm only few parameters of the algorithm are relevant to guarantee, as far as possible, to find the optimal solution of the problem. Therefore, behavioural parameters such as the population size, the total number of generations, the social and cognitive

attraction coefficients were taken into account during the meta-optimization process realized by means of MOEA-MAC. For each function, the lower and upper boundaries of the PSO-OAE were assumed corresponding to functions' properties (12-16), whereas in the case of MOEA-MAC boundaries were declared in such a way, that the population size was equal from D to $2D$, the total number of generations from 5 to 100, the cognitive and social attraction from 0 to 4. The heuristic rules given in the literature were employed to get the best results from the MOEA. The fitness function was declared following to (11), where MBF was computed by averaging the best fitness function (for ten trials) and FES was obtained as the product of the population size and the total number of generations of the OAE. It was decided that individuals in the population of the MOEA were composed of genes representing real numeric values of behavioural parameters (the integer parts of the population size and generations parameters were used during the computations). The total number of generations of MOEA was set to 30. The population size of this algorithm was equal 40. The feasible population method was adapted to create a random well-dispersed initial population that satisfies all bounds in (11). Fitness scaling was realized using the rank method, whereas the selection of the parents to the next generation was achieved by applying the stochastic uniform method. Additionally, two reproduction options – the elite count and crossover fraction were chosen. The first one specifies the number of individuals that are guaranteed to survive to the next generation (it was equal 2). The second deals with the fraction of the next generation, other than elite children, that are produced by crossover. It was decided to use a heuristic crossover operator where the user-defined parameter was set to 1.2, and the crossover probability was equal 0.8. The remaining individuals are mutation children and they were obtained using the adaptive feasible method.

TABLE I: Optimal values of behavioural parameters for benchmark functions

Function	D	Cognitive attraction	Social attraction	Generations	Population size
F_3	2	2.180	0.706	74	4
	100	1.019	1.164	99	196
F_4	2	0.789	2.267	69	4
	100	1.393	1.319	96	100
F_5	2	0.712	1.125	88	4
	100	1.362	1.039	99	190
F_6	2	0.350	0.826	100	4
	100	1.290	1.375	81	188
F_7	2	0.988	0.920	67	4
	100	1.055	1.474	99	142

The meta-optimization process was carried out for two cases $D = 2$ and $D = 100$. The achieved results are presented in Tab. I. Besides, in Figs. 2(a,c,e-k) there are given graphs with the visualisation of selected Pareto fronts (for functions F_3, F_6 and F_7, $D = 2$ and $D = 100$, respectively) based on which the optimal values of behavioural parameters were chosen. In this case study, the authors selected non-dominated optimal solutions that were characterized by the highest accuracy of the cost function (in a statistic sense) with the minimum as possible time complexity of the algorithm. In order to have much more understandable and comparable results the tuning of behavioural parameters was also carried out with the use of expert's knowledge and trial and error procedure. In the first case, the suggestions proposed in [31] were applied (cognitive attraction = 0.5, social attraction = 1.25). In the second case values of behavioural parameters were changed several times for obtaining satisfactory solutions. The optimization process was run ten times for each case and afterwards the results were averaged. Overall, the comparison results of meta-optimization (○) and classic strategies (□, △) for adjusting behavioural parameter values were included in Tab. II. The most important statistic measures such as AVG and STD show that the best option is to find optimal values of behavioural parameters by means of the meta-optimization method. It is also confirmed by results presented in Figs. 2b,d,f-l (for functions F_3, F_6 and F_7, $D = 2$ and $D = 100$, respectively). These plots demonstrate mean values of the best scores of the cost function (MS) vs. the number of function evaluations (FES) for investigated cases. Each of these examples illustrates the effectiveness of the proposed meta-optimization method when it is compared to classic approaches.

B. Description of the damage identification problem

The testing data was achieved during experimental measurements (modal analysis) of artificially damaged square composite plates clamped on the edges. The damages with depth of 0.5 mm (ca. 19% of total thickness) were included using numerical milling machine. In the first case there was through-the-length crack, in the second case there was a spatial square damage and in the last case there were multiple

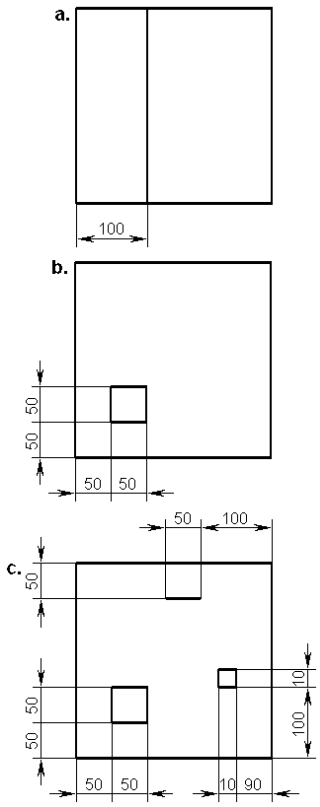

Fig. 3: Damaged plates considered in the analysis

damages: one small crack and two square spatial damages. The specific dimensions of damaged plates were presented in Fig. 3. During the scanning procedure the displacements in the net of 64×64 equidistant points were collected. The details of experimental setup and performing measurements can be found in [18].

First five modal shapes of each investigated case were considered in further analysis. Then, the collected data was exported to MATLAB® environment.

C. Results of damage identification

In this case study, the meta-optimization process was carried out on data collected using finite element (FE) analysis. The numerical models were prepared according to the geometry specification presented in Fig. 3 using MSC.Marc/Mentat® FE commercial software. The plates were modelled as 3D structures with the lay-up of a laminate and respective material properties presented in [17] and meshed using 8-node hexagonal elements. The boundary conditions were the same as for experimental study, i.e. all of the edges were clamped. The analyses were defined as normal mode evaluation, where the displacements in normal direction to the surface of a plate in 64×64 equidistant points of the first five modal shapes were considered for further studies. Due to the above-presented problem definition the numerical data was used as training data.

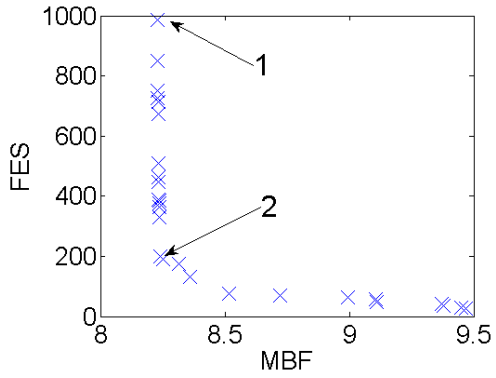

Fig. 4: Pareto front with optimal solutions obtained in the meta-optimization process

TABLE III: Optimal values of behavioural parameters for the damage identification purpose

No.	Cognitive attraction	Social attraction	Generations	Population size	FES	MBF
1	0.4324	0.8390	34	29	986	8.2307
2	0.1353	1.0078	25	8	200	8.2411

The extreme was found with the help of the PSO-OAE. The cost function in the PSO-OAE was evaluated using the indirect utility function (9) for three damaged plates at the same time. The lower and upper boundaries for α and τ in the PSO-OAE were assumed taking into account wavelet's properties ($\alpha^{(L)} = \tau^{(L)} = 0$, $\alpha^{(U)} = 2.5$,$\tau^{(U)} = 6$). Behavioural parameters were selected during the meta-optimization process realized by means of MOEA-MAC. The boundaries for these variables were declared in such a way, that the population size as well as the total number of generations were equal from 5 to 35, the cognitive and social attraction were equal from 0 to 4. The rest of the features of MOEA-MAC were selected in the same way as in the previous case.

The key results from the meta-optimization were shown in Fig. 4. This plot presents the Pareto front that means the set of non-dominated solutions. Due to the form of the plot it was possible that two optimal solutions were chosen for the further analysis. The values of behavioural parameters for these cases were included in Tab. III. It should be easily noted, that almost the same values of MBF can be achieved with the smaller number of function evaluations FES.

The damage identification experiments and the main optimization process were also repeated for real-world data. The values of behavioural parameters in this instance were the same as for the numerical data. Despite this, it was enough to obtain the high performance of damage identification for real measurements. Figs. 5a, 6a, 7a illustrate the main optimization processes (PSO-OAE) conducted applying the 1st and 2nd set of optimal values of behavioural parameters. In this way, it was possible for each case to obtain such values of parameters for which the total number of function evaluations was not larger than 200 to be enough to find the final solution.

(b) for the 1st solution (c) for the 2nd solution

Fig. 7: The comparison of two non-dominated solutions from meta-optimization in the identification of the third damage

From the Pareto fronts presented in Figs. 5a-7a one can conclude that the compromise between time complexity of computations and the accuracy of the final solution has been reached. It is also conducted by the obtained results (see Figs. 5b,c-7b,c), where the optimized parameters of a wavelet in solutions obtained by the proposed method have almost identical values with those obtained using typical optimization procedure (1st solution), however these values were obtained much earlier in the 2nd solution than in the 1st one. It could be also noticed that the obtained values for α and τ cause that the applied wavelet has a great filtering ability and simultaneously short effective support, which cause that all of the damages were detected and located properly. The optimization algorithm solves the problem with selection of wavelet parameters, which influences much on the ability of damage detection and localization, i.e. in the case of underestimated value of α the obtained sets of coefficients are highly biased by the rests of a filtered signal due to inappropriate filtration, while in the case of overestimation of α the resulted sets of coefficients are blurred in the locations of singularities (damages) due to the power losses of a wavelet with the wide effective support, which makes the decision process about damage presence and location difficult and unambiguous.

V. Conclusions

In this paper, the authors proposed a new method for finding optimal values of behavioural parameters of the optimization procedure that is used in order to identify damages in composite structures. The proposed approach is based on the meta-optimization concept. The novelty of the proposed method depends on that the meta-optimization can be realized using multi-objective cost functions.

The preliminary verification of the elaborated approach in optimization tasks was carried out for well-known benchmark functions. The results achieved in this part of investigations demonstrate the capabilities of the approach for solving different kinds of optimization problems. The fundamental verification was conducted for the experimental data measured during tests on the artificially damaged composite plates. The problem of optimization of wavelet parameters applied for the structural damage assessment in composites was studied before by the authors, but the meta-optimization approach allows to obtain several new advantages. The parameters of optimization algorithm do not require to be known since they are determined by the meta-optimization procedure. This excludes the difficulties of determination of these parameters, which are often difficult to achieve and automates the method. Moreover, different cases of damages were analyzed together, which allows for the determination of global parameters of the applied fractional B-spline wavelets and guarantee the best possible results for the damage detection and localization problems. Finally, the compromise between the time complexity of computations and the accuracy of the final solution could be reached in the automated manner.

***Abstract*—This paper proposes a new method to provide personalized tour recommendation for museum visits. It combines an optimization of preference criteria of visitors with an automatic extraction of artwork importance from museum information based on Natural Language Processing using textual energy. This project includes researchers from computer and social sciences. Some results are obtained with numerical experiments. They show that our model clearly improves the satisfaction of the visitor who follows the proposed tour. This work foreshadows some interesting outcomes and applications about on-demand personalized visit of museums in a very near future.**

I. Introduction

MUSEUMS are no longer only institutions that acquire, store and expose our heritage. Going to a museum is a learning activity but also an enjoyment for visitors. With the emergence of the Web, curators and cultural mediators decided to get involved in collaborative and numerical culture to attract a larger public. Today, almost all museums have a website but few of them allow the visitors to prepare their visit in the best conditions.

Some art, science and society museums are collaborating with research laboratories to develop new technologies that improve services in museums in response to the desires of existing and potential visitors.

However, there are still difficulties, epistemological barriers, to study the expectations and the intentions of different publics, including online visitors. Knowing why people want to come and visit museums could allow automatic systems to suggests their tour, save their time and give them the best of the knowledge of the exhibited arts.

Among all possibilities, a recommendation system for personalized routing is by far one of the best improvements. Indeed, some museums exhibit thousands of artworks and it is not conceivable for a visitor to admire all of them because he might spend time in front of artworks which do not match his interests and he might not be able to see other more interesting artworks due to tiredness or a lack of time. A few museums, as The Louvre, offer a recommendation system[1] but they are limited to the selection of a route in a pre-established set. Moreover, in this particular case, the personalization is restricted to the selection of a theme and the duration of the visit in a set of no more than 10 themes and 4 different durations.

It is essential to propose a personalized route for each visitor or group of visitors according to their interests while taking into account their constraints such as limited schedule, physical handicap or a list of artworks to include of the tour. This operation may also reduce unuseful moves (avoid round trips). But to calculate an optimal tour, we need to assess the visitor interest for each artwork by asking his preferences.
