***Abstract*—We present a method for fair agent scheduling in transportation scenarios. The approach is designed to first ensure the scheduling of all required task locations and, once this is achieved, focus on a balancing the workload across the population of transportation units. This, while almost certainly sub-optimal in the context of efficiency, facilitates the speedy allocation of new geographically located tasks due to the distribution of the remaining capacity across the agent population.**

We discuss our method, present results from simulations and discuss the advantages and disadvantages of the approach.

I. Introduction

LARGE scale transportation scheduling is a well known high complexity problem [1]. Arguably, the best known instance is the class of *Travelling Salesman Problems*, of which there are many variations which have been extensively discussed in the literature. Generally speaking, the problem is known to be NP-complete, meaning that while it is straight forward to check whether a given solution is correct, it is extremely difficult to construct such a solution [2].

In the classic *Travelling Salesman Problems* (TSP) one is concerned with finding the shortest path that connects a finite set of locations; in the multiple travelling salesman problem (MTSP) this is extended to a finite set of disjoint / mutually exclusive routes. The method presented in this paper solves a problem similar to the MTSP with the difference that we are not interested in the shortest path but in a collection of paths that do not exceed a certain length or agent capacity.

A. Motivation

The motivation for this is the idea that in the considered use cases we are in charge of a fleet of mobile agents which have a certain capacity (fuel, battery level, working time, etc) which we deem an acceptable investment.

While it is of course of interest to reduce the aggregated amount of the consumed resources we focus instead on the quick adaptation we can offer in a dynamic environment. Specifically, the empirical results we present are generated using a simulation that adds tasks to the problem after the initial solutions have been created. The motivation for this is that we consider scheduling scenarios where locations may be added throughout the active period of the fleet.

B. Aim of the paper

The aim of this paper is to present the method used and prove its performance through empirical results. The evaluation is intentionally kept generic and the focus is on providing the reader with all the information required to apply the method to specific problem instances. To this end, a variety of parameters are reported without any claim regarding their optimal settings (since we present results on a generic simulation it is of little interest to report on tuning results).

C. Application scenarios

The initial use case for the approach is the dispatch of service personnel to a number of locations, as major telecom operators or internet providers would routinely do. This can be extended to maintenance personnel as well as corporate security services on large estates. It should be noted that neither time windows, nor ordering locations according to some priority are currently supported.

We are at the moment considering the approach for allocating computational tasks to processing resources (e.g. servers in a server farm), also, the approach has potential in large scale disaster relief or humanitarian aid scenarios.

II. Method

We present a novel method [3] for adaptive scheduling in dynamic environments. At the core of the approach is a self determined paradigm shift [4] which enables a population of agents to switch their priorities on the basis of their (locally) available information: agents are assumed to have a limited view on the tasks, meaning that they are only aware of tasks within a certain distance from their position or their path. Their decisions are based on this limited partial visibility [5].

By *stance* we understand a predisposition to act one way or the other [6]. Specifically, agents are considered to be *maximizing* (which we will abbreviate to *max*) if they are aware of un-scheduled tasks, and *balanced* (*bal*) otherwise.

During each iteration all agents are triggered to locate a task within their reach (i.e. within their remaining capacity) and to attempt to assimilate this task into their own schedule. They will make this decision stochastically and depending on their and the other agent's remaining capacity. The other agent here is the agent to whom the task is currently scheduled, if there is no such agent the decision is foregone and the agent will simply schedule the task (cf. Figure 1). If the task is already scheduled to an agent then a value is calculated for both agents and from these a probability for re-allocating the task is derived.

978-83-60810-58-3/$25.00

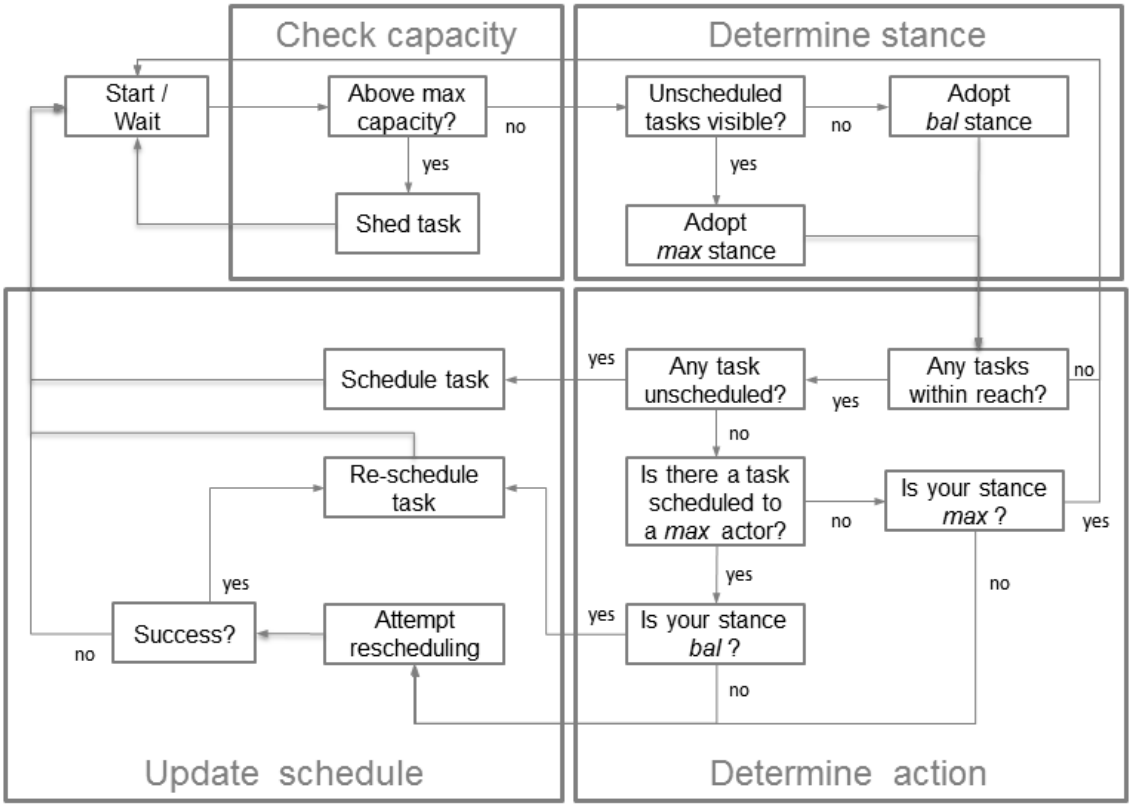

Fig. 1. Flow diagram of the approach

By reversing this value (the probability of successfully assimilating a task) we enable the agents to shift between two polar opposite stances: *rich gets richer* and *rich gets poorer*, where richness is associated with load (i.e. the higher the load the *richer* the agent). While the *max* stance means that an initially homogenous population will split into two groups: one that is maximised its load and one that is minimizing it, the *bal* stance results in agents with a higher load constantly losing tasks to agents with a lower load, effectively balancing their loads between themselves and their neighbours.

We require the approach to be non-deterministic (through the use of random elements like. e.g. the order in which agents are triggered, the choice of which task to consider for re-allocation and the stochastic decision whether they will win or lose the bid for re-allocating a task), as well as to be applied many times over. This will not result in an immediate convergence towards the best possible load distribution, but instead will slowly converge towards a *fair* state, i.e. the load distribution that results in roughly even loads for all agents.

Given that the choice of which task to consider is non-deterministic (and thus not related to the stance of either agent) we have 4 possible situations to consider (2 stances for each of 2 agents) when defining the interaction between any two agents. For the remainder of the paper we will call the initiating agent *active* and consequently call the other agent (the agent to whom the task in question is scheduled) *passive*. These 4 combinations and the resulting interactions are:

- **bal-bal** (*active* agent *balanced* - *passive* agent *balanced*): Agents that are not aware of unallocated tasks pursue their long term objective (load balancing). The agents will follow the *rich gets poorer* paradigm when calculating whether to reschedule the task.
- **max-max** (*active* agent *max* - *passive* agent *max*): If both agents are aware of un-allocated tasks they will focus on their short term objective, which is to quickly assimilate new/unscheduled tasks. They will follow the *rich gets richer* paradigm which will result in some agents depleting their capacity almost entirely while others are freed up, enabling them to assimilate the new tasks.
- **max-bal** (*active* agent *max* - *passive* agent *balanced*): If an agent is aware of unallocated tasks it is not interested to receive any tasks from an agent that is not. In this case, the interaction is aborted (this is simply prevented by restricting the choice of tasks, and thus agents).
- **bal-max** (*active* agent *balanced* - *passive* agent *max*): Balanced agents that happen to come across a task currently scheduled to an agent that is aware of unallocated tasks will always take the task in question. The reasoning is that the overall aim is to remove as many tasks as possible from the agents that are struggling to accommodate unallocated tasks.

III. Model

A. Parameters

The following are the parameters used for the model:

- number of agents
- number of tasks
- capacity (the same for all agents per simulation run)
- visibility range (considerably smaller than capacity)
- map size (this was 100x100 for all simulations)
- single depot versus individual depots

In line with our intention to enable the reader to implement and evaluate the approach independently, we also briefly discuss the only tuning parameter which we have included in this paper: α (used in the formulae in §III-B). Changes in α will affect the speed with which the approach converges to a somewhat stable solution, while on the other hand determining the degree of change in the environment which the algorithm can handle while still performing well.

B. Formulae

The decision whether to re-allocate a task from the active agent to the passive agent is stochastic. The probability of a *max* agent stealing as task from another *max* agent is:

$$P_A^{max} = \frac{(rem.capacity_B)^\alpha}{(rem.capacity_A)^\alpha + (rem.capacity_B)^\alpha} \quad (1)$$

with P_A^{bal} the probability of agent *A* stealing a task from *B*, and $rem.capacity_X$ the remaining capacity of an agent *X*.

The corresponding P_A^{bal} is simply the opposite of P_A^{max}:

$$P_A^{bal} = 1 - P_A^{max} \quad (2)$$

In other words, $P_A^{bal} = P_B^{max}$, which preserves the symmetry of the probabilities in the opposing stances, i.e. if *A* were likely to win for *rich gets richer*, it should be equally likely to loose for *rich gets poorer*.

C. Scenario

a) Agents: have a capacity, a visibility range, a starting depot and a route. The capacity is static, while the *remaining capacity* is the capacity minus the cost of the current route.

b) Tasks: have a location, expressed by x-y coordinates.

c) Depots: mark the beginning and the end of each route. Each agent is assigned a depot, expressed by x-y coordinates.

d) Routes: start and end with the depot of the respective agent. Routes are assigned a cost, which is the sum of the travel distances between the individual entries in the route. The distance is calculated as the Euclidean Distance.

e) World: has a map, a list of agents and a list of routes (schedules). The act of re-allocating a task from one route to another is assumed to be instantaneous and cost free.

IV. Simulations

A. Scenarios

Two scenarios were used for the simulations:

1) 40 tasks were added to the map once (at iteration 25): This is used for smaller scenarios, where the 40 tasks constitute a substantial percentage of the existing tasks, and where a small number of agents attempt to efficiently schedule the new tasks. This scenario is used to see whether, and how fast, the new tasks can be allocated and how long it takes for the average of the individual schedules to converge to a somewhat stable value.
   All tasks were randomly given coordinates in the range ($[50, 70]$, $[-50, 50]$); since the board is initialized to $[-50, 50]$ for both x and y coordinates these new tasks appear across the range of the y axis and further on the x than any other tasks.
2) 100 tasks are added every 25 iterations:
   This scenario is used to investigate the robustness of the approach and to see how a simulated population holds up in the face of a task load that is getting closer and closer to the total capacity of the population. Contrary to the above these tasks were placed all over the map ($[-50, 50]$, $[-50, 50]$).

B. Route calculations

We are interested in the least cost for a schedule, that is, the shortest path thorough all tasks in a list. This is the well known *Travelling Salesman Problem*, which is known to be NP-complete. Since the algorithm will need to calculate this for every task in the vicinity of an agent when computing the list of visible or reachable tasks, this is a calculation that is performed many times (millions of times, to be more precise, for any of the presented simulations).

To reduce the computation times two steps are taken: First of all, for routes of short length ($\leq$8) the best route is calculated via brute force, as this has proven to be the most effective approach for us. Secondly, for longer routes, we use simulated annealing with very soft convergence criteria. Because paths are recalculated and built upon at every iteration, repeatedly accepting a sub-optimal path still tends to progressively improve the solutions, yielding good results.

C. Extremely large scenarios

We investigated the performance of the approach for very large scenarios to verify that the approach is a) scalable and b) does indeed perform better with larger agent populations. To this end we simulated a scenario with 10,000 initial tasks and 1000 agents. We then added 100 tasks every 25 iterations and let the simulation run for 1000 iterations. This was done 4 times with different seeds. The generation of the results took 4-5 weeks because of the massive number of route calculations that had to be done.

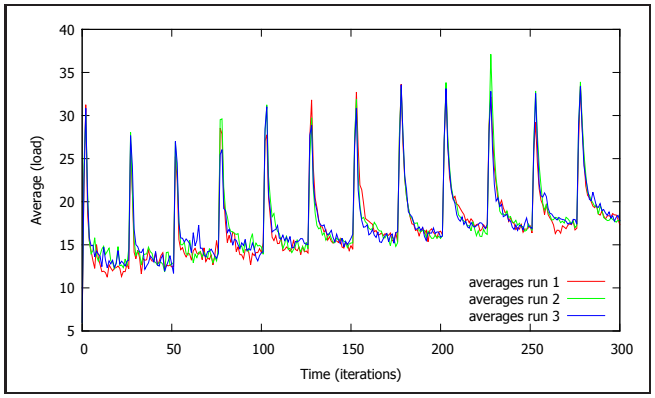

Fig. 2. Three separate runs of the simulation (x-axis: iterations; y-axis: load). Simulation setting: Scenario 2, agents = 50, tasks = 100, capacity = 75, 300 iterations, visibility = 40, map = 100x100. Δ: 100 new tasks every 25 steps

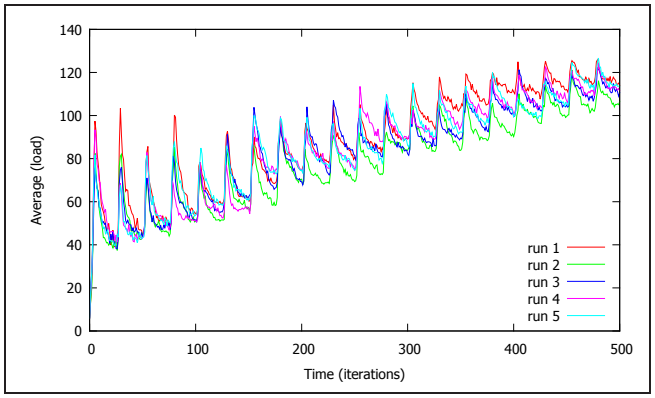

Fig. 3. Five separate runs of the simulation (x-axis: iterations; y-axis: load). Simulation setting: Scenario 2, agents = 50, tasks = 100, capacity = 150, 500 iterations, visibility = 40, map = 100x100. Δ: 100 new tasks every 25 steps

V. Results and Discussion

A. Parameter space exploration

We ran a number of identical simulations (for each agent population size, simulations were ran multiple times with different seeds, the seeds used for the different population sizes were the same so as to ensure comparability of the results) where we increased the number of agents to investigate the relevance of the size of the agent population. To this end, Scenario 1 was used and separate batches were run for small populations (20-100 agents, increasing in steps of 10) and large populations (200-1000 agents, increasing in steps of 100). The adaptation of the new tasks worked equally well across all population sizes, with tasks being assimilated into schedules as fast as possible (considering that each agent can only add one task per iteration; larger populations could assimilate tasks faster). The same holds for the aggregated load as well as the individual agents' loads. Other than the obvious differences in the performance, the algorithm performed well, even for very small numbers of agents (e.g. 20 agents for 500 tasks).

B. Performance evaluation

1) Adaptation of new tasks: To investigate the adaption of new tasks into schedules we looked at the average load of the *max* agents (as their the presence indicates the existence of unallocated tasks). For very small numbers of agents (fewer than the number of new tasks that were added) there is a noticeable difference, but as soon as the number of agents equals the number of new tasks there is no more difference in the number of turns it takes for all new tasks to be assimilated.

2) Optimization of the aggregated load: Addition of new tasks accounts for a sudden increase in the averages. For all but the smallest agent populations, however, we can see a steady and fast decrease in the reported averages. As expected, smaller populations struggle more with the process of decreasing the aggregated workload. This can be explained by the fact that for smaller populations the exchange of tasks is much more likely to have a more dramatic impact on their route length. This was also reflected in the standard deviations.

3) Optimization of the individual agents' loads: Population size has an impact on the standard deviation itself as well as on the rate of its decline. Smaller populations seem to quickly decrease the standard deviation between time step 120 and 140. This was, however, not reflected in the averages themselves. For larger populations we witnessed a much smoother return to small standard deviations, with the largest populations reaching a plateau very quickly.

4) Adaptivity and resilience: In order to evaluate the resilience of the approach and to investigate how the approach performs when it subjected to repetitive heavy strain, we ran a number of concurrent simulations for 300, 500 and (due to time constraints) one single simulation for 1000 time steps. All simulations started with 100 initial tasks which were supplemented by another 100 every 25 iterations thereafter (Scenario 2). The first set of simulations increased the number of tasks to 1200, the second set to 2000 and the final simulation ended with 4000 tasks all-together. While the first of these 3 batches was run with a capacity of 75, the latter two used a capacity of 150 (so as to provide the agents with the capacity required to accommodate all the new tasks). As before, we investigated the performance with regard to the aggregated load of all agents as well as the load of the individual agents:

a) Aggregated load of the population: Figures 2, 3 and 4 show the average loads of the agents over the course of the simulations. Even for large (and very large, as depicted in Figure 7) numbers of added tasks, the rate of convergence towards a good average remains stable. The overall increase of the load is not very large, and is decreasing with time as new tasks are added. This is understandable since the agents are using the shortest path through all tasks to calculate their load, and for increasing task numbers new tasks are more likely to be very close to already scheduled tasks.

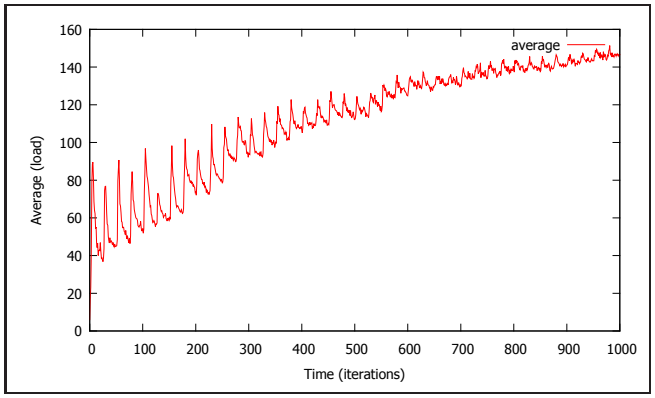

Fig. 4. The average load (y-axis) for one long simulation (x-axis: iterations). Simulation setting: Scenario 2, agents = 50, tasks = 100, capacity = 150, 1000 iterations, visibility=40, map=100x100. Δ: 100 new tasks every 25 steps

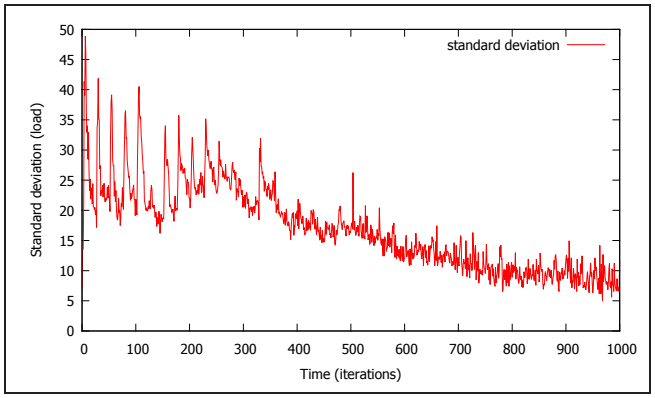

Fig. 6. The standard deviation (y-axis) from the average load for agents over 1000 iterations (x-axis). Setting: Scenario 2, agents = 50, tasks = 100, capacity = 150, visibility = 40, map = 100x100. Δ: 100 new tasks every 25 steps

b) Performance of max agents: Regarding the performance of the *max* agents, we can see in Figure 5 that each time new tasks are added there is a quick burst of activity before the averages drop again sharply. This corresponds to the number of *max* agents dropping to zero and the balanced agents optimizing their schedules. Besides showing us that the time used for the assimilation of the new tasks does not increase with larger task counts, it also demonstrates the effectiveness of the paradigm shift. These claims are best discussed in combination with the next paragraph.

c) Load balancing between individual agents: Regarding the performance of the individual agents, the graphs presented in Figure 6 show the standard deviation from the averages (already discussed above). We can see that the deviation from the average more than doubles briefly as the balanced agents take on tasks from the *max* agents. However, in all simulations it then drops almost immediately to the previous values. There seems to be a turning point around time step 200 (or when the task count has reached 900) after which the deviation is slowly decreasing. This is to be expected: with an increasingly denser task distribution we can realistically assume that the individual agents can balance their load more minutely.

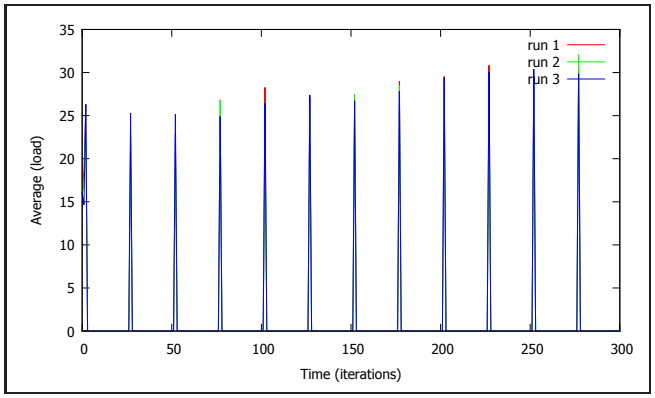

Fig. 5. The averages (y-axis) of the *max* agents for 3 separate runs (x-axis: iterations). Setting: Scenario 2, agents = 50, tasks = 100, capacity = 75, 300 iterations, visibility = 40, map = 100x100. Δ: 100 new tasks every 25 steps

d) Performance of balanced agents: We observed that the averages of the balanced agents jumped each time a new batch of tasks was added to the map but quickly dropped again, with the standard deviation following shortly thereafter.

Figures 4 and 6 report on results from small agent populations while Figures 7 and 8 show the performance of very large populations, both running for 1000 iterations, but with widely different task counts.

In Figure 4, the averages of the balanced agents increased slowly for smaller agent populations (capacity = 150) but their averages converged towards a plateau at around 120. The standard deviation, converging towards 25 (which is about the remaining capacity left for the agents) explains this plateau.

Regarding the corresponding standard deviation (Figure 6), we noticed a decrease in the deviation with increasing task counts. This matches the increased averages (decreased remaining capacity) but can also be explained by the fact that in larger task count new tasks are placed in closer proximity of existing (and already scheduled) tasks. In addition, the load balancing improves with the number of tasks to exchange.

As for the much larger simulation reported upon in Figures 7 and 8, we argue that the results show that the approach is scalable. We furthermore suggest that the increases in average load and standard deviation are stable because, unlike the other simulation discussed above, the agents had sizable remaining capacity and the sheer number of the agents in the simulation resulted in a much higher chance of tasks being placed in close proximity of agents.

The patterns observed in the other simulations are repeated here: after tasks are added a brief period of ensues within which the agents change paradigm, assimilate the new tasks and increase their load. This is followed immediately by a steady optimization which reduces the average load to (almost) the values from before the adding of the tasks. As far as the standard deviation is concerned, while the above graph (Figure 6) shows a convergence towards somewhat stable values, the much larger simulation (Figure 8) does not. This is because in the larger scenario agents can still assimilate far away tasks.

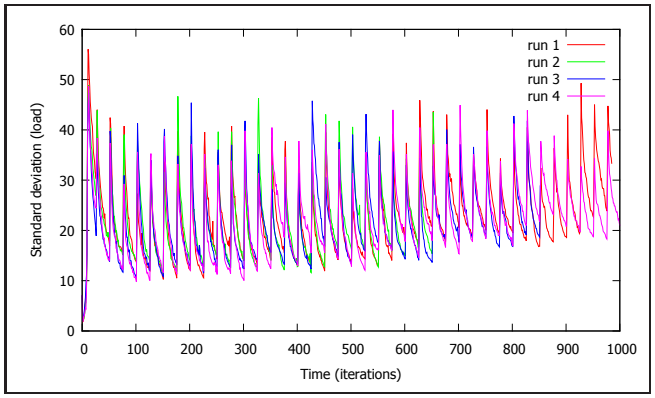

Fig. 8. The standard deviation (y-axis) from the average load for 4 runs (x-axis: iterations) of a very large simulation (Scenario 2, with 1000 agents) starting with 10,000 tasks and increasing to 14,000 tasks. Setting: see Fig. 7

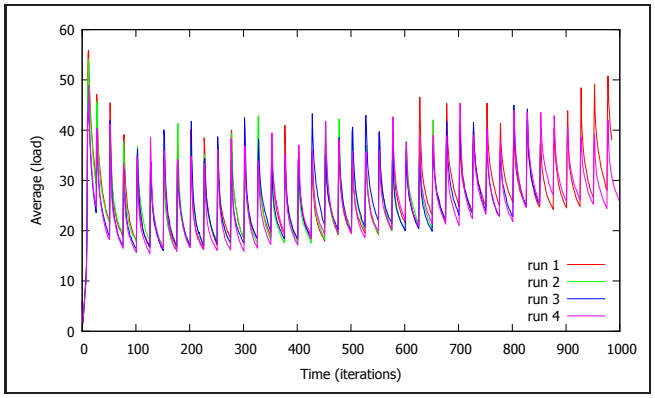

Fig. 7. The average load (y-axis) of the agents for 4 runs (x-axis: iterations) of a very large simulation (Scenario 2, with 1000 agents) that started with 10,000 tasks and over the course of 1000 iterations increased to 14,000 tasks. Setting: capacity = 400, visibility = 40, map = 100x100. Cf. also Fig. 8

C. Restrictions to the approach

The proposed method relies on a number of agents working in proximity, such that the schedule assigned to a specific agent can be partly absorbed into another agent's schedule. It is expected that there is a critical mass which is required in order for the method to outperform other approaches. We tested the approach against small numbers (as few as 20) of agents and it performed well; however the critical mass depends on the size of the map, the visibility and the capacity of the agents.

Furthermore, there is an upper limit to the degree of change over time in which the method can be expected to perform well. If the changes are too rapid or dramatic, recalculating the entire solution will be the better approach. This is due to the iterative nature of the approach, which will quickly adapt to changes and follow moving centers of gravity in the problem space. If such centers appear and disappear seemingly at random it becomes impossible to follow them, and thus the method loses its edge over other approaches.

D. Closing remarks

The combination of probabilistic decision making as well as the balancing and maximizing paradigm results in the minimization of agents to which a subset of the tasks (i.e. tasks from some region of the problem space) is scheduled to. This means that under the right conditions some agent might have very few or no tasks scheduled, which enables them to take on tasks from other regions of the problem space. This is expected to result in the ability to cross over large distances and effectively to reallocate agents within a problem space. Local optimization techniques normally consider only local alterations to a solution and recalculating the complete set of schedules for the whole problem space may be expensive in terms of computational effort.

Abstract— Logistics or supply-chain services provide enterprises and organizations with the necessary level of flexibility and efficiency in order to retain competitiveness under the increasingly turbulent e-business area. Web-Services are utilized by organizations in order to integrate high and low level applications, thus providing a collaborative environment without affecting inter- and intra-enterprise processes. Nevertheless, the above context should be enhanced in order to comply with the Web-of-Things concept. This paper describes a sustainable approach towards the above requirement by employing ONS based services able to provide targeted information regarding RFID-enabled physical objects that are handled in an organization agnostic collaborative environment.

I. Introduction

RADIO Frequency Identification (RFID) technology has already delivered revolutionary aspects in various areas such as logistics (supply chains), e-health management and materials identification / traceability. RFID technology itself allows an object's identification with effectiveness and efficiency. However traceability of an object calls for a robust and reliable system operating seamlessly over its entire lifecycle. Such a traceability system has to be implemented so as: a) its data model allows unique object identification and scalable, often big-data, databases, b) its underlying framework supports interoperability and c) its mechanism is capable to achieve end-to-end tracing providing full history information.

Despite RFID technology's nature in tracking, there are several challenges that need to be addressed. Since an RFID tag can be read from a quite long distance without requiring line-of-sight, it is possible that collisions may occur whereas also multiple tags could be read simultaneously. Therefore, there is no guarantee that a single tag will be consecutively detected on consecutive scans. Moreover, the use of RFID may constitute a serious threat for the information privacy, as it could be easily facilitated to espionage or unauthorized requests.

Based on the previously described situation there is a real need for an underlying framework able not only to support and complement the tracing functionality offered by the RFID technology but also to take into consideration the relevant tracking information of a physical object through its entire lifecycle in a secure and effectively protected way.

The work presented in this paper focuses in the challenging concept of an RFID-enabled, organization unaware, logistics management, by introducing an architecture that utilizes components of the Electronic Product Code (EPC) global network, such as the Object Naming Services (ONS) and the EPC Information Services (EPCIS), in order to support the Internet of Things concept. Our implementation is capable of enhancing the architecture of e-business frameworks, thus introducing an innovative collaborative business model which seamlessly integrates the inter-enterprise (public) with the intra-enterprise (private) processes.

The implemented architecture is demonstrated by the presentation of a case study in documents (books, papers, etc.) tracking and management in an academic library environment. Despite the fact that such an environment has quite lot variations from an e-business logistics environment, it has the potential to illustrate (and, even, simulate) the key-points of the presented architecture when not a standalone but a whole network of academic libraries are taken into account.

II. Current Status

Traceability is defined as the ability to trace the history, application or location of an entity, by means of recorded identifications. It also may be defined in general as the ability to trace and follow any product through all stages of production, processing and distribution. Traceability itself can be divided into three types:

- Back traceability (supplier traceability)

This work was financially supported by the General Secretariat for Research and Technology (GSRT) [16] of the Hellenic Ministry of Development in the framework of project SELIDA – contract #09SYN-72-646 which runs under the "Cooperation", 2009 Call.

- Internal traceability (process traceability)
- Forward traceability (end-user traceability)

Having the end-to-end traceability encompasses all three types of traceability and since traceability is defined over every stages of a value-chain, several researchers have pointed out various elements that should be taken into account.

Traceability systems store information and show the path of a particular object of interest along the whole value-chain from the supplier/producer to the retailer/distributor and eventually to the consumer/end-user. Throughout this process, secure, reliable and automatic object identification is crucial to provide effective and efficient tracing.

Barcode technology, in the past, has been used for the identification of items. However, in order to meet the traceability requirements imposed by the governments, a new technology that allows automated recording of information was needed. This need has been partially fulfilled by the revolutionary developments regarding the RFID technology.

Many logistic services have already integrated RFID identification technology into their services and products but these solutions most often implement a custom or proprietary communication flow. This means that it is quite difficult to come up with a generic approach against these solutions.

On the other hand, providing traceability services apart from trading logistics services i.e. physical documents interchange is even more demanding since existing services (e.g. Xerox Docushare, Papyrus, etc.) refer only to digitized documents management. Nowadays, document interchange between organizations, authorities and citizens is realized via the well-known courier shipping services (i.e. FedEx, etc.), but these services are almost always built into proprietary protocols while a gap often occurs when different services, even of the same type, in inter-continental transactions are involved.

Especially for book tracking (i.e. lending libraries, etc.) libraries and Inter-Librarian Loan (ILL) services in general employ standard interchange formats, exploited via web services, in order to share repositories and establish collaboration among them. However, a global standard elaborating libraries worldwide does not exist.

III. Architecture of the Deployed Information System

In the context of this section we are going to concisely present the architecture of the Document Tracking System (DoTS), which has been designed in order to tackle the issues mentioned in the previous section.

Section A concisely describes the technologies employed whereas section B presents a brief description of the entire architecture and its basic components.

A. Technologies and specifications employed

The following technologies and specifications have been utilized in the context of the system: **RFID**, used to uniquely identify physical objects and **EPC**, providing the underlying framework that the system takes advantage of in order to offer standardized tracking services.

a) RFID

The RFID (Radio Frequency IDentification) is a well-documented [1]-[6] and widely adopted [7], [8] technology, that provides the ability to uniquely identify objects tagged with RFID tags using special readers [9]. The main goal of the architecture is to be able to track documents on a potentially global scale. RFID provides significant advantages over other automatic ID technologies (specifically the widely applied bar and QR codes), as RFID tags:

- can be detected in bulk
- don't need to be aligned with the reader (line of sight) in order to be read
- can be detected from a greater distance
- have a larger data capacity
- are less susceptible to damage

These outweigh the benefits of the bar and QR code tags (which are less expensive and quite ubiquitous compared to RFID tags) for the application on important documents and can enable the introduction of innovative services, such as real time traceability and theft prevention. Additionally, RFID is intrinsic in the framework of global standards published by the GS1 that concern the EPC, which have been exploited in order to provide a method to globally provide tracking information services.

b) EPCglobal

The GS1 EPC global is a suite of standards and specifications that leverage the RFID technology in order to globally enable visibility and collaboration on an item level. These standards comprise the framework depicted in Fig. 1.

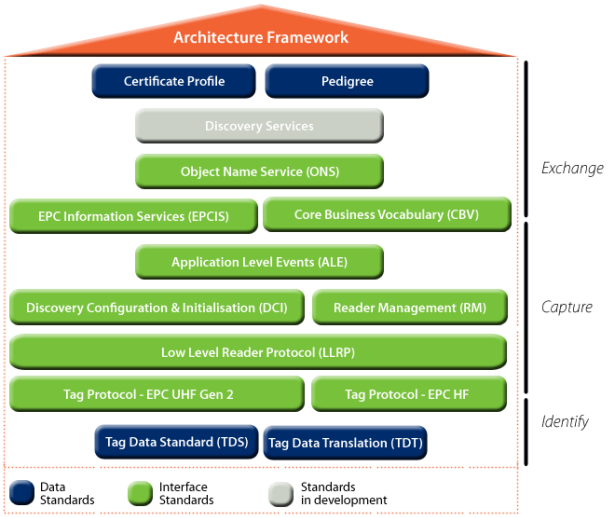

Fig. 1 GS1, EPCglobal framework standards, 2014 [6]

Information about these standards can be found in the GS1 website [5]. In the context of the proposed system, most of the EPC related GS1 standards have been utilized.

c) Object Name Service Specification

The discovery and tracking service of physical documents that has been implemented exploits the Object Name Service (ONS) 2.0.1 [5] and the EPC Information Services (EPCIS) 1.0.1 [2], in order to enable the mapping of EPC tagged documents to addresses of arbitrary, but with a standardized interface, object management services (OMS).

B. Framework Architecture

The proposed framework aims to support as many of the EPC global standards as possible; in order to provide the ability to map single physical objects to URIs and to track related information regarding the entire lifecycle of the representation for all involved organizations in the value chain, together with the realization of ONS-based web services available in the cloud.

The proposed architecture is value chain agnostic pertaining:

- common logistics value-chain (i.e. manufacturer, logistics service, retail and end-user/customer)
- physical documents inter-change value-chain between public authorities or organizations of the public sector and citizens or companies of the private sector
- objects inter-change value-chain in demanding cases such as insurance organizations, shipping companies, courier companies, etc.

Fig. 2 illustrates the incorporation of the aforementioned technologies in the proposed framework architecture.

The proposed ONS service layer consists of a collection of ONS-based web services that are able to provide information from the organization's internal hierarchy model breakdown, using the global EPC notation, without affecting the existing processes of the value chain. Each organization's ONS service layer is responsible for providing per object, both public and private information, using the global EPC notation.

The private web services satisfy per sector- needs for real-time, synchronous physical objects tracking. These needs have various orientations, depending on the corresponding node of the chain. The public web services address needs of common operations, regarding single object's lifecycle information, such as location, history etc.

The integration of the RFID subsystem, into the architecture framework raises two main issues. The first regards the capturing of tags' information as well as the identification of the tags themselves. The RFID reader scaling, range and reading angle are of major importance since it is incorporated in a versatile environment (many different types of organizations performing totally different internal processes). The second issue regards security and privacy issues that are raised when the identified object's data should be classified. Security and privacy issues are presented in detail in next paragraph.

a) RFID Middleware

The RFID middleware is responsible for receiving, analyzing processing and propagating the data collected by

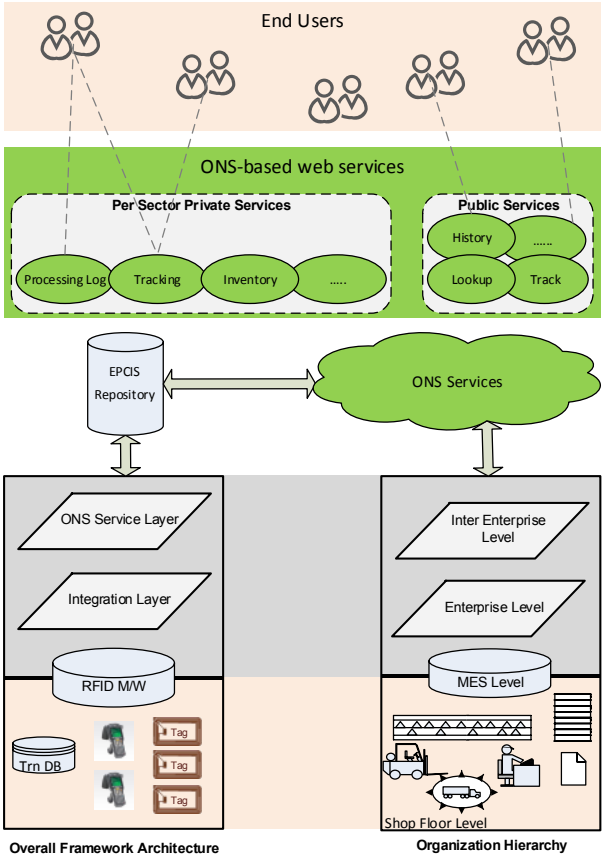

Fig. 2. Proposed framework architecture.

the RFID readers to the Information System that supports the business processes. The middleware hides the complexity of the actual RFID infrastructure and only provides business events. On the other hand, the middleware is oblivious of how the data it provides gets handled afterwards.

Specifically, the RFID middleware provides facilities for:

1. EPC Allocation
2. Device Management and Monitoring
3. Data Collection and Integration
4. Data Structure and Data Association
5. Data Filtering and Data Routing
6. Line Coordination and Process Control
7. Legend and Graphics Creation
8. Visibility and Reporting
9. Track and Trace Applications

b) ONS Resolver

The purpose of the ONS Resolver is to provide secure access to the ONS infrastructure, so that its clients would not only be able to query for the OMSs related to EPCs (which is the de facto use case of the ONS), but also introduce new or delete any existing OMSs for the objects. This has been accomplished by creating a SOAP web service layer that functions on top of the ONS, which provides authenticated and authorized users with the capability to query the whole

ONS infrastructure and discover the OMSs for the given EPCs, to add or delete OMSs or to add or delete users of the ONS Resolver, depending on their permissions.

In addition to the secure access to the ONS infrastructure, the ONS Resolver acts as an authorization server [10] for the relevant OMSs. This way, whenever a user uses the ONS Resolver to get the address of an OMS and authenticates successfully, an access token will be returned along with the result of the query, which, if used in the subsequent interaction between the user and the OMS, it can provide privileged access to the service. The authorization procedure that has been developed is depicted in Fig. 3.

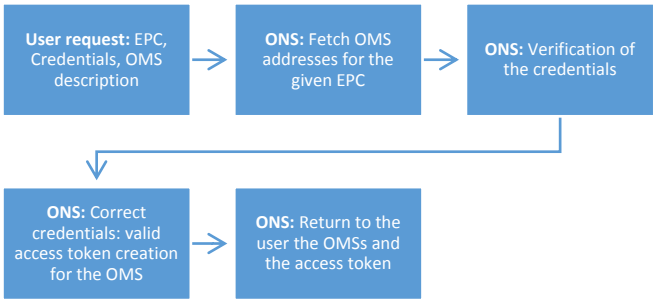

Fig. 3. ONS authorization procedure.

c) Object Management Services

The object management services (OMS) provide management, tracking and other value added services for the EPC tagged objects. The ONS Resolver maps the object management services to the objects according to their owner and type (for example the OMS for objects tagged using an SGTIN EPC is going to be determined by their GTIN; i.e. the OMS for the EPCs with the same GTIN is common [5]) and they should be implemented according to the EPCIS specification [2].

The most common case of the aforementioned context is the presentation of all historical data relevant to a single physical object. The resulting historical data can contain information regarding object transactions within locations controlled by the owner of the item or other organizations, as long as all the implicated parties implement the described framework; this was rendered possible through the utilization of the ONS Service Layer. The data of the objects stored by the different parties adhere to the same API and, as a result, one can select the exact kind of these data that are to be presented. For example historical data could describe an object's transaction only with dates on interaction with an RFID M/W, or with geographic interpreted location of the interaction, or even with more meta-data of the object like its purpose of transportation, original owner, final destination and whether it is classified or not. In an expanded version of multiple organizations running the presented framework, any tagged object (document, package, suitcase, etc.) could be easily and reliable recognized in the entire framework's context.

Finally, the arbitrary nature of the OMS themselves, even though they are implemented with standardized formation, enables each organization to level-up objects' related information according to the specific organization needs and requirements.

d) Security and Privacy aspects

Since the proposed architecture is based on web services, our first goal is to identify and classify those services in regards to their security requirements. Even before that, we can safely assume that all web services can and should implement TLS as a standard form of encrypting the data channel in use (usually the Internet).

Based on the aforementioned architecture diagram, we can easily identify that there are public and non-public facing web services. In regards to the non-public facing web services, the ones that reside within the internals of the proposed architecture stack, we can exploit the useful fact that both the clients and the servers of this part of the architecture are known and can be controlled in regards to their implementation of the security mechanisms. Therefore it is safe to assume that the use of client certificates is a feasible security mechanism. Client certificates are a very robust way of handling secure and, in conjunction with TLS, encrypted authentication and authorization and the issues with scalability and deployment that are usually encountered in more general scenarios are not applicable to our proposed architecture. As for the public facing web services, we follow the industry standard of API keys due to the fact that although we name those services "public facing", in reality those services will be accessed not by casual end users but by the information systems of the organizations that will employ that services of our proposed architecture. A case study of such a deployment is described in the next chapter.

Moreover, all the web services should follow a standard of secure design that, although already a common practice in popular web services around the web, we will briefly describe below.

As mentioned above, all services should be authenticated over an encrypted communication channel. Messages should be digitally signed, as well as encrypted, to provide privacy and tamper-proofing when the message travels through intermediary nodes route to the final destination even within different organizations that implement the same proposed architectural stack. The usage of the access token (a unique ID or nonce, a cryptographically unique value) generated by the ONS Resolver within every request, will, obviously, provide protection against unauthorized usage and it will also aid to the detection message replay and man in the middle attacks. HTTP methods should be valid for each API key and associated resource collection and method by white-listing allowable methods. Any request for exposed resources should be protected against CSRF and insecure direct object references should be avoided.

IV. Case Study on Physical Documents Tracking in a Library Environment

In order to evaluate the applicability of the proposed architecture on a real environment we deployed it on the existing Integrated Library System (ILS) that is being used in the central university library of Patras, Greece. The ILS that is being used by the institution is the well-known open source ILS named KOHA [11].

As with all ILS, KOHA supports a variety of workflows and services to accommodate the needs of the institution. Our proposed scheme focuses on a handful of those services and augments them with additional features. This is generally done by adding, in a transparent way, the additional UI elements and background processes that are needed for our scheme to work.

The specifics on how this is done will be presented in the following section, while first we will discuss briefly on the exact services of the KOHA ILS that our scheme aims to augment.

A. Supported services

In its initial design, our scheme aims to provide additional functionality on the core services of an ILS. Those services are:

- Check Out
- Check In
- New Record
- Delete Record

There are also a number of tracking services that our scheme aims for and those are:

- History
- Location
- Search

To elaborate, when the check-out or check-in services are called in KOHA, an additional call is made on the SELIDA (the name of the developed framework from the related project) middleware that updates the status of the affected documents on the SELIDA database. The details on how those calls are made will be described in the next section. Similar functionality can be seen on the entire core and tracking services that are applicable in our scheme as described in the previous chapters.

B. Integration layer

In order to provide the added functionality to the existing KOHA services we designed and implemented an integration layer that seamlessly handles all the extra work along with the usual service workflow.

The primary reason to provide a seamless layer instead of changing the actual services (i.e. the source code) is the fact that every integrated system that is actually in a production environment needs the benefits of a continuous and stable update process that is offered by the systems development team along and implemented by the organization's administrator. Adding extra functionality in the form of changes to the system's code would require continuous maintenance of this part of the system on par with the normal updates of the KOHA ILS.

To overcome this obstacle, and given to the fact that KOHA is a web based application as most of the modern ILS, we designed the integration layer so that it is injected upon page load as a JavaScript file on the pages that we are interested in. On our specific case study, we used the "mod_substitute" directive on the Apache web server that was serving the KOHA web pages. Each time a module/page of interest is requested by the server (i.e. check-out), the web server adds a <script> tag that loads all the additional functionality in the form of a JavaScript file.

This layer, in the form of a JavaScript application module, adds the required UI elements for our proposed scheme to work and handles all the web service requests that are necessary.

As an example, we will showcase the check-out process. When the user navigates to the check-out KOHA module by requesting the module's URL, the apache server injects the selida.js file which is the integration layer code (so called SELIDA module). SELIDA module starts executing upon page load and adds the button "Scan" next to the button "Checkout". When the user presses the button "Scan", a web service request is launched from the SELIDA module which starts up the RFID reader via the SELIDA middleware services. The results (per example the barcodes and titles of the documents that the reader identified) are communicated back to the SELIDA module which in turn shows a pop-up window to the user indicating those results. After this procedure, the normal check-out workflow resumes by sending the required POST requests to the KOHA web server (just like when the user presses the "Checkout" button after adding the barcode). When the check-out process ends and the web server responds with the next web page as per KOHA workflow, the SELIDA module sends a second web service request to the middleware indicating that the check-out is complete so that the rest of SELIDA architecture continues with its own check-out workflow presented in the previous chapters.

As we can see on this example, the extra steps that are needed for our scheme to work are completely transparent from the ILS itself. KOHA as an application retains its original functionality and workflow while the user benefits from the added services that our SELIDA module provides.

Fig. 5 illustrates the framework's activities during the first object identification phase, previously described.

C. Object Management Services

Since RESTful [12] web services are becoming the most common developers' choice for implementing API's and data retrieval services SELIDA's services have been designed following the RESTful architectural style and JavaScript Object Notation (JSON) [13] for data exchanging. Although these technologies do not comply with a specific standard, as other technologies do, i.e. SOAP, XML web services, when combined together they constitute a lightweight data-interchange mechanism that is easy for humans to read and

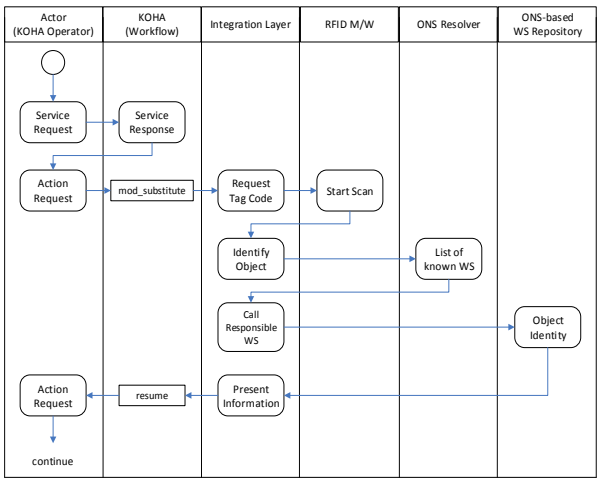

Fig. 5. Framework's activities during an object identification phase.

write and also easy for machines to parse and generate, thus appearing to be the easiest and most comprehensive messaging way among web services. Moreover, nowadays numerous open standards-like specifications (i.e. JSONDoc [14], Swagger [15], etc.) have been presented towards describing, producing, consuming, and visualizing RESTful web services so as RESTful web services can become a complete framework.

Currently, based on the deployment of the proposed architecture on the existing Integrated Library System (ILS) that is being used in the central university library of Patras, Greece, three types of management services (history, location and search) have been implemented, as described in paragraph A.

                }
        },
        ]
}
```

Fig. 4. An example of JSON request and response data structure for status OMS.

As for an example, the JSON schemes for the request and response of the search service is presented in Fig. 4.

As depicted in Fig. 4 request to the status OMS may contain multiple EPC tags at a time, while the implemented system response contains an indicative error code (0 in case of no error) and relevant data for recognized books. In the illustrated example the first two EPCs belong to books owned by the central university library of Patras, Greece (LIS UPATRAS) while the third belongs to a book owned by the university library of Athens University of Economics and Business, Athens, Greece (LIS AUEB).

V. Benefits and Scalability

Although the described framework has been deployed in an ILL (Inter-Librarian Loan) environment its initial inspiration and design has been originated in general logistics or warehouse inventory stocktaking environments. Based on this origin the whole framework has been designed and deployed so as to offer organization agnostic information, supported by ONS-based web-services that are integrated at the top of each organization's hierarchy stack, as illustrated in Fig. 2.

The proposed architecture offers a set of versatile characteristics due to the combination of reliability and uniqueness, induced by RFID technology along with the ONS perspective implementation throughout the architecture that derives interoperable information exchange. These characteristics could constitute the basis for the employment of such a framework so as to derive into a generic Internet-Of-Things service platform able to handle information and processes of any value-chain type, including and not limited at food supply chain, luggage handling, physical document interchange, etc.

This prospect could be further substantiated by the nature of the ONS, which is actually a mechanism that leverages Domain Name System (DNS) to discover information about an object and its related services from the EPC code. Conclusively, the presented architecture could be scaled in the same way as internet does, since internet is based on DNS and the presented architecture is based on ONS, inheriting DNS scalability capabilities.

VI. Conclusion

In spite of the promising nature of RFID technology, numerous applications in the actual logistics field area have not been reported. Only a few pilot studies as well as experimental tests have proved that RFID would be a successful tool to enable supply chain traceability. The reasons why companies are yet reluctant to have confidence in adopting the technology to gain their product visibility may be attributed to the several challenges such as lack of standards, immaturity of RFID, and privacy issues.

This paper presents a ubiquitous approach towards a collaborative logistics environment and concludes with a case study implementation involving physical documents tracking

in an academic library. The main focus of the proposed methodology and implemented architecture addresses the issue of empowering the whole framework with a standard specification for objects tracking services, thus the integration of the ONS-perspective in the architecture. The integration itself, which, within the EPC global framework is mainly achieved by utilizing the Object Naming Service, enables involved organizations to act agnostically of their entities and provides them with the ability to resolve EPC tagged objects to arbitrary services, but with a standardized manner.

However, security and privacy issues should be further investigated as future work, apart from the issues already covered though the implementations of the framework's web services, so as the presented framework will be promising enough for evolutionizing the way currently exploited for tracking items in the supply chain.

***Abstract*—The paper presents a concept and implementation of a novel hybrid approach to the modelling, optimization and analysis of the supply chain problems. Two environments, mathematical programming (MP) and constraint programming (CP), in which constraints are treated in different ways and different methods are implemented, were combined to use the strengths of both.**

This integration and hybridization, complemented with an adequate transformation of the problem, facilitates a significant reduction of the combinatorial problem. The whole process takes place at the implementation layer, which makes it possible to use the structure of the problem being solved, implementation environments and the very data. The superiority of the proposed approach over the classical scheme is proved by considerably shorter search time and example-illustrated wide-ranging possibility of expanding the decision and/or optimization models through the introduction of new logical constraints, frequently encountered in practice. The proposed approach is particularly important for the decision models with an objective function and many discrete decision variables added up in multiple constraints.

The presented approach will be compared with classical mathematical programming on the same data sets.

I. Introduction

The supply chain is commonly seen as a collection of various types of companies (raw materials, production, trade, logistics, transport, etc.) working together to improve the flow of products, information and finance. As the words in the term indicate, the supply chain is a combination of its individual links in the process of supplying products (material/products and services) to the market.

Huang [1] studied the shared information of supply chain production. This consists in the information shared between each network node determined by the model, which enables production, distribution and transport planning dependent on the purpose. The shared information process is vital for effective supply chain production, distribution and transport planning. In terms of centralized planning, the information flows from each node of the network where the decisions are made. Shared information includes the following groups of parameters: resources, inventory, production, transport, demand, etc. Minimization of total costs is the main purpose of the models presented in the literature, while maximization of revenues or sales is considered to a smaller scale [12].

The vast majority of the works reviewed [2]–[7], [9],[10],[12] have formulated their models as linear programming (LP), integer programming (IP) and mixed integer linear programming (MILP) problems and solved them using the Operations Research methods. Nonlinear programming, multi-objective programming, fuzzy programming with stochastic programming are used much less frequently [12] [25].

Problems related to the design, integration and management of the supply chain affect many aspects of production, distribution, warehouse management, supply chain structure, transport modes etc. Those problems are usually closely related to each other, some may influence one another to a greater or lesser extent. Because of the interconnectedness and a very large number of different constraints: resource, time, technological, and financial, the constraint–based environments are suitable for producing "natural" solutions for highly combinatorial problems. In the literature, references to modeling and optimizing supply chain problems using constraint–based environments are relatively few in number [11], [12].

This paper deals with a problem of supply chain modelling, optimization and analysis. An important contribution of the presented hybrid CP/MP approach is to propose a hybrid implementation platform that supports the modelling, optimization and analysis of decision problems in the supply chain. In this platform two environments, mathematical programming (MP) and constraint programming (CP), in which constraints are treated in different ways and different methods are implemented, were combined to use the strengths of both in the presented platform.

The rest of the paper is organized as follows: Section II describes our motivation and analyses the state of the art in this domain. Section III gives the concept of the novel hybrid CP/MP approach and implementation platform. The optimization model as an illustrative example is described in Section IV. Computational examples and tests of the implemented model are presented in Section V. The discussion on possible extensions of the proposed approach and conclusions is included in Section VI.

II. MOTIVATION

We strongly believe that the constraint-based environment [13], [14], [16], [19] offers a very good framework for representing the knowledge and information needed for the decision support. The central issue for a constraint-based environment is a constraint satisfaction problem (CSP) [13]. Constraint satisfaction problem is the mathematical problem defined as a set of elements whose state must satisfy a number of constraints. Constraint satisfaction problems (CSPs) on finite domains are typically solved using a form of search. The most widely used techniques include variants of backtracking, constraint propagation, and local search. Constraint propagation embeds any reasoning that consists in explicitly forbidding values or combinations of values for some variables of a problem because a given subset of its constraints cannot be satisfied otherwise [16]. CSPs are frequently used in constraint programming. Constraint programming is the use of constraints as a programming language to encode and solve problems. Constraint logic programming (CLP) is a form of constraint programming (CP), in which logic programming is extended to include concepts from constraint satisfaction. A constraint logic program is a logic program that contains constraints in the body of clauses. Constraints can also be present in the goal. These environments are declarative. The declarative approach and the use of logic programming provide incomparably greater possibilities for decision problems modelling than the pervasive approach based on mathematical programming. Unfortunately, discrete optimization is not a strong suit of these environments.

Based on [8], [15], [16] and previous work [14], [17], [18], we observed some advantages and disadvantages of these environments. An integrated approach of constraint programming (CP) and mathematical programming (MP) can help to solve optimization problems that are intractable with either of the two methods alone [20]–[23]. Although mathematical programming and constraint programming have different roots, the links between the two environments have grown stronger in recent years.

Both MP and finite domain CP/CLP involve variables and constraints. However, the types of the variables and constraints that are used, and the way the constraints are solved, are different in the two approaches [23].

In both MILP and CP/CLP, there is a group of constraints that can be solved with ease and a group of constraints that are difficult to solve. The easily solved constraints in MILP are linear equations and inequalities over rational numbers.

Integrity constraints are difficult to solve using mathematical programming methods and often the real problems of MILP make them NP-hard.

In CP/CLP, domain constraints with integers are easy to solve. The system of such constraints can be solved over integer variables in polynomial time. The inequalities between more than two variables, general linear constraints and symbolic constraints are difficult to solve, which makes real problems in CP/CLP NP-hard. This type of constraints reduces the strength of constraint propagation. As a result, CP/CLP is incapable of finding even the first feasible solution. This is the greatest weakness of this approach.

As mentioned earlier, the vast majority of decision-making models for the problems of production, logistics, supply chain are formulated in the form of mathematical programming (MIP, MILP, IP).

Due to the structure of these models (adding together discrete decision variables in the constraints and the objective function) and a large number of discrete decision variables (integer and binary), they can only be applied to small problems. Another weakness is that only linear constraints can be used. In practice, the issues related to the production, distribution and supply chain constraints are often logical, nonlinear, etc. For these reasons the problem was formulated in a new way

The motivation and contribution behind this work was to create a hybrid method for supply chain decision problems modelling and optimization instead of using mathematical programming or constraint programming separately. It follows from the above that what is difficult to solve in one environment can be easy to solve in the other. Furthermore, such a hybrid CP/MP approach allows the use of all layers of the problem to solve it (Fig. 1). And finally, the transformation of the problem to a form that can fully exploit the strengths of the constraint propagation.

The hybrid method is not inferior to its component elements applied separately. This is due to the fact that the number of decision variables and the search area are reduced. The extent of the reduction directly affects the effectiveness of the method.

III. THE CONCEPT OF THE CP/MP HYBRID APPROACH

Due to the structure of the decision models for supply chain problems (summing of discrete decision variables in the constraints and the objective function) and a large number of discrete decision variables (integer and/or binary) they can only be applied to small problems. Another disadvantage is that only linear constraints can be used. In practice, the issues related to the production, distribution and su25]5ply chain constraints are often logical, nonlinear, etc. For these reasons the problem was formulated in a new way.

In our approach to modeling and optimization these problems we proposed the implementation platform, where:

- knowledge related to the supply chain can be expressed as linear and logical constraints (implementing all types of constraints of the previous MILP models [17], and introducing new types of constraints (logical, nonlinear, symbolic etc.));
- the decision models solved using the proposed platform can be formulated as a pure model of MILP or of CP/CLP, or it can also be a hybrid model with logical and other types of constraints;
- the problem is modelled in CP/CLP, which is far more flexible than MILP;

- the possibility to transform the problem of using the flexibility of declarative environment (CP/CLP) is introduced;
- the novel method of constraint propagation is proposed (obtained by transforming the decision model to explore its structure and properties);
- constrained domains of decision variables, new constraints and values for some variables are transferred from CP-based environment into MP-based environment;
- the efficiency of finding solutions to larger size problems is increased.

The concept of the proposed implementation platform is presented in Fig. 1. In the first stage, a formal model is implemented in the form of predicates in CLP and the data in the form of facts. In the next step constraint propagation is performed. Constraint propagation is one of the basic methods of CLP. As a result, the variable domains are narrowed, and in some cases, the values of variables are set, or even the solution can be found. In order to increase the efficiency of the constraint propagation transformation of the problem and its representation can be made. The transformation uses the structure and properties of the problem. The most common effect is a change in the representation of the problem by reducing the number of decision variables, and the introduction of additional constraints and variables, changing the nature of the variables, etc.

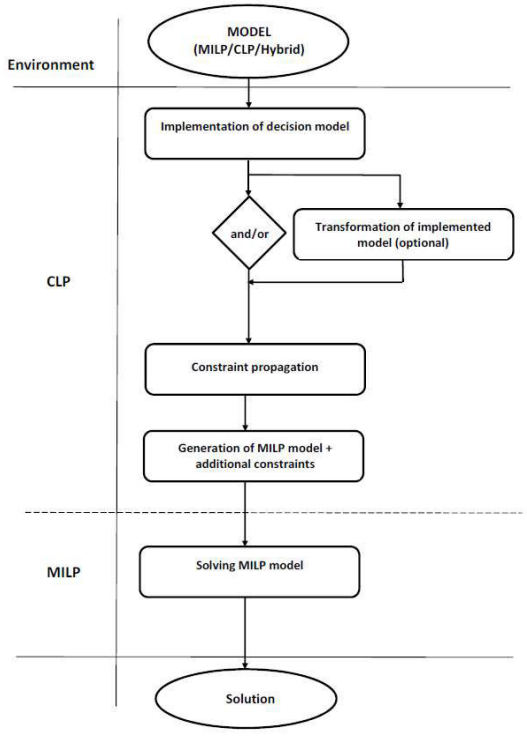

Fig. 1 Concept scheme of the CP/MP hybrid approach

The next step is the generation of the MILP model using predicates in CLP. All the information obtained in previous stages are used during the generation of the model. The final step is to solve the model by the solver MILP.

The implementation details of the CP/MP hybrid approach have been discussed in [24]. The motivation was to offer the most effective tools for model–specific constraints and solution efficiency.

IV. EXAMPLES OF SUPPLY CHAIN OPTIMIZATION

The proposed approach was used and tested on two supply chain optimization models.

First model was formulated as a mixed linear integer programming (MILP) problem [18] under constraints (2) .. (23) in order to test the proposed approach (Fig. 1) against the classical integer programming approach [17]. Then the hybrid model (1) .. (26) was implemented and solved. Indices, parameters and decision variables used in the models together with their descriptions are summarized in Table I. The simplified structure of the supply chain network for this model, composed of producers, distributors and customers is presented in Fig. 2.

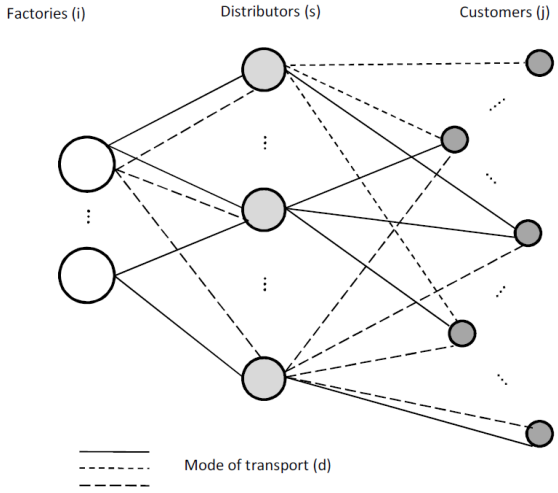

Fig. 2 The simplified structure of the supply chain network

Both models are the cost models that take into account three other types of parameters, i.e., the spatial parameters (area/volume occupied by the product, distributor capacity and capacity of transport unit), time (duration of delivery and service by distributor, etc.) and the transport mode.

The main assumptions made in the construction of these models were as follows:

- the shared information process in the supply chain consists of resources (capacity, versatility, costs), inventory (capacity, versatility, costs, time), production (capacity, versatility, costs), product (volume), transport (cost, mode, time), demand, etc;
- part of the supply chain has a structure as in Fig. 2.;
- transport is multimodal (several modes of transport, a limited number of means of transport for each mode);
- the environmental aspects of use of transport modes are taken into account;
- different products are combined in one batch of transport;
- the cost of supplies is presented in the form of a function (in this approach, linear function of fixed and variable costs);

- the models have linear or linear and logical constraints.

TABLE I.
INDICES, PARAMETERS AND DECISION VARIABLES

Symbol	Description
Indices	
k	product type (k=1..O)
j	delivery point/customer/city (j=1..M)
i	manufacturer/factory (i=1..N)
s	distributor /distribution center (s=1..E)
d	mode of transport (d=1..L)
N	number of manufacturers/factories
M	number of delivery points/customers
E	number of distributors
O	number of product types
L	number of mode of transport
Input parameters	
F_s	the fixed cost of distributor/distribution center *s*
P_k	the area/volume occupied by product *k*
V_s	distributor *s* maximum capacity/volume
$W_{i,k}$	production capacity at factory *i* for product *k*
$C_{i,k}$	the cost of product *k* at factory *i*
$R_{s,k}$	if distributor *s* can deliver product *k* then $R_{s,k}$=1, otherwise $R_{s,k}$=0
$Tp_{s,k}$	the time needed for distributor *s* to prepare the shipment of product *k*
$Tc_{j,k}$	the cut-off time of delivery to the delivery point/customer *j* of product *k*
$Z_{j,k}$	customer demand/order *j* for product *k*
Zt_d	the number of transport units using mode of transport *d*
Pt_d	the capacity of transport unit using mode of transport *d*
$Tf_{i,s,d}$	the time of delivery from manufacturer *i* to distributor *s* using mode of transport *d*
$K1_{i,s,k,d}$	the variable cost of delivery of product *k* from manufacturer *i* to distributor *s* using mode of transport *d*
$R1_{i,s,d}$	if manufacturer *i* can deliver to distributor *s* using mode of transport *d* then $R1_{i,s,d}$=1, otherwise $R1_{i,s,d}$=0
$A_{i,s,d}$	the fixed cost of delivery from manufacturer *i* to distributor *s* using mode of transport *d*
$Koa_{s,j,d}$	the total cost of delivery from distributor *s* to customer *j* using mode of transport *d*
$Tm_{s,j,d}$	the time of delivery from distributor *s* to customer *j* using mode of transport *d*
$K2_{s,j,k,d}$	the variable cost of delivery of product *k* from distributor *s* to customer *j* using mode of transport *d*
$R2_{s,j,d}$	if distributor *s* can deliver to customer *j* using mode of transport *d* then $R2_{s,j,d}$=1, otherwise $R2_{s,j,d}$=0
$G_{s,j,d}$	the fixed cost of delivery from distributor *s* to customer *j* using mode of transport *d*
$Kog_{s,j,d}$	the total cost of delivery from distributor *s* to customer *j* using mode of transport *d*
Od_d	the environmental cost of using mode of transport *d*
Decision variables	
$X_{i,s,k,d}$	delivery quantity of product *k* from manufacturer *i* to distributor *s* using mode of transport *d*
$Xa_{i,s,d}$	if delivery is from manufacturer *i* to distributor *s* using mode of transport *d* then $Xa_{i,s,d}$=1, otherwise $Xa_{i,s,d}$=0
$Xb_{i,s,d}$	the number of courses from manufacturer *i* to distributor *s* using mode of transport *d*
$Y_{s,j,k,d}$	delivery quantity of product *k* from distributor *s* to customer *j* using mode of transport *d*
$Ya_{s,j,d}$	if delivery is from distributor *s* to customer *j* using mode of transport *d* then $Ya_{s,j,d}$ =1, otherwise $Ya_{s,j,d}$ =0
$Yb_{s,j,d}$	the number of courses from distributor *s* to customer *j* using mode of transport *d*
Tc_s	if distributor *s* participates in deliveries, then Tc_s=1, otherwise Tc_s=0
CW	Arbitrarily large constant

A. Objective function

The objective function (1) defines the aggregate costs of the entire chain and consists of five elements. The first element comprises the fixed costs associated with the operation of the distributor involved in the delivery (e.g. distribution centre, warehouse, etc.). The second element corresponds to environmental costs of using various means of transport. Those costs are dependent on the number of courses of the given means of transport, and on the other hand, on the environmental levy, which in turn may depend on the use of fossil fuels and carbon-dioxide emissions [26],[27].

The third component determines the cost of the delivery from the manufacturer to the distributor. Another component is responsible for the costs of the delivery from the distributor to the end user (the store, the individual client, etc.). The last component of the objective function determines the cost of manufacturing the product by the given manufacturer.

Formulating the objective function in this manner allows comprehensive cost optimization of various aspects of supply chain management. Each subset of the objective function with the same constrains provides a subset of the optimization area and makes it much easier to search for a solution.

$$\sum_{s=1}^{E} F_s \cdot Tc_s + \sum_{d=1}^{L} Od_d \left(\sum_{i=1}^{N}\sum_{s=1}^{E} Xb_{i,s,d} + \sum_{s=1}^{E}\sum_{j=1}^{M} Yb_{j,s,d}\right) + \sum_{i=1}^{N}\sum_{s=1}^{E}\sum_{d=1}^{L} Koa_{i,s,d} + \sum_{s=1}^{E}\sum_{j=1}^{M}\sum_{d=1}^{L} Kog_{s,j,d} + \sum_{i=1}^{N}\sum_{k=1}^{O}\left(C_{ik} \cdot \sum_{s=1}^{E}\sum_{d=1}^{L} X_{i,s,k,d}\right) \quad (1)$$

B. Constraints

The model was based on constraints (2) .. (26) Constraint (2) specifies that all deliveries of product *k* produced by the manufacturer *i* and delivered to all distributors *s* using mode of transport *d* do not exceed the manufacturer's production capacity.

Constraint (3) covers all customer *j* demands for product *k* ($Z_{j,k}$) through the implementation of delivery by distributors *s* (the values of decision variables $Y_{i,s,k,d}$). The flow balance of each distributor *s* corresponds to constraint (4). The possibility of delivery is dependent on the distributor's technical capabilities – constraint (5). Time constraint (6) ensures the terms of delivery are met. Constraints (7a), (7b), (8) guarantee deliveries with available transport taken into account. Constraints (9), (10), (11) set values of decision variables based on binary variables Tc_s, $Xa_{i,s,d}$, $Ya_{s,j,d}$. Dependencies (12) and (13) represent the relationship based on which total costs are calculated. In general, these may be any linear functions. The remaining constraints (14)..(23) arise from the nature of the model (MILP).

Constraint (24) allows the distribution of exclusively one of the two selected products in the distribution center *s*. Similarly, constraint (25) allows the production of exclusively one of the two selected products in the factory *i*.

Constraint (26) allows the transport of exclusively one of the two selected products in the same route and transport unit.

Those constraints result from technological, marketing, sales or safety reasons. Therefore, some products cannot be distributed and/or produced and/or transported together. The constraint can be re-used for different pairs of product *k* and for some of or all distribution centers *s* and factories *i.* A logical constraint like this cannot be easily implemented in a mathematical programming model. Only declarative application environments based on constraint satisfaction problem (CSP) make it possible to easy implement constraints such as (24), (25), (26).

The addition of constraints of that type changes the model class. It is a hybrid model (1)..(26).

$$\sum_{s=1}^{E}\sum_{d=1}^{L} X_{i,s,k,d} \cdot R_{s,k} \le W_{i,k} \text{ for } i=1..N, k=1..O \quad (2)$$

$$\sum_{s=1}^{E}\sum_{d=1}^{L} (Y_{s,j,k,d} \cdot R_{s,k}) \ge Z_{j,k} \text{ for } j=1..M, k=1..O \quad (3)$$

$$\sum_{i=1}^{N}\sum_{d=1}^{L} X_{i,s,k,d} = \sum_{j=1}^{M}\sum_{d=1}^{L} Y_{s,j,k,d} \text{ for } s=1..E, k=1..O \quad (4)$$

$$\sum_{k=1}^{O} (P_k \cdot \sum_{i=1}^{N}\sum_{d=1}^{L} X_{i,s,k,d}) \le Tc_s \cdot V_s \text{ for } s=1..E \quad (5)$$

$$Xa_{i,s,d} \cdot Tf_{i,s,d} + Xa_{i,s,d} \cdot Tp_{s,k} + Ya_{s,j,d} \cdot Tm_{s,j,d} \le Tc_{j,k} \text{ for } i=1..N,\ s=1..E,\ j=1..M,\ k=1..O, d=1..L \quad (6)$$

$$R1_{i,s,d} \cdot Xb_{i,s,d} \cdot Pt_d \ge X_{i,s,k,d} \cdot P_k \text{ for } i=1..N, s=1..E, k=1..O, d=1..L \quad (7a)$$

$$R2_{s,j,d} \cdot Yb_{s,j,d} \cdot Pt_d \ge Y_{s,j,k,d} \cdot P_k \text{ for } s=1..E,\ j=1..M,\ k=1..O, d=1..L \quad (7b)$$

$$\sum_{i=1}^{N}\sum_{s=1}^{E} Xb_{i,s,d} + \sum_{j=1}^{M}\sum_{s=1}^{E} Yb_{j,s,d} \le Zt_d \text{ for } d=1..L \quad (8)$$

$$\sum_{i=1}^{N}\sum_{d=1}^{L} Xb_{i,s,d} \le CW \cdot Tc_s \text{ for } s=1..E \quad (9)$$

$$Xb_{i,s,d} \le CW \cdot Xa_{i,s,d} \text{ for } i=1..N, s=1..E, d=1..L \quad (10)$$

$$Yb_{s,j,d} \le CW \cdot Ya_{s,j,d} \text{ for } s=1..E, j=1..M, d=1..L \quad (11)$$

$$Koa_{i,s,d} = A_{i,s,d} \cdot Xb_{i,s,d} + \sum_{k=1}^{O} K1_{i,s,k,d} \cdot X_{i,s,k,d} \text{ for } i=1..N, s=1..E, d=1..L \quad (12)$$

$$Kog_{s,j,d} = G_{s,j,d} \cdot Yb_{j,s,d} + \sum_{k=1}^{O} K2_{s,j,k,d} \cdot Y_{s,j,k,d} \text{ for } s=1..E, j=1..M, d=1..L \quad (13)$$

$$X_{i,s,k,d} \ge 0 \text{ for } i=1..N, s=1..E, k=1..0,\ d=1..L \quad (14)$$

$$Xb_{i,s,d} \ge 0 \text{ for } i=1..N,\ s=1..E,\ d=1..L, \quad (15)$$

$$Yb_{s,j,d} \ge 0 \text{ for } s=1..E,\ j=2..M,\ d=1..L, \quad (16)$$

$$X_{i,s,k,d} \in C \text{ for } i=1..N, s=1..E, k=1..0, d=1..L, \quad (17)$$

$$Xb_{i,s,d} \in C \text{ for } i=1..N,\ s=1..E,\ d=1..L \quad (18)$$

$$Y_{s,j,k,d} \in C \text{ for } s=1..E, j=1..M,\ k=1..0, d=1..L \quad (19)$$

$$Yb_{s,j,d} \in C \text{ for } s=1..E,\ j=1..M,\ d=1..L, \quad (20)$$

$$Xa_{i,s,d} \in \{0,1\} \text{ for } i=1..N,\ s=1..E,\ d=1..L, \quad (21)$$

$$Ya_{s,j,d} \in \{0,1\} \text{ for } s=1..E,\ j=2..M,\ d=1..L, \quad (22)$$

$$Tc_s \in \{0,1\} \text{ for } s=1..E \quad (23)$$

$$ExclusionD(k_1,k_2,s) \text{ for } k_1,k_2 \in 1..O,\ s \in 1..E,\ k_1 \ne k_2 \quad (24)$$

$$ExclusionP(k_1,k_2,i) \text{ for } k_1,k_2 \in 1..O,\ i \in 1..N,\ k_1 \ne k_2 \quad (25)$$

$$ExclusionT(k_1,k_2) \text{ for } k_1 \in 1..O,\ k_2 \in 1..O,\ k_1 \ne k_2 \quad (26)$$

C. Model transformation

Due to the nature of the decision problem (adding up decision variables and constraints involving a lot of variables), the constraint propagation efficiency decreases dramatically. Constraint propagation is one of the most important methods in CLP affecting the efficiency and effectiveness of the CLP and novel hybrid implementation platform (Fig. 1). For that reason, research into more efficient and more effective methods of constraint propagation was conducted. The results included different representation of the problem and the manner of its implementation. The classical problem modeling in the CLP environment consists in building a set of predicates with parameters. Each CLP predicate has a corresponding multi-dimensional vector representation. While modeling both problems, (1) .. (23) and (1) .. (26), quantities *i, s, k, d* and decision variable $X_{i,s,k,d}$ were vector parameters. The process of finding the solution may consist in using the constraints propagation methods, labeling of variables and the backtracking mechanism [13]. The quality of constraints propagation and the number of backtrackings are affected to a high extent by the number of parameters that must be specified/labeled in the given predicate/vector. In both models presented above, the classical problem representation included five parameters: *i, s, k, d* and $X_{i,s,k,d}$. Considering the domain size of each parameter, the process is complex and time-consuming. Our idea was to transform the problem by changing its representation without changing the very problem. All permissible routes were first generated based on the fixed data and a set of orders, then the specific values of parameters *i, s, k, d* were assigned to each of the routes. In this way, only decision variables $X_{i,s,k,d}$ (deliveries) had to be specified. This transformation allows only one parameter search instead of five. This is possible due to the flexibility and features of the CLP environment.

This transformation fundamentally improved the efficiency of the constraint propagation and reduced the number of backtracks. A route model is a name adopted for the models that underwent the transformation (MILP-R).

D. Decision-making support

The proposed models in this platform can support decision-making in the following areas:

- the optimization of total cost of the supply chain (Table II);
- the selection of the transport fleet number, capacity and modes for specific total costs;
- the sizing of distributor warehouses and the study of their impact on the overall costs (Table III, Fig. 3.);
- the selection of transport routes for optimal total cost (Fig. 4.).

Detailed studies of these topics are being conducted and will be described in our future articles.

V. NUMERICAL EXPERIMENTS

In order to verify and evaluate the proposed approach, many numerical experiments were performed. All the examples relate to the supply chain with seven manufacturers *(i=1..7),* three distributors *(s=1..3)*, ten customers *(j=1..10),* three modes of transport *(d=1..3),* and twenty types of products *(k=1..20).* Experiments began with nine examples of P1 .. P9 for the optimization MILP model (1) .. (23). The examples differ in terms of capacity available to the distributors *s* *(V_s),* the number of transport units using the mode of transport *d* *(Zt_d)* and the number of orders (*No*). The first series of experiments was designed to show the benefits and advantages of the hybrid approach. For this purpose the model (1) .. (23) was implemented in both the hybrid and integer programming environments. The experiments that follow were conducted to optimize examples P1..P9 for the optimization HP model (1) .. (26) in the hybrid approach.

Numeric data of input parameters for examples P1.. P9 are shown in Appendix A1. The results in the form of the objective function and the computation time are shown in Table II.

TABLE II
THE RESULTS OF NUMERICAL EXAMPLES FOR BOTH APPROACHES

P(No)	Hybrid Approach		Integer Programming		Hybrid Approach

Fc	the value of the objective function					
T	time of finding solution (in seconds)					
*	the feasible value of the objective function after the time T					
**	calculation was stopped after 900 s					
MILP	MILP model implementation in the IP environment.					
MILPT	MILP model after transformation-implementation in the hybrid implementation platform.					
HM	Hybrid model after transformation-implementation in the hybrid implementation platform.					

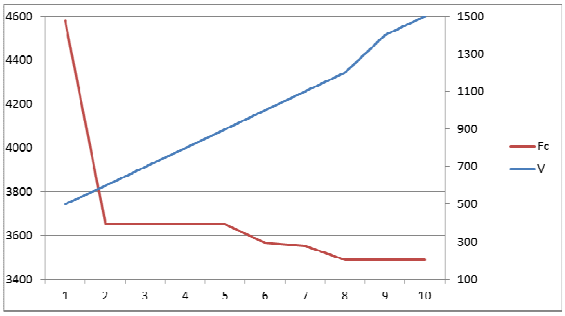

Fig. 3 The value of the objective function depending on the parameter V (Example P6)

For each example the solution for the MILP-R implementation was found faster than that for the MILP implementation. Moreover, for examples P1 .. P4, the traditional approach based on integer programming gives only feasible solution (calculation was stopped after 900 s) despite using highly efficient MILP solvers. It is obvious that the solution of the hybrid model (HM) was, due to its nature, only possible using the hybrid platform. Also, the proposed environment brought the expected results. The results were obtained in only a slightly longer period of time than that necessary for MILP-R (examples P1 .. P9).

1000	3567	188	968	0
1100	3554	130	1026	0
1200	3488	0	1156	0
1400	3488	0	1156	0

VI. CONCLUSION

The efficiency of the proposed approach is based on the reduction of the combinatorial problem. This means that using the hybrid approach practically for all models of this class, the same or better solutions are found faster (the optimal instead of the feasible solutions). Another element contributing to the high efficiency of the method is a possibility to determine the values or ranges of values for some of the decision variables (phase P3). All effective LINGO solvers can be used in the hybrid method.

It should be emphasized that with the used approach it is possible not only to solve optimization problems faster, but also to solve much larger problems than in the [17].

Therefore, the proposed solution is highly recommended for all types of decision problems in supply chain or for other problems with similar structure. This structure is characterized by the constraints of many discrete decision

variables and their summation. Furthermore, this method can model and solve problems with logical constraints.

In addition to the undoubted effectiveness of the proposed hybrid approach, should underline the possibility of modeling decision problems. The proposed approach can be created a new class of decision problems - hybrid problems that are not only familiar with the constraints from mathematical programming models but also new types of constraints such as logical constraints.

Further work will focus on running the optimization models with non-linear and other logical constraints, multi-objective, uncertainty etc. in the hybrid optimization framework. It is planned also apply this method to various types of scheduling problems [14],[28],[29].

Abstract— Radio frequency identification (RFID) is untouched automatic identification technologies in which information can be transmitted by radio frequency. In this study, an RFID system which can determine the position and place of any desired vehicle is designed and developed. Microprocessor transmitter devices, on which the vehicle information is loaded, are placed on the vehicles. Receiver circuits are located at certain points in order to receive the RF signals sent by these transmitter devices. The communication of all the points with each other is maintained by connecting the receiver circuits via the internet. The functionality of the system is tested by performing receiver-transmitter experiments based on the various speeds and locations of the vehicles. According to the results obtained in the experiments, it is seen that the system designed in the study could be used in place of the GPS system for determining the place and position of vehicles, since it is more economical when compared to the GPS system.

I. Introduction

Nowadays, private organizations, individuals, and particularly public institutions have a rapidly increasing need for the positional information of various objects. The increase in the demand for information and in variety requires the collection of the positional information of individuals, institutions and regions in a faster and more economical way. The desire to maintain continuity and speed in the currency of information has resulted in rapid developments in Global Positioning Systems (GPS). The need for information can be evaluated on three basic scales, as local, regional and global.

The use of GPS systems is expensive and limited, and such systems have strategic importance. For this reason, it is necessary to create alternative systems. Different from the systems that are established and used by developed countries and the use of which by other countries is restricted, in the present study, a system whose use is not dependent on the permission of other countries, which does not require the use of satellites and which is considerably economical when compared to other systems is designed. Vehicle recognition, tracking and positioning system is implemented in order to determine the location and position of vehicles by using RF signals. In this way, although not point-wise, it is possible to determine the position of a vehicle in a narrow area.

Various results have been obtained in previously conducted similar studies [1]. A vehicle management system based on UHF band RFID technology is proposed in [2]. This system is applied to vehicles entering/leaving at road gates. The system consists of tag-on-car, reader antenna, reader controller, and monitoring and commanding software. Schneider proposes radio frequency identification technology for potential applications in the commercial construction industry [3]. It is defined that RFID can increase the service and performance of the construction industry with applications in materials management, tracking of tools and equipment, automated equipment control, jobsite security, maintenance and service, document control, failure prevention, quality control, field operations, and construction safety. Tu et al. examine radio frequency identification (RFID) tags, which are increasingly being used in pervasive healthcare applications [4]. Specifically, they study the dynamics of locating and identifying the presence of a tag in such systems. In [5], web servers build the agents by themselves and an agent-based interaction works with the support of Web services. Thus, they supposed to build an agent-based structure for transportation control that is similar to the structure of the Internet. Agent-based transportation management is a possible contribution to make transportation management more effective in regard to saving energy (fuel) and protecting our environment by stopping the increase of existing traffic ways. Liu et all. study on a platform for moving vehicle detection and tracking [6]. A novel Marr wavelet, kernel-based background modeling method and a background subtraction method based on binary discrete wavelet transforms (BDWT) are introduced. In addition, an automatic particle filtering algorithm is used to track the vehicle after detection and obtaining the center of the object. Böse et al. investigate an innovative approach to autonomous control in automobile logistics, considering as example the logistic order processing of an idealized automobile terminal of the company [7]. They present the results of an executed case study concerning the implementation and test of an

This work was not supported by any organization

autonomously controlled, radio frequency identification (RFID) based storage management system. In [8], an in-vehicle signing system is built and assessed that uses general-purpose RFID tags as digital traffic signs, and a field test is conducted using tags installed on a road to verify whether the system works effectively. In [9], a radio frequency identification (RFID) system for defining railway vehicles and an antenna is designed for the receiver/transmitter circuit of the RFID system is proposed. An intelligent traffic management system by using RFID technology is proposed in [10]. Using the system, important traffic and control data is obtained in a practical way, and also illegal vehicles, such as those which have been stolen are tracked.

II. GLOBAL POSITIONING SYSTEM

Global Positioning System (GPS) is a satellite network which conveys coded information in a regular manner. This system is composed of 24 satellites which continuously move in orbit and broadcast very low-power radio signals. The GPS receiver on the Earth's surface makes it possible to determine our definite position on the Earth by receiving those radio signals and measuring our distance from the satellites [11]. The functioning structure of the global positioning system is presented in Figure 1.

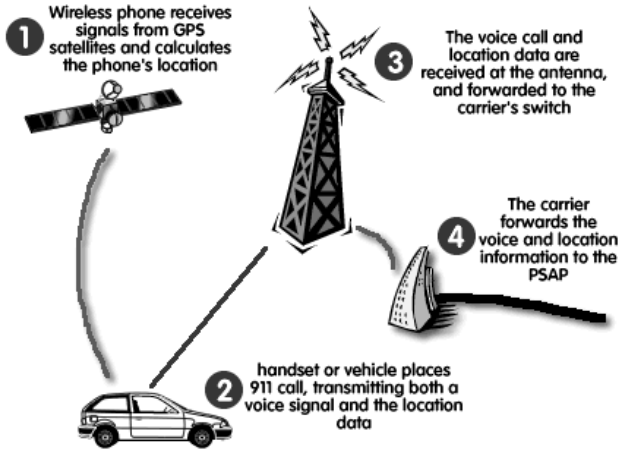

Fig. 1. The structure of the GPS system

The structure of the GPS system is composed of three major parts: the space segment, the control segment and the user segment. The space segment consists of at least 21 active satellites and 3 on-orbit spares. Each of the satellites transmits radio signals on two different frequencies. Civilian GPS satellite signals are transmitted at a frequency of 1575.42 MHz in the UHF band, while military GPS signals are transmitted at a frequency of 1227.6 MHz and are used by the US defense unit. Each satellite broadcasts two special pseudo-random codes which enable the receivers on the Earth to recognize the signals. These signals include the orbit, time, general system and ionospheric delay information of the satellite. The control segment obtains the exact orbit and time information by continuously tracking the satellites. There are several control stations on the surface of the Earth [12]. The user segment is comprised of all of the GPS receivers on the Earth.

The GPS tracking system was originally intended for military applications, but in the 1980s, the system was made available for civilian use upon the increasing demand. The proportion of the civilian use of GPS systems has reached a high rate of 90% compared to its use for military purposes [13].

III. RF COMMUNICATION

Communication technology, which has gained a new dimension and speed in recent years, has led to the development of techniques that enable the use of the air as a transmission environment and the sending of information to the desired point by coding the signal on a high frequency carrier wave, which is also named as modulation.

An electromagnetic wave is formed when an electric field combines with a magnetic field. These waves, which are combined and sent by the RF transmitter, are separated by the RF receiver and transformed into electric and magnetic waves [14].

Devices which are used for modulating the amplitude, frequency or the phase of the information signal and the high frequency carrier signal and then transmitting the information through the air or a conductive environment are called RF transmitters. RF receivers are devices by which the signals coming from the RF transmitter are received by an antenna and amplified by the power amplifier, then mixed with the local oscillator signal. Then, the RF signal is transformed to information by being demodulated at the output of the mixer. The operating principles of RF transmitter and receiver circuits are presented in Figure 2 [14].

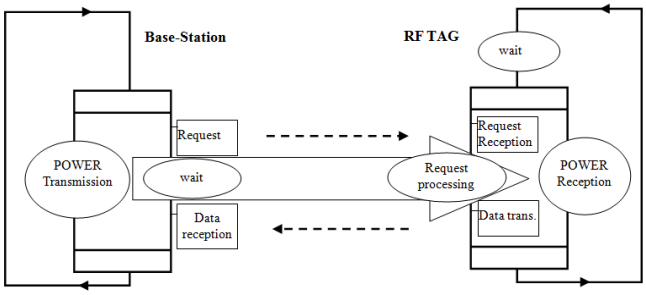

Fig. 2. RF Receiver and Transmitter Circuit Block Diagram

As shown in Figure 2, RFID system is composed of tags, which carry the data in suitable transponders, and an RFID reader, which retrieves the data from the tags, and software such as a driver and middleware. The main function of the RFID system is to retrieve information (ID) from a tag (also known as a transponder). Tags are usually affixed to objects such as goods or vehicles so that it becomes possible to locate where the goods and vehicles are without line-of-

sight. A tag can include additional information other than the ID, which opens up opportunities to new application areas. In these systems, the RF area is broken down into a number of grouped frequencies that are called bands. The frequencies used in RFID systems are analyzed below:

• Less than 135 kHz: This is the low frequency (LF) which allows the detection of RFID tags in a short range. The data reading speed is low and in this frequency the electromagnetic waves penetrate water but not metal. This frequency is used for animal identification, inventory control and car immobilizer [15].

• 13.56MHz: This frequency, which is called as high frequency (HF), allows the detection of RFID tags for a distance of up to 1.5m. The data transfer rate for this specific frequency is approximately 25 Kbits per second. In this frequency, the electromagnetic waves can penetrate water but have poor performance around metal. This frequency is used for applications related to access, security payment and various item levels tracking such as books, luggage, etc. [16].

• 433MHz, 850–956MHz: The frequencies which belong to this range are characterized as ultra-high frequencies (UHF). This frequency allows high reading speed as approximately 100 Kbits per second. The frequencies at this range are used for applications in vehicle tracking, railway vehicle monitoring [16].

• 2.45-5.8GHz: This frequency enables an RFID reader to detect a tag from a distance of ten meters. This specific frequency is characterized as microwave frequency. Data transfer rates are fast but the reading range is similar to UHF. The specified frequency is used for applications related to industrial automation [16].

In our vehicle tracking system, an ATX-34 circuit is used as the RF transmitter and an ARX-34 circuit is used as the RF receiver. ATX-34 and ARX-34 circuits are preferred for their high stability and wide area of use. These circuits comply with the radio standard EN 300 220 at 433.920 MHz UHF band, have high frequency stability and are ideal for battery applications with their low current consumption [17].

In this study, the PIC16F877 microcontroller manufactured by Microchip Technology Inc is used for entering the license plate information of the vehicles, and programming and storing the information coming from the transmitter [18]. This microcontroller is programmed using the JAL programming language [19]. The antenna used in the study has an impedance of 50 Ω and is approximately 17.3 cm.

The transmitter circuit is programmed together with the license plate information. The PIC16F877 integrated circuit can be locked against rewriting and reading during the programming process. In this way, the access of unauthorized persons to the license plate information of vehicles can be restricted. The license plate information is not transferred by using a standard on the transmitter circuit so that it cannot be easily acquired. The circuit transmits the license plate information through a completely specific protocol. Figure 3 shows the fundamental steps of the RFID system.

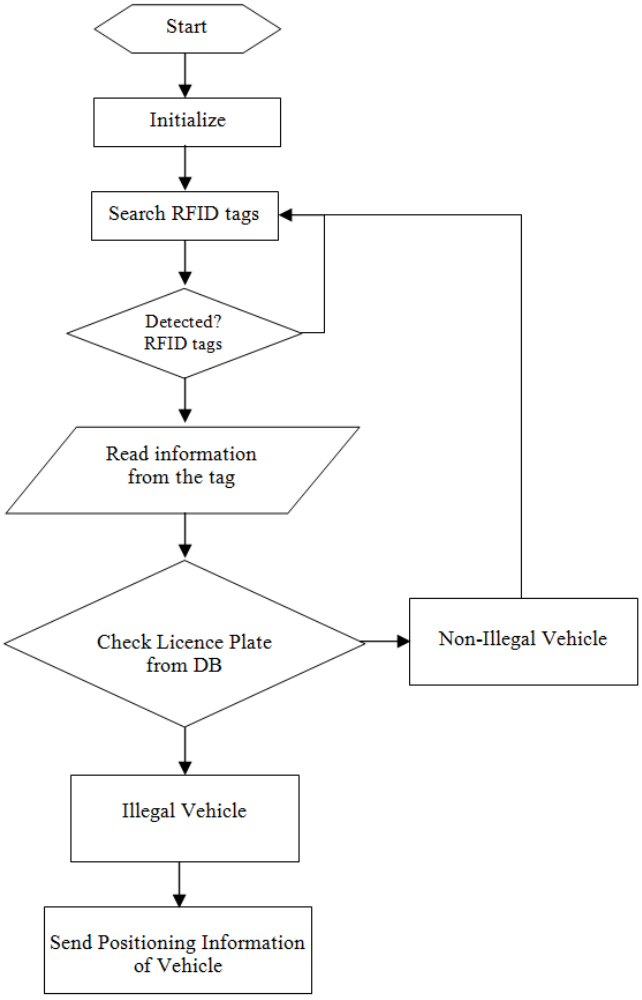

Fig. 3. Diagram of the RFID system for vehicle identification

In each transmission, the transmitter circuit sends a data package. The eight-character license plate information is transmitted in this data package as shown in Figure 4. The license plate information is added to the beginning of the preamble data package. The radio preamble is a section of data at the head of a packet that contains information the access point and the client devices need when sending and receiving packets. The preamble data is a leading signal which is composed of 6 bits and each period of which is 1ms. This signal is used in order to prevent the faulty reception of the initial data by a receiver. The faulty reception of the initial data is prevented by sending a leading preamble data. After this, the synchronous signal and the 8-byte data are transmitted. The permanent duty of the transmitter circuit is to continuously broadcast the recorded license plate information.

4	2	B	V	0	2	1	3

Fig. 4. 8-bit license plate information data

The general structure and functioning of the system is presented in the block diagram of the circuit shown in Figure 5.

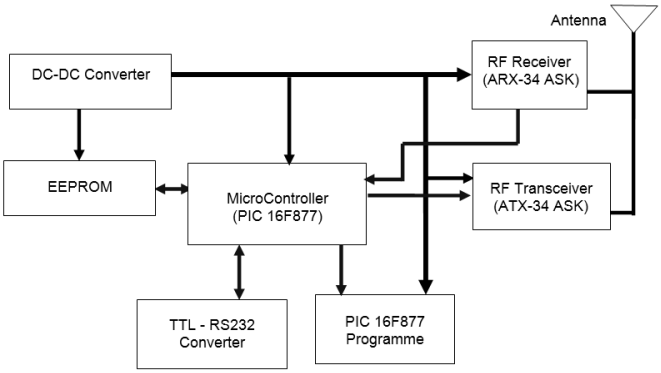

Fig. 5. The circuit block diagram of the designed RFID system

When the receiver circuit receives RF information from the transmitter circuit that complies with its protocol, it transmits this information to the computer through the RS232 port. The data is stored on the computer and the desired information can be selected. The searched license plates are reported to the program and the program searches for the wanted plates among the received data. When one of the searched license plates enters into the coverage area of the tracking system, the program records the entry with date and time, and displays an alert on the screen to warn the user. The circuit transmits the data which is only in a compatible format at a speed of 115.200 bps.

The signals received from the receivers are processed by the interface program. There is a transmitter circuit which has a specific code on each vehicle. As it can be seen in Figure 6, the interface consists of three main parts. The first of these is the Passing Vehicles Part, the second is the part where we enter the license plate information of the vehicle we want to find, and the third is the part where we determine at what time a certain vehicle passes a certain point.

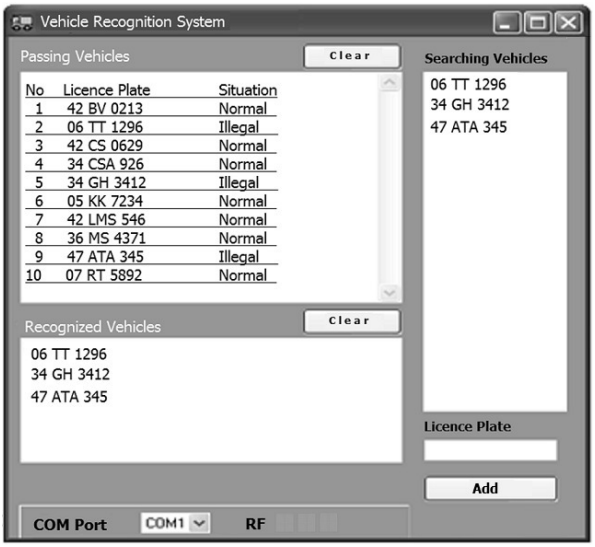

Fig. 6. The interface program developed for the vehicle tracking system

When the program is started, the information obtained in the three parts begins to be stored in the database. In this way, access is provided to the information concerning a desired time, day and hour.

IV. EXPERIMENTAL RESULTS

Two transmitter and one receiver circuits are used in the system designed for this study. The receiver circuit is located at a point on the route determined for the study. The two transmitters are placed on two different vehicles. The vehicle information of each vehicle passing along the route is read by the RF receiver. In this way, it is known which city the vehicle travels to, where it stops over and from which direction the vehicle enters the city. An area on which the license plate information of the searched vehicles can be entered is added to the computer software used for recording and monitoring vehicle information. In this way, when the sought vehicle enters the coverage area of the receiver, the vehicle information is delivered to the system user through the computer.

The license plate information of the sought vehicle is entered to the system by the traffic data processing unit of the city and it can be seen by the traffic information centers of all the cities with the help of a computer network. When the vehicle is detected within the borders of a city, the location of the vehicle is transmitted to the system users of all the cities via the computer network.

In this study, it is planned to place the system at the entrance and the exit of the city. However, the system can also be used at traffic points, intercity traffic stations, intersections and highway entrance and exit booths.

In the present study, a total of five experiments are conducted on; the distance required for the recognition of the vehicles equipped with a transmitter by the receiver, the speed of the vehicle which is effective on recognition,

weather conditions, the effect of the position of the receiver and the transmitter on the recognition of the vehicle.

A. Determination of the Recognition Distance

The receiver is placed 1 m above the ground, and the approach and deviation distances are found to be 30 m at the 10 passes made at a speed of 50 Km/h by the transmitter placed on the vehicle, as shown in Figure 7.

When the receiver is placed at a height of 2.20 m, it is observed that the approach and deviation distances are found to be still equal at the 10 passes made at a speed of 50 Km/h, but the recognition distance of the vehicle has increased to 50 m.

When the receiver is placed at a height of 4.60 m, it is observed that the approach and deviation distances are found to be still equal at the 10 passes made at a speed of 50 Km/h, but the recognition distance of the vehicle has increased to 75 m.

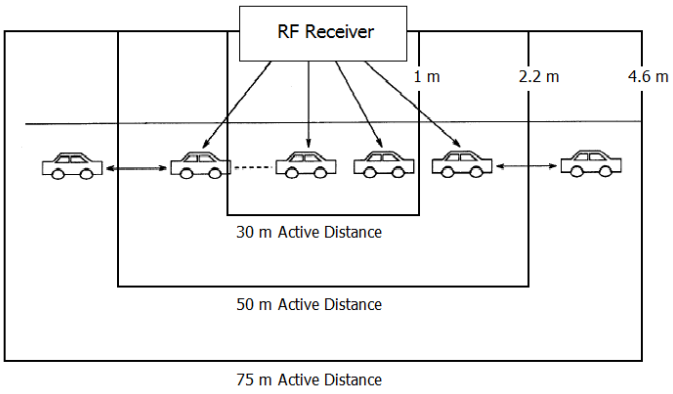

Fig. 7. The distances at which the transmitter is detected by the receiver

B. Determination of the Speed that Prevents the Recognition of the Vehicle

It is necessary that the vehicles passing the areas where the receivers are located be sensed by the receiver. The receiver may not sense the vehicle due to several factors, such as the passing of more than one vehicle simultaneously and the speed of the passing vehicle. The height of the receivers and the speed of the vehicles are important for sensing the passing vehicles in a reliable manner. For this reason, the receiver is placed at a height of 2.20 m and the approach and deviation distances of the vehicle are found to be the same at the passes made at speeds of 20 Km/h, 50 Km/h, 80 Km/h, 100 Km/h and 120 Km/h, and the recognition distance of the transmitter by the receiver is found to be 50 m.

C. Recognition Number of the Vehicle

It is necessary that the receiver senses the vehicles passing the active region and obtains reliable data. For this reason, it is important how many times the receiver communicates with the transmitter in the active region. In this study, it is determined how many times the receiver recognizes the transmitter in the active region depending on the speed of the vehicle and the obtained number is compared with the calculations performed based on the frequency of the transmitter. When the period required for the wavelength of the transmitter broadcasting at a frequency of 433.927 MHz is calculated.

$$T = 1 / f \quad (1)$$

where; T is the period (s), f is the frequency (Hz). Thus period is obtained as 2.3 ns.

When the distance covered by a vehicle travelling at a speed of 100 Km/h is calculated.

$$S = V / t \quad (2)$$

where; S is the distance traveled in 1 s; V is the speed of the vehicle (m/s); t is the total time (s).

In Eq. 2, S is calculated as 100.000 / 3.600 = 27.7 m. Therefore, the vehicle would pass the 50m active region in 2 s considering the length of the vehicle (supposing that the vehicle is a passenger car).

A number of 2 s / 2.3 ns = 0,869 x 109 signals are sent to the receiver from the transmitter. The vehicle license plate consists of 8 characters. Each character requires successive continuous data transfer at periods of 1 ms. For this reason, information of a vehicle is sent over to the receiver every 8 ms. Moreover, when we add the starting and ending bits, this period is extended to 10 ms. That is, a vehicle information reaches the receiver every 10 ms, therefore the receiver can read the information from the transmitter 2 s / 10 ms = 200 times within a passing period of 2 s. Each piece of information is read 4 times consecutively in the interface program to ensure that the vehicle is completely recognized. Thus, the vehicle information is read 200 / 4 = 50 times. It is expected that this number of readings will be adequate for the receiver to read the transmitter without missing the receiver even if there is more than one vehicle in the active reading area.

The receiver is placed at a height of 2.20 m and the experiment is repeated by passing the transmitter by the receiver point 5 times at each speed of 20 Km/h, 50 Km/h, 80 Km/h, 100 Km/h and 120 Km/h.

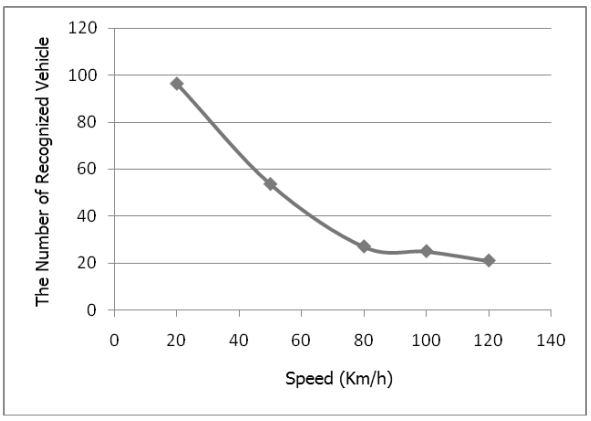

Fig. 8. Speed – Number of Detection Graph

The data obtained as the result of this experiment is shown in Figure 8. As it can be seen in the graph, as the speed of the vehicles increase their number of detection decreases. The maximum speed limit is 120 Km/h in our country. For this reason, our experiment is conducted up to this limit.

When more than one vehicle enters the recognition distance of the receiver at the same time, the number of detection of each vehicle is measured separately. As it can be seen in Figures 9 and 10, the entry of two vehicles of the same type into the active area does not affect the detection of the vehicles. However, although the distance of detection remains the same, the number of detection decreases to half, even to 40-45% when compared to the experiment conducted with one vehicle.

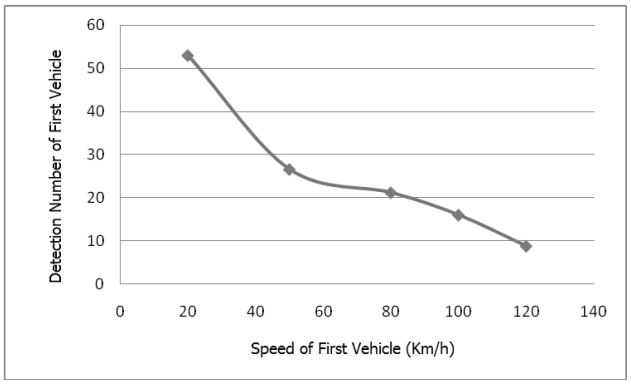

Fig. 9. 1st Vehicle Speed – Number of Detection Graph

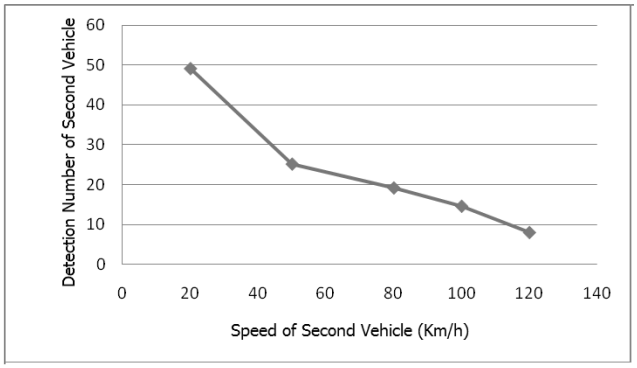

Fig. 10. 2nd Vehicle Speed – Number of Detection Graph

In a further experiment, the transmitter vehicle is passed by a heavy vehicle at different speeds as shown in Figure 11, and the values presented in Table 1 are obtained as the result of the experiment.

As it can be seen in Table 1, the number of detection of the transmitter vehicle which is behind the heavy vehicle significantly decreased. This could be considered as a disadvantage of our vehicle tracking system.

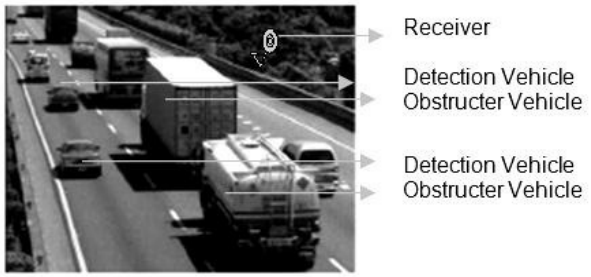

Fig. 11. Moment of passing of the undetected vehicles

TABLE I.
NUMBER OF DETECTION OF A VEHICLE BEHIND HEAVY VEHICLES

Speed (Km/h)	Number of Detection					Mean
	1st Pass	2nd Pass	3rd Pass	4th Pass	5th Pass	
20	45	15	14	14	15	20.6
50	6	5	8	7	8	6.8
80	3	2	0	0	2	1.4
100	2	1	0	0	1	0.8
120	0	0	1	0	0	0.2

In this study, an RFID system for tracking and determining the position of vehicles is designed. In this system, all the vehicles on which transmitters are placed are detected and recognized by the system when they pass by the points where receivers are located. Experiments are conducted in order to determine the speed that prevents the recognition of the vehicle, to recognize each vehicle when more than one vehicle enters the recognition distance of the receiver at the same time and to determine the physical obstacles that might prevent the recognition of the vehicle. In the designed system, the license plate information of the vehicles can be viewed in the interface program. This information is recorded on the computer via the interface program. When the license plate information of the sought vehicle is entered into the interface program, the exact time when the vehicle passes a previously determined point is displayed as day, hour, minute and second. Furthermore, all the vehicles detected by the receiver are listed in the interface program. The process of determining the place and position of a vehicle, which can be carried out using the GPS system whose use is restricted, is easily performed. In this way, a moving vehicle can be tracked by using the system developed in this study.

It is observed that the performance of the system decreases when the experiments described above are performed under maximum conditions, that is, under very heavy traffic and unfavorable weather conditions. Under such conditions, the performance of the system can be enhanced by placing the receiver in a higher position, adjusting its direction and increasing the signal level of the transmitter.

The system designed in the present study can be adjusted in a manner that enables access to insurance, vehicle inspection, vehicle license and driving license information

through certain changes and additional software. Access to the mentioned information can be rendered exclusive to certain institutions, organizations and individuals. In this way, it can be possible to receive information regarding when and from where a vehicle passes and also to access vehicle license and driving license information.

D. Conclusion

This research has investigated the practical issues of deploying the RFID technology for the vehicle identification started from hardware procurement process. The paper has researched several technical aspects of RF-ID implementation. Microprocessor transmitter devices, on which the vehicle information is loaded, are placed on the vehicles. Receiver circuits are located at certain points in order to receive the RF signals sent by these transmitter devices. The communication of all the points with each other is maintained by connecting the receiver circuits via the internet. According to the results obtained in the experiments, it is seen that the system designed in the study could be used in place of the GPS system for determining the place and position of vehicles, since it is more economical when compared to the GPS system.

The results of the experiments indicate that even implementing the system in a small scale (prototype system), there are a number of challenges to be solved in the middleware development phase, and extraordinary challenges in the configuration and tuning phases. Therefore to gain a cost effective system from deploying RFID for vehicle tracking in practice, extra attention is definitely required, and further experimentation on a real-life scale (e.g., real vehicle and gate) and/or using different sets of equipment will help confirm the results from this research.

Collaborative Human-Machine Intelligence 20th Conference on Knowledge Acquisition and Management and 2nd Workshop on Artificial Intelligence for Knowledge Management

KNOWLEDGE management is a large multidisciplinary field having its roots in Management and Artificial Intelligence. Activity of an extended organization should be supported by an organized and optimized flow of knowledge to effectively help all participants in their work.

We have the pleasure to invite you to contribute to and to participate in the conference "Knowledge Acquisition and Management" and 2nd Workshop on "Artificial Intelligence for Knowledge Management" (KAM&AI4KM'14). The predecessor of the KAM conference has been organized for the first time in 1992, as a venue for scientists and practitioners to address different aspects of usage of advanced information technologies in management, with focus on intelligent techniques and knowledge management. In 2003 the conference changed somewhat its focus and was organized for the first under its current name. Furthermore, the KAM conference became an international event, with participants from around the world. In 2012 we've joined to Federated Conference on Computer Science and Systems becoming one of the oldest event.

The "Artificial Intelligence for Knowledge Management" Workshop was initiated by IFIP Group TC12.6 in 2012 as the separate event during European Conference on Artificial Intelligence in Montpellier (ECAI'2012). From the beginning the workshop aims in bringing together researchers and practitioners involved in Knowledge Management using the methods and techniques of AI for building and improving all aspects of KM and of knowledge flow, among others, improvement of the innovation process. This year both teams KAM and AI4KM, have decided to join efforts in the FedCSIS framework with common challenge: "Collaborative Human-Machine Intelligence" under IFIP supporting.

The aim of this common event is to create possibility of presenting and discussing approaches, techniques and tools in the knowledge acquisition and other knowledge management areas with focus on contribution of artificial intelligence for improvement of human-machine intelligence and face the challenges of this century. We expect that the conference&workshop will enable exchange of information and experiences, and delve into current trends of methodological, technological and implementation aspects of knowledge management processes.

Topics

The following group topics, concerning both theory and applications, will be included (unavoidably incomplete):

- Knowledge discovery from databases and data warehouses
- Methods and tools for knowledge acquisition
- New emerging technologies for management
- Organizing the knowledge centers and knowledge distribution
- Knowledge creation and validation
- Knowledge dynamics and machine learning
- Distance learning and knowledge sharing
- Knowledge representation models
- Management of enterprise knowledge versus personal knowledge
- Knowledge managers and workers
- Knowledge coaching and diffusion
- Knowledge engineering and software engineering
- Managerial knowledge evolution with focus on managing of best practice and cooperative activities
- Knowledge grid and social networks
- Knowledge management for design, innovation and eco-innovation process
- Business Intelligence environment for supporting knowledge management
- Knowledge management in virtual advisors and training
- Management of the innovation and eco-innovation process
- Human-machine interfaces and knowledge visualization

***Abstract*—Knowledge management has become a vital strategy to conserve company knowledge and to reuse them. Research in this area has always been consenting on domain knowledge, domain ontology, expert systems etc. have been developed to manage professional domain knowledge, but less effort has been done on cooperative knowledge. In this paper, a cooperative knowledge discovery method DKD is proposed, we elaborated this method in design project knowledge management area.**

I. Introduction

COOPERATIVE activity is defined as an activity of several actors having a given goal [1], communication, coordination and collaboration are the three dimensions of cooperative activity [2]. Workflow, Groupware tools [3], design-rationale approaches [4] have been developed for CSCW issues. Design is a highly cooperative activity, in which people from different background, different organizations and with different skills work together to reach a given goal. Knowledge are produced in design activities. As design project team is a short-lived organization, in the end of a project team members will be engaged into another project under another project organization, the challenges for design project knowledge management is to enhance learning in an organization from experiences [5]. As in this paper, we will focus our knowledge management on cooperative knowledge produced in design projects.

Recent knowledge management research has proposed community of practices and story telling to enhance knowledge sharing in an organization. Experience shows that the success of these techniques depend on the dynamic of animation in these communities. Our work is based on knowledge engineering approaches. We believe that learning from experience requires two fundamental elements: reasoning strategies (also called behavior laws) [6] and production context of these strategies [7]. "The learning content is context specific, and it implies discovery of what is to be done when and how according to the specific organisations routines"[8]. These two elements are especially important for cooperative knowledge representation.

This paper will propose a cooperative knowledge discovery model CKD. It will be elaborated in design project knowledge management area. Our ambition is to define a cooperative ontology and a classification framework for cooperative knowledge management.

II. Cooperative Knowledge

Cooperative knowledge is defined as knowledge produced in cooperative activities [7]. As we mentioned above, three dimensions have to be considered in cooperative activities: communication, coordination and cooperative decision-making. In order to define cooperative knowledge in a formalized manner. We are going to propose a cooperative activity ontology. Ontology is a description of shared concepts. It consists of term, definitions, axioms, and taxonomy. It facilitates knowledge comprehension and knowledge sharing by setting the standard knowledge structure [9][10]. Traditional ontology consists of a hierarchy of concepts. However, in cooperative activity, concept can only have a sense when it is put in a specific context, in other words, interactions between concepts instead of concepts themselves are considered essential in cooperative activity. Hence, we come up with a cooperative activity ontology consisted of types of actions.

III. Cooperative Knowledge in Design Project

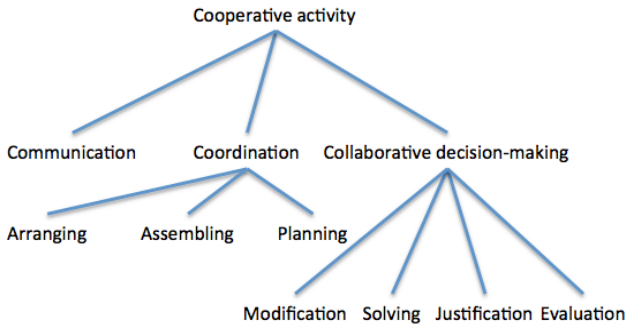

Fig 1. Cooperative activity ontology

Design activities have gone through some major changes with the use of IT tools in design projects. At the same time, developing pace of high technology pushes each day design product to be more and more complex. These changes

require design project to be multi-organizational and multi-disciplinary [11] [12]. Moreover, linear project management can no longer be applied on long-period multi-organizational and multi-disciplinary projects, a new concurrent working mode has emerged to allow people to work in a parallel manner, which necessitate more cooperative activities.

Both domain knowledge and cooperative knowledge are produced in design project. Past researches have progressed a lot on design domain knowledge management, but cooperative knowledge produced in design projects is different from design domain knowledge:

- The nature of knowledge is different: The domain knowledge is related to a field and contains routines and strategies developed individually from experiences, which involve a number of experiments. The cooperative knowledge is related to several fields, i.e. several teams (of several companies) and in several disciplines collaborates to carry out a project. So there is a collective and organizational dimension to consider in cooperative knowledge. Representing domain knowledge consists in representing the problem solving (concepts and strategies) [13]. On the contrary, emphasizing knowledge in cooperative activity aims at showing organization, negotiation and cooperative decision-making [14]. Otherwise, knowledge observed in a corporative constitutes examples to be structured in order to extract strategies.
- Capturing of knowledge is different: The realization of a project in a company implies several actors, if not also other groups and companies. For example, in concurrent engineering, several teams of several companies from several disciplines collaborate to carry out a design project. The several teams are regarded as Co-partners who share the decision-makings during the realization of the project. This type of organization is in general dissolved at the end of the project [15]. In this type of organization, the knowledge produced during the realization of the project has a collective dimension that is in general volatile. The documents produced in a project are not sufficient to keep track of this knowledge. In most of the cases, even the project manager cannot explain it accurately. This dynamic character of knowledge is due to the cooperative problem solving where various ideas are confronted to reach a solution. So acquisition of knowledge by interviewing experts or from documents is not sufficient to show different aspects of the projects, especially negotiation [16]. Traceability and direct knowledge capturing are needed to acquire knowledge from this type of organization.

For the same object, people with different background can give different interpretations; concept alters according to different context. As for design project, design decision-making process has always been the main research subject. However, decision-making process can not be fully represented without its context. Normally a decision-making process relies not only on design rationales, but also organizational influence, project constraints etc.. Therefore, we have to focus on design rationale representation as well as its interaction with other parts of a project. In other words, a global representation of all design projects modules as well as interactions between them are needed for design project. We should represent specially:

1. The design rationale (negotiation, argumentation and cooperative decision making)
2. The organization of the project (actors, skills, roles, tasks, etc.)
3. The consequences of problem solving (evolution of the artefact)
4. The context of the project (rules, techniques, resource, etc.)

We called the structure representing this type of knowledge project memory [17]. From the knowledge structure proposed by project memory, we will elaborate our CKD model.

IV. CKD IN DESIGN PROJECT

A. CKD framework

The principle of CDK method is to classify similar concept schemas of cooperative activities to identify certain repetitive ones as routines with a weight factor that indicates their importance. Classification can be defined as the process in which ideas and objects are recognised, differentiated, and understood; classifiers are widely used in biology, documentation, etc. [18]. A routine is defined as a recursive interaction schema of cooperative activity concepts. The weight factor is defined as percentage of recurrence of a routine among past similar project events. Therefore, the result of classification will be an ensemble of interactions between cooperative activity concepts. This result routine can be considered as a knowledge rule for cooperative actors to learn from, and future cooperative activities should pay attention to past knowledge rules. Before classification, cooperative activity information have to be structured, and we believe that semantic network graph is the perfect representation for that. A semantic network graph enable knowledge engineers to communicate with domain experts in language and notations that avoid the jargon of AI and computer science [19].

B. Design project structure

Section 3 has introduced “project memory” that list the four essential parts of design project. Current representation approaches emphasise on organising and structuring project information and expect users to learn from them. The problem is that human can only learn from others by matching to one’s own experience, and the knowledge level or even knowledge context between expert and learner are always not the same. Traditional knowledge engineering method usually doesn’t take project context into consideration (e.g. IBIS, QOC), or they neglect the interaction between different project modules (e.g. CommonKADS, DRCS). Therefore, we have to come up with classification models suited within specific contexts to show organisational knowledge in its specific context [20].

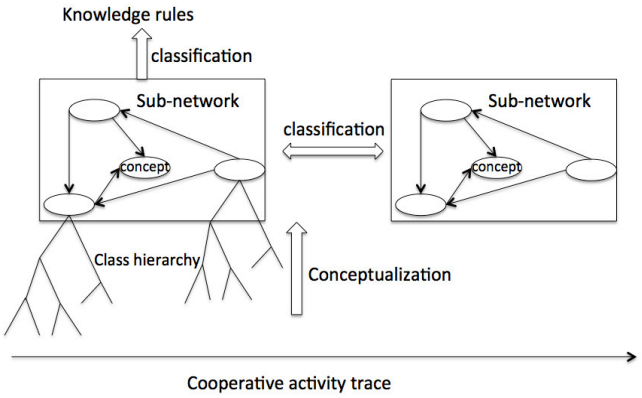

Fig 2. CKD framework

Project memory is be decomposed into smaller modules in order to show project memory in different perspective with different context to provide a better learning angle. The general semantic network of project memory is decomposed into 4 sub-networks:

- Decision-making process: this part represents the core activity of design project, which helps designers to learn from negotiation and decision-making experience.
- Project organisation makes decision: this part represents interaction between organisation and decision, which provides an organisational view of decision-making.
- Project organisation realises project: this part represents arrangement of task and project team organisation, which focuses learning on project management.
- Decision-making and project realisation: this part represents the mutual influence between decision and project realisation, which reveals part of work environment and background.

In each project memory module, a sub-network is built with concepts and relations. These project memory concepts are identified based on the research on engineering design and knowledge representation method for design activities [11] [21] [22] [23]. These concepts are employed and rearranged to represent the elements in project memory. Foundational ontologies serve as a starting point for building

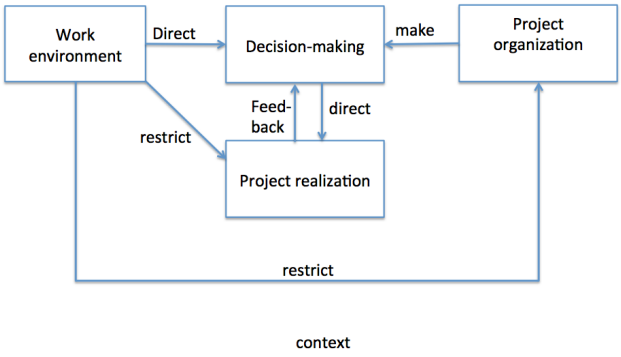

Fig 3. Project memory modules

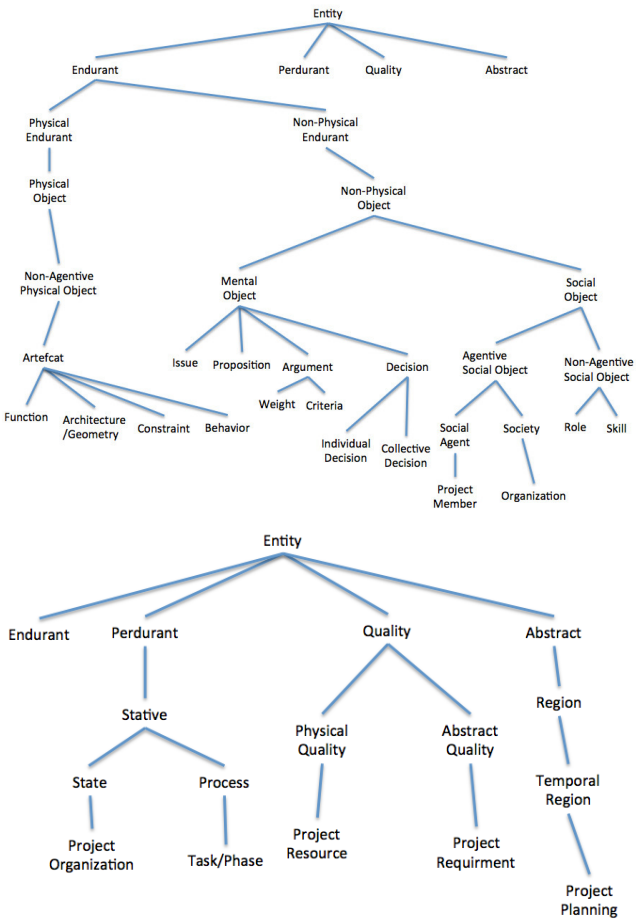

Fig 4. Design project concept aligned with dolce ontology

new domain and application ontologies, provide a reference point for different ontological approaches and create a framework for analysing, harmonising and integrating existing ontologies and metadata [24]. The project memory concepts are aligned with the general Dolce ontology.

Based on these concepts, we are going to build our sub-networks to represent especially interactions between concepts in order to show the cooperative knowledge.

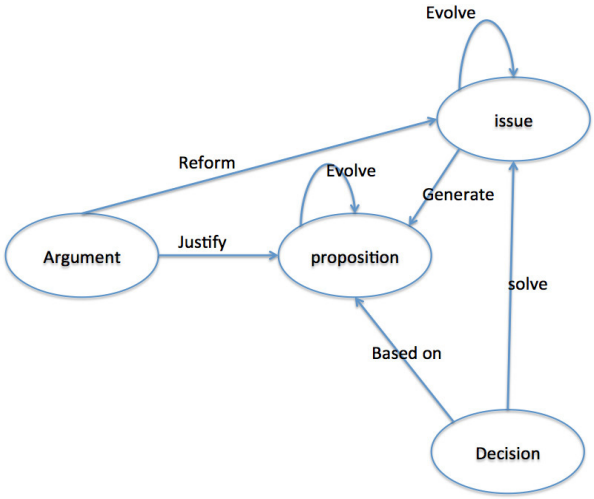

Fig 5. Decision-making sub-network

The first part of project memory is design rational; decision-making process is one of the most important parts in project memory. It contains negotiation process, decision and arguments that can reveal decision-making context. Concepts that are identified in a decision-making process are: issue, proposition, argument and decision. Issue is the major question or problem that we need to address, it can be about product design, organisation arrangement or project realisation etc.; proposition is solution proposed to solve issue by project team member; argument evaluates the proposition by supporting or objecting it, which can push proposal to evolve into another version [4] [23] [25]; argument can also aims at issue which can possibly modify the specification of the issue. Propositions are considered to be possible solutions for issue, and arguments are supposed to explain the reason why. Decision is made by selecting some of the propositions for the issue and setting up a goal for next step of project realisation. Figure 5 shows the decision-making process sub-network.

One of the most important and useful knowledge that we want to represent is the context of design rationale (Moran et al, 1996). This sub-network shows an interaction schema of concepts in decision-making process. Moreover, other project memory modules can also have mutual influences with decision-making process module. Therefore, we connect decision-making to project realisation to show consequences of decision and connect decision-making to project organisation to reveal an organisational influence.

In the sub-network below (figure 6), we want to find a concept that serves as a bridge to connect project organisation and decision-making process. So the concept “member” is introduced into decision-making sub-network to add an organisational dimension into decision-making process. Member is an important concept of project organisation that links to competence, role and task.

The sub-network in figure 7 offers a learning perspective on project realisation with an organisational dimension. Il presents us the interaction schema between task and project organisation. Task is linked to two important attributes of project member: competence and role.

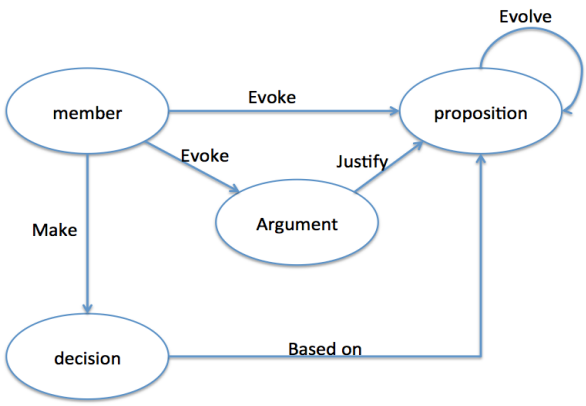

Fig 6. Project organization makes decision

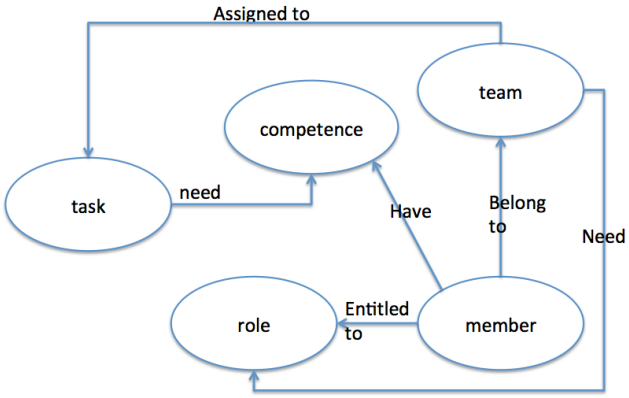

Fig 7. Project organization realizes a project

At last, we want to represent the triangle between task, decision and issue in order to show a mutual influence of task arrangement and decision-making process. A decision sets up a goal for a task; another issue can be evoked during a task, which initiate another decision-making process. The triangle ends by achieving the final result of a task. During a product design, the result of a task can be a new version of a product, and the version of product evolves between decision-making meeting and tasks.

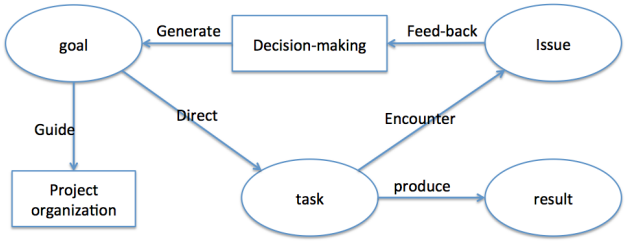

Fig 8. Mutual influence between decision-making and project realization

C. *Knowledge Classification*

The ability to extract general information from example sets is a fundamental characteristic of knowledge acquisition. Machine learning technique is now a hot topic at present, it can figure out how to perform important tasks by generalising from examples. One of the most mature and widely used algorithms is classification [26]. However, design project information are usually not voluminous and quite distinctive; they are highly structured in a computer-aided design environment. Due to these particular characteristics of design project information, present machine learning techniques are not suitable for design project memory classification. We studied four major categories of machine learning algorithms: statistical methods, decision tree, rule based methods and artificial neural network [27] [28] [29] [30]. These methods are not considered for two reasons: 1). Classification process is not transparent to human interpretation. 2). A large recursive training set is needed for classification. The advantage of our classification model in project memory is that it is guided by

semantic networks that indicate knowledge rules resided in interaction schemas. Therefore, according to these semantic networks, we classify interaction schemas instead of concepts. The amount of repetitive interaction schemas is significantly fewer compared to a concept; a large set of instances can be conceptualised into one class, while the probability of similar interaction schemas between concepts is much less. Additionally, the learning process will not ignore non-recursive schemas; on the contrary, they will be put aside as explorative attempts with an explanation.

Two tablet applications have been developed to capture project traces. They can register meeting information and generate XML files (Matta et al, 2013). Project information will be structured according to a XML schema as follow:

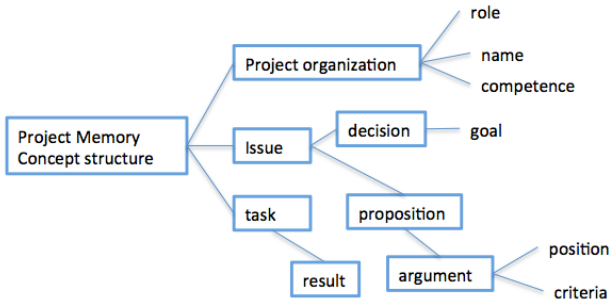

Fig 9. XML schema of project memory

```
<xs:element name="member">
  <xs:complexType>
    <xs:sequence>
      <xs:element name="role" type="xs:string" />
      <xs:element name="competence" type="xs:string" />
    </xs:sequence>
  </xs:complexType>
</xs:element>
<xs:element name="issue">
  <xs:complexType>
    <xs:sequence>
      <xs:element name="decision" type="xs:string">
      <xs:element name="proposition">
        <xs:complexType>
          <xs:sequence>
            <xs:element name="argument">
              <xs:complexType>
                <xs:sequence>
              <xs:element name="criteria" type="xs:string" />
              <xs:element name="position" type="xs:int" />
                </xs:sequence>
              </xs:complexType>
            </xs:element>
          </xs:sequence>
        </xs:complexType>
      </xs:element>
    </xs:sequence>
  </xs:complexType>
</xs:element>
<xs:element name="task">
  <xs:complexType>
    <xs:sequence>
      <xs:element name="result" type="xs:string" />
    </xs:sequence>
  </xs:complexType>
      </xs:element>
```

Then project information will be classified according to different views to extract knowledge rules. Here we propose three classification views:

1. Problem-solving view: at a specific project phase, we can classify decision-making process for one particular issue. Solutions that are repetitive will be classified as essential solutions, the solutions that are distinctive will be considered as explorative attempt with its precondition as an explanation.

If

$(\text{decision}(d_1) \wedge \ldots \wedge \text{decision}(d_n)) \wedge \text{issue}(i_i) \Rightarrow \text{decision}(d') \wedge \text{issue}(i_i)$,

then

$\text{decision}(d') \wedge \text{issue}(i_i) \Rightarrow \text{essential}(e_i) \wedge \text{issue}(i_i)$

2. Cooperation view: an important subject that we tried to study in our model is cooperation. This classification view allows us to verify whether there are parallel tasks that involve cooperative design or regular meetings concerning whole project team. Projects that are not undertaken concurrently can lead to unsatisfactory results, e.g. solution duplication or excess of project constraint. This rule will reveal the influence of concurrent design on project result.

If

$\exists(\text{issue}(i) \wedge \text{entire\_team}(m)) \wedge \exists(\text{task}(t_1) \wedge \ldots \wedge \text{task}(t_n))$,

then

$\exists \text{cooperation}(m)$

3. Management view: this classification view will focus on project organisation influence on different project memory modules. For example, we can classify project realisation with an organisational dimension to examine how project organisation arrangement can influence project realisation.

A weight factor that indicates recurrence rate will be attributed to each classification result to show the importance of this result. The three aspects proposed above

are the most interesting and practical classification views that we find so far, however we do not exclude the possibility that more useful classification views exist. In the next section, CKD according to these three views will be applied to two example projects.

V. EXAMPLE AND RESULT

Two software design projects were undertaken by two teams in the year 2012 and 2013. The group members are students majored in computer science or mechanic design. The goal of the project is to design a tablet application, which proposes solutions for product maintenance; it should allow a technician to access and modify PLM and ERP information in order to facilitate information flow in supply chain. MMreport and MMrecord were employed to keep track of meetings from the beginning to the end of the project, they can be downloaded in App Store for free. XML documents were generated by these two applications. We analysed these XML documents as well as other documents (email, forum discussion and result) according to the XML schema above. Next we are going to demonstrate three rules extracted by comparison between these two projects.

A problem-solving rule on the issue "function definition" can be extracted by comparing the decision-making process on this issue of both projects. We classify repetitive solutions as essential solutions for the issue function definition, and distinctive solutions as explorative cases with a precondition. The detailed classification is shown in figure 10.

Cooperation rules on this project can be extracted by classifying project planning, which is represented by the sub-network decision-making process and project realisation. If there are tasks concern module integration and

Tablet application for product maintenance				
Year	2012		2013	
Issue	Function definition		Function definition	
Negotiation	Proposition	Argument	Proposition	Argument
	Automatic object reconnaissance	• More efficient • Help operator with little mechanical knowledge • More expensive • Technology obstacle	Manuel object search engine	• Easy to design • Require operator to have certain mechanical knowledge
	ERP and PLM connection	• Reduce data redundancy • Technology obstacle	Tablet connection with PLM and ERP	
	Tablet connection with ERP and PLM			
Decision	• Automatic object reconnaissance • Tablet connection with ERP and PLM		• Manuel object search engine • Tablet connection with ERP and PLM	

Tablet application for product maintenance		
Issue	Function definition	
Essential solutions	Tablet connection with PLM and ERP, object search with tablet applications	
Conditional solutions	Solution	Condition
	Automatic object reconnaissance	Enough budget
	PLM and ERP connection	Feasible technology

Fig 10. Classification on "function definition"

Tablet application for product maintenance				
Year	2012		2013	
Phase	Project realization		Project realization	
Project organization	Three sub-groups for each application module (ERP,PLM, Object reconnaissance)	Competence distribution: ERP(computer science) PLM (mechanical design) Object reconnaissance (computer science)	Three sub-groups for each application module (ERP, PLM, object search engine)	ERP(computer science) PLM (computer science, mechanical design) Object search engine (computer science, mechanical design)
Project planning	• 4 working meetings inside each sub-group to validate project specification • A final meeting to simply collect each sub-group's work		• 12 work meetings of whole project team • Sub-group meetings are organized freely	
Result	• Each module has its own database, the application has 3 databases in total • Automatic image recognition increase the cost drastically		• Client-server architecture that requires only one database • Centralized data management	

Fig 11. Classification on project planning with organizational influence

regular meetings on project specification of whole project team, then this project is undertaken concurrently. If no meetings are held with the whole group or no integration task is assigned to more than one sub-group, then this project is considered failed at concurrent design. We can see from the project information 2012, four meetings were held inside each sub-group and only one final meeting involved the entire project group, but the issue of the final meeting was "collecting each group's work", which means no integration issue was dealt with. Apparently in the project 2012, design activities were not organised concurrently, which leads to the result "database duplication" and "expensive project cost".

Linear project planning leads to bad communication between different sub-group designers, which result in poor integration design. From the management point of view, we can further this classification by adding an organisational dimension to project planning. These two classification is shown in figure 11.

By comparing these two project organisations, we can see that in the project team 2012, competence was distributed homogeneously for each group, members were divided into computer science group and mechanical design group; whereas competence was paired in the project team 2013, computer science and mechanical design both exist in each sub-group. From this classification view, we may draw the conclusion that if designers with different skills are assigned to the same task, project tends to be carried out more concurrently, which leads to a more satisfactory result.

Extraction of these rules are all guided by comparison of structured information according to different project views, rules may change as more project information will be captured. CDK classification will progress in a cumulative manner.

VI. CONCLUSION AND PERSPECTIVE

This paper presented our research work on cooperative knowledge, especially on how to discovery cooperative knowledge in order to reuse them. A CKD method was proposed for this purpose in design project field. It is a knowledge classification guided by semantic network

schemas. Instead of classifying domain expert knowledge, interaction schemas between concepts were classified; it allows us to put each important concept in its interactive context. A CKD classification is semantically expressive and comprehensible by users. Therefore, it is up to users to choose which classification view to use for knowledge extraction. We tested CKD method on two example projects, which shows that cooperative knowledge can be extracted by interaction schema classification, more importantly, the knowledge rules extracted can be quite useful for learning purpose.

No classification can be argued to be a representation of the true structure of knowledge, the design project knowledge classification showed in this paper is a application field of CKD method, class conceptualisation, semantic network structure and knowledge classification views are strictly linked to design project context. In other words, a CKD classification model should be built according to application domain features. In order to enrich this application, we will try to formalise classification rules with programming languages and test our model on more complicated projects.

***Abstract*—Social media increases the connectivity of people inside and outside an organisation. It is not just the implementation of communication technology, but the transformation of working and organisational cultures. The paper presumes that social media provides new opportunities to the organisational knowledge creation process by amplifying knowledge created by individuals as well as crystallising and connecting it to an organisation's knowledge system. The process depends fundamentally on the individual's tacit knowledge and its conversion into organisational explicit knowledge. Knowledge conversion is not a linear and sequential process, but a process which is affected by the individual's emotions. This paper explores the interplay between knowledge and emotions in the organisational knowledge creation process in the context of social media. The paper concludes that knowledge and emotion shared in social media contribute to the social identity, which increases the odds of altruistic behaviour towards others in a way that benefits the organisation.**

I. Introduction

Social media increases the connectivity of people within and across organisational boundaries. It provides new opportunities for acquiring and sharing information to be exploited in strategic decision-making and leadership, innovation, marketing and customer service, and organisational communication. It has been suggested that social media revolutionises the ways information and knowledge are managed in organisations [1]. An extensive literature argues that information requires interpretation to become knowledge [2, 3, 4]. Consistent with previous studies, this paper supposes that the value of information shared through social media depends on the organisation's ability to use it. This is because "information will only acquire meaning for the organisation when meaning is assigned to that information within the receiving organisation" [5]. Information becomes a valuable resource only when it is interpreted and connected to already existing knowledge. Information is never a "pre-given reality" for organisations, but a process of interpretation by the organisation and its individuals [6, 7].

Nonaka [6] has defined *organizational knowledge creation* as a "process of making available and amplifying knowledge created by individuals as well as crystallizing and connecting it to an organization's knowledge system". Turning information into usable knowledge depends fundamentally on the individual's *tacit knowledge* and its conversion into organisational *explicit knowledge*. Knowledge conversion is not a linear and sequential process, but a process which is affected by the individual's *emotions*. Emotion is not seen as opposite of reason, but a different form of it. Along with knowledge, emotion and intuition have an important role in organisational decision-making [8, 9].

From a technological point of view, knowledge conversion presents a challenge because tacit knowledge is difficult to communicate to others as information. Many studies proclaim that tacit knowledge sharing by information technology (IT) is quite impossible [10, 11]. Johannessen et al. [12], among others, have pointed out that by investing in IT, organisations emphasise explicit knowledge at the expense of tacit knowledge. Paradoxically, the mismanagement of tacit knowledge may yield to deterioration of the organisation's competitive advantage, which is reported to be more dependent on tacit than explicit knowledge [13, 14].

The importance of tacit knowledge and emotion in the organisational knowledge creation process on the one hand, and the rapid growth of social media on the other hand, beg to explore and analyse their interoperability. This is not a trivial question as social media transforms the organisation's social practices and therefore enables *or* stifles organisational knowledge creation. This paper explores the interplay between knowledge and emotion in the organisational knowledge creation process in the context of social media.

II. Social media – activities, means, contents and features

There is no single and universally accepted definition of social media. Typically, it is loosely referred to the means of interaction among people in which they create, share, and exchange information in networks. Social media merges technology, people and contents. When emphasising the actions enabled by social media, one possible approach is to characterise social media as a context for communication, collaboration, connecting, completing and combining (5C). The 5C's categorisation is briefly discussed below. Unless otherwise stated, the discussion contained herein is based on work by Vuori [15].

For *communication* purposes, social media provides new tools to share, store and publish contents, discuss and express opinions and influence. Communication is executed through blogs (e.g. Blogger) and microblogs (e.g. Twitter), podcasts (e.g. iTunes) and videocasts (e.g. YouTube), media sharing systems (e.g. SlideShare), discussion forums (e.g.

978-83-60810-58-3/$25.00

Apple Support Communities) and instant messaging (e.g. Skype). Blogs and microblogs – particularly Twitter – have changed our media landscape rapidly. Schultz et al. [16] have pointed out that blogs and microblogs affect the society in which they play a role not only by the content delivered over the media, but also by the characteristics of the communications media themselves. Seemingly, the medium has become the message, as McLuhan once predicted: "the medium is the message" [17]. In *collaboration*, social media enables collective content creation and edition without location and time constraints. Wikis (e.g. Wikipedia) and shared workspaces (e.g. GoogleDocs) are typical social media applications supporting collaboration. They enable collaborative authoring, empowering the users to create, edit and update contents. Empowering the users reminds the prediction made by Alvin Toffler. Toffler predicted as early as 1980 the rise of a society of prosumers. Toffler identified various forms of prosumers but common for all of them is that the roles of producers and consumers are blurring and merging in a way which inevitably transforms the relationship between inside and outside the organisation. It has been suggested, for example, that firms do not create value for customers anymore but with customers [18]. For *connecting* purposes, social media platforms offer new ways of networking with other people (e.g. Facebook), socialising oneself into the community (e.g. LinkedIn) and creating virtual worlds (e.g. Second Life). Social network sites, especially Facebook, are usually seen as a synonym for social media. This is no wonder, as a conservative estimate is that social networks gather worldwide well over one billion users. Social network sites connect people with similar interests and enable the creation of communities around these interests. In *completing*, social media tools are used to complete content by describing, adding or filtering information, tagging contents, and showing a connection between contents. Commercial completing social media applications are, for example, Pinterest, Google Reader and Digg. *Combining* social media tools are developed for mixing and matching contents. The logic behind these tools is simple: users need versatile tolls which able to combine the contents from different applications. Combined social media sites are typically called as mash-ups meaning "a coherent combination of pre-existing web services that allow a certain user within a platform to use another application, in a specific window, without the need to get out of the initial website" [19]. Google Maps, for example, allows geographically pinpoint the locations of hotels and restaurants, and so on.

Due to technological convergence and users' needs, the categorisation of 5C's is only suggestive. Many social media tools support two or more functionalities. As Vuori [15] has pointed out, Facebook and Twitter, for example, make it possible to embed videos and photographs from another location on the Web, whereas wikis can provide RSS feeds to keep up with updates on a certain article. In addition to functionalities, social media has been approached from the point of view of its characteristics. Typically, user-friendliness, interactiveness, openness and transparency, participation and democracy, uncontrollability, velocity, and real-timeness have been mentioned to be the main characteristics of social media [20, 21, 22, 23].

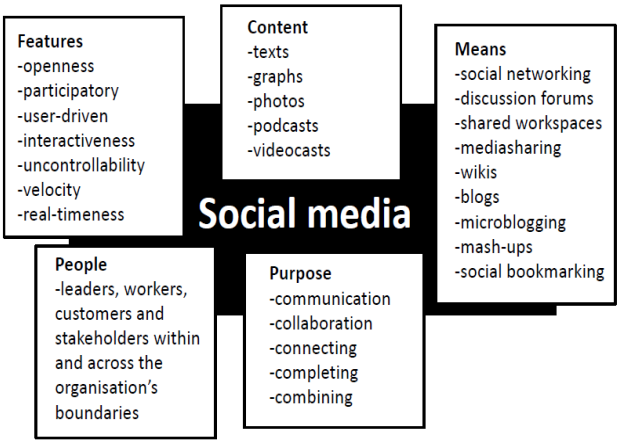

Figure 1. Social media – activities, means, contents, features and actors.

Based on the above mentioned, it is relatively easy to agree with the judgements which claim that social media is not just the implementation of communication technology, but the transformation of working and organisational cultures. Adapting Berthon et al. [24], the transformation can be summarised into three aspects: social media shifts i) the locus of activity from the desktop to the Web, ii) the locus of power from the firm to the collective, and iii) the locus of value production from the firm to the customer. At the heart of this transformation are new possibilities for acquiring, storing, sharing and using information within and across organisational boundaries.

A little pointedly, it can be argued that many behaviours that sociologists study are nowadays taking place in social media. The need to be connected through networked technological applications has become a necessary strategy for postmodern humans [25] and is blurring the boundaries between the reality and virtual and the boundaries between an organisation and its environment. Presumably, it also changes the ways humans deal with knowledge and emotions.

III. Knowledge creation in organisations

Although knowledge has been seen as a virtue to be sought since the days of Plato and Aristotle, it was works by Teece [26] and Nelson & Winter [27] in which knowledge became an important part of organisation science. They were followed by Barney [28] Nonaka [6], Grant [29] and Spender [13], among others, who used knowledge as an explanatory factor for the idiosyncrasies of firms. Barney [28] characterised knowledge as a costly-to-imitate resource and therefore vital for the organisation's competitive advantage. Grant [29] developed ideas further and laid down the premises of "knowledge-based theory of the firm" (KBV). Extending the resource-based view of the firm (RBV), Grant argued that knowledge is not just a generic resource, but the

special one, which is embedded and carried through multiple entities including organisational culture and identity, policies, routines, documents, systems, and employees. The KBV states that heterogeneous knowledge bases and capabilities among firms contribute to competitive advantage and superior performance.

Nonaka [6] contributed to the academic discussion by providing the theory of *organizational knowledge creation*. The theory can be seen as complementing the knowledge-based view of the firm because it explains the dynamic processes of organisational knowledge creation Nonaka et al. [30]. Seemingly Nonaka [6] and many his co-authors thought that knowledge creation is needed to achieve competitiveness through innovation rather than an intrinsic goal per se. Nonaka defined organisational knowledge creation as a dynamic process in which knowledge created by individuals is connected to an organisation's knowledge system. The theory is based on two premises: *tacit* and *explicit knowledge* can be conceptually distinguished along a continuum, and *knowledge conversion* explains the interaction between tacit and explicit knowledge [7].

Tacit knowledge covers knowledge that is "unarticulated and tied to the senses, movement skills, physical experiences, intuition, or implicit rules of thumb" [6]. Knowledge of baking a cake or interpreting the moment of closing a deal are everyday examples of tacit knowledge. In order to succeed in those situations, the baker and the salesperson need tacit knowledge which is not embedded only in individuals, but also encultured in the organisation's practices and procedures [31]. Tacit knowledge differs from "explicit knowledge", which is uttered and captured in documents and stored in certain media [6]. The information contained in manuals and procedures is a typical example of explicit knowledge. Explicit knowledge is encoded [31] – i.e. it is conveyed in signs and symbols (books, manuals, databases, etc.) and decontextualised into codes of practice. It is accessible through consciousness [30]. Compared to tacit knowledge whose locus is in the knower's mind, explicit knowledge can be readily transmitted within and across organisational boundaries.

Knowledge conversion refers to the process through which "one overcomes the individual boundaries and constraints imposed by information and past learning by acquiring a new context, a new view of the world and new knowledge" [30]. Nonaka [6] proposed that in organisational context, knowledge conversion happens in the Socialisation–Externalisation–Combination–Internalisation process (Fig. 2).

Nonaka & von Krogh [7] positioned the organisational knowledge creation theory as an opposite to "correspondence doctrine", which was based on the idea of "pre-given" reality which exists irrespective of the observer. In so doing, correspondence doctrine also implied that an individual's main task was to improve the representation of pre-given reality by processing information about it. Although gathering information improves the organisation's decision-making, the problem is that it cannot improve the organisation's ability to foster creativity, create opportunities and enable innovation [7]. Knowledge has no value in its own right. The value of knowledge comes from its ability to produce change or action.

	TACIT KNOWLEDGE	EXPLICIT KNOWLEDGE
TACIT KNOWLEDGE	**Socialization** -aims at sharing tacit knowledge between individuals	**Externalization** -aims at articulating tacit knowledge into explicit concepts
EXPLICIT KNOWLEDGE	**Internalization** -aims at embodying explicit knowledge into tacit knowledge	**Combination** -aims at embodying explicit knowledge into tacit knowledge

Figure 2. Knowledge conversion [13].

IV. Emotion in organisational knowledge creation

Conventionally, emotion refers to a feeling state involving thoughts, physiological changes, and an outward expression or behaviour. Emotions are expressed in facial reactions, gestures or postures. The behavioural side of emotion means that emotion has a target at which it is intuitively or intentionally directed. [32, 33] Emotions are typically categorised into six universal "basic emotions", which are happiness, surprise, anger, disgust, sadness and fear [34, 35]. Happiness is a positive emotion, whereas anger, disgust, sadness and fear refer to negative valence of emotion. Surprise, in turn, can be either positive or negative. In some circumstances, individual may feel both positive and negative emotions simultaneously [36]. An individual may, for example, evaluate his/her colleague's success positively, while, at the same time, he/she may feel disappointed about his/her own lot. It should also be noted that positive and negative emotions are not necessarily exclusionary to each other. Based on work of Chang et al. [37], Cameron et al. [36] have pointed out that "exclusive focus on negative emotions cannot allow – even by inference – conclusions about positive emotions". Likewise "the possession of conflicting positive and negative reactions by a person experiencing an emotion need not be confined to negative emotions" [36]. Pride and shame, for example, may be both useful for positively motivating individuals in certain instances [38]. Emotion is also biological response triggered by a particular situation or event [33]. Feeling fear and your heart starts beating faster, and your breathing deepens. There are also emotions which are not responses to "external" past happenings. These are called as "anticipated emotions". They refer "to purposive activities concerning goal-directed behaviour" [36]. When the goal is attained, we feel satisfaction, and when the goal is not achieved, we feel dissatisfaction. The locus of emotions is typically seen resided in the individual, although, some authors have argued for collective emotions [39]. Collective emotion refers to the experience reinforced among the community (in contrast to group-based emotions) of large numbers of individuals [39]. This also explains that emotional

experience varies greatly across cultures [40]. Cacioppo & Gardner [33] summarise the above mentioned nicely by stating that emotion "is a short label for a very broad category of experiential, behavioral, socio-developmental, and biological phenomena".

The relationship between emotion and cognition dates back to the ancient Greeks. An assumption has been that "higher forms of human existence – mentation, rationality, foresight, and decision making – can be hijacked by the pirates of emotion" [33]. Throughout the rationalist tradition, emotions have been belittled. 'Reason' has been treated as good for individuals and societies, whereas 'emotions' have been deemed as detrimental and intimidating. Also within organisational studies, emotions have long been seen as disturbing elements and opposite to rational thinking. Studies, however, have changed the understanding of emotions. This is particularly due to works of Herbert Simon, especially his criticisms of human rationality. According to Simon, cognitive limitations of human mind and complexity of situations, the choices made by individuals, are rational only in relation to their own mental models. In other words, individuals' rational actions are limited by irrational elements. Simon [41, 42] has called this kind of rationality as "bounded rationality".

Recent psychological research has questioned the notion of emotions just primitive reflexes. Berntson et al. [43], for example, have found that emotions are more than "disruptive force in rational thought". It has been argued that emotion contributes intelligence [44] and improves decision-making [8, 9]. The opposite of reason is not emotion, but lack of reason [44]. Nowadays, emotion is seen in organisational research as a key resource in (rational) decision-making. It has been shown, for example, that consumers' behaviour and decisions are affected by emotions [45, 46]. Furthermore, there is a growing number of management studies which embrace emotional skills as a key part of management practices [47, 48].

Nonaka & Takeuchi [13] defined knowing as a process in which "knowledge is created by the flow of information (messages) anchored in the beliefs and commitment of its holder... Knowledge is essentially related to human action". Given that emotion strives to action, it can be supposed that emotions also play an important role in organisational knowledge creation. One can expect that emotions affect individuals' willingness to expose themselves into the social situations in which knowledge can be created and shared. Individuals who feel comfortable and not threatened are probably more inclined to share knowledge than those individuals who fear conflict of interests among the individuals. Von Krogh [49], for example, has spoken for the importance of "care" and "empathy" in knowledge creation. Estrada et al. [50] and Isen [51], among others, have shown that positive emotion enhances innovation. Moreover, Isen & Baron [51] have found that positive mood state generally encourages the display of helping behaviour in organisations. It has also been shown in several studies that leaders' mood states affect their followers [52, 53, 54]. Leaders can shape the arousal of their subordinates and hence contribute to organisational knowledge creation.

In addition to positive consequences, emotions can be negative inhibiting organisational knowledge creation. This is the case, for example, when individuals fear that their knowledge can somehow or other be used against them. It is not at all rare, that pure envy, jealousy or anger create an obstacle for knowledge sharing. A bit more rationally, but still very much emotionally, motivated is knowledge hoarding, which happens when an individual prefers to maximise his/her personal pay-off instead of the interest of the organisation [55]. One emotional reason for knowledge hoarding is leaders' behaviour. Leaders who show negative emotions, such as anger and sadness, evoke less enthusiasm within their subordinates [56. Supposedly, individuals who lack of enthusiasm are reluctant to devote their time to participate in knowledge creating and sharing activities within the organisation.

As mentioned before, positive emotion (e.g. happiness) does not necessarily produce positive behaviour or negative emotion (e.g. shame) negative behaviour. This is because individuals are goal oriented. In goal-directed behaviour, individuals "anticipate" what emotions both the goal success and goal failure will awake [57]. According to Bagozzi [57], anticipated positive emotions energise volitions positively (because goal achievement is desirable and motivating), and anticipated negative emotions also energise volitions positively (because goal achievement is a remedy for the bad feeling). The key question, therefore, is how emotions can be "managed" in an organisation in a way which contributes to knowledge creation and sharing.

V. Creating knowledge and sharing emotions through social media

Defining knowledge creation as a dynamic and emotionally affected process of amplifying an individual's knowledge and connecting it to an organisation's knowledge asset, begs the question where does the process take place? Nonaka et al. [58] have introduced a concept of 'Ba' referring it to the context for knowledge sharing, creating and utilising. 'Ba' means not just a physical space, but a specific time and space. Combining physical, virtual and mental spaces, 'ba' provides energy, quality and place to perform not only knowledge sharing activities, but also interpretation of ambiguous information cues [58]. Nonaka et al. [58] have identified four types of 'ba', which are originating 'ba', dialoguing 'ba', systemising 'ba' and exercising 'ba'. The 'ba's are defined by two dimensions (Fig. 3).

Each 'ba' offers a context for specific step in the knowledge-creating process [58]. In the *originating ba*, individuals meet face-to-face sharing emotions, feelings and experiences. It represents socialisation among individuals. Originating 'ba' helps an individual to transcend "the boundary between self and others, by sympathising or empathising with others" [58]. In the *dialoguing ba* individuals' tacit knowledge is shared and articulated through dialogues amongst participants. It differs from originating 'ba', as the dialoguing 'ba' is more consciously constructed. It offers a context for externalisation. *Systemising ba* is defined by collective and virtual interactions. It offers a context for the

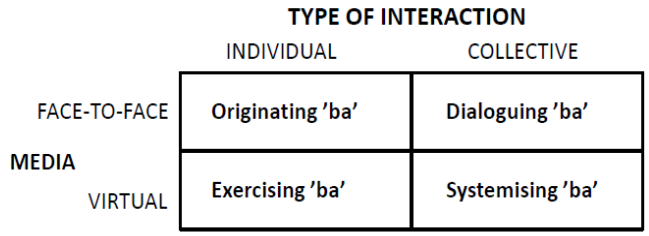

Figure 3. Four types of 'ba' [58]

combination of existing explicit knowledge, as explicit knowledge can be relatively easily transmitted to a large number of people in written form [58]. In the *exercising ba*, individuals embody explicit knowledge that is communicated. Exercising 'ba' offers a context for internalisation.

The classification of 'ba's can be analysed through *media richness theory*. According to media richness theory, communications media can be differentiated based on their abilities to process information and convey meaning [59]. A communications medium is rich when it contains not only factual information, but also provides multiple cues via non-verbal communication and allows immediate feedback. Face-to-face is typically classified as the richest communications medium, whereas numeric documents are seen the less rich [59]. Seemingly, based on the media richness theory, the originating 'ba' and dialoguing 'ba' are rich media as they provide a context for sharing emotions, feelings and experiences. In contrast, as suggested in the introduction, information technology is typically seen quite poor for sharing tacit knowledge. In Nonaka's et al. [58] model, information technology is important particularly in systemising 'ba' and exercising 'ba' because it offers a virtual collaborative environment and an effective way to share explicit knowledge.

Uncertainty and *equivocality* constitute two epistemological forces which exist in organisations that influence information and knowledge processing. The usefulness of IT in reducing uncertainty is well reported in several studies [60]. However, one cannot say the same when it comes to relation between IT and equivocality. It has been shown that IT is a poor medium to share implicit knowledge and emotions as it does not convey important social cues such as body language [61, 62]. In addition, the lack of synchronicity and immediacy inhibits the establishment of mutual understanding to comprehend conversation and knowledge contribution [63].

However, since the advent of social media, application areas of technology-based interaction have significantly expanded. Social media goes beyond systemising and exercising 'ba's by capturing features also from originating and dialoguing 'ba's. Potentially, it offers a context for connections which enable both increasing the amount of available information – i.e. helping to deal with uncertainty – and achieving shared meanings – i.e. helping to deal with equivocality.

This paper argues that enabling organisational knowledge creation through social media, three aspects are especially important. Firstly, social media means a new kind of context, which can be used not only for sharing explicit knowledge but also for making tacit knowledge visible. The argument is based on Michael Polanyi's [64] distinction of tacit knowledge into two separate forms, namely, *proximal* and *distal* [65]. Proximal refers to the thing that is closer to us, while distal thing is further away. This is what is meant with the statement "we know more than we can tell". For an R&D engineer, for example, it is impossible to express all her/his knowledge about the process of new product development. In the words of Polanyi, she/he is not able to "identify particularities" related to product development. However, experienced engineers "know these particularities, without becoming able to identify them" [64]. An R&D engineer's interests (e.g. why a new product is needed, how and who is going to be using it, how success in new product development affects her/his career) and her/his knowledge about R&D techniques, procedures and processes constitute the proximal dimension of his/her tacit knowledge. Given that R&D is typically a knowledge-intensive and often quite complex process, it is expected that the process involves activities which are difficult to communicate outsiders. Searching information, sharing knowledge and assessing others' ideas, to name a few 'innovation activities', represent distal dimension of individuals' (e.g. an R&D engineer) tacit knowledge. By conducting R&D activities, an engineer explicates her/his interests, "without becoming able to identify them" [64]. Social media offers accessibility of an individual's tacit knowledge through features such as keyword searches, personalised content feeds, blogging and microblogging, social bookmarking and mash-ups that identified content relevant to the user. Worth noting is that information communicated through social media is not restricted to pre-given and intended audience, but it might be "overheard" by others, who, in turn, may participate in knowledge creation.

Secondly, emotions cannot be ignored in organisational knowledge creation. Many studies have shown that social media can modulate human *collective emotional* states both in good and bad [66, 67, 68, 69]. Tadic et al. [68], for example, have found out that what happens in social media cannot be explained through real-world events. Seemingly, social media promotes idiosyncratic non-linear dynamics in which individuals contribute to building up a social network, which then propagates the contents of future messages (information *and* emotion), which often escalates into "bursts of emotional messages that involve many users" [67, 68]. Social media offers opportunities for spreading emotionally motivated information in a way which cannot be controlled by the organisation: "everything that can be exposed will be exposed – for all intents and purposes" [23]. This was the case faced by United in 2009 when it failed to appease Canadian amateur musician whose guitar was mishandled by the airline company. Musician posted a YouTube video entitled "United Break Guitars", which became hugely popular, within couple of weeks it was viewed over 3.5 million times. According to Hemsley & Mason [1], United was ill-prepared to deal with "a fast moving story" what became "a symbol of a lone person trying to deal with a large, uncaring corporation". "United Breaks Guitars" is an example of unpleasant event. However, there is nothing like natural law, which ordains that the content of social media is biased to negative emotions.

Thelwall et al. [70], for example, have founded that two thirds of the comments of social network site (Myspace) expressed positive emotion, while only one fifths contained negative emotion. Based on the above mentioned, this paper argues that the organisations should encourage behaviours that induce the emergence of positive collective emotions. In this respect, Nonaka's & Takeuchi's [13] notions of active empathy, leniency in judgement and trust as enabling conditions are extremely relevant also in social media. Collective emotions have been identified as important elements in developing a sense of online community [71]. Worth noting is that, collective positive emotions create an opportunity for the organisation to integrate also external stakeholders into knowledge creation. At best, positive emotions enable unintended collaboration and intensify the effect of knowledge spillover – i.e. diffusion of knowledge across organisational and/or sectorial boundaries.

Thirdly, connections enabled by social media do not only change the information flow within and across organisational boundaries but also affect *social identity*. Social identity consists of three components: 1) a cognitive component refers to self-awareness of organisational membership, 2) an emotional component reflects involvement with the organisation, and 3) an evaluative component means value connotations attached to the organisation [36]. Social identity evolves in a process of social identification referring to "perception of oneness with a group of persons" which, in turn, may "lead to the activities that are congruent with the identity" and "reinforce the antecedents of identification" [72]. In so doing, social identification is both the cause and the result. Several studies have suggested that social identity affects organisations' behaviour. However, as suggested by Bagozzi [57] and many others, the relation between social identity and organisational behaviour is not direct, but mediated by emotions. Social identity increases an individual's emotional commitment to the organisation. Bergami & Bagozzi [73], for example, have found that social identification leads to positive emotions toward the organisation, positive emotions from the organisation, and positive self-esteem as a consequence of organisational membership. Most importantly, from this paper's perspective, these personally felt emotions may induce individuals "to perform discretionary acts that are not part of the job description but that benefit other employees directly and the organization indirectly" [57]. Presumably, personal experiences also bring about the change how explicit and, especially, tacit knowledge are managed in the organisation. As social media potentially changes the process of social identification, it can also promote altruistic organisational culture. Altruistic organisational culture may have different manifestations, but one of the most obvious ones is that knowledge creation and sharing are preferred to knowledge hoarding and egoist behaviour. Social media is convenient for organisational identity as it makes individuals' identities visible to others through the conscious or unconscious 'self-disclosure' of subjective information such as feelings, likes, and dislikes [20, 22]. Although the identification of a collective can arise without interaction (as an individual need only perceive himself or herself as psychologically intertwined with the fate of the group, however, this paper argues that social media changes the process of identity formation within organisations. Adapting the concept of symbolic interactions [74], it is argued that social media offers a context for verbal and nonverbal interactions of individuals. Congruently with Weick's [75] thoughts, the meaning is not a given but evolved and emerged from these individual acts. Worth noting is that individuals "cannot not communicate" [76]. Social identity is continuously created and re-created through intentional and conscious *and* unintentional and unconscious interactions inside and outside the organisation.

The relationship between knowledge, emotion and social identity in organisational knowledge creation is presented in the Figure 4.

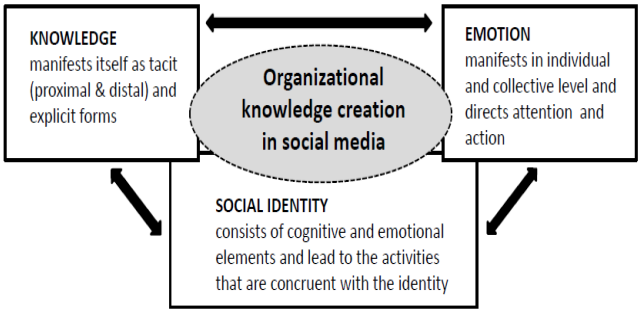

Figure 4. Knowledge, emotion and social identity in organisational knowledge creation in social media.

It is important to notice that the elements of organisational knowledge creation are not independent, but instead related to one another.

VI. Conclusions

This paper has discussed the interplay between (tacit and explicit) knowledge and emotion in the organisational knowledge creation process in the context of social media. The paper argues that social media provides new opportunities to the organisational knowledge creation process amplifying knowledge created by individuals as well as crystallising and connecting it to an organisation's knowledge system. However, the organisational knowledge creation is not a rational process, but a process that entails emotional elements. Emotions influence organisational knowledge creation. This is because emotions act as mediators between social identity and organisational behaviour. Therefore, the paper concludes that knowledge and emotion shared in social media contributes to the social identity, which reduces individuals' risk of being abused, which, in turn, increases the odds of altruistic behaviour that benefits the organisation.

However, as described earlier, social media consists of a bunch of activities, means, contents and features, it is obvious that different social media platforms have different abilities to contribute to organisational knowledge creation. More research is needed into uncovering which platforms are the most useful in organisational knowledge creation.

ACKNOWLEDGEMENT

This paper is part of research project NEMO (Business Value from Negative Emotions) and has been funded by TEKES – The Finnish Funding Agency for Innovation and Turku University of Applied Sciences.

***Abstract*—The paper presents the application of various classification schemes for actuator fault diagnosis in industrial systems. The main objective of this study is to compare either single or meta-classification strategies that can be successfully used as reasoning means in off-line as well as on-line diagnostic expert systems. The applied research was conducted on the assumption that only classic and well-practised classification methods would be adopted. The comparison study was carried out within the DAMADICS benchmark problem which provides a popular framework for confronting different approaches in the development of fault diagnosis systems.**

I. Introduction

THE INCREASING complexity of recent industrial objects makes the issue of fault diagnosis one of the most important directions of research in modern automatic control and robotics [1], [2], [3]. Technical systems and processes are required to be safely and reliably operated due to the protection of human life and health, the quality of the environment, as well as the economic interests. It is possible to specify numerous areas of interdependence of human and technical means, where safety plays a key role, such as aircraft, spaceship, automotive, power or chemical industry. The above mentioned factors cause that new developments in control theory such as passive and active fault-tolerant control approaches are more often applied in these areas of the industry [4], [5], [6]. A special attention is currently paid on the second type of the advanced control methodologies, where fault diagnosis methods hold a critical importance. The present state of the art in the field of fault diagnosis shows the really need for development of fault diagnosis expert systems. The goal is to elaborate general-purposes systems with multi-domain knowledge representations and multi-inference engines [7], [8], [9]. Generally, the fault diagnosis can be divided into three steps [10]: fault detection, fault isolation and fault identification. Moreover, each of them can be developed by means of model-free (based on data), model-based and knowledge-based approaches [4]. In this paper the first approach, where experimental data are exploited was discussed. In this kind of methods data that represents normal and faulty situations can be obtained from historical databases or from simulators as well as laboratory stands.

There are many types of classifiers available in the literature, as well as different concepts are introduced [11]. Examples are methods based on the similarity between objects in the feature space, probabilistic methods or methods based on black box models. Generally, the classification problems can be divided into two groups including approaches of the machine learning techniques: supervised learning and unsupervised learning. In the paper, the authors concentrated the attention only on methods belonging to the first group.

Currently, the information fusion and meta-classification problems are recognized as the most important directions of the research in the domain of supervised learning. The main idea in this approach is the application of simple classifiers working together to solve a problem with better results than it can by means of single one or more complicated classifiers. There are a lot of different kinds of information fusion methods, but the most popular are majority voting, weighted voting, boosting, AdaBoost [11]. On the other hand, meta-classifiers are very often used for the same reason that its efficiency is higher, than the efficiency of the best single classifier [12].

The current research trends in developing machine learning methods are focused on ideas of improving the general efficiency of different classification and meta-classification methods. The main directions are concentrated on optimization techniques which are used to tune relevant parameters of the classical methods, e.g. with the use of evolutionary and particle swarm algorithms [13], [14], [15], [16], [17], [18]. A number of results included in the works show the benefits of using these methods. In case of a task of fault detection and isolation the key features of the signals in time or frequency domains are most commonly used. Industrial actuators may be characterized by a very high complexity which affects the large number of measuring signals and their features. Therefore, another approach aimed at improving the efficiency of the classifier, and often also shortening the time of its learning, is to remove irrelevant variables [19]. There are various methods that can be used in this procedure, e.g. forward or backward selection methods, as well as elimination methods based on

978-83-60810-58-3/$25.00

statistical measures. Another group of methods are known as fusion methods such as bagging, boosting, and development of these concepts that is AdaBoost method [20], [21]. These methods are often more effective than simple classifiers but also show some drawbacks. Some advanced concepts were developed to take advantage of positive aspects of classic methods and to eliminate their limitations [22]. There are also attempts to connect together several different methods such as selection of relevant features and usage of boosting into one algorithm [23]. Such approach may lead to the final result that should be better than the results of the methods applied separately.

The paper is organized as follows. In Section I a brief introduction to the problem is given. Section II illustrates the issue of fault diagnosis using the model-free fault detection and isolation methodology. The next section deals with several classification schemes that can be applied to develop fault detection and isolation systems. A case study is included in Section IV. This example shows the comparison research of the classification schemes for creating fault diagnosis system of the benchmark actuator [24] which were elaborated on the basis of the activity of the DAMADICS (Development and Application of Methods for Actuator Diagnosis in Industrial Control Systems) Research Training Network funded by the European Commission. The last section is focused on conclusions.

II. Model-free fault detection and isolation

One of the most often used model-free fault detection and isolation methods is presented in Fig. 1. It can be seen, that faults are detected and distinguished using primary and redundant process variables. In this method two separated classifiers must be created. The first classifier uses the subset of process variables ($U' \cup Y'$) as its input and it is dedicated for generating diagnostic signals (S), whereas the second one has the same set of input variables but its task is to calculate a fault signature (F). This classifier is triggered in case when the diagnostic signal indicates a fault scenario.

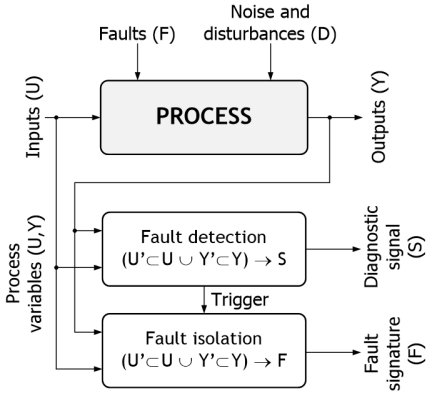

Fig. 1: A diagram of model-free fault detection and isolation

The algorithms corresponding to the diagram presented in Fig. 1 can be designed using different classification methods [10], [4], [25]. Generally, it is possible to apply so-called classical (e.g. decision trees, k-nearest neighbour, naive Bayes, etc.) or soft computing approaches (e.g. neural networks, bayesian networks, fuzzy systems, neuro-fuzzy systems, etc.). The paper deals with the first group of the methods only.

III. Model-free fault diagnosis using different classification schemes

In the next part of the article, model-free fault detection and isolation approaches with the use of different classification schemes were described. As it was mentioned above, these kinds of methods require data (process variables) corresponding to regular (fault-free) and faulty states of the system. In this section, different variants of three basic concepts with a single classifier, meta-classifier and bank of classifiers were applied in order to provide the fault detection and isolation system that is directly based on the process variables.

A. Fault detection

The first concept of the fault detection was presented in Fig. 2 and was elaborated basing on a single classifier, which returns a diagnostic signal corresponding to fault or faultless states of the device. In this method, the process variables were converted by a moving window in order to compute scalar features of the measuring signals. These values were used as input of a single classifier, which generates directly the diagnostic signal. The second detection method was presented in Fig. 3. In this approach a series of two-state classifiers was applied and their task was to determine the degree of the belief for fault detection. The level of belief about faults occurring was a numerical value from 0 to 1. The signal values returned from each classifier were connected to the meta-classifier as its input. The features of the process variables were also connected to the meta-classifier, as the additional input.

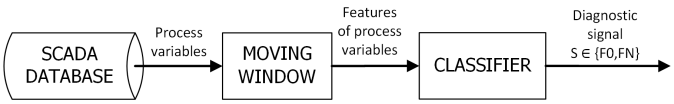

Fig. 2: A scheme of fault detection using the global classifier

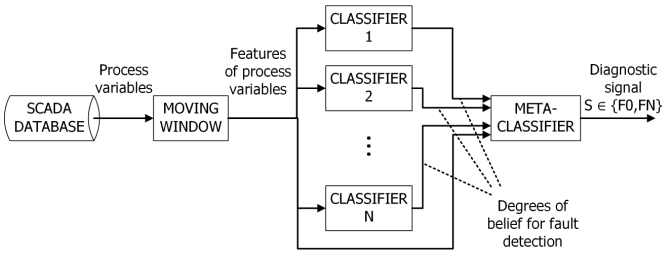

Fig. 3: A scheme of fault detection using the set of various classifiers and meta-classifier

The result of both methods was a diagnostic signal, which indicated fault occurrence. When a classifier or a meta-

classifier detects a fault, the second part of the fault diagnosis system was run in order to isolate the faults.

B. Fault isolation

The first method of fault isolation was comparable to the method that was proposed for the fault detection. It was presented in Fig. 4. As one could see it was a single global classifier. Its task was to determine a type of the fault. Similarly to the previous method, in this case the process variables were calculated in the moving window to obtain scalar features of the measuring signals. The preprocessed signals were connected to the input of a global classifier. This classifier returns a fault signature.

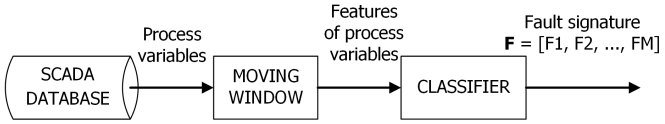

Fig. 4: A scheme of fault isolation using the global classifier

The next fault isolation scheme was presented in Fig. 5. In this approach a set of classifiers of different types was used in order to calculate the degrees of beliefs that were related to fault signatures. These values were given to the input of the meta-classifier and the final decision (fault signature) was obtained.

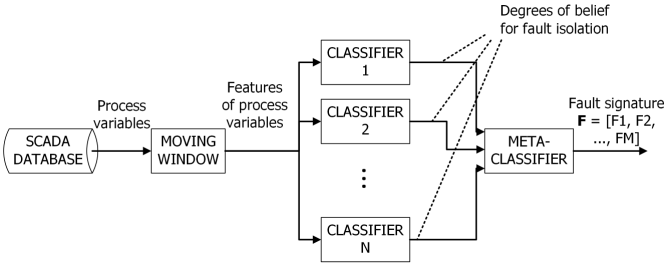

Fig. 5: A scheme of fault isolation using the set of different classifiers and meta-classifier

The last concept of fault isolation was shown in Fig. 6. The main idea was based on a bank of classifiers that were used to calculate degrees of beliefs for specific faults and unknown states of a device. In this case, M single classifiers must be created for M faulty states. Each classifier was dedicated for one state only (it was used for detection one fault solely). In the next step, all available variables (features of the process variables and outputs from base classifiers) are linked to a single dataset. The prepared signals were sent to the input of the meta-classifier which was employed to return the final decision.

C. Used classifiers

The schemes of fault detection and isolation presented in Sections III.A and III.B can be elaborated with use of basic classification methods. The classification problem is possible

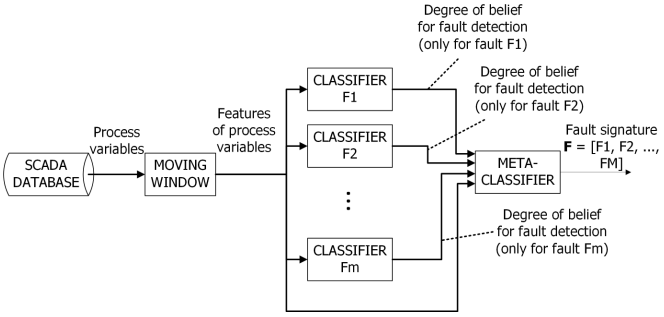

Fig. 6: A scheme of fault isolation using the set of local classifiers (fault detectors) and meta-classifier

to be solved using many known approaches, however, in this research the following methods were applied:

- k - nearest neighbour,
- naive Bayes,
- decision tree,
- rules inductions.

Each of these classifiers returns a label of a chosen class and the degrees of belief for all predicted classes. The best solution is when one of the class is characterised by the belief level equal to 1 and the rest of them are equal to 0. It gives us 100% certainty that a new element should be classified as this particular class. In the next subsections a more precise description of the selected methods was given.

1) k - Nearest neighbour: This is one of the simplest classification techniques. The class label assigned to an example is based on the similarity of this example to one or more prototypes. Typically, the similarity is defined in a geometrical sense using a certain distance. The smaller distance between new object and classified element means the higher similarity between new element and the class represented by the known object. The classifier looks for one nearest neighbour, then it is called 1NN or search for more nearest neighbours, then decision is made by voting. In kNN method, different types of distance measures can be used, e.g. Euclidean (1), Manhattan (2) or Chebyshev (3) distances [26].

$$D(x,y) = \sqrt{\sum_{i=1}^{n}(x_i - y_i)^2} \tag{1}$$

$$D(x,y) = \sum_{i=1}^{n}|x_i - y_i| \tag{2}$$

$$D(x,y) = \max_{i=1:n}(|x_i - y_i|) \tag{3}$$

The level of confidence about a result of classification depends on a value of k parameter. For k equal to 1, the confidence level for the classification result is always equal to 1. For k greater then 1, when the final result is determined by majority voting, the confidence level depends on the number and types of classified elements in the considered group [27].

2) Naive Bayes [28]: This is a simple probabilistic classification method which is based on bayesian theory. However the naive Bayes classifier considers each of existing features independently.

$$P(d_i|V_1,\cdots,V_n) = \frac{P(V_1,\cdots,V_n|d_i)P(d_i)}{P(V_1,\cdots,V_n)} \quad (4)$$

Taking into account this assumption, the bayesian equation (4) can be transformed to (5), where the denominator of the equation is replaced by a constant C and the conditional probability is calculated by the multiplication.

$$P(d_i|V_1,\cdots,V_n) = C \cdot P(V_1|d_i) \cdot ... \cdot P(V_n|d_i) \cdot P(d_i) \quad (5)$$

The degrees of beliefs for the classification results are equal to probability values obtained from the bayesian equation.

3) Decision tree: This is the classifier based on the tree-like graph created by nodes and connections between them, where the end nodes are called *leafs* and the rest of them have conditions. The result of a decision tree application depends on a chosen leaf. In the algorithm different split evaluation criteria (e.g. ratio gain in C4.5, information gain in ID3, the Gini impurity measure in CART, etc.) can be used [29], [27]. The confidence levels about the classification results are calculated separately for all leafs of the tree during the learning process. Sometimes, when learning data is very complex, the results of the decision tree may be uncertain since some of the leafs may be connected to more then one class. The class which is described by more elements then others (in specific leaf) is chosen as the main class for this leaf. The ratio between the number of elements for available classes is used to calculate the probability for each class in the leaf.

4) Rules induction: The method is based on Repeated Incremental Pruning to Produce Error Reduction (RIPPER) [30] algorithm. The confidence level is calculated in the same way as in the decision tree method.

IV. Verification studies

The proposed schemes of fault detection and isolation were implemented using RapidMiner software. It is an open source software created for solving data mining problems. The verification studies were conducted on data generated using the DAMADICS simulator [31] in order to investigate selected classification schemes. The research problem was actuator fault diagnosis.

A. Benchmark problem

DAMADICS was elaborated for scientists and engineers to simplify the process of evaluating and comparing different methods of fault detection and isolation for industrial systems. In the literature there were available several papers where case study results deal with this problem were presented [32], [33], [34]. The numeric model is used to simulate an electro-pneumatic valve (Fig. 7) which is a part of the production line in Lublin sugar factory in Poland. The model was created in MatLAB/Simulink®software and was on a careful study of the physical phenomena that gave the origin to faults in

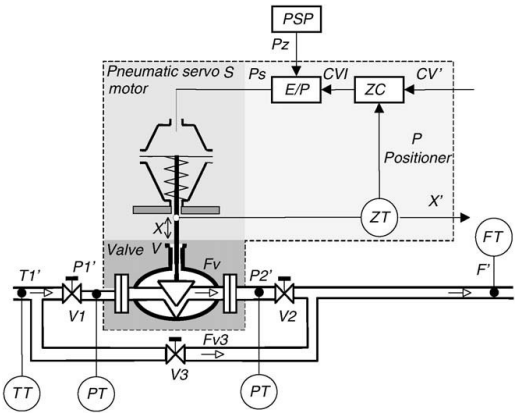

Fig. 7: Structure of benchmark actuator system [24]

the actuator system. This simulator generated the following signals of the process variables:

- CV - process control external signal,
- P1 - inlet pressures on valve,
- P2 - outlet pressures on valve,
- X - valve plug displacement,
- F - main pipeline flow rate,
- T - liquid temperature,
- f - standard diagnostic signal.

All of these signals are normalized to the range between 0 and 1. The DAMADICS simulator allows to choose only one from nineteen available faults (due to this, only scenarios with single faults were taken into account). A part of them is considered only as incipient faults or as abrupt faults (there are three sizes of abrupt faults: small, medium and big) and some of them as both. In this paper the authors decided to investigate only abrupt faults, such as:

- f1 - valve clogging,
- f2 - valve or valve seat sedimentation,
- f7 - medium evaporation or critical flow,
- f8 - twisted servo-motor stem,
- f10 - servomotor diaphragm perforation,
- f11 - servomotor spring fault,
- f12 - electro-pneumatic transducer fault,
- f13 - stem displacement sensor fault,
- f14 - pressure sensor fault,
- f15 - positioner spring fault,
- f16 - positioner supply pressure drop,
- f17 - unexpected pressure change across valve,
- f18 - fully or partly opened bypass valves,
- f19 - flow rate sensor fault.

The list does not have some faults, because the incipient faults such as f3 - *Valve or valve seat erosion* or f4 - *Increase of valve friction* were not considered. The verification tests were performed basing on the process variables generated by the DAMADICS simulator for fault-free and faulty scenarios.

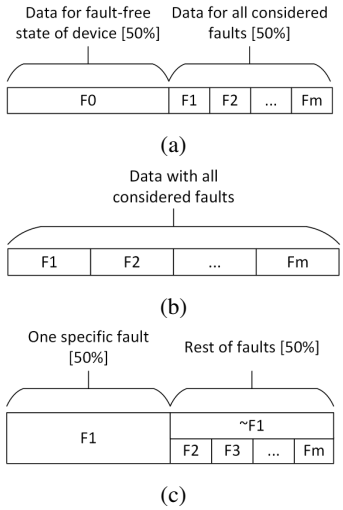

Fig. 8: Examples of data groups for specific methods

B. Data preparation

Collections of data for the training, testing and verification of classifiers were prepared in such a way that the results of classifiers were very similar to classifiers working in a real environment. The process of learning (training and testing) and verification for the applied classifiers was described in this section.

1) Data for fault detection classifiers: Data preparation is a very important part of the classifier learning process. The dataset should be divided into two equal parts, where the first part describes correctly working device (fault-free state) and the second part corresponds to situation when fault occurs (Fig. 8a). It was important to divide the prepared data again to two separated groups (learning group and verification group). For the meta-classifier the number of groups was extended to four, because the first and the second groups were used in the learning and verification process for the base classifier. The other two groups were used for a meta-classifier. In this approach, the size of the dataset for each group was equal 10000 samples, where 5000 samples were prepared from data without faults and rest of them contained data with all considered faults.

2) Data for fault isolation classifiers: The data prepared for the first two fault isolation methods (Fig. 2, 3) consists of characteristic process values for all chosen faults (Fig. 8b). The number of elements for each fault was the same for all sets. For learning and verification process four independent groups of data were prepared (like in fault detection methods, two for base classifiers and two for meta-classifier). The dataset for a single fault for one group contains approximately 600 samples, while the full dataset size is about 8000 samples. The third method of fault isolation requires a different type of data. The initial classifier needs data, where a half of the elements describes an actuator device working with one specific fault and the rest of the elements describe the device working with the other faults (Fig. 8c). In this case, a classifier can generate a two-state signal where the first state defines one specific fault and the other ones are correlated with unknown faults. The size of the dataset in this approach is similar as in case for the method of fault detection. The size of the dataset for the considered fault is equal to 5000 samples and it is equal to the rest of a dataset which contains samples corresponding to other faults.

C. Statistical analysis

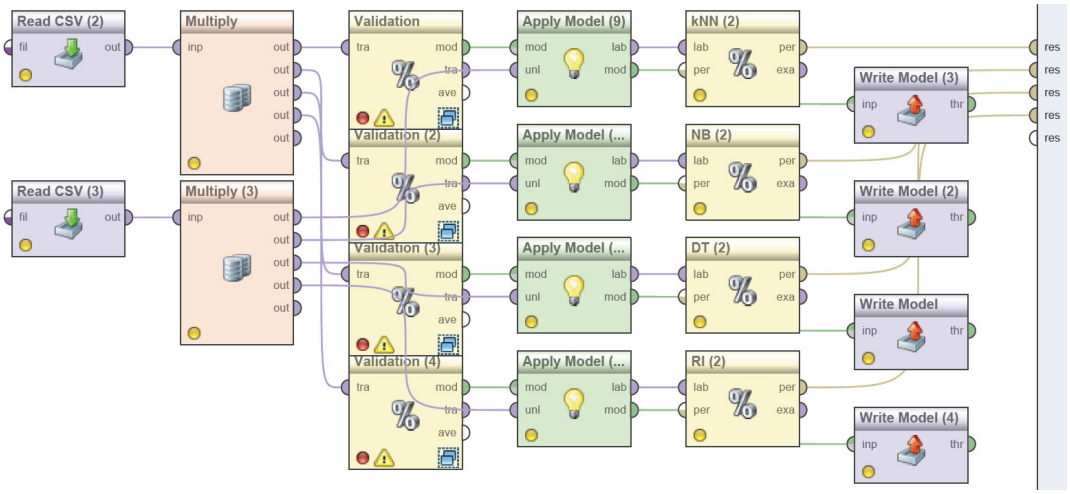
Linear correlation and mutual information analysis were used for choosing relevant process variables and a proper value of the width of a moving window function. In the analysis, all of available process variables were compared between themselves for different device status (e.g. device without faults and with a chosen fault). The results of these tests showed very strong correlations between states F8, F14 and F0. A group of useful process signals was prepared on the basis of results of these tests. Most of the process signals had very difficult character for model-free fault detection and isolation methods. Therefore, the authors decided to apply scalar features of the process variables. Among all available functions in RapidMiner software, four of them were tested: moving average, moving median, maximal value, minimal value.

The scalar features were computed using a moving window of 100 samples width. Such the width value was assumed on the basis of frequency of the harmonic control signal of the valve which was equal to $0,01$ Hz. The authors also studied other values of the window width, however, expected effects in increasing of the efficiencies of the models were not observed. In Fig. 9 exemplary process variables and their features as the time function are plotted. Figures 9a, 9b and 9c show time series of measured signals X, F, P2 for fault F17, whereas figure 9d presents the change in the temperature signal T1 as a result of the fault F7. The sudden change of this signal and its scalar features can be observed at around 800 second when the fault F7 starts affecting the process.

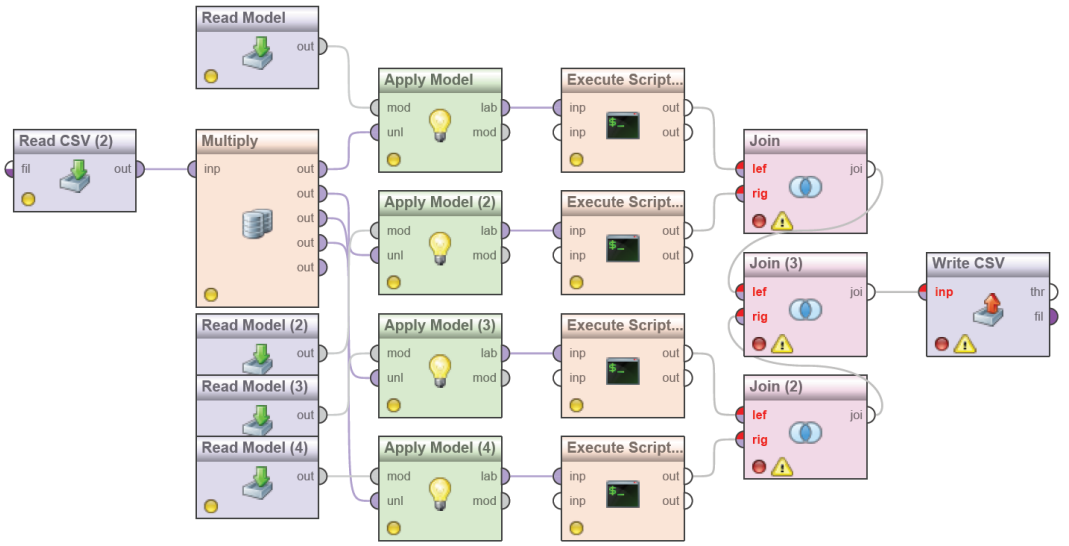
D. Classification schemes implementation

The RapidMiner®software allows to create data mining processes with the use of a visual programming language. This tool gives the opportunity for developing different classification schemes using so-called drag and drop methodology. In this way the classification processes can be viewed as dataflow graphs (Fig. 10).

Fig. 10a presents the scheme of learning and verification processes using four different classifiers. In the first step, the data is red from CSV files by means of *Read CSV* blocks. Next, the learning dataset from the first step is sent to validation blocks, where the learning and evaluation processes for each classifiers is run. The output of these blocks is the ready-to-use classifier, which is applied in *Apply model* block using another dataset read in *Read CSV (2)* block. In the *Performance* block, the process of classifier evaluation is again carried out, but the data are completely different than those in the learning process. *Write Model* blocks are



(a)



(b)

Fig. 10: Selected examples of RapidMiner processes

used in order to write the models into files, because these classifiers are necessary during the process of meta-classifier learning. This scheme can be employed for creating single and meta classifiers. Although, there is a small difference between these two cases in the manner of pre-processing input data. Figure 10b illustrates the process that is applied to generate either learning or verification datasets for meta-classifiers. The data for meta-classifiers is forwarded to their inputs. These samples are totally different from those used at the learning and verification stage of the base classifiers. *Read Model* blocks are employed for reading models of base classifiers. The results of these classifiers are degrees of belief for faultless and faulty states of the actuator. In order to use the data in the next part of the classification process, the pre-processing operations must be done in the *Execute Script* blocks. In the last phase of the process relevant information generated by base classifiers is put together in the form of a coherent dataset which is written in the other file.

E. Results of verification studies

The learning process for the whole set of applied classifiers was conducted using the X-validation method. At firs the case study tests were carried out to choose the most important parameters for X-validation method. The described schemes of fault detection and isolation were examined with all types of classifiers.

1) Results of fault detection: In the first concept of fault detection (see Fig. 2) four single classifiers were compared. In each table the following notation was assumed: kNN - k-nearest neighbours, NB - Naive Bayes, DT - Decision Tree, RI - Rule Induction. The letter M before each label (kNN, NB, etc.) means meta-version of a classifier, for example, the

label MNB denotes a meta-classifier which is based on a naive Bayes classifier.

Table I shows results of two concepts of fault detection realized by schema presented in Fig. 2 and 3. The effectiveness of the classifiers is given in columns. The column indicated as "All" includes the general efficiency calculated on the basis of the confusion matrix which was generated after the classifier verification process. The next column (F0) includes the efficiency obtained for faultless states. The rest of the columns (F1-F19) show the efficiency of fault detection for all considered faults, separately. Above these columns the general result of the efficiency of fault detection is presented. Rows from 1 to 4 show results for single classifiers, whereas the next four rows show results for considered meta-classifiers.

2) Results of fault isolation: The results of comparison of the first fault isolation method (Fig. 4) are included in Tab. II. The same types of classifiers were used. The column indicated as "All" includes values of the global efficiency for single classifiers of different types. The rest of the columns show information about the efficiency of fault isolation for each scenario.

The second method presented in Fig. 5 use four classifiers as in the previous method but the outputs of these classifiers are connected to a meta-classifier. The results obtained for the meta-classifier are compared in Tab. III. Tab. IV presents the general efficiency of single classifiers (rows from 1 to 4) and meta-classifiers (rows from 5 to 8) for the fault isolation process.

TABLE IV: Comparison between all methods of fault detection for the learning and verification stages

	Learning and testing stage	Verification stage
kNN	0,988	0,844
NB	0,722	0,661
DT	0,176	0,177
RI	0,989	0,808
MkNN	0,990	0,837
MNB	0,860	0,835
MDT	0,890	0,777
MRI	0,982	0,812

The last method of fault isolation (Fig. 6) is based on series of single classifiers, where each classifier is used for detecting a single fault. The first task of the verification process was to choose a single classifier (from four available) for the fault

detection purpose. To solve this problem the authors tested all classifiers for all available faults. The results are presented in Tab. V. The values included in the table present the general efficiency of each classifier. The bolded values are related to the classifiers which were chosen as the basic classifiers for the meta-classifier.

In the next step of the method the meta-classifier is used. Its inputs are connected to the outputs of basic classifiers (the degrees of the belief for single fault detection). The main task of this meta-classifier is to compute the final result. Table VI presents results of different types of classifiers which are presented in the same form as in the second method of fault isolation (Tab. III). In the first column indicated as "All" there are included values of the general efficiency of the meta-classifiers. In the next columns the efficiency values of single fault isolation obtained by means of meta-classifiers are included.

3) Discussion of the results: The comparison of two schemes of the fault detection (Fig. 2 and 3) as well as different types of classifiers (kNN, NB, DT, RI) showed that results which were obtained using these schemes were very similar to each other. Moreover, the comparison between the same classifiers and other methods showed that the meta-classifier was characterized by the highest fault detection efficiency at the expense of the fault-free state. Both methods revealed the some problems with detection of faults F8 and F14, because these faults were very strong correlated with faultless state. The best meta-classifier returned more accurate results then the best single classifier, but the difference between them was too small to conclude that this meta-classifier could be better than the second one. The last three methods concerned fault isolation without taking into account a faultless scenario. In the first method (Fig. 4) the global single classifier was used in order to qualify the current fault class of the device. The results of tested classifiers were different, e.g. the global efficiency of DT was 0.177 and the second one (sorted by their efficiency values) was 0.661. Decision tree was able to recognize fault F7. However, value 1.000 for fault F1 indicated 100% efficiency of detection fault F1, but on the other hand the rest of faults were also recognized by this classifier as fault F1. The next classifier (NB) had better results than a decision tree algorithm. The last two classifiers showed a similar global efficiency. The k-Nearest Neighbour classifier (kNN) provided the best basic efficiency for most of single faults. The exception was fault F16 which was better recognized by the rule induction classifier (RI) and fault F14 which was better detected by the Naive Bayes (NB). The results obtained for the second scheme of fault isolation (Fig. 5), which was based on the meta-classifier were more similar to each other than in the first case (Fig. 4). There was a group of faults which were very easy to isolate by all meta-classifiers (F1, F2, F7, F10, F11, F12, F15, F17, F19). The general level of the efficiency in this method was increased significantly in some cases. But the comparison between the best single classifier and the best meta-classifier showed that in the second case, the global efficiency was worse. The more careful analysis of the results for these two classifiers showed that most of the best meta-classifier results were better than the results of the best single classifier. Some exceptions were faults F16 and F18. In the second case deterioration was very sizeable and it was the main reason of the worse result for this classifier. The third scheme of fault isolation (Fig. 6) was divided into two parts. The first part was dealt with the selection of the basic classifiers, applied to isolate a single fault. After the analysis of the results presented in Table V the authors nominated the classifiers for single fault detection. These classifiers were chosen on the basis of general results. In case more than one classifier had the same efficiency value (more classifiers with the efficiency equal to $1,000$ for the fault at the same time) the authors pointed out a classifier with more stable results in the time domain. The previous analysis showed that this type of classifiers carried with it the increase of the efficiency of the meta-classifier. In the second part different types of meta-classifiers were compared. The final results of this method showed that the difference between the efficiency of specific fault isolation for a single meta-classifier was sizeable. Also the difference for the global efficiency among all met-classifiers was sizeable. The best result was obtained for the decision tree (0.840) and it was comparable with a case of the best efficiency level for the single global classifier (k-nearest neighbours: 0.844) in the first method (Fig. 4). The meta-classifier based on the naive Bayes method demonstrated the smallest efficiency for this approach.

V. CONCLUSION

In the paper the application of selected classification schemes for fault diagnosis of the actuator systems was presented. The main purpose of the paper was to compare single and meta-classification strategies that could be successfully used as reasoning approaches in off-line as well as on-line diagnostic expert systems. The research was realized basing on the classical and well-practised classification methods. The comparison study was carried out within the DAMADICS benchmark problem. The classification schemes were implemented in RapidMiner software which is a well-known open source system for data mining and knowledge discovery. The particular results of the fault detection study showed that for simple industrial actuators it is possible to apply simple classification schemes without the necessity of using more advanced methods which are based on meta-classifiers. Significant differences can be observed in case of the results that are related to fault isolation schemes. The best evaluation results obtained from the three classification methods are ranged from 0.835 to 0.844. It should be stated that it is possible to observe some important differences in outcomes obtained using simple classification methods in the first fault isolation scheme (see Fig. 4) and similar results in the second one (see Fig. 5). The third concept (see Fig. 6) leads to the varied results of the classification process. The merits in the case of using meta-classifier (the second method applied according to Fig. 5) can be seen for several faults, especially when compared this to the best single classifier. The last scheme (see Fig. 6) is the most complicated and there is the need to test various classifiers and to have additional learning datasets. Moreover, in this scheme the general efficiency of fault isolation is close to the result achieved by means of the single classifier.

In this study, the authors used a confusion matrix in order to evaluate fault diagnosis systems that were created applying different classification schemes. Nevertheless, this measure can be directly compared with false and true detection/isolation rates proposed by the authors of the DAMADICS simulator [24]. The results of fault detection and isolation using single or meta-classification strategies that were achieved in this study are comparable to even more advanced methods described in the literature [35], [36]. Furthermore, in this study the whole set of potential faults were investigated, whereas in the related papers only selected states were taken into consideration.

Overall, the application of single or meta-classification strategies allows to create effective as well as relatively less-complicated computational fault detection and isolation systems that can be successfully employed for on-line and off-line fault diagnosis of industrial actuators.

ACKNOWLEDGEMENT

The research presented in the paper was partially financed by the National Centre of Research and Development (Poland) within the frame of the project titled "Zintegrowany, szkieletowy system wspomagania decyzji dla systemów monitorowania procesów, urządzeń i zagrożeń" (in Polish) carried out in the path B of Applied Research Programme - grant No. PBS2/B9/20/2013. The part of the research was also financed from the statutory funds of the Institute of Fundamentals of Machinery Design.

***Abstract*—SMEs are encouraged to collaborate for research and innovation in order to survive in tough global competition. Even the technology SMEs with high knowledge capital have the fear to collaborate with other SMEs or bigger companies. This study aims to illuminate the preferences in customer, supplier and competitor collaboration within industry or inter industry. A survey is run on more than 110 companies and Machine Learning methods are used to define the association rules that will lead for success.**

***Index Terms*—Collaborative Innovation, Association Rules, SVM, SOM**

I. Introduction

KNOWLEDGE based SMEs need to construct successful alliances in order to have sustainable business in a competitive environment. Global experiences with randomly chosen collaborators have shown failures that caused the fear of new collaborative work. Causes of failure based on the culture and the type of collaboration are studied [1]. Alliance in new product development has been the focus of industrial researchers [2][3][4].

This study aims to provide a pre-analysis of the path for successful alliances that will lead improvements in innovative power. Both qualitative and quantitative analysis of the SME alliances is realized to find the conditions causing failures and supporting the success in innovation. Support Vector Machine and Self Organized Maps are used to define the most frequent patterns that will give the support and confidence to identify the relationships. Association rules achieved will determine the optimal use of resources.

This paper is so organized that the literature review will be given in the second section and the methodology definition will follow. The fourth section will be reserved for presenting the survey and the results. The conclusion will be given in the fifth and last section.

The implication of the study is generic enough to help any SME or research organization or large business to reduce risks in future alliances.

II. Background

The first research on Association Rule Mining and Methods is found in 1996 [5] trying to find the most frequent occurrences of events to support the linked processes. The research in the field followed the timeline shown in Figure 1.

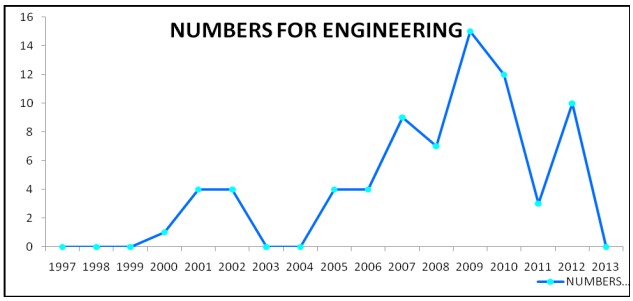

Figure 1. Research timeline on Association Rules

Post et Al. showed the fact that SMEs would like to collaborate only for developing new products [6]. However, Kakabadse et Al. showed that using improved communication and information technologies will improve the SME collaboration[1]. New product based collaboration has evolved fast [7]. Corporation and competition are found as flaming collaboration types that feed the SME improvements in innovation [8]. Association rules defined for the failure types have opened a new dimension for the research on failure of collaboration [9]. The first study on mining the SME innovation by Wang et Al has found some patterns for allocating the R&D resources [10]. Suh & Kim have detailed the R&D collaboration in service industries detected the positive relations of technology and the product or process innovation[11]. Swarnkar et Al. analyzed when and how the collaboration strategies will be used in virtual organizations[12]. Wiltsey et Al. claimed that extent, nature or impact of R&D programs are studied rarely. The interactions among the influences must be given in multiple levels and fidelity and changes must be observed in time [13]. Woodland & Hutton introduced the social dimension

on the collaborative success [14]. Both the fear issues and the success causes studied by Bouncken et Al defined technology influencers, sharing the knowledge and learning from the partner as the main influencers [2].

Knowledge management and data mining overviews [15] and Knowledge Management performance studies [16] realized recently do not show any association rule study for the collaborative innovation success and failure.

METHODOLOGIES

A. Association Rules

Given a set of transactions, rules are defined that will exhibit that the occurrence of an item based on the occurrences of other items in the transaction. This is the association analysis. It is useful to explore the interesting relations, which are embedded in the huge data sets. These hidden interactions can be stated in the form of association rules[17]. The strength of an association rule is measured with its support and confidence values. Support shows the how often that rule is applicable to a given dataset. The Confidence is the occurrence frequency of the item in that transaction [5].

Support (s) is the fraction of transactions that contain an itemset

$$\text{Support, } s(X \longrightarrow Y) = \frac{\sigma(X \cup Y)}{N}; \quad (1)$$

Confidence (c) measures how often items in Y appear in transactions that contain X

$$\text{Confidence, } c(X \longrightarrow Y) = \frac{\sigma(X \cup Y)}{\sigma(X)}. \quad (2)$$

The item set patterns are found in various methods which could be apriori or aposteriori. The overview of all the methods used in association srule studies are given in Figure 2.

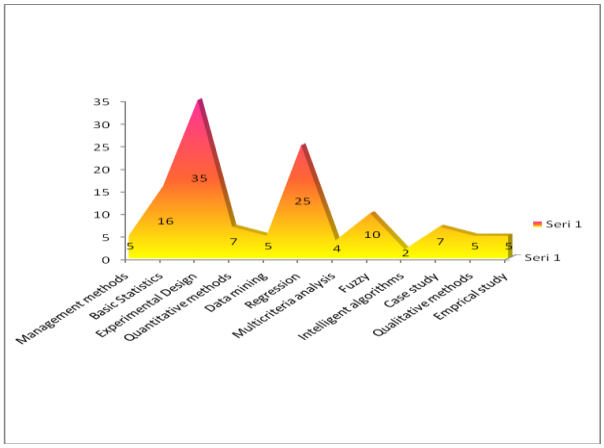

Figure 2. Overview of Association rule techniques

B. Support Vector Machines

It is a machine learning technique, which is mainly introduced for classification in two classes [18] but further used in clustering[19].

It can be analyzed as an optimization problem as in equation 3 [20] relaxed with Lagrange multipliers in objective function as in equation 4.

$$\min z = \frac{1}{2}\|w\|^2 \quad \text{s.t.} \quad r_i(w_i x_i + w_0) \geq 1 \quad (3)$$

Data is separated with a hyper-plane multiplied by -1 or +1.

$$L_p = \frac{1}{2}\|w\|^2 - \sum_i \lambda_i r_i (w_i x_i + w_0) + \sum_i \lambda_i \quad (4)$$

Using Using a Gaussian Kernel as defined in Eq. 5. will increase the reliability on dissimilarities [22].

$$K(x, x_i) = \exp\left(-\frac{\|x - x_i\|^2}{2}\right) \quad (5)$$

C. Self Organized Maps

Self-Organizing Map (SOM) is a widely used artificial neural network technique in clustering with unsupervised learning algorithm. This technique clusters according to the similarities to the input data [23]. SOMs structure the output with individual node similarity as well as cluster center distance. This technique is based on competitive learning, where the output nodes are made of the winning node activated by one input node. The output nodes would have scoring values using a function, most commonly Euclidean distance between the inputs and weights. For each input vector x, and for each output node j, the value D (w_j, x_n) of the scoring function. Euclidean distance function is shown in Eq. 6

$$D_{w_j, x_n} = (w_{ij} - x_{ni})^2 \quad (6)$$

The winning node therefore becomes the center of a neighborhood of excited nodes. In self- organizing maps, all nodes in the given neighborhood share competition. Therefore, even if the nodes in the output layer are not connected directly to the input layer, they tend to share common features, of the neighborhood [24]. The nodes in the neighborhood of the winning node participate in adaptation, which is, learning. The weights of these nodes are adjusted to improve the weights defined in Eq. 7., until a threshold is reached.

$$w_{ij}\ new = w_{ij}\ current + \alpha\ x_{ni} - w_{ij}\ current \quad (7)$$

In Eq 7. α is the learning rate. If it is necessary, the learning rate and neighborhood size are adjusted.

APPLICATION

A survey is run with the technology firms sited in Techno-parks of linked , 5 are about competences and 4 four the technologychoices. 130 firms responded but only 105 are included in the analysis. 14% of the companies were medium size and 37 % of them were aged more than 10 years. They have chosen the type of collaboration among the SME and Big firms as well as among the customers, suppliers and competitors as shown in Figure 3.

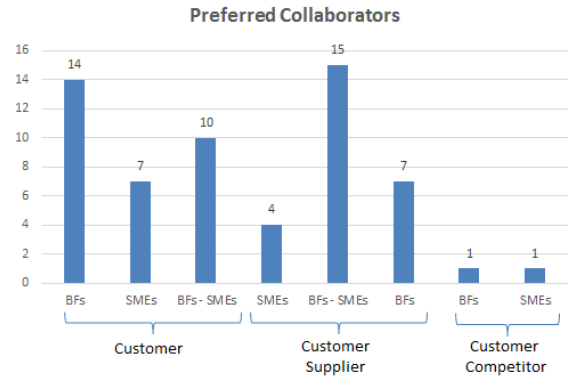

Figure 3. Choice of collaboration according to size and relation

The reason for innovative collaboration is stated as shown in Figure 4.

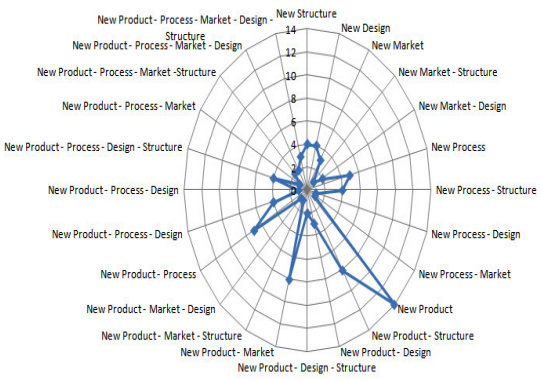

Figure 4. Innovation causes in collaboration

SVM is applied to classify the collaboration made specifically for innovation, validated by Cronbach alpha, that resulted as more than 0.7. SOM is used to cluster those to show the supporting frequencies of choices. Then the cross tables are achieved as a basis for the association rules. The first achievement was micro companies would like all the collaborators to have innovation culture which is less important for the bigger companies. Some other samples of cross tables are given as below.

Table 1 gives the fact that majority of responders prefer for at least one collaborator to have design competence.

Table 1. Business Understanding and Design Competence

			DESIGN		
INNOV			All	At least one	Negli ge
Collaboration for others	Bus-Under	All	4	14	
		At least one	2	15	
Collaboration for innovation	Bus-Under	All	14	26	4
		At least one	7	13	2
		Neglig.	1	1	2

In the firms collaborating for innovation for 1 to 3 years for the success of innovation it is necessary understanding the market requirements by all the firms together with the well-developed innovation culture.

Table 2. Age-Innovation Culture and Market Requirements Relation

			INNO_CULT		
COLLAB_Age			All	At least one	Neglige
0	UNDERSTD_REQ	All	13	8	
		More than one	6	6	
		At least one	0	1	
<1 year	UNDERSTD_REQ	All	9	1	0
		More than one	3	1	1
1-3 years	UNDERSTD_REQ	All	13	1	
		More than one	1	1	
		At least one	4	2	
3-5 years	UNDERSTD_REQ	All	6	1	
		More than one	3	2	
		At least one	0	1	
>5	UNDERSTD_REQ	All	8	2	0
		More than one	3	2	2
		At least one	2	2	0

RESULTS

The Reliability analyzes have been done on the results of the questionnaires, the Cornbach's Alpha value is 0.602; this value is in the acceptable range.

In the logistic regression model, the determined significance level is 0.100. The values of attributes of innovation are neglected, since they are greater than 0.100. Innovation related criteria in this study have no significance based on firm size and collaborator types of these firms.
In other words, firms care the technological features but ignore the innovative attributes.
In the table below, the significance values are shown for the other 3 attributes and the results of analyzes for features of the questions. The significance values less than 0.100 are used here (Figure 5).

Figure 6. Regression Coefficients & Significancies

The cross relation tables have been constructed to define the rules obtained from the model.

Finance Related Criteria :

RULE 1:

IF

(Firm Size = “Micro” AND Firm Age ≤ “1”)

THEN

(Innovation operation expenditure = “proportionally shared” AND Price = “important”)

MEANING:

- ✓ Preferences for the initiating micro SMEs emphasize the innovation operation expenditures according to the collaborator sharings and market value (price) of the innovated product (Figure 7).

Finance Related Criteria		Capital_More than Average of Sector (A)	Capital_Average of Sector (B)	Innovation Operation Expenditure_Balance (A)	Innovation Operation Expenditure_More is more (B)	Price_Important. (A)	Price_Only motivation (B)	Exportation_All collaborators (A)	Exportation_Only one (B)

MEDIUM (3)	< 1 YEAR OLD (A)								
	1-3 YEARS OLD (B)								
	3-5 YEARS OLD ©						■	■	
	5-10 YEARS OLD (D)								

Figure 7. Cross – relations Table: Firm Size – Firm Age – Finance Related Criteria

RULE 2:

IF

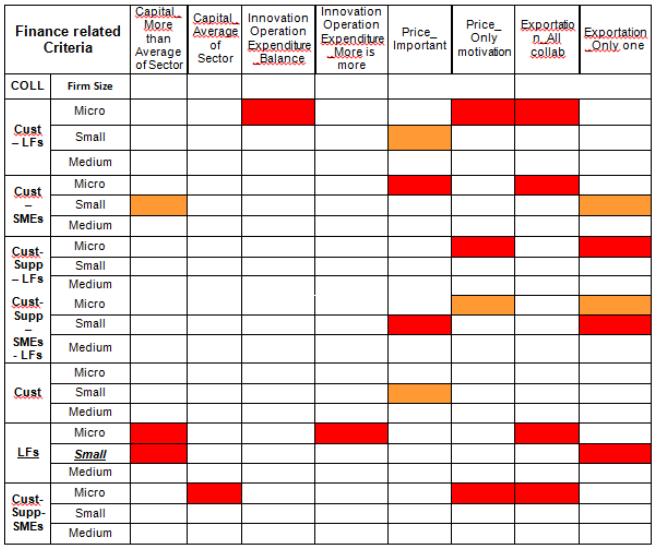
(Firm Size = “Small” AND Collaborate = “Large Firms”)

THEN

(Capital = “more than average” AND Exportation facilities = “only one firm”)

MEANING:

- ✓ Small SMEs emphasize that capital of the collaborators are to be more than the sector average and exportation facilities are done by only one collaborator for innovation (Figure 8).



Finance related Criteria		Capital_ More than Average of Sector	Capital_ Average of Sector	Innovation Operation Expenditure _Balance	Innovation Operation Expenditure _More is more	Price_ Important	Price_ Only motivation	Exportatio n_All collab	Exportation _Only one

Figure 8: Cross – relations Table: Collaboration – Firm Size – Finance Related Criteria

RULE 3:
IF
(Firm Age = "> 10 years old" AND Collaboration Duration = "3-5 years")
THEN
(Capital = "more than average" AND Price = "motivation")

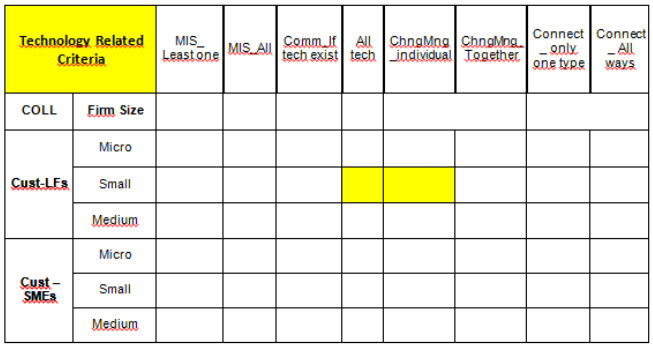
MEANING:

- ✓ 10 years (and more) old SMEs emphasize capital of the collaborators have to be more than the sector average whereas market value (price) of the innovated product is only a motivation.

Technology Related Criteria :

IF
(Firm Size = "Small" AND Firm Age = "3-5 years old")
THEN
(Connectivity = "All possible ways" AND Change Management = "All Collaborators")
MEANING:

- ✓ SMEs with age 5 to 10 years old emphasize change management is to be applied by all collaborators and use all possible connectivity possibilities.



Technology Related Criteria		MIS_ Least one	MIS_All	Comm_If tech exist	All tech	ChngMng _individual	ChngMng_ Together	Connect _ only one type	Connect _ All ways
COLL	Firm Size								
Cust-LFs	Micro								
	Small								
	Medium								
Cust – SMEs	Micro								
	Small								
	Medium								

Figure 9. Cross – relations Table: Collaboration – Firm Size – Technological Criteria

Figure 9 shows the cross – relations between collaborator type (customer – supplier – SMEs – large firms) and firms' size for the technology related criteria. Also this mentioned model makes sense statistically significant as a result of the logistic regression analysis.

RULE 2:
IF
(Firm Size = "Small" years old" AND Collaborate = "Customers" and "LFs")
THEN
(Communication technologies = "All opportunities" AND Change Management = "Individual")
MEANING:

- ✓ Small SMEs who are collaboraing with the customers which are large firms (LFs) emphasize usage of all communication technologies opportunities and change management is can be individual choice (Figure 9).

Management Related Criteria :

RULE 1:
IF
(Firm Size = "Medium" AND Firm Age = "5-10 years old")
THEN
(Professionalism = "Motivation" AND Organizational Structure = "Effective" AND Cooperation & Coordination = "All" AND Leadership = "Only one")
MEANING:

- ✓ Medium size SMEs of age 5-10 years prefer to collaborate with companies which have effective organizational structure with both cooperation and coordination attitude; in the collaboration a single leader is preferred and professionalism can be taken only as the motivator.

RULE 2:
IF
(Firm Size = "Micro" AND Collaborate = "Customers" and "SMEs")
THEN
(Professionalism = "All" AND Business Experience = "All" AND Leadership = "All")
MEANING:

- ✓ The micro SMEs collaborating with the customers emphasize professionalism, business experience for the problem solving and they prefer all the collaborators to have the leadership features.

CONCLUSION

This study investigates the most preferred conditions for a successful collaboration for innovative SMEs. SVM and SOM are used to construct the basis for creating the association rules. As the result of a survey in Turkey, there are hundreds of relations depicted in the analysis.

The achievements are interesting enough to show that the technology companies are confused in differentiating the technology and innovation concepts. It was interesting to observe micro and young companies not willing to collaborate with the big and overwhelming companies. Everybody asks for full communication technology, but only small SME with 5-10 years of experience ask for the collaborators to have effective organization and full professionalism.

The validation by logistic regression on the same data is in process. All the results achieved using logistics regression will be cross-validated with machine learning application results. Future survey will be aiming to improve the innovation concept of the technology firms in detail.

***Abstract*—Privacy protection issues in Social Networking Sites (SNS) usually raise from insufficient user privacy control mechanisms offered by service providers, unauthorized usage of user's data by SNS, and lack of appropriate privacy protection schemes for user's data at the SNS servers. In this paper, we propose a privacy protection model based on danger theory concept to provide automatic detection and blocking of sensitive user information revealed in social communications. By utilizing the dynamic adaptability feature of danger theory, we show how a privacy protection model for SNS users can be built with system effectiveness and reasonable computing cost. A prototype based on the proposed model is constructed and evaluated. Our experiment results show that the proposed model achieves 88.9% detection and blocking rate in average for user-sensitive data revealed by the services of SNS.**

I. Introduction

NOWADAYS, people tend to use Social Networking Sites (SNS) to keep personal connections with others. According to Ho et al. [1], SNS is a website that provides a virtual community for people with similar interests in particular subject, or just to "hangout" together. Based on the definition of SNS, people can use SNS services to share information, thoughts and feelings, chat with other users, play online games with other users, and even promote their own businesses to other users [2]–[5]. The rapid growth and huge amount of service usage of SNS show that SNS has taken a significant role on communication media and culture among people in modern societies. For instance, Facebook Message is a social service provided by Facebook that allows people to chat online or message with each other offline.

During chatting or messaging sessions of SNS services, people may consciously or unconsciously input sensitive user information into their exchanging messages. Facebook provides a set of rules to protect its user's privacy [2], and it allows its users to determine who can access and see information shared by individual user. However, these rules cannot protect sensitive information shown within shared messages. When it comes to user privacy protection, it all depends on individual user itself to carefully avoid inputting user-sensitive data during the usage of SNS services.

This work was supported by Taiwan Information Security Center (TWISC) and National Science Council, Taiwan, under Grant no. NSC 102-2218-E-011-013

In the past few years, several mechanisms had been proposed by researchers to protect individual privacy for different occasions. User anonymization [6]–[10] and data encryption [11]–[14] are two major investigation directions.

User anonymization schemes as described in [6]–[10] protect a user from being identified from a set of data records by replacing user-related data within these records with system-generated strings before outputting these data for people to use. However, Beye et al. [3] explained that this kind of mechanisms still cannot defend against re-identification threat. Moreover, these mechanisms are not suitable to apply directly onto real-time chatting or messaging services since these mechanisms are only suitable for large dataset which contains thousands of different users' information. In addition, users have to identify themselves with a set of unique personal attributes first before they use any service offered by SNS.

Data encryption schemes as described in [11]–[14] protect communication privacy between users by encrypting communicating data or messages. Both communicating parties have to get corresponding keys in advance to encrypt and decrypt messages transmitting between them. Inevitably these mechanisms have key distribution/management problem to be resolved in practice. In SNS services, a real time message is usually shared or broadcast to multiple users/friends. Therefore, it is not easy to do group key management for SNS services provided that data encryption schemes are adopted directly. As the friend list of individual user will dynamically change from time to time, group key management for individual user will become an annoying routine job if the complexity of key management is endurable. In SNS environment, it is desirable to have a dynamic information protection mechanism that meets individual user's need. Since not all information shared by using SNS services is user-sensitive, a user privacy protection mechanism should be able to filter and determine which information is sensitive and needs to be protected.

Danger theory has been investigated in the field of Artificial Immune System [15] for its built-in ability to adapt dynamic changes automatically. Some researches using danger theory to construct application systems such as virus detection, network intrusion detection, and message filtering; have been conducted and shown its effectiveness.

978-83-60810-58-3/$25.00

In this paper we propose a privacy protection model for SNS Messaging System based on danger theory concept. Messages that does not contain sensitive information are defined as healthy cells. In contrary, messages that contains sensitive information are defined as injured cells. Danger signal defines what kind of dangers should be detected by the system. Danger signal in our model is the signal sent out by SNS messaging system when user-sensitive information inside a message is detected. Antigens are defined as the collection of user-related information. Based on our antigen's definition, we define the antibodies as a set of rules that regulate user-related information and determine what information is allowed to be shared to other users. Binary string is adopted to represent antigens and antibodies. Specific semantics of each bit within a binary string format are defined to indicate user-related data items and rules, respectively. A prototype was built based on the proposed model and performance evaluation was conducted accordingly. Based on the experiment results, the average accuracy rate for the proposed privacy protection model to correctly detect and protect user-sensitive information among shared messages is 88.9%.

II. Literature Review

A. Privacy Issues on Social Networking Sites

There are several user-related data that must exist and store in a SNS according to Beye et al. [3] such as profiles, connections, login credentials, messages, multimedia, groups, tags, preferences/rating/interests, and behavioral information. In this paper, we focus on one of the most popular services provided by SNS, i.e., online messaging service. This kind of service allows a user to exchange data/messages online or offline with another user or a group of users in SNS.

Since social networking sites such as Facebook usually collect and store all user-related data as stated by Beye et al., it raises two types of privacy issues. User-related privacy issues are generally caused by limited or lack of privacy control functionality support from service providers of SNS for their users [2], [3]. When SNS services provide a convenient platform for users to freely share information, individual user's sensitive information may be revealed by a user itself and freely accessed by other SNS users or even anonymous attackers. Another privacy issue is inability to hide user-sensitive information from other parties (friends or a specific group of users) [16], [17] because SNS vendors did not provide suitable privacy protection mechanisms. Another issue in this type category is user-sensitive information leakage caused by other users. When someone posted sensitive information related to a user of some SNS, it can harm the privacy of the indicated user.

As user's sensitive information can also be used to make profits for SNS service providers or other third-party companies that gain user information from SNS, the second type of privacy issues is often involved by SNS vendors and other companies cooperated with SNS vendors. According to Smith et al. [18], SNS users have no control over their published information on social network sites. In addition, users often do not know what SNS companies will do with their published data/messages. This kind of user privacy concern affects trust relationship between users and SNS service providers. Data retention on SNS is an example of the second type issues, in which all information that a user has ever been posted on the site is often impossible to be removed. Another example of privacy issues in this type category is unauthorized access to user data done by employees of SNS. Beye et al. [3], S. Mahmood [17], and D. J. Weitzner [19] indicated that most cases of privacy issue are related to sell user information to another party, such as an advertising company. Since SNS users cannot remove posted messages in SNS, those valuable information related with some users can be sold to other user-hunting companies such as advertising providers or insurance companies.

B. Privacy Protection Techniques

1. Privacy protection at service provider side

To solve privacy issues at service provider side, it is necessary for service providers to develop a privacy protection mechanism. One technique used to protect data privacy is to reduce the possibility that a user is identified based on data collected by a service provider. Several techniques have been proposed by researchers in the past to work on this issue, such as l-diversity [6], (α, k)-anonymization [7], and t-Closeness [8].

According to Machanavajjhala et al. [6], each row of data is composed from three different types of attributes: key attributes, quasi-identifiers, and sensitive attributes. Generally in published dataset, the value of a key attribute is in encrypted form to protect individual user's privacy. Aside from key attributes, quasi-identifiers might also be released in partial-encrypted form or in plain-text form. As for sensitive attributes, it is always released in plain-text form without any modification.

Based on the attribute structure for data records proposed by Machanavajjhala et al., user anonymization techniques developed in [6]–[8] can anonymize user-related information in published dataset. However, these mechanisms applying for huge dataset are not suitable to be applied directly in SNS environment, especially in real-time chatting or messaging services.

2. Privacy protection at the user side

Data encryption schemes were introduced to protect user's privacy in [11]–[14]. Privacy protection techniques based on encryption algorithms can be applied not only by SNS service providers but also by users of SNS. Since SNS users might be aware of privacy protection concern in SNS, they could take the initiative to protect their own privacy. In [11], Koch et al. presented a way to secure information shared among Facebook users by developing a third-party browser plug-in for Mozilla Firefox.

Since the plug-in utilizes cryptographic mechanisms, a user have to provide some information to invoke the plug-in.

The required data are targeted SNS URLs, usernames in the targeted sites, cryptographic algorithms, and their corresponding keys. Once the plug-in is activated, all messages entered by the user within targeted SNS web pages will be encrypted. To display the original messages posted in SNS, a user needs to present the corresponding key to the plug-in.

The mechanism in [11] has key distribution/management problem in practice. Since a real time message in SNS services is usually shared or broadcast to multiple users/friends, therefore group key management in SNS services is not an easy thing to do. Given that individual user's friend list is dynamically changed from time to time, it makes group key management become an annoying routine job. A dynamic user privacy protection should be able to manage this group key distribution/management problem. A good privacy protection mechanism should be able to filter sensitive information and protect it, because not all information shared using SNS services is user-sensitive.

C. Danger Theory

The original danger theory concept proposed by Polly Matzinger [20], [21] is a novel explanation on how the human body's immune system works. It is also an adaptive algorithm in the field of Artificial Immune System that generally used to perform virus detection, network intrusion, and message filtering. According to Lin et al. [15], this theory supersedes traditional self – non-self model, where the traditional model is more focusing on coping with any danger possibilities that may come from individual itself or outside of individual. The danger theory offers two advantages: the ability to prevent dangers in the future and the ability to defend against currently identified dangers.

There are several biology terms used in danger theory:

1. Tissue: a collection of cells in an organized form; multiple tissues can be organized to form an organ.
2. Cell: the basic structural, functional and biological unit of all known living organisms. In danger theory, there are two types of cell: normal cell and injured cell. A cell that does not cause harm to the corresponding organism is known as a normal cell. A cell that harms the corresponding organism is known as an injured cell.
3. Lymphocyte: any one of three types of white blood cell in a vertebrate's immune system. These three types of white blood cell are natural killer cell, T-cell, and B-cell.
4. B-cell: a type of lymphocyte in adaptive immune system. B-cell can be distinguished from other type of lymphocytes because it can bind to a specific antigen.
5. Antigen: any substance or incident that provokes an adaptive immune response in the body of an organism.
6. Antibody: Y-shape protein produced by plasma cells. Antibody is used by the immune system to identify and neutralize foreign objects such as bacteria and viruses.
7. Danger signal: an alarm signal sent out by a cell that is in distress or by an injured cell. The form of danger signal is varied in each immune system. For example, Lu et al. in [22] defined their danger signals based on the spreading and the damaging characteristics of mobile phone virus.

Fig. 1 shows an immune response according to the danger theory concept. A cell that is in distress sends out an alarm signal, known as the danger signal, whereupon antigens in the neighborhood are captured by *Antigen Presenting Cells* (APC), which then travel to local lymph nodes and present these antigens to lymphocytes. Essentially, the injured cell will establish a danger zone around itself. B-cell, one type of lymphocyte, will produce antibodies. Antibodies that can neutralize the antigens within the danger zone will perform clonal expansion process. Those antibodies that cannot neutralize the antigens or are located far away from the injured cell will not be stimulated and performed the clonal process.

Based on [23]–[25], the danger theory model can be

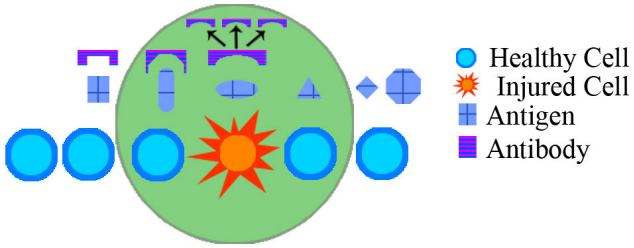

Fig 1. Danger theory model

viewed as an extension of Two-Signal model. In Two-Signal model, the two signals are antigen recognition (signal one) and co-stimulation (signal two). Co-stimulation signal is used to indicate the corresponding antigen is a dangerous one.

According to U. Aickelin and S. Cayzer [25], lymphocyte behaviors in danger theory are determined based on three laws:

- Law 1: A lymphocyte will be activated if the system receives both signal one and signal two altogether. If the system only receives signal one without signal two, then an activated lymphocyte will die. If the system only receives signal two without signal one, then it ignores the signal.
- Law 2: A lymphocyte only accepts signal two from Antigen Presenting Cells. Any cells can issue signal one to the system. Notice that an experienced T-cell or B-cell can act as Antigen Presenting Cells.
- Law 3: After the activation of a lymphocyte, the lymphocyte will revert to the resting state after a short time.

III. Proposed Privacy Protection Model

One of the most important privacy protection issues in SNS is the unintentional leakage of user-sensitive information caused by individual user's own carelessness. The importance of privacy protection on the data/messages shared by SNS users is not only for users' own interest, but also for service providers of SNS by offering privacy-aware SNS

TABLE I.
DEFINITIONS OF DANGER THEORY TERMINOLOGY FOR AISMPP

Danger Theory	AISMPP
Tissue	A message sent by a user to the other user(s).
Healthy cell	A message that does not contain any sensitive information related to individual user.
Injured cell	A message that contains any kind of sensitive information related to individual user.
Antigen (AG)	Collection of sensitive information related to individual user.
Antibody (AB)	A set of rules that regulates sensitive information, related to individual user, to decide which information is allowed to be shared to other(s).
Lymphocyte	The decision center.
Danger signal	A signal sent out by SNS messaging system indicating detected sensitive information inside one message and the user's response according to the given signal.
Signal one (danger signal)	A signal sent out by the SNS messaging system each time it detects user-sensitive information in one message.
Signal two (danger signal)	A signal used to indicate user's response or action toward the notification email sent by the system.
Danger zone	A status (state) indicator for a suspected message which might reveal user-sensitive information.
APCs	Messages received by users with alarm indication.

services to gain more users. To resolve this important user privacy issue in SNS environments, we propose the *Artificial Immune System Model for Privacy Protection* (AISMPP), which is derived from the concept of *Danger Theory* proposed by Polly Matzinger [20], [21]. To investigate detailed design of AISMPP, we select the most popular service among SNS functionalities, i.e., the messaging service, as the objective for AISMPP. The architecture of this system model is shown as Fig. 2.

In AISMPP design, there are six main components: SNS messaging service system, users database, user privacy settings, decision center, general rule repository, and antigen-antibody (AG-AB) database. As seen in Fig. 2, a user utilizes the messaging service offered by SNS to socialize with other users.

Each SNS has its own users and user privacy settings database. The privacy settings database contains a collection of rules and settings. These rules help the user to configure what data item in a user profile can be viewed by others, a black user list for each user, and a user data sharing list for third-party services (e.g. search engine services).

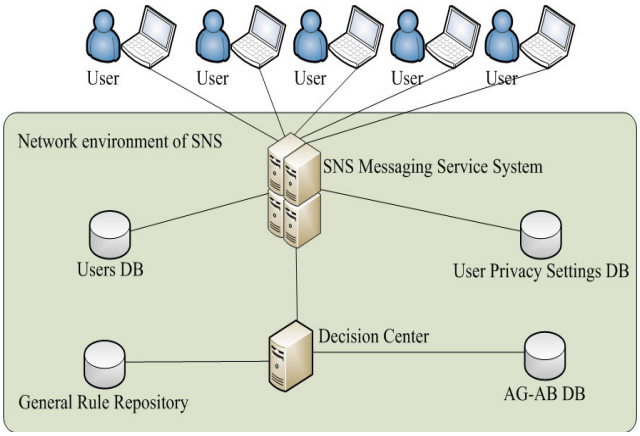

Fig 2. AISMPP architecture design

The decision center is responsible for processing danger signals, building danger zones, receiving antigens, generating and distributing antibodies. The decision center communicates with general rule repository and AG-AB database. The general rule repository describes all default actions for messages containing user-sensitive information. The AG-AB database stores all antigens and antibodies generated by the system.

The corresponding element definitions for AISMPP based on the danger theory are described in Table I.

Based on rules settings in [26] and [27], and our observation on E-Commerce websites and social networking websites; we propose 22 personal data items that are usually collected by SNS services. Thus in our design, an antigen is defined as a 22-bits binary string, where each bit represents one of 22 user's personal data items.

In Fig. 3 the AISMPP data flows are depicted. We describe each one of the flow processes as below:

1. AISMPP data flow processes start when user *A* sends a message *M* to user *B* using SNS's chatting/messaging service. Both user *A* and user *B* are participants in this chatting session.
2. Within the message SNS messaging system searches for user-sensitive information related with user *A*, user *B*, and their SNS friends list. If the system detects user-sensitive information in the message, then it will create an appropriate antigen based on the detected information.
3. After creating the appropriate antigen, the system will check the user privacy settings database for the privacy-affected user (or one of its friends) whether the disclosed user information is allowed to be shared or not. In our scenario, we assume that every user disallows any of its information to be shared by others.

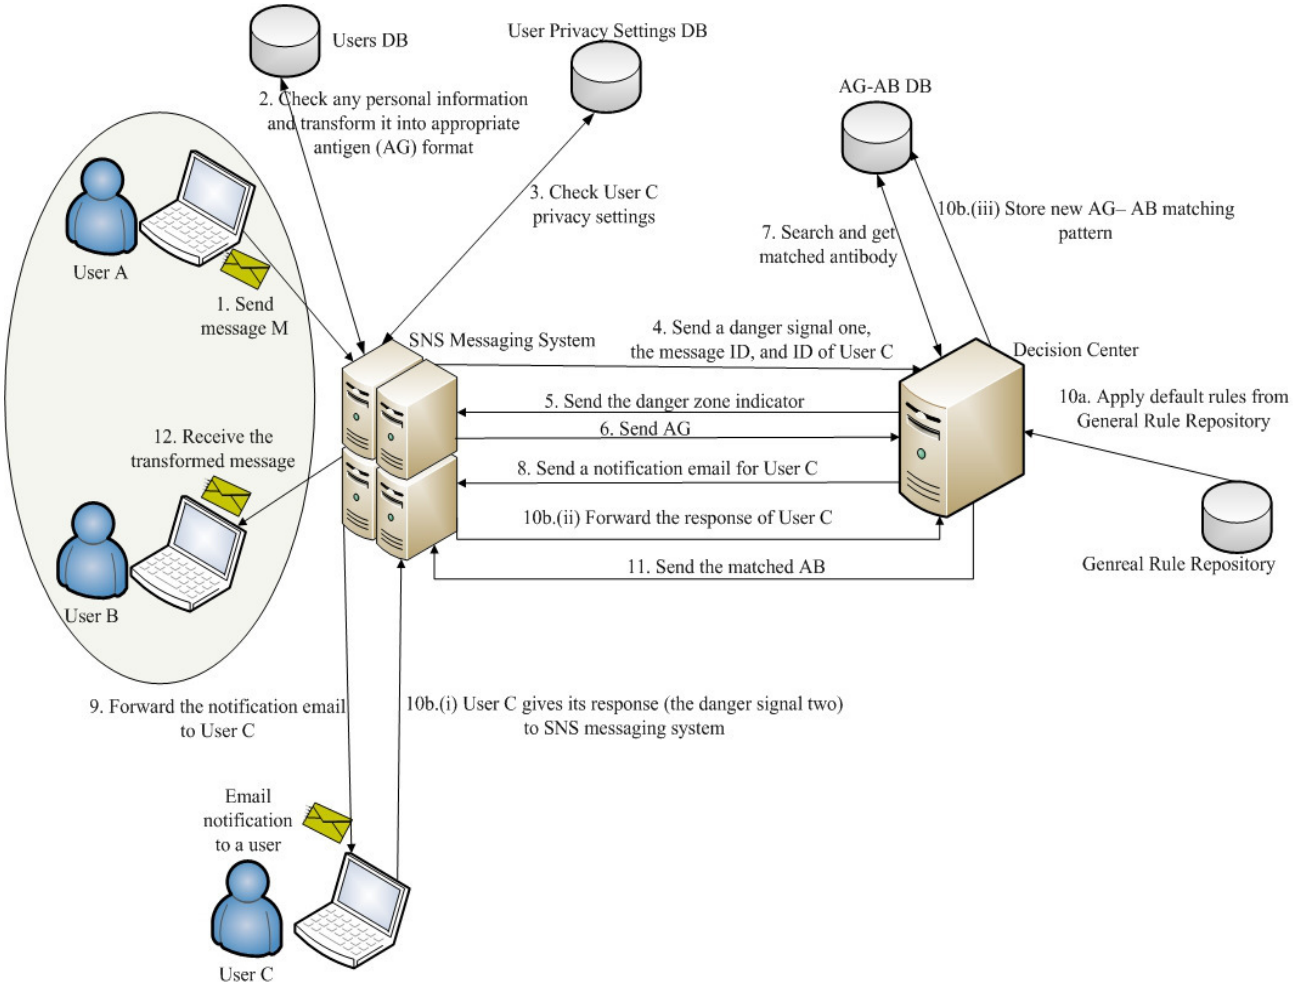

Fig 3. AISMPP data flow diagram

4. Every time the system detects any user-sensitive information in a message, the system will generate and send a danger signal (signal one) to the decision center along with the suspected message ID and the user ID of which user privacy has been breached.
5. The decision center will create a danger zone indicator on the suspected message based on the message ID and send the indicator to SNS messaging system.
6. After receiving the danger zone indicator from the decision center, the SNS messaging system sends the suspected antigen data to the decision center.
7. The decision center then check the antibody database to search the matched antibody for the received antigen.
8. If there is no matched antibody found on the antibody database, the decision center will request the SNS messaging system to forward a notification email to the message-affected user (assume it is user *C*) whose privacy is breached. The email notifies user *C* whether its sensitive information displayed in a message can be shared or not. If the decision center finds a matched antibody, then it will use this antibody and proceed to Step 11.
9. SNS messaging system will forward the notification email to User C.
10. Step 10 is divided into two cases based on how fast user *C* gives its response after the notification email sent by SNS messaging system:
    a. If there is no response from user *C* to SNS messaging system within a given period of time or in case that the decision center does not receive any response of user *C* forwarded by SNS system, then the decision center will apply default conservative rules stored in general rule repository for this suspected message.
    b. (i) If User C gives its response (the danger signal two) in time to SNS messaging system. (ii) SNS messaging system forwards the response of user *C* to the decision center. (iii) Based on the user response, the decision center will create a new antigen-antibody matching pattern and store it into the AG-AB database.
11. The decision center sends the matched antibody to the SNS messaging system. This antibody will be used by SNS messaging system to transform the message sent by user *A*.

12. After transforming the message, SNS messaging system will relay the message to user *B*.

IV. Prototype Design

Based on the data flow and functionality design shown in Section 3, an AISMPP prototype is developed. The AISMPP prototype consists of two stages. In the initialization and training stage, the prototype is initialized with default users list, default antigens, default antibodies, and initial message log based on real Facebook user data. In the system execution stage, the prototype will dynamically identify user-input messages with user-sensitive information and transform these message contents before they are displayed to designated users to preserve user privacy.

Fig. 4 shows the pseudocode of initialization and training stage. In addition to initialize the users list, default antigens are generated in the form of 22-bit binary string for each antigen pattern. If our prototype detects any specific user-sensitive information in a message, then the corresponding

```
PROCEDURE Init_Training_Model()
  INIT USERS ← LOAD (initial users list)
  INIT AG_DB ← LOAD (initial antigen
    data)
  INIT AB_DB ← LOAD (initial antibody
    data)
  INIT L ← LOAD (initial message log
  data)
  FOREACH (person P ∈ USERS)
    FOREACH (message M ∈ L)
      IF (message M contains sensitive
        information)
        new_ag ← create an antigen
          record from the found
          sensitive information
        new_w ← detected sensitive
          words
        new_ab ← create new antibody
          based on new_ag
        IF (new_ag ∈ AG_DB)
          UPDATE the number of
            occurrence of detected
            words based on new_w and
            promote the antigen new_ag
            to have longer life time.
        ELSE
          ADD new_ag to AG_DB
        ENDIF
        IF (new_ab ∈ AB_DB)
          UPDATE the number of usage
            of the antibody new_ab
        ELSE
          ADD new_ab to AB_DB
        ENDIF
      ENDIF
    ENDFOREACH
  ENDFOREACH
ENDPROCEDURE
```

Fig 4. Initialization and training stage of AISMPP

binary bit that represents one specific user-sensitive data item will be set to 1, otherwise 0. A corresponding antibody pattern for each antigen is also generated, in which a 22-bit binary string is used to indicate whether the data item in the corresponding antigen should be encrypted; the corresponding bit of the antibody is set to 1, if the data item in the antigen needs to be encrypted.

The user profile in our prototype contains user's real name, user's email(s), user's birthday date, user's address (city, region, and country), user's phone number(s), and other private information, e.g. religious and political views. According to [26] and [27], we define all items in user profile as user-sensitive information.

The prototype also loads friend information of users from real Facebook user data. The friend information getting from Facebook is limited to the full user name, email addresses, and phone numbers.

Some historical messages in plain-text form are stored in the message log during the initialization and training stage. These historical messages are used as the training data for our prototype. All historical messages will be processed in the initialization and training stage to make our prototype ready for regular operation. Each time the prototype receives an input message, the system will search the message for any user-sensitive information. If there is no user-sensitive information found in the message, then the message will be forwarded directly to the recipient without any transformation. Otherwise, the message-related data will be recorded, i.e., the receivers, the sender, and the message itself.

After the suspected message data has been recorded, a temporary antigen pattern is created and the suspected words in the message are recorded. In case the created antigen exists at antigen database, our prototype will update the number of occurrence of the words at the antigen database, which cause the system to generate the corresponding antigen. Otherwise, the newly created antigen will be added into the antigen database. Furthermore, our prototype will also create new antibody pattern based on the newly created antigen.

In Fig. 5 we show regular operation process of AISMPP at system execution stage. Two additional processes, user feedback processing and user message transformation, are included in this stage in comparison with the process for initialization and training stage.

In Fig. 6 the user feedback process assigns a flag indicator along with the user-affected message based on the user's response. Notice that if the user does not give any response after receiving notification email from SNS messaging system, then the prototype will assume the message possesses user-sensitive information and apply the message transformation process to protect user-sensitive information inside the message.

User message transformation process in Fig. 7 will transform all the detected words, which are user-sensitive information, within a message into encrypted ones. Considering robust security, SHA-256 algorithm is adopted for data encryption operation in our prototype.

```
PROCEDURE Execution_Process()
  LOOP
    M ← a new message inputted by user
    U ← a user ID that generates the
      message M
    FOREACH (person P ∈ friends of U)
      IF (M contains sensitive
        information)
        IF (person P responds to
          system notification)
          SET the flag of applying
            default rules F = FALSE
        ELSE
          SET flag F = TRUE
        ENDIF
        DF = Process_Feedback(M,
          default flag F)
        new_ag ← create an antigen
          record from the found
          sensitive information
        new_w ← collection of detected
          sensitive words
        new_ab ← create new antibody
          based on new_ag
        IF (new_ag ∈ AG_DB)
          UPDATE the number of
            occurrence of detected
            words based on new_w and
            promote the antigen
            new_ag to have longer
            life time.
        ELSE
          ADD new_ag to AG_DB
        ENDIF
        IF (new_ab ∈ AB_DB)
          UPDATE the number of usage
            of the antibody new_ab
        ELSE
          ADD new_ab to AB_DB
        ENDIF
        IF (DF)
          M = Transform_Message(M)
        ENDIF
      ENDIF
    ENDFOREACH
    SEND M to user
  ENDLOOP
ENDPROCEDURE
```

Fig 5. System execution stage of AISMPP

V. Implementation and Experiments

The prototype is developed on Windows 7 platform within a PC hardware of Intel Core i5 3.1 GHz CPU and 4 GB RAM. For prototype initialization, user profiles are generated based on the 274 friend contacts of one real Facebook user account and 100 user contacts generated by the Web service of generatedata.com. The historical message log from the same Facebook user account is loaded for the training stage. In initialization stage, 6 antigen patterns are defined in which 7 user data items including name, email, social security number, phone number, passport number, credit card number and credit card expiration date are used and

```
PROCEDURE Transform_Message(message M)
  M' = M
  FOREACH (get each word string W in M)
    IF (W is user-sensitive data)
      W' = ENCRYPT(W)
    ELSE
      W' = W
    ENDIF
    M' = REPLACE(W,W')
  ENDFOREACH
  RETURN new message M'
ENDPROCEDURE
```

Fig 7. The function to transform a user's message in AISMPP

combined to generate these patterns. In addition, 6 corresponding antibody patterns are generated based on the assumption that any revealed user data item should be blocked (by data transformation). For the system execution stage, extra 200 friend contacts from another Facebook user account and 300 new user contacts generated by the Web service of generatedata.com are loaded into our prototype. In addition, 5000 newly generated messages using the Web service of RandomTextGenerator.com combined with the historical message log from the second Facebook user account are imported to evaluate the effectiveness of our prototype.

Fig. 8 shows the time distribution for processing 5000 messages within 1000 experiments. The processing time includes the time for message scanning process and the time for detecting user-sensitive information among 5000 messages. The higher processing time during the first 30 experiments is caused by adding more antigen and corresponding antibody patterns based on the self-adaptive capability of danger theory model as shown in Fig. 9. Notice that the processing time gradually reaches stable condition around 25 seconds during our experiments.

Fig. 9 shows the distribution of total number of antigen patterns within 1000 experiments. After completing the training stage of our prototype, the total number of antigen is around 260. In the first couple of experiments, it can be seen that the total number of antigen increases quickly and reaches beyond 500. The reason is the patterns of newly generated messages for our experiments are different with the message patterns applied in the training stage. As the number of antigen increases, the message processing time is

```
PROCEDURE Process_Feedback(message M,
  flag F)
  IF (!F && user consider the sensitive
    information in message M is alright
    to be shared)
    ASSIGN the safe flag DF=FALSE to
      message M
  ELSE
    ASSIGN the danger flag DF=TRUE to
      message M
  ENDIF
  RETURN DF
ENDPROCEDURE
```

Fig 6. The function to process user feedback in AISMPP

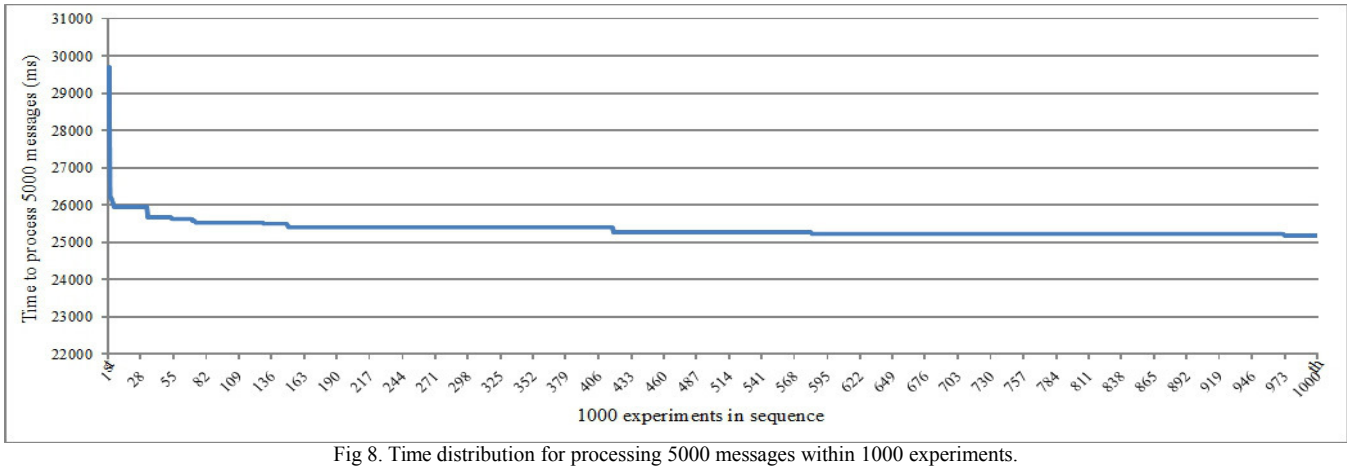

Fig 8. Time distribution for processing 5000 messages within 1000 experiments.

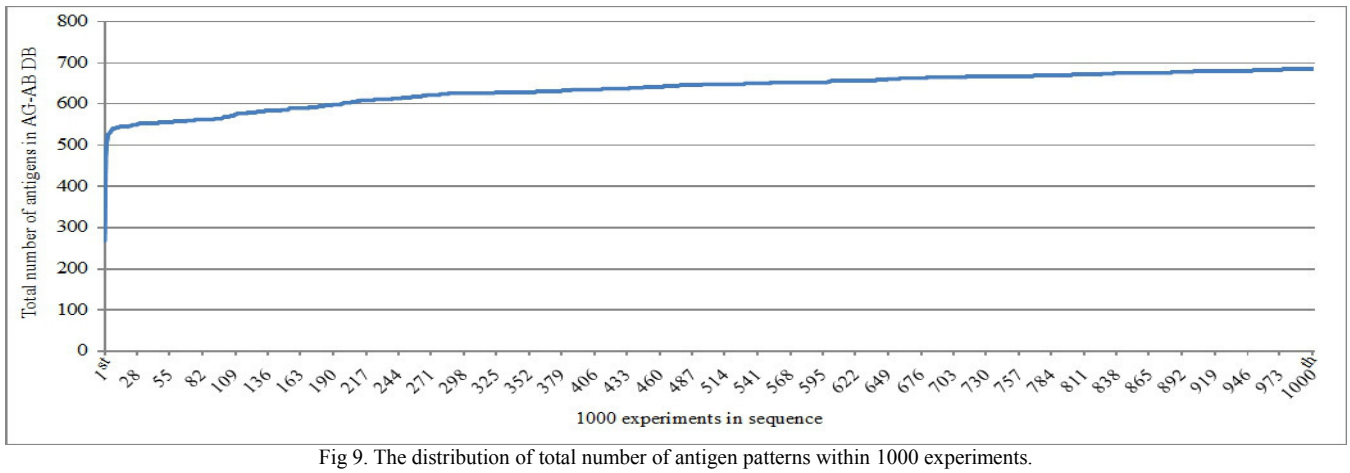

Fig 9. The distribution of total number of antigen patterns within 1000 experiments.

gradually reduced based on the observation of both Fig. 8 and Fig. 9.

Fig. 10 shows the time distribution for processing a message from the first message to the 5000th message at the 50th experiment. In Fig. 10 there are many messages been processed within 10ms. The reason is existing antigens have recognized this message pattern. Therefore, it does not require much time for the prototype to process these messages. For messages with new pattern, the prototype requires more time to process and generate new antigens and antibodies if necessary.

Fig. 11 shows the average time for our prototype to process one message in the first 100 experiments. For example, the average time to process one message in the 51st experiment is 5.21ms as shown in Fig. 11. Based on Fig. 11, we can know that the average time to process one message is ranged between 5ms and 10ms. We think the processing time is acceptable for a SNS messaging service.

We define a true positive (TP) value as our prototype correctly predicting one user-sensitive data shown in a message. A true negative (TN) value is defined as our prototype correctly predicting no user-sensitive data shown in a message. A false positive (FP) value is defined as our prototype wrongly predicting one user-sensitive data shown in a message. A false negative (FN) value is defined as our prototype wrongly predicting no user-sensitive data shown in a message. The precision rate is defined as TP / (TP + FP). The recall rate is defined as TP / (TP + FN). The accuracy rate is defined as (TP + TN) / (TP + TN + FP + FN). The average precision rate of our prototype is around 91.7% and the average recall rate is around 96.7%. The average accuracy rate of the prototype to correctly detect user-sensitive information in messages is around 88.9%.

VI. Conclusion

Lacking of automatic user privacy control mechanisms and privacy protection schemes is one of the most concerning issues in Social Networking Sites (SNS). In this paper, a privacy protection model based on danger theory is proposed. Several danger theory components are re-defined to fit into SNS environment and binary string format is adopted to represent antigens and antibodies used in our privacy protection model. Specific semantics of each bit within a binary string format are defined to indicate user-related data items and rules, respectively. Based on these components, an automatic adaptive immune system for user-sensitive information protection during online chatting/messaging is designed.

A prototype of our design was built based on the proposed model and performance evaluation was conducted accordingly. Based on the experiment results, the average accuracy rate for the proposed privacy protection model to correctly

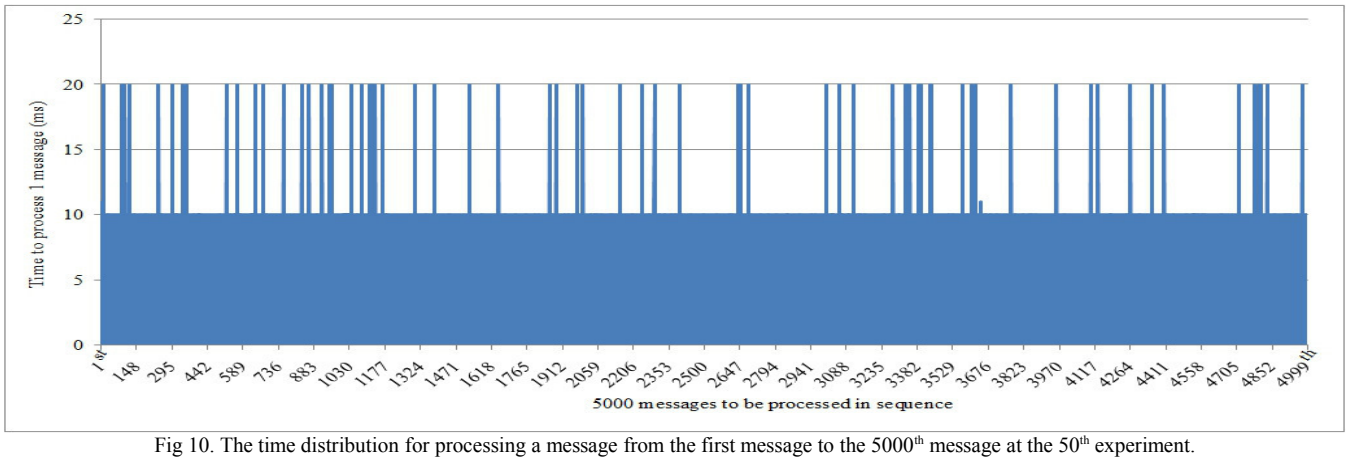

Fig 10. The time distribution for processing a message from the first message to the 5000th message at the 50th experiment.

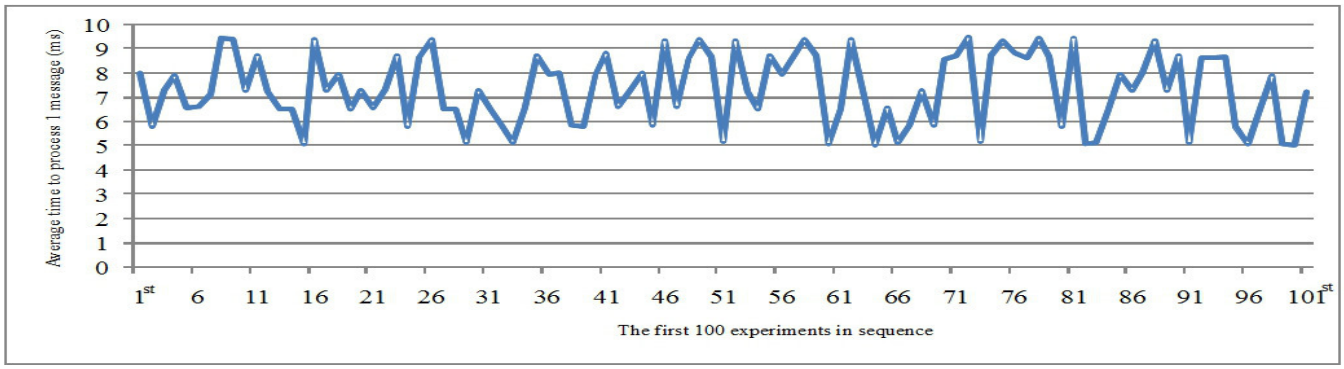

Fig 11. The average time for our prototype to process one message in the first 100 experiments.

detect and protect user-sensitive information among shared/broadcast messages is 88.9%. In addition, we found that the system processing time for each shared message is reduced with the increase of the number of recognized anti-gen patterns.

***Abstract*—Some professional e-mails contain knowledge about how actor face problem in order to realize projects. This type of knowledge is produced in cooperative activity. Representing project knowledge leads to structure link between coordination, cooperative decision-making and communication. The main objective of our work is to extract knowledge from daily work. So the main questions of our research are:**

- **Can we extract knowledge from professional e-mails?**
- **If so, which type of knowledge can be represented?**
- **How to link this knowledge to project memory?**

We present in this paper our first work in this aim. Our hypothesis is tested on a software development application.

***Index Terms*—Knowledge Engineering, Knowledge Management, Project memory, Traceability, Professional e-mails, Pragmatics analysis.**

I. Introduction

CURRENTLY, Designers use knowledge learned from past projects in order to deal with new ones. They reuse design rationale memory to face new problems. Knowledge Management provides techniques to enhance learning from the past [5]. Their approaches aim at making explicit the problem solving process in an organization. Their techniques are inherited mainly from knowledge engineering. So, we find in these approaches in one hand, models representing tasks, manipulated concepts and problem solving strategies, and in the other hand, methods to extract and represent knowledge. We note for instance MASK [7], [14] and REX [11] methods. These methods are used mainly to extract expertise knowledge and allow defining profession memories.

But, design projects involve several actors from different fields. These actors produce knowledge when interacting together and take collaborative decisions. So, it is important to also tackle this type in knowledge, which is generally volatile.

We deal, in our approach with this type of knowledge, called Project memory [13]. Project memory must represent organizational and cooperative dimension of knowledge. Current techniques used in Knowledge management, based on expert interviews are not adapted to extract these dimensions of knowledge. To tackle knowledge produced in collaborative activity, we need techniques that help to extract knowledge from daily work. In this paper, we present a technique that help to extract knowledge from professional e-mails. The presented approach allows structuring extracted concepts and linking them to the project context. We use pragmatics analysis and knowledge engineering techniques for this aim.

II. Project Memory

A project memory is generally described as "the history of a project and the experience gained during the realization of a project" [13]. It must consider mainly (Fig. 1.):

- The project organization: different participants, their competences, their organization in sub-teams, the tasks, which are assigned to each participant, etc.
- The reference frames (rules, methods, laws, ...) used in the various stages of the project.
- The realization of the project: the potential problem solving, the evaluation of the solutions as well as the management of the incidents met.
- The decision making process: the negotiation strategy, which guides the making of the decisions as well as the results of the decisions.

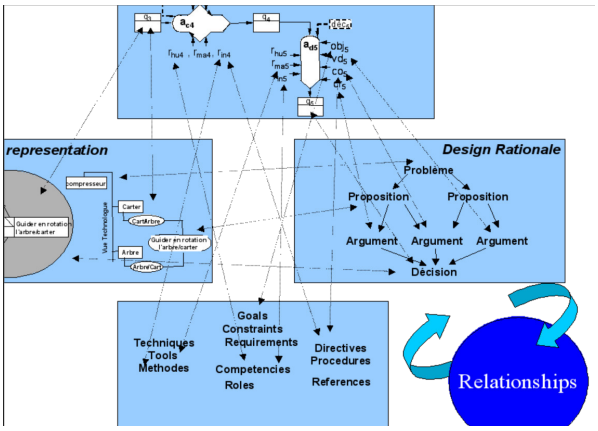

Fig. 1. Project memory

Often, there are interdependence relations among the various elements of a project memory. Through the analysis of these relations, it is possible to make explicit and relevance of the knowledge used in the realization of the project. The traceability of this type of memory can be guided by design rationale studies and by knowledge engineering techniques.

III. PRAGMATICS ANALYSIS

The act of request has been extensively studied in the field of theoretical linguistics (Searle 1969), intercultural and inter-language pragmatics [2], NLP community on automated speech act identification in emails [3], [11] etc. However, as pointed by *Rachele De Felice et al. [4]* there is very little work concerned with data other than spoken language and few researches seem to fully respond to requirements of being sufficiently general, non-domain specific, and easily related to traditional speech acts. In addition, few researchers have focused their research requests in business written discourse (workplace email communication). Lambert et al 2010 try to create tools that assist email users to identify and manage requests contained in incoming and outgoing email. Atifi et al. [1] analyze email effectiveness from the professional's point of view by mixing two kinds of analysis: a content analysis of interviews of professionals and a pragmatic and conversational analysis of emails. *Rachele De Felice et al. [4]* propose a global classification scheme for annotating speech acts in a business email corpus based on traditional speech act theory described by Austin and Searle [15].

.

IV. RELATED WORK ON E-MAILS ANALYSIS

Several approaches study how to analyze e-mails as a specific discourse. We note for instance, tagging work [17], in which Yelati presents techniques that help to identify topics in e-mails, or the use of zoning segmentation in [10]. Other works use natural language processing in order to identify messages concerning tasks and commitment [8]. They parse verbs and sentences in order to identify tasks and they track messages between senders and receivers.

Even there is lot of work on pragmatics, which study dialogue and distinguish techniques in order to identify speech intention (Patient/doctor dialogue analysis [8]), coding dialogue scheme [Core et al, 1997], etc. Pragmatics analysis of e-mails uses only some of these methods like ngrams analysis by Carvalho in [16], Verbal Response Mode scheme by Lampert in [10]or a custom coding scheme like De Felice [4].

Techniques studying e-mails, often do not consider the context of discussions, which is important to identify speech intention. We deal with our work with professional e-mails, extracting from projects. So, we mix pragmatics analysis and topic parsing and we link this type of analysis to project context (skill and role of messages senders and receivers, project phases, and deliverables, etc.) in order to keep track of speech intention. As pragmatics analysis shows, there is not only one grid to analyze different types of speech intention. In project memory, we look for problem solving, design rationale, coordination, etc. In this study, we focus on problem solving and we build an analysis grid for this purpose.

V. PROJECT KNOWLEDGE EXTRACTION FROM E-MAILS

The main objective of our work is to extract knowledge from daily work. So the main questions of our research are:

- Can we extract knowledge from professional e-mails?
- If so, which type of knowledge can be represented?
- How to link this knowledge to project memory?

To answer these questions, we analyze professional e-mails related to projects. In last studies, we identify a structure to analysis coordination messages [12]. Based on pragmatics analysis, we defined a grid to structure coordination messages based on the main act to do (inform, request, describe, etc.) and the objects of coordination (task, role, product, etc.). In this paper, we will go ahead and define an approach that helps to extract knowledge from professional e-mails. So, we identify firstly step by step how to isolate important messages and how to analyze them. Knowledge from e-mails, as knowledge produced in daily work, cannot be very structured. It is related closely to context. In our work, we focus on knowledge produced during project realization. We will show in our method how information from project organization help in e-mails knowledge extraction.

A. Classification of e-mails

Firstly, we have to identify important messages (Fig. 2). For that, we have to gather messages in subjects. Then, we can identify the volume of messages related to each subject. Then we analyze only messages that heave more then 4 answers; we believe that knowledge can be extracted based on interaction. Finally, we link the messages to be analyzed to project phases.

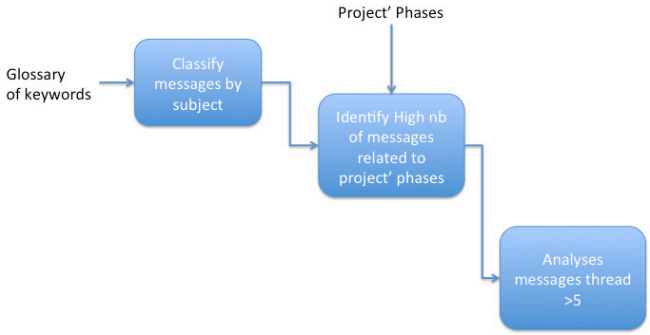

Fig. 2. First e-mails analysis

B. Messages analysis

For each message thread (message and answers), we identify (Fig. 3) :

- Information to be linked to organization:
  - Authors, To whom, In Copy
- Information about phases:
  - Date and hour of messages and answers
- Information about product:
  - Topic and joined files
- Information about message intention:
  - Main speech act and intention of message

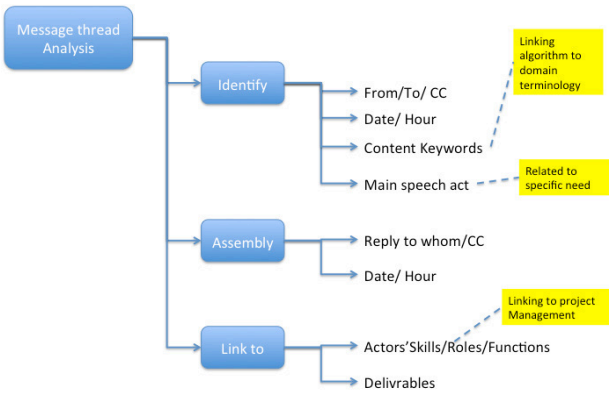

Fig. 3. Analysis of messages

By linking messages to project organization, we help in making sense of interactions between actors. In fact, the role and skill of messages' senders and receivers help to analyze the role of the message in problem solving and the nature of the content (solution answering a problem, proposition discussions, coordination messages, etc.). In the same way, linking messages to phases help to identify main problems to deal in each phase of the same type of projects.

As first work, we focus our speech act analysis on problem solving by identifying request and solution. So, we identify first speech acts that help to localize a request in a message (**Erreur ! Source du renvoi introuvable.**). Then, we study the organization of related messages thread in order to identify the solution proposed (if it exists) to the request. Our analysis is based first on pragmatics in order to characterize request speech act, and that by identifying request verbs and forms. In the present study we limited our research to the analysis of the act of requesting in problem solving sequences.

From a pragmatic point of view, a request is a directive speech act whose purpose is to get the hearer to do something in circumstances in which it is not obvious that he/she will perform the action in the normal course of events [15]. By introducing a request, the speaker believes that the hearer is able to perform an action. Request strategies are divided into two types according to the level of interpretation (on the part of the hearer) needed to understand the utterance as a request. The two types of requests include direct request and indirect requests. The request can be emphasized either projecting to: 1- the speaker (Can I do X?) or 2- the hearer (Can you do X?). A direct request may be use an imperative, a performativity, obligations and want or need statements.
An Indirect request may use query questions about ability, willingness, and capacity etc. of the hearer to do the action or use statements about the willingness (desire) of the speaker to see the hearer doing x. At last, for us, a grammatical utterance corresponds to only one speech act as in TABLE1.

TABLE 1.
GRID OF REQUEST SPEECH ACT

Request Form	Linguistic form	Examples
Direct request	Imperative	Do x
	Performative	I am asking you to do x.
	Want or Need statements.	I need/want you to do x
	Obligation statements	You have to do x
Indirect request	Query questions about ability of the hearer to do X	Can you do x? Could you do x?
	Query questions about Willingness of the Hearer to do X	Would you like to do x?
	Statements about the willingness (desire) of the speaker	I would like if you ca do X I would appreciate if you can do X

Then, we complete our analysis by from one side identifying answers verbs and from another side, linking answers to actors' role and skills and also joining files. The date of answers can be an indicator of several elements in the organizations: engagement, difficulty of time spending of solution, stress and multi-responsibilities, etc. We aim at analyzing in the future the frequency of answers.

VI. EXAMPLE

A. *Example description*

INFOPRO Business Publishing Company asked a software Company to develop a workflow tool that helps journalists to edit their articles and to follow the modification of the journal. The period of the project was more than one year. Nearly all negotiations and discussions were through e-mails. In this project, the actors were:

- SRA: an editing responsible (skill: law and management, Role: Contractor)
- JBJ: Information System Manager (Skill: Information system, Role: Contractor)
- FX: Information System Developer (Skill: Software Engineering, Role: Development manager)
- CV: Prototyping (Skill: Human Machine Interface, Role: User Interface Modeling)
- RT: Information System Developer (Skill: Software Engineering, Role: Sub-contractor)

Principles phases of the project were (TABLE 2):

TABLE 2.
PHASES OF THE PROJECT

	2009											2010									
	Feb	Mar	Apr	May	June	July	Aug	Sep	Oct	Nov	Dec	Jan	Feb	Mar	Apr	May	June	July	Aug	Sep	Oct
XML Import from existing Database																					
Document DataBase specification and development																					
Workflow link specification and development																					
User Interface specification																					
Export to magazine and website																					
Web service specification and development																					
Application test																					

B. *E-mails Analysis*

As first step, we identify messages topics based on e-mails subjects. In our project, we identify main discussions topics based on keywords:

- XML : structuration, tag, tree, xsd, dtd, schema
- BDD : Data base, table, editing part, code part
- Interface workflow : UI, Workflow, User Interface, login, user management,
- Code : Insurance Code, Legifrance, auto code, vehicle code, mutu code, chapter, article
- Document : new collection, construction, document
- Export paper : Indesign, layout, mapping, tag indd, indd template
- Export site: export web, web tag, web format, dtd web
- Export Author: word, author, xslt author
- Services: update legi, Legifrance update, FTP
- Word : macro word, addin, web service, word 2007, wordlink

Based on these topics we use a Lucene based algorithm, to compute distance and similarity between words in order to identify main topics of messages (boosting email subject importance compared to email body (Fig. 4). It is to be noted that some preprocessing occurred before on raw email body to remove duplicated answers):

$$score(q,d) = coord\text{-}factor(q,d) \cdot query\text{-}boost(q) \cdot \frac{V(q) \cdot V(d)}{|V(q)|} \cdot doc\text{-}len\text{-}norm(d) \cdot doc\text{-}boost(d)$$

Fig. 5 shows first step of analysis of these messages; in which we show senders and receivers and their skills, topics of messages and date of messages.

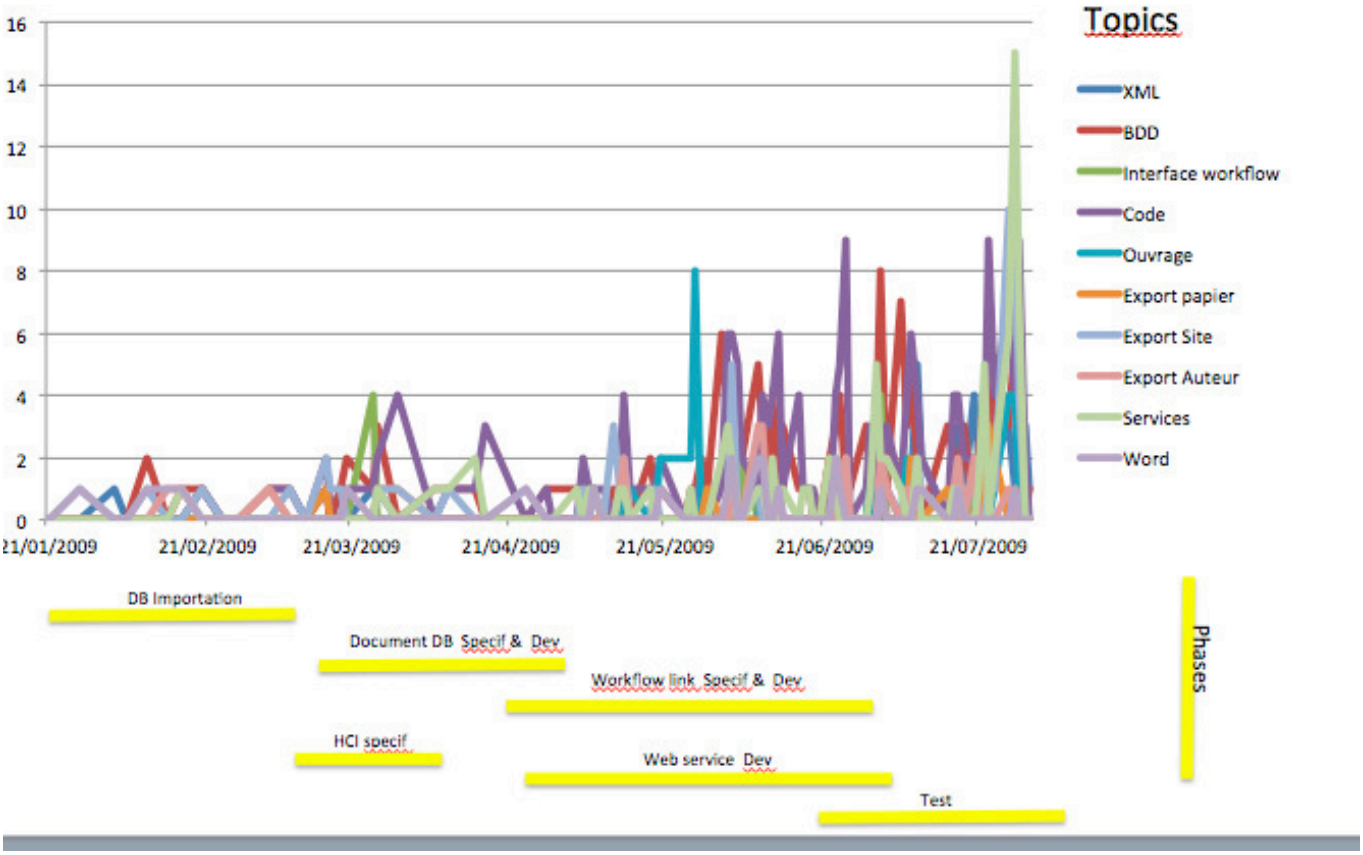

Fig. 4. Topics analysis

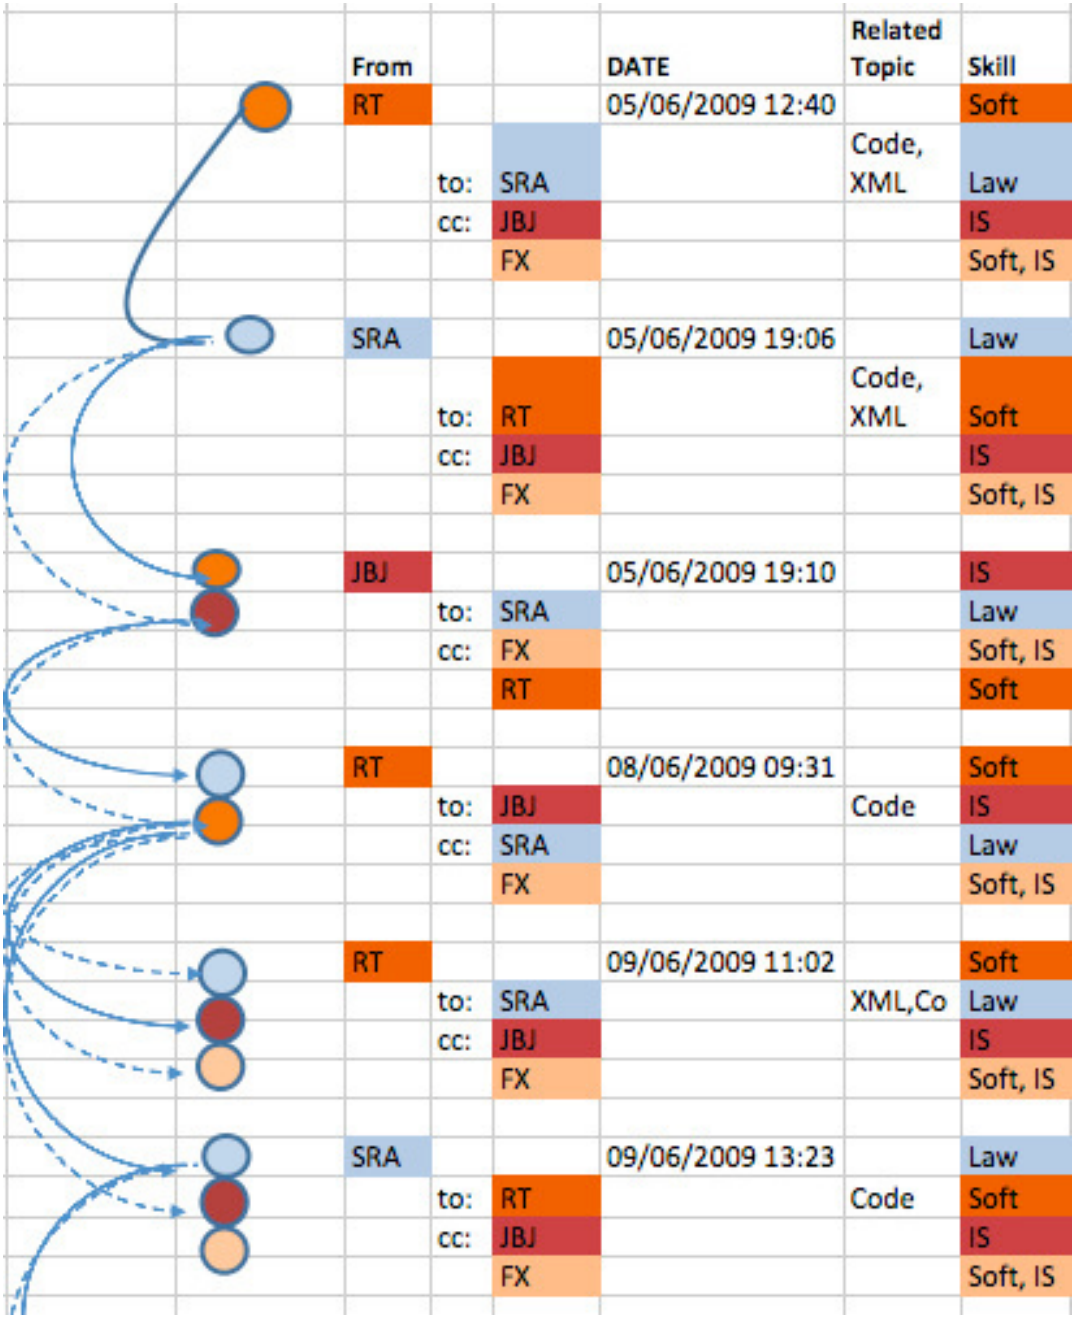

Fig. 5. First analysis of messages: representing of senders/Recievers/Copy, date and actors role and skill

To analyze messages text, we use pragmatics in order to identify problem and solution discussions. For that, we identify Request messages based on Request speech acts. Then, we identify related answers messages. In these messages we look for senders skill and joined files. So, we identify for the "Annexes" topic, in which there are 23 messages, related topics are XML and code. Messages were during 12 days from 5th until 17th June. They concern workflow development phase. Based on the Request-Answer grid and role actors, we analyze messages, in order to identify problem-solving intentions. So, we identify for instance, the problem Insurance Text extraction. SRA; the editing responsible (contractor) asks FX to extract Insurance text in a good format. When FX; the Information System Developer (Development manager) answer him, we suppose that as an answer, based on the role

of sender of message and the main topic. We consider also joined files as part of this answer. Fig. 6 shows this example.

From			Date	Sentence elements	Related Topic	Function
SRA			2009-06-05 12:40:46.	I put in "Bold", what **I need**:		Request
	to:	FX		1- *Inssurances*		
	cc:	JBJ		2- Text without tags Texte in XML files	Code	
		CV		3- Tag Pb : Text outside tag in XML	XML, Code	
		RT		4- Tag Pb <b> is opened and not closed, as same as, tag is badly imbircated		
FX			2009-06-05 19:06:34.			Answer
	to:	SRA		1- *Inssurances*		
	cc:	JBJ		I propose to convert: Xpress format in XML	XML	
		CV		Beware, the text will contain a lot of error blanc, "enter" and image	Code	
		RT		I can transform it on enriched XML	XML	
				It containts a lot of reference, so we have to compose with links		

Fig. 6. Example of messages analysis

VII. Conclusion

The aim of our study is to identify knowledge from daily work. In this paper, we show that it is possible to study professional e-mails for this aim. We consider e-mails as specific discourse. So we use pragmatics generally used to analyze discourse and to categorize it to identify knowledge from professional e-mails. Our hypothesis is can we identify a grid as guide to analyze professional e-mails? If so, can the result be relevant as project knowledge?

Based on this hypothesis, we know that pragmatics intention must be based to context. So, we consider the project context from different aspect: organization and environment. We believe that this context is very helpful to clarify ambiguity of sentence analysis. We show in the example how sender/receiver role can identify problem-solving answer. Adding this analysis to the identification of keywords of messages, as topics can be a first step, towards a structuring of knowledge: Problem related to a topic, possible answers.
We will continue to validate this work on other type of projects. This work can open to identify other grid analysis like: engagement of actors, design-rationale, coordination [12], etc.

Finally, this study is a part of our work on project memory: Keeping track and structuring knowledge in daily work realization of project. We developed techniques to extract knowledge from project meetings [6] and to identify occurrences in order to identify concepts in project memory.

Abstract—Exclusion phenomenon in common understanding denotes processes in which some group of people or individuals are permanently blocked from resources (mostly considered as social exclusion). For sure such sort of phenomena is observed as unwanted not only from "outsiders" but also from local and global society point of view. The exclusion (and its antonym inclusion) phenomenon can be investigated including many aspects: starting from identifying exclusion as a process, multidimensional research in this area up to solutions available in the domain.
In order to be successful in overtaking this phenomenon groups and institution involved in this process should be supported by ICT solutions. The paper consists of five parts which gradually present context of the problem and proposed solutions. After short introduction concerning research background the discussed concept of exclusion processes is presented. In the main section real examples of exclusion processes are investigated which allows to define assumptions of knowledge portal architecture and some examples of performed services. It creates opportunities for formulation final conclusions about the necessity and usability the developed platform.

I. Introduction

Nowadays people, especially in the era of information society, know more and more about a man, groups and the whole nations, about their needs and levels of satisfaction of the human beings alone or of human associations. If so, natural tendency - present in democracy - to treat all citizens equally becomes very important. Any form of discrimination some group of people is against the democratic order and societies and governments try to counteract with this unwanted phenomenon.

The roots of the exclusion phenomena "discovering" (or better reflexion on human sense of equality and justice) can be found in the discourse in France in the mid 1970s (see: N. Rawal review of social inclusion and exclusion - [11]). A bit later H. Silver (see: [1]) formulated three paradigms of social exclusion: solidarity (stressing social dimension of human interactions), specialization (discovering exclusion as a form of discrimination) and monopoly (interpreting exclusion as a consequence of the existing group monopolies). Anyway in older and later approaches to the phenomena research many aspects of social exclusion and inclusion were analysed.

In order to be successful, a problem of exclusion should be investigated, reasons of its occurrence should be discovered and solutions for inclusion should be proposed. According to EU policy the poverty and exclusion problems are very important and responses could be projects prepared in the Europe 2020 strategy (Societal challenges section in Horizon 2020 programme, see: [14]).

Two examples should be stressed as promising solutions in the discussed area:

- GSDRC – Applied Knowledge Services devoted to maintaining knowledge about exclusion phenomena (see: [12])
- Exclusion-Inclusion Suburbs – prepared for knowledge services essential in city environments (see: [13]).

In both cases presented solutions are limited to selected phases or areas of exclusion phenomena. Therefore lack of common platform developed for the whole community seems to be obvious.

The paper is managed as follows. In the next section theoretical background of the investigated phenomena is described including nature of exclusion and inclusion phenomena, reasons of its occurrence is discussed and multidimensional characteristics of investigation is stressed. An essence of knowledge portals developed for modern society is presented in the subsequent section with focus on society needs and functionality such portals, offered architectures and applications useful for different segments of the society. The most innovative part of the research is presented in the main section of the paper devoted to concepts of the knowledge portal addressed to exclusives covering: assumptions, architecture and examples of supported tasks. The paper ends conclusion remarks and future research.

II. Exclusion Processes as Research Challenges

No doubts, exclusion as a phenomenon seems to be very important and difficult problems to solve in modern society. There are many contexts in which exclusionary processes can occur including different objects, or time- and territory-aspects. At least two approaches should be taken into account actors-oriented and capability-oriented.

In accordance of the first one the critical thing is: relationships between "actors" essential for the exclusion. It is very important in understanding the "exclusion" idea as a concept. According to R Saith: [2] "Social exclusion is a

socially constructed concept, and can depend on an idea of *what is considered 'normal'*". So here crucial topic of understanding discussed phenomenon is definition of normality which, in turn, depends on standard living, hierarchy of values, assumed criteria of society organization and the like what finally can be identified with "actors".

On the other hand A.Sen (see: [3]) keeps that an essence of social exclusion relates to 'functionings' and 'capabilities' concepts. Functionings denotes things important in leading life (health, education, cultural life etc.) while capabilities concerns individual combination of different functionings specific for human-beings or some group of people. So, social exclusion relies on inability of achieve certain 'functionings' or difficulties with reaching the goals which leads to deprivation and poverty - unwanted states in of any society.

Multidimensional character of exclusion has been stressed by the following authors: De Haan [4], Bhalla and Lapeyre [6], Burchardt et. al. [5] and Fisher [7]. Potential dimensions cover the different aspects: un/employment, markets (so difficulties with access to goods and services), neglecting of political laws and social relationships. Therefore in research conducted in this domain all aspects of exclusion processes should be examined not only individually but also from more general point of view. There are many intersections between the mentioned dimensions, for example: unemployment has the strong impact on poverty, poverty in turn causes limited access to services and products available on a market in local and global range and so on.

From individual as well as from society point of views the mentioned manifestations of exclusion processes lead to segregation of many sorts, sense of social inequality and conflicts in broader perspectives. Monitoring and investigation of the discussed phenomenon need to be performed continuously and be supported by information and communication technologies or better by specialized knowledge portal(s).

The described phenomenon basically relates to social exclusion which should be separated from voluntary exclusion – see Barry [8]. Exclusion of this short is a specific one and not always is regarded as unwanted process. On the contrary, as intentionally prepared and performed activities cannot be integrated with social exclusion.

The process considered as the solution to neutralize exclusion effects is called social inclusion. The social inclusion can be defined as ..."a process of improving the terms on which people take part in society" - see World Bank definition [15]. In sociology social inclusion means the provision of certain rights to all individuals and groups in society, such as employment, adequate housing, health care, education and training, etc. – see Collins Dictionary [12]. Of course social inclusion – as the process of organizing social life – sometimes is problematic or even inequitable – see Hickey and du Toit [9]. The concept of 'adverse corporation' brings better results because of its implementation in particular contexts – see [9].

Social inclusion as the process of counteraction negative results of exclusion should be supported in many ways by information technologies. Social equality should be enforced by access to information and knowledge available in computer networks; M. Warschauer discussed many aspects of usability and consequences of technology and social inclusion intersection see [10]. In the next part importance of knowledge portals as natural source of information for modern society is presented.

III. KNOWLEDGE PORTAL FOR THE MODERN SOCIETY

Portal - a website presenting the overview and systematic form the most important and best - developed articles, as well as other content related to the topic. It presents readers with the resources available on the subject in a more accessible and attractive than categories, indirectly encouraging the active involvement in the development of the content.

Web Portal (or Internet Portal) - an online information services extended to a variety of Internet functions, available from a single Internet address (compare [17]). Typically, the portal contains information of interest to a wide audience. As an example, you can specify the content of the portal: forum news, weather, web directory, chat, forums and mechanisms for information retrieval in the same or in external Internet sites (search engines). In addition, portals may offer free services such as email, web hosting.

Knowledge Portal (our interpretation) - an online service that includes a generally reliable information about a specific fragment of reality and can be used in the further development of the issues or bind it with another issue. Knowledge expressed in many forms including its own theories is a crucial component of the discussed portals. The classic approach takes into account the following elements:

- beliefs, judgments logically,
- justification belief is justified,
- veracity, the belief is true.

Examples of category knowledge portals:

- social sciences and humanities, such as astronomy, biology, chemistry, genetics, medical science, zoology,
- society, such as: anarchism, atheism, bible, biographies, philately, Hinduism, Judaism, Catholicism, the saints, the religious,
- geography, for example: individual continents, different countries, different cities,
- national, for example, Poland, Germany, USA,
- culture - fiction, film, comics, art, games, anime,
- sports, for example, the Olympic Games, check, ski jumping, rallies,
- technique, such as: architecture, electronics, energy, computers, mobile phones, websites, army,
- social sciences and humanities, such as philosophy, history, psychology, sociology, foreign languages,

The intentions of the portal is to encourage users to set the address as the portal home page in a Web browser, and treat

it as a gateway to the Internet. There is a tendency as a synonym for the treatment of portal website.

One of the oldest knowledge portals is presented in Fig. 1 (see: [19]). Main functionality of the portal concerns to co-operation with experts, e-learning offerings, Case Law Directory apart of typical FAQ (frequently asked questions) capabilities.

Fig. 1. An example of RTI Knowledge Portal

Another example of knowledge portal is depicted in Fig. 2 (available at [20]). The goal of its solution is to convince to company products as well as to offer complete courses devoted to accelerate user skills.

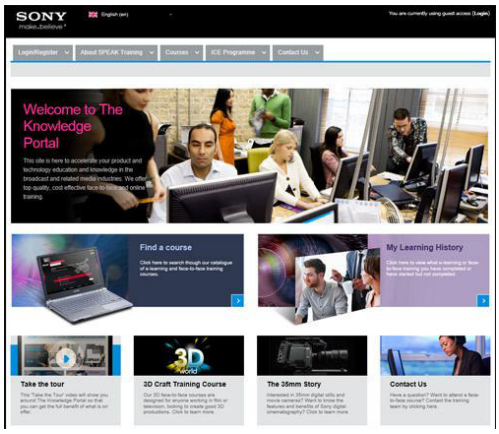

Fig. 2. Working with SONY Knowledge Portal

A useful tool for strengthening a network of people who are excluded can be a portal of knowledge. It serves not only as a tool to convey information, but above all to enrich and exchange their knowledge resources. Knowledge portal provides access to knowledge resources that are owned by all of the entities forming the network issues excluded people. The first impulse to gain specific knowledge resources is to determine your needs. Information goes to the portal, which locates the appropriate resource, a category of knowledge transfer process. Then the knowledge portal allows supplement domain knowledge. In this way, the knowledge portal becomes a compendium of knowledge on the particular matter. Site work requires not only knowledge of information technology, but appropriate organizational structure and knowledge management strategy. The proper functioning of the portal of knowledge brokers play an important role. They should be in the portals of knowledge as individuals or institutions performing oversight knowledge development in the portal. The main task of the broker is:

- assessment of the needs of the knowledge,
- location of resources,
- supervision of the transfer,
- assessment of the degree of absorption and utilization of knowledge.

All operators should be interested in the proper functioning of the portal of knowledge. Knowledge that remains in the resources the organization is the basis for the acquisition of new resources. We have in this case to deal with a spiral of knowledge that all time develops, through which actors are able to develop. Basic knowledge resources of the company are based on five categories of knowledge (compare [18]):

- codified knowledge,
- explicit knowledge,
- knowledge protected,
- tacit knowledge,
- latent knowledge.

The portal should provide exploration of tacit knowledge and latent. These two categories can contribute significantly to the development of the organization, and thus to achieve a competitive advantage. Portals should not only be sauce for the implementation of business functions typically associated with competitiveness, achieving measurable financial results. They should also be used for indirect actions that will achieve the objectives of a typical business. Different types of social organizations also need such solutions. A multitude of knowledge, which allows to solve problems of social institutions requires her to organize and codify the first stage of creating the portal. The next step is to complement this knowledge different solutions at the local or individual. The establishment and operation of such a portal will allow institutions to function more efficiently to deal with the problems of excluded people. Perhaps those who are excluded will return to society. However, their efficiency and effectiveness will be determined only by which time after testing.

IV. A Concept of Knowledge Portal for Exclusives

Considering development of dedicated knowledge portal at least the following aspects should be taken into account: purpose and audience, technology and tools useful for the creation and maintenance stages. Initially our proposal of the portal is expressed in two parts: assumptions and architecture.

Assumptions

We assume the following groups of people are the target users of the proposed portal:

- Policy makers – represented by politicians and officials who are responsible for legal solutions, law creation and adjustments.
- Social workers employed in:
  - Governmental / local governmental units.
  - NGO's – Non-governmental organizations.
- Institutions interested or engaged in the exclusion problem like universities/ scientific organisations and their researchers, media and journalists,
- Independent entities who are interested in the exclusion problem
- Commercial enterprises who develop programs / solutions targeted to help excluded groups

By using another perspective we can divide the users into:

- Corporate users representing authority organisations
- Individuals representing basically themselves that consist of:
  - Authorities that should be verified
  - Regular users

The main basis of the portal assume that every published content is available for all portal users. There will be no confidential matters stored in the portal so there is no need to build sophisticated information protection module.

No confidentiality assumption determines the simplicity of permissions model in the portal. The administrators of the portal will be able to configure it's modules and manage the permissions for every defined role, but there is no need to limit the access to the specific content.

We perceive that if we build a dedicated authentication module with separated credential management it will become a serious pain point for the users who will be forced to create and remember yet another user login and password. That is why we would like to integrate with as many as possible authentication providers that can exchange the data with the portal. Such approach will allow the users to use in our portal the same credentials as they are using in their enterprise systems or social solutions. Our portal will be integrated with:

- LDAP solutions,
- Facebook/ twitter / google accounts.

Our authorisation module architecture approach will allow organisational users to authenticate in our portal with the corporate login and password or even include the portal into the corporate SSO (single sign-on) solution. Individual users will be able to access the portal with the private facebook account and sign in automatically.

Of course we can use the mixed mode of authentication which means that corporate users can use also their private social accounts if their prefer or if the integration with the corporate LDAP will be impossible.

The corporate users of the portal should be verified by:

- Portal administrators,
- Organisation representatives.

In case of the individual users that should be verified – this task will be done by portal administrators.

One of the most important assumptions regards the functional offerings of the portal. It is not designed to work with specific excluded people and solve their particular problems. The main aim of the portal is to connect, enhance the interchange of ideas, knowledge and experience between the experts engaged in exclusion problem. It is designated to inspire all the stakeholders to solve the general problem of exclusion and provide them relevant information and knowledge. That is why the portal will not consist workflow functionality/ application processing capabilities but it is focused on information and knowledge tools processing, ideas management, communication platform and e-learning modules.

Architecture

We propose the portal to be built in traditional three layers architecture presented in Fig. 3:

- **Database layer** – built as a database storing the business and process objects. In this layer all documents, multimedia files, learning objects that has no relational structure will be stored. This layer will also provide the services of reporting and integration with other systems.
  Database layer will be supported also with Knowledge Base. The knowledge to the Knowledge Base will be supplied by:
  - Experts (portal users)
  - Knowledge exploration module that will be operated by portal power users with data exploration skills.
- **Application layer** that will be responsible for whole business logic. It will provide:
  - the basic portal functionality,
  - the communication services that will give the users possibility for on-line bilateral communication, teleconference services, off-line communication,
  - e-learning services with all capabilities for hosting and providing on-line courses,
- **Presentation layer** built in portal technologies (which means that all the portal features will be accessible by web browser). We must take into account that for some users the portal will not be a tool in which they will work every day. That is why from user perspective it is crucial to provide them notifications of all important event happening in portal as new available content, tasks for users, activities expected to be done by users and others. Such notifications will be provided by:
  - Automatically generated emails,
  - Mobile application push notifications,
  - Newsfeed published by social portal as Twitter or Facebook.

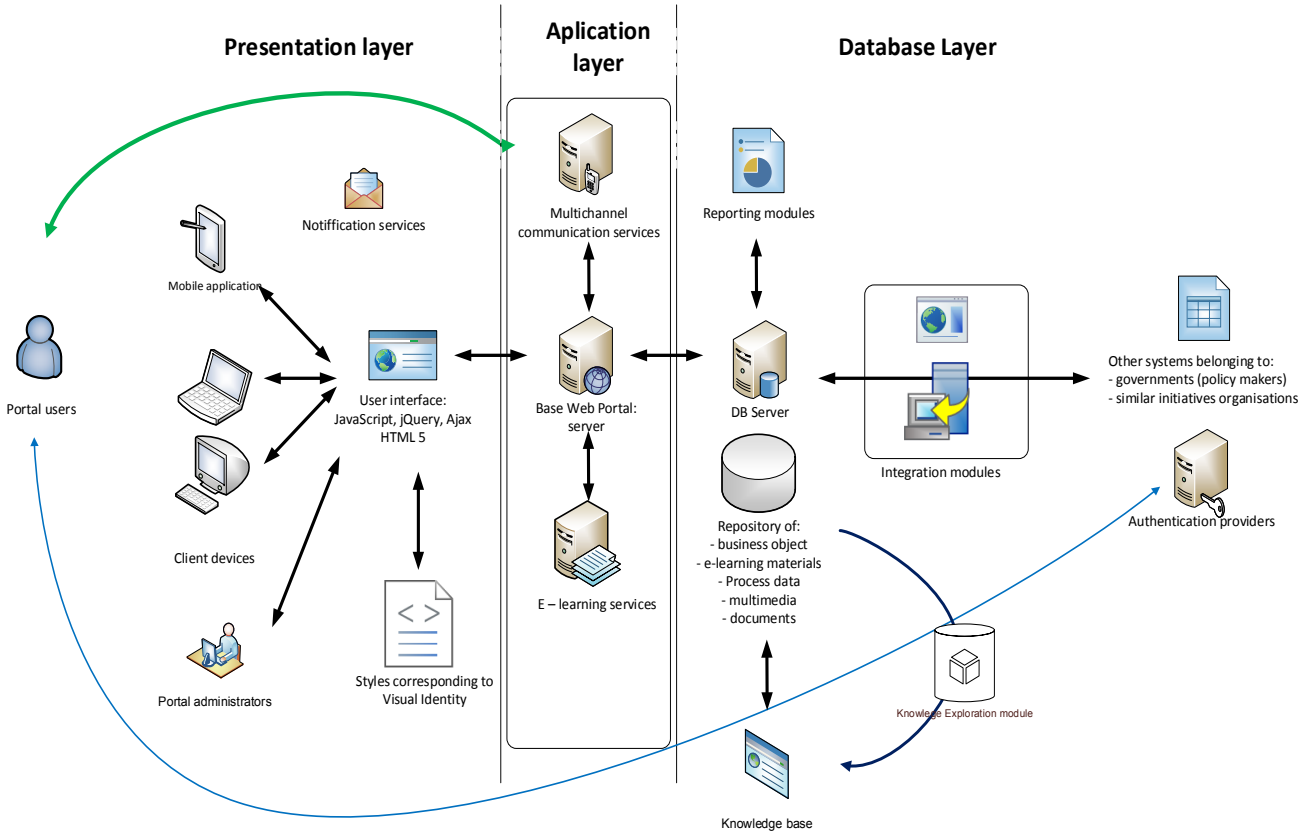

Fig. 3. Architecture of Knowledge Portal for Exclusives

Presentation layer will provide end users access to the information and knowledge stored in the database layer with regard to: users permissions and users preferences (content should be targeted to end user's needs and requirements).

V. Conclusions and Further Research

One of the most important problems of the modern society at the local, national and global levels is exclusion processes. The next findings can be formulated from the research:

- phenomena exclusion and inclusion in society are complex and multidimensional. Therefore investigation of such processes is difficult also because of differentiation of components, approaches and dimensions,
- information and communication technologies must support all processes belonging to registration and all services typical for exclusion and inclusion phenomena in modern society,
- the best solution for the discussed problems is specialized knowledge portal – proposed in the paper as a form of an initial version. At the beginning architecture will be developed for some narrow application and systematically extended covering new areas and levels of supporting.

Further investigations can be devoted to more deeply analysis of the problem in order to fulfill requirements of knowledge portal users. For example specification of knowledge bases and courses essential at local and/national level of administration.

Abstract—**The main objective of conducting this research is to investigate empirically the role of data warehouse (DW) in enhancing decision-making or, more precisely, the researchers surveyed the top management of Jordanian firms regarding the role and importance of DW in improving the effectiveness of decision-making. It is believed and assumed that meaningful and significant information can be acquired from DW which provides valuable knowledge to support business process and decision-making.**

A mail questionnaire survey was regarded as the appropriate method for gathering data. The questionnaire was developed based on the findings from related literature and other related research questionnaires. All the firms (277), which were listed on Amman Stock Exchange (ASE), at the time of data collection, were selected over half answered positively. The researchers arrived at scores of significant and remarkable results regarding DW and its role in enhancing the process of decision-making. The survey's findings showed that the percentage of implementing DW in the Jordanian firms involved is 35%. In general, the respondents had a positive attitude towards the implementation of DW.

I. Introduction

Today's organizations face a very hard time, largely as a result of competition, globalization, automation and scarcity of resources. As the business environment is changing. Companies rely more and more on changing technology. At the same time, those companies are likewise evolving. In this changing environment, companies are much more eager in getting immediate and accurate information to make better decisions. Successfully supporting managerial decision-making has become critically dependent upon the availability of integrated and high quality information organized and presented to managers in a timely and easily understood manner [1].

Nowadays there is a need for more advanced and accurate systems. Today's systems are more likely to produce more accurate information than previous systems. Traditional systems, indubitably, are more likely to produce less accurate data and information which lead to bad and incorrect decisions. However, the situation will be different if the firms implement data warehouse (DW) technology, which has emerged as a key source and powerful tool for delivering and accessing information for decision-makers ([2]; [3]; [4]; [1]). Since the 1990s [5], DWs have been an essential information technology (IT) strategy component for large and medium-sized global organizations [5].

Large organizations are facing significant challenges in maintaining an integrated view of their business [6]. In an ever more complex and competitive world, the complexity of the organizational context and the management task involving decision-making and assessment of information has increased [7]. Decision-making in those environments involves large data volumes and includes a wide variety of decision tasks [8]. In such environments it is important to assure decision-makers of the quality of data they use ([13; [8]). DW systems are perceived to be important tools in the modeling of that complexity, however, reports of high failure of DW systems are common ([7]; [5]; [9]). [10] claim that DW hastens the process of retrieving information needed for decision-making.

Despite the recognition of data warehousing as an important area of practice and research, there is little empirical research [1] about implementation of DW in general ([11]; [9]; [1]).

The changing business environment has an impact on the nature of decisions and decision-making drivers [12]. Timely and informed decision-making is becoming crucial for the long-term success of businesses [13]. [14] claims that business decisions must be made with speed and accuracy if organizations are to remain competitive. There is quasi-consent that DW provides more detailed and accurate information for decision-makers to improve their decisions. Considering the usefulness of DW there has been little research in Jordan on DW, i.e. it has been comparatively less investigated in Jordan. Therefore, the main focus of this study is on the advantages of DW as a provider of information to the process of decision-making. It investigates mainly the relation between decision-making, the need for information and the employment of DW in Jordanian firms.

In addition, this study investigates how top management of Jordanian firms perceives the effectiveness (usefulness) of DW as a source of reliable and accurate information for decision-making. Although many studies to DW have been published, they have been concerned with technical issues. However, it has been understood recently that the information systems (IS) failure is due to psychological, environmental, organizational issues etc. rather than

This work was not supported by any organization

technological issues, hence individual differences must be addressed [15]. Overall, there is a scarcity of empirical studies that examine the data warehousing success within an integrative model [9].

II. AIMS OF THE STUDY

In this paper, a field study of DW and its role in easing and enhancing the process of strategic decision-making among top managers in Jordanian firms were investigated. Therefore, the main aim of this study is to investigate the role, which is played by DW, in decision-making.

In realizing this aim, the researchers believe that the following matters in particular deserve careful investigation largely due to their close connection with the aim and its achievement:

1. To investigate the relationship between the implementation of DW by Jordanian firms and the effectiveness of strategic decision-making (assuming that there is a positive association between the implementation of DW and the degree of decision performance).

It has been ascertained that DW is superior to traditional database and improves the process of decision-making. Therefore, one of the study's aims is to investigate empirically whether or not the DW provides better and more accurate information. It is anticipated in this study that the enhancement of decision-making's process might drive Jordanian firms to employ DW. Thus, another aim of this study is to identify the Jordanian firms' reasons for implementing DW.

2. To identify the grounds of implementing DW by Jordanian firms.

A study of a large number of data warehousing practitioners and experts by [16] showed that the implementation of DW was motivated more by internal pressures than external. A majority of the respondents said that the need was information related. [17] are of the opinion that improving access to information and delivering better and more accurate information are motivations for using DW.

III. THE STUDY'S QUESTIONS AND HYPOTHESES

The hypotheses are formulated in the light of the study theoretical and conceptual framework and partially based on related previous studies. It is assumed that the outputs of DW, such as data and information, have more positive effect on the process of decision-making by comparison with traditional database systems. This assumption leads the researchers to question whether there is a direct positive relationship between improving the process of decision-making and the implementation of DW? In other words, does the DW provide relevant, reliable and sufficient information for decision-makers to take and achieve sound and effective decisions? This question leads to hypothesis 1.

Hypothesis 1: There is a strong association between employing DW in Jordanian firms and improving the process of decision-making (soundness and effectiveness of decisions).

In addition to the principal objective of this study, the researchers attempt to achieve multiple aims through this study, including the grounds, which drove Jordanian firms, of implementing DW. This aim led to question what the Jordanian firms' grounds of implementing DW are. This question, in turn, led the researchers to formulate hypothesis 2.

Hypothesis 2: The dearth of reliable information for taking decisions, the highly competitive environment, the need for more accurate, reliable, relevant and timely information, the changes in manufacturing technology, techniques and processes, the unreliability of existing systems of decision support and inability of the existing systems of decision support to provide reliable, useful and relevant information to the process of decision-making are the major grounds of implementing DW in Jordanian firms.

IV. THE NOVELTY VALUE OF THE STUDY

This study was applied in Jordan, which is one of the developing countries in the Middle East. As Jordan's firms are not in isolation from the rest of the world, they are also influenced by the current competitive environment. The implementation of advanced and recent innovations, such as DW, is essential for the firms in developing economies, such as Jordan. Therefore, investigating their implementation in Jordanian firms is well worth considering. However, a few empirical studies, which had been identified on Jordanian firms, prompted the researchers to examine whether this innovation has been successfully implemented in Jordan. Because of the need for further investigation on this topic, considering its importance and the shortage of the empirical research, the researchers have every reason to investigate this issue which has not been given the proper attention in Jordanian environment.

Despite the exaltation and adulation of DW, There is a need for evidences that the implementation of DW improves the quality and accessibility to information. Therefore, this study aims to practically investigate whether or not the implementation of DW improves the quality and accessibility to information and enhances the process of decision-making. [18] drew attention to the role and importance of information accessibility. The authors claim that the information accessibility is a precursor of information quality-it has a significant impact on the information's usage, and consequently is an indicator of the DW's success in storing and processing information.

In addition to information's quality, previous literature and studies on DW have emphasized the importance of accessing information. The accessibility to information and their quality are crucial to the success of their use. It has been claimed that the use/ implementation of DW improves the quality and accessibility to information, and consequently leads to sound decisions. In other words, it leads to more fact-based decisions. DW has, according to

DW literature, the ability to store a vast amount of data in a usable and appropriate form for the decision-makers' needs and uses. Although a wide range of primary and secondary sources has emphasized the importance and role of information quality and accessibility in enhancing the process of decision-making, little empirical research has been conducted so far. Such claims need to be tested empirically. It is essential, therefore, that the researchers investigate whether or not DW provides easy access to data and information, frequent, accessible and timely reports and more accurate, useful, reliable, complete and relevant information to decision-makers.

Based on extensive literature review, the researcher has identified that firms are often unsuccessful due to a lack of appropriate information or more precisely their inability to get the right information to the right person at the right time. The availability of apposite information to decision-making helps managers in taking reliable decisions, which improve the firm's performance. For this reason, this study is one of the few empirical studies (e.g. [4]), which attempts to examine the effect of DW on decision effectiveness. In addition, previous research has not empirically tested its effectiveness in DSSs contexts in Jordanian firms "to the researchers' knowledge".

Additionally, the researchers have not found and are completely unaware of any empirical studies regarding the implementation of DW in Jordan. Therefore, it is hoped that the findings of this study give the readers and those who are interested in these issues practical insights into DW's field in Jordan. To some extent, it is one of the academic contributions. It contributes to our understanding of the DW in general and in Jordan in particular, and may form a basis and motivation for future research in the important fields. It is also believed that the final outcome of this paper adds up to the improvement and development in DSS, such as DW, by helping their users and developers to be more aware of the data and information's quality.

V. RESEARCH METHODOLOGY

The writing of this paper is passed in different phases. In the initial phases of the study, renowned journals, publications, conferences proceedings and books were reviewed. In addition to these sources, the findings of numerous empirical studies were researched and analyzed. Based on the literature review the study' hypotheses were formulated. As the researchers previously pointed out, the sample of the study comprises all the 277 firms, which are listed on ASE at the time of the data collection. Thus, a questionnaire was found to be the best instrument for collecting the data in this study. During the next phases, therefore, a survey questionnaire was conducted with the top managers of Jordanian firms. The questionnaire, which is used in this study, is based on previous studies and the researchers' assessments and discretion and adapted to suit the objectives and requirements of the study. The primary objective of the questionnaire is to amass appropriate data and responses from the potential respondents for testing the significance of hypotheses.

In order to answer the study's questions, fulfill its aims and find out whether or not there is a positive relationship between independent and dependent variables, the study's hypotheses were statistically tested. The data, which were collected, is very quantitative in nature. Therefore, in the final phases of the study, the data were statistically analyzed by employing Statistical Package for the Social Sciences (SPSS) in order that proper descriptive and inferential statistics to analyze the results and draw conclusions can be reached, including means, frequencies, standard deviation, t-test, f-test and chi-square.

VI. LITERATURE REVIEW

The concept of data warehousing has evolved out of the need for easy access to a structured store of quality data that can be used for decision-making [19 p. 5]. Organizations have vast amounts of data but have found it increasingly difficult to access it and make use of it. This is because it is in many different formats, exists on many different platforms, and resides in many different file and database structures, and, as a result, organizations have had to write and maintain perhaps hundreds of programs that are used to extract, prepare, and consolidate data for use by many different applications for analysis and reporting [19 p. 5].

As an attempt to solve the problem, DWs were introduced. DWs have become the focal point for decision support in organizations today [20] and emerged as a key platform for the integrated management of decision support data in organizations [3]. [19 p. 5] claim that the data warehousing offers a better approach. Data warehousing implements the process to access heterogeneous data sources; clean, filter, and transform the data; and store the data in a structure that is easy to access, understand, and use. The data is then used for query, reporting, and data analysis [19 p. 5]. [21] also claim that the data warehousing has emerged as an effective mechanism for converting data into useful information.

DW systems offer efficient access to integrated and historical data from heterogeneous sources to support managers in their planning and decision-making [22]. [23] also claim that data warehousing provides an infrastructure that enables businesses to extract, cleanse, and store vast amounts of data. According to [19 p. 1], businesses of all sizes and in different industries, as well as government agencies can realize significant benefits by implementing a DW. Most medium to large organizations, according to [24], operate DWs.

It has been claimed that the main DW's role is to support decision-making. However, the role of DWs has been broadened. [25] state that DW provides information from external data sources for decision-making. DW has the potential to create radical changes to existing business processes and is often viewed within the context of business process reengineering [11]. Accordingly, [26] claims that

DW gives business' users the ability to analyze data. [27] also claim that DWs enable organizations to exploit decision-making.

According to [28], DWs provide the basis for management reports and decision support. They added that the purpose of DWs is to take that vast amount of data from many internal and external sources and present them in meaningful formats for making better decisions. In support of the above mentioned claims participants to a study by [3] agreed that the Return on Investment (ROI) for the DW was well justified through considerable gains in productivity and enhanced quality of customer service. Moreover, in an independent detailed study of 62 organizations worldwide [34], the major findings of International Data Corporation (IDC) based upon 62 case studies of organizations that have successful DWs in use are an average three-year ROI of 401percent was realized by organizations building DWs. Although this study is primarily focused on quantitative information, there are several qualitative benefits [34], such as providing standardized, clean and value-added data to create information from disparate sources. In addition, the DW makes the data available across corporate organizations and provides the needed information quickly.

The DW is developed in order to support the integration of external data sources [29] for the purpose of advanced data analysis. [40 p. 35] argues that a DW produces tangible impacts to the quality of day-to-day business transactions. Previous research on DW has produced some encouraging findings about its benefits and indicated that a DW can offer several benefits to an organization [11], such as enabling effective decision support; ensuring data integrity, accuracy, security, and availability; easing the setting and enforcing of standards, facilitating data sharing, and improving customer service [35]. [30] presented time savings for data suppliers and for users, more and better information, better decisions, improvement of business processes, and support for the accomplishment of strategic business objectives as benefits from data warehousing.

Furthermore, [2], who examined data warehousing at the Housing and Development Board (HDB) in Singapore, found that the main benefits of the DW, which were developed by HDB, are enabling the users to have access to consistent and reliable data in a timely fashion which facilitated forecasting and planning efforts and improved decision-making. In addition, a study by [31] revealed that DW appears to be used more to improve the flow of information in an organization than to change the way the organization does business. The authors found that more and better data is the greatest realized benefit from DW. Moreover, a study by [32] identified time savings, new and better information, and improved decision-making as benefits of DW.

[33] conducted an explanatory case study at a financial services organization to investigate how DW provides decision support to individual decision-makers. The results showed that the organizations successfully automated the retrieval and input of data for front-end users. [40 p. 33-34], who interviewed people from seven companies, found that the benefits of implementing DW were improving asset management, reducing customer support costs, auditing billing practices, terminating unprofitable product, reducing staff requirements and running the business. [28], who described the DW implementation at Blue Cross and Blue Shield of North Carolina (BCBSNC), claim that the DW had resulted in many organizational benefits, including better data analysis and time savings for users. [34], who looked at the DW of Egypt's Cabinet Information and Decision Support Center, found that the DW provides a lot of benefits to the users, including ease of access to the information, fast and more consistent reports, support the decision-makers and integrating the data from various sources.

Additionally, [4], who conducted a laboratory experiment in 2006, found that the implementation and use of DW improves the DSS users' decision performance, by which he means improving the quality of the DSS by adding a DW can improve information availability and quality and enhance DSS users' decision performance. In conclusion, the study showed that DW can have a positive impact on decision-making.

[35], who described an example of implementing DW in medical institutions, found that the DWs provide the users access to important information. [36], who conducted a survey to find out how DW assists decision-making process in healthcare, found that the DW provides better accessibility to data, integrated disparate data sources and improved decision-making. [37] found that all companies, which are studied, recognized some benefits such as cost reduction, reach-out to other markets, increase in sales, time saving in amount and preparation of reports and more effective decision-making based on the obtained information. [38], who conducted two case studies on American Airlines and Hallmark Cards, found the easy to use, speedy information retrieval, more information, better quality information, improved productivity, and better decisions as benefits of DW. [39], who examined the implementation of DW in public security, found that the DW is very important in improving the comprehensive ability of leadership and decision-making. In addition, it quickly and efficiently integrates heterogeneous data sources.

Previous literature on DW, such as [31] and [22], claims that the DW does not create value by itself; the value comes from the use of the data in the DW. [22] claim that improved decision-making results from the better information available in the DW. By making the right information available at the right time to the right decision-makers in the right manner, DWs empower the users with the ability to make the right decisions [40]. [31] also claim that this use can result in numerous benefits, including more and better information, improved user ability to produce information and reduced effort by developers to produce information. [41] also maintain that DWs have tremendous potential to present information. The greatest potential benefits of the

DW occur when it is used to redesign business processes and to support strategic business objectives [30].

[42] also identified many different measures of success; these include benefits such as data accuracy, useful information, accurate information, ease of use, user satisfaction, time to make decision and increased revenue. However, [43] claims that despite clear evidences that many DW projects have resulted in interesting business benefits, there are also many examples of cost and schedule overruns and dissatisfaction regarding the results from these projects. [44] argue that DW is one of the key developments in the IS field and has plentiful benefits. In addition, [45] indicates that the introduction of a new IS into an organization should deliver multiple benefits.

Since the early 1990s, DWs have become the technology of choice for building data management infrastructures [5] and been investigated and implemented around the world in many areas and by many researchers, authors, and scholars [46]. According to [47 p. 13], the early successful implementation of DW dates back to mid-1980s at ABN AMRO Bank (Netherlands). The author claims that the end-user's needs were the key feature behind the implementation. As a result, those requirements were modeled rather broadly, and all available data was stored in the DW. In fact, in the first few years of general use, its usage had grown at an annual rate of 50%, and by 1995 the DW had supported some 3,000 end-users. [47 p. 17] also mentioned that a study of 62 DW projects, which was conducted in 1996, showed an average return on investment (ROI) of 321% for these enterprise-wide implementation in an average payback period of 2.73 years.

In addition, [48], who investigated whether lodging companies are involved with DW technology through a sample of twelve large lodging corporations, found that the most of hotel corporations in the study were using their DWs to support market analysis. However, [13], who conducted a survey on a large Australian public organization, found that 60% of the users were with limited or no usage (or were anticipating the use in the future) of the DW. The data also helped the users to make informed decisions and the data, which was retrieved from the DW, was also presented to the senior management and other strategically oriented sections in the form of reports i.e. annual and quarterly reports.

Similarly, [11], who surveyed DW's managers and data suppliers from 111 organizations in different regions of the United States (US), also found that all companies had operational DW and nearly all of them considered that their initiative is successful. In other words, 26% of the respondents considered it runaway success. Another survey by Forrester showed that 878 IT decision-makers in the US enterprises were somewhat satisfied with the accessibility and quality of customer information; 82% of these respondents are satisfied or very satisfied [49]. [27] also found that about 55% of 196 respondents firms (107) in two major states in the US had already adopted and used DWs.

Similarly, [23 p.192-196) found that 60% of the respondents consider the functionality of their DW below expectations. 40% of the dissatisfied group was actually still using it. This means that 80% of the respondents were still using their internal DW, which is a good indication of the overall degree of satisfaction.

In addition to those studies, [50], who reported the results of a survey which was conducted at The Data Warehousing Institute (TDWI) World Conference in New Orleans 2003, found that 45% of the respondents had been already in production with their current DW or implementing a second or third release.

In Taiwan, [51], who conducted a survey on Taiwanese banks, found that 53.33% of 30 respondent banks had DW functions or capabilities, 31.25% (5) out of 16 respondent banks had already implemented the DW and 68.75% (11) were still in the process of development to implement DW. 85.71% (12) of 14 banks which had not implemented the DW were evaluating the possibility and/or potential of adopting DW. Another study in Asian countries was conducted by [52]. [52], who surveyed 115 users of DW in four Korean financial companies, also found that the participated companies had been using their data warehousing systems for approximately two years. In addition, the findings also showed that all the respondents were end-users of DWs in their companies, using the systems mainly for financial analyses. The majority of data warehousing users (approximately 70–75%) use the DWs regularly, i.e. every day.

The 2007's IBM Data Warehousing Satisfaction Survey showed that 56% of those questioned were very successful with their DW (200 end-user enterprises were participated), however, 43% of the respondents acknowledged the need for improvement, as there are still a number of business and technical challenges confronting the enterprises which make use of DWs according to the survey [53]. The success of DW's implementation, according to [53], is growing as 56% of the respondents were very successful and satisfied. [54], who conducted a survey on 84 users of DW, found that the majority of respondents (73%) in the surveyed firm were successful in obtaining and accessing the needed data and information from the DW, only two respondents indicated that they were not at all successful, while 56% indicated somewhat successful and 13% indicated very successful. In addition to these results, 67% and 33% of the respondents rated the importance of the obtained information in performing their job better as vital and somewhat important respectively.

Numerous studies have also shown successful implementation of DW. For example, [55] used a case study and conducted a series of interviews at Continental Airlines. The results showed that the organization has realized an enviable level of DW maturity and significant cumulative benefits. [56], who surveyed 244 members of TDWI, found that 51.2% of the respondents had at least one DW application and 30.3% were still in development stage.

17.2% were still in planning stage and 1.2% of respondents had no any efforts made in their organizations to implement the DW. This result showed that more than 80% of respondents had implemented DW.

According to [9], there is a scarcity of empirical studies that examine the DW success. In the study population, i.e. Jordan, there is not a shred of empirical evidence that the DW has been investigated or showed the degree of DW implementation, to the best of the researchers' knowledge. However, the literature review was limited to materials which have been published in English language only– evidence in languages other than English could be possible. Therefore, this paper investigates the extent to which Jordanian firms implemented DW and the reasons for implementing DW. It is aimed at providing empirical evidence, thereby extending the body of research regarding the implementation of DSSs in general and DW in particular.

VII. RESULTS, FINDINGS AND DISCUSSION

As mentioned earlier, the study's sample consists of the Jordanian firms' top management. [57 p. 142) claim that although the large populations are referred to as ideal populations, sampling every person in these populations is not realistic or doable. They believe that time, money, and other restrictions make it impossible for the average survey researcher to reach all members of an ideal population. Therefore, the researchers have to forgo these grand expectations and select a smaller or realistic population. This argument forms the basis for this study's population, therefore, the study's population, which is selected, is only the Jordanian firms that are listed on ASE. It is believed that this category is more likely to use the outputs of DW for strategic decision-making, i.e. the data, which is obtained from these respondents, fulfill the purpose of this study. Therefore, the potential respondents were solicited for their opinions. The covering letter was addressed to the top management of each firm. The questionnaire, along with a self-addressed stamped envelope (SASE) and a covering letter were posted to the potential respondents. The potential respondents were requested to return the completed questionnaires in the enclosed SASE.

As the main aim of this study is to investigate the role of DW in strategic decision-making, the choice of the target population (Jordanian firms which are listed on ASE) and potential respondents (top management) is made on the basis that those firms have sufficient resources to implement such expensive and time-consuming systems and the respondents have sufficient knowledge about their firms and take the strategic decisions. In other words, they are the main consumers of the DW reports. In addition, the companies' Guide by ASE is the only listing that specifically covers all sectors and industries in Jordan. This directory lists the names, titles, and the general information about the listed companies. Top management of Jordanian firms, which are listed on ASE, constitutes the population of this study. A total of 277 questionnaires were sent out by post along with a covering letter. The potential respondents were assured that all data, which would be provided by them, would be treated by complete confidentiality.

The results of the study's sample analysis are shown in the table below (Table 1). In this table, the sample results are broken down by responses.

TABLE 1.
THE STUDY'S POPULATION ANALYSIS

The state of the survey's responses	Number	Percentage %
Usable responses	120	43.3
Unusable responses	20	7.2
Non-response	137	49.5
Total number of responses	277	100

Source: The figures are based on the responses to the survey.

As can be seen from these results, 140 completed questionnaires were returned to the researcher's address with a response rate of 50.5%. According to these figures, usable questionnaires accounts for 43.3% of the total sample. 20 of the questionnaires were discarded as unreliable, i.e. there were many essential questions missing from the questionnaires. To sum up, all the firms (277), which were listed on ASE at the time of data collection, were selected. 140 filled questionnaires were returned generating 50.5 %. This response rate somehow on average comparison to many similar studies such as ([58]; [59]). [58], who studied 350 Jordanian companies, had a response rate of 30%. [59], who used a self-administered questionnaire and targeted similar population in Jordan, had a response rate less than 50%.

The reliability, internal consistency and validity of the Likert scale questions are assessed by using Cronbach's alpha. It was found that Cronbach's alpha is the most popular method for assessing the reliability of scales. It has been used by many researchers, including [60]-[63]. Cronbach's alpha determines the internal consistency of the items in a survey instrument (questionnaire) to assess its reliability [64]. Table 2 shows Cronbach's alpha for all Likert-scale questions. In addition, the table demonstrates the mean, SD, sum of item variances (V) and standard error (SE) for the rating scale questions.

TABLE 2.
THE STATISTICAL ANALYSIS OF RELIABILITY AND VALIDITY

Questions	Items	Mean	SD	V	Cronbach's alpha	SE
Q 11	6	4.80	1.64	2.70	0.711111	1.0
Q 14	12	4.20	5.21	27.2	0.998288	1.6

Source: The figures are based on the study's questionnaire.

As can be seen from these figures, Cronbach's alpha coefficient is more than 0.9 for question 14. Overall, the results of the statistical computations show high reliability of

both questions, as evidenced by the high value of the Cronbach's alpha, i.e. more than 0.7.

The survey's results showed that 80% of respondents were males and 20% were females. In addition, the survey results were broken down by age. The 51-55 age bracket is the highest among the others (33.3%). According to these figures, the 56-60 age bracket accounts for 29.3% of the respondents. From the data, which were obtained, it is apparent that only 5.8% of the respondents are below 40 years old.

The results also showed that almost half (56) of the 120 respondents surveyed have a bachelor degree. 32.5% of the respondents are postgraduate, i.e. have master degrees, considerably more than those who hold PhD (18.3%). Moreover, one-third of the respondents (40) have from 11 to 14 years of experience. Similarly, almost a third of the respondents (29.2%) have more than14 years of experience, considerably higher than those who have from 3 to 6 years (8.3%) and less than 3 years (1.7%).

The survey results were broken down by industry group. The results showed that the financial services industry is the highest among the others (14.2%). According to these figures, the insurance industry accounts for 11.7% of the industry groups. The survey's figures also show that 9.2% of the firms are within the banking industry, considerably higher than the 0.8% of firms within the glass and ceramic, textile, leather and clothing and utilities and energy industries and 2.5% within the pharmaceutical and medical, electric and educational services industries.

Almost a quarter (30) of the 120 firms involved in the survey has from 100 to 500 employees. The figures also show that 20% of the firms are in the range 501 to 900 employees, considerably more than those who are in the ranges 901 to 1300 (14.2%), 1301 to 1700 (10.8%), 1701 to 2100 (9.2%), 2101 to 2500 (8.3%) and more than 2500 (5%). In addition to these results, almost a quarter of the firms have a capital from 51 to 100 million dollar. The survey also found that 16.7% of the firms are in the 10 to 50 million capital range. A small proportion (4.2%) of the firms is in the range of 1501 to 2000 million. Another and last characteristic to be discussed is the annual revenues of the firms. The results showed that the highest percentage (23.3%) of firms involved has annual revenue from 11 to 50 million. The results also show that 20% of the firms involved are in the 51 to 100 annual revenue range.

This result is virtually identical to the 1 to 10 revenue range (18.3%). the survey also found 5 (4.3%) of the 120 firms involved in the survey have more than 1000 million, considerably lower than the rest of the categories. Based on these figures, it can be concluded that the rate of implementing DW in Jordanian firms is very low and less than other countries. For example, [27] found that about 55% of 196 respondents firms (107) in two major states in the continental US had already adopted and used DWs. [56], who surveyed 244 members of TDWI, found that 51.2% of the respondents had at least one DW application. However, the results of this study are similar to some previous studies' results. For example, [51], who conducted a survey on 16 Taiwanese banks, found the rate of implementing DW among those banks is 31.25%.

The 42 respondents, who their firms implemented DW, were solicited for their opinions regarding the reasons behind the plan (decision) to implement a DW. The likely and expected reasons, which were measured on a five-point scale ranging from 1 (unimportant) to 5 (extremely important), are shown in Table (3). The table shows the mean and standard deviation (SD) for all the select reasons.

As can be seen from these results, the need for more accurate, reliable, relevant and timely information (mean= 4.28) were the most important reason to implement DW. According to these figures, the existing systems of decision support have not provided reliable, useful and relevant information to the process of decision-making (mean=4.24) were the next second important reason to implement DW. Other important reasons include the existing systems of decision support have not been reliable (mean= 4.09) and there is a dearth of reliable information for taking decisions (mean=4.07). From the data in the table, it is apparent that the highly competitive environment created the need to replace the existing systems of decision support and changes in manufacturing technology, techniques and processes created the need to replace the existing systems of decision support mean= 2.59 and 2.47 respectively were the least important reasons to implement DW.

The researchers believe that some of the keys to measure success are satisfaction and approval. This is why it is essential that DW (if it is to be a success) must satisfy the needs (requirements) of its users. Similarly, the users need to be satisfied of the need for DW.

TABLE 3.
THE REASONS FOR IMPLEMENTING DW

The reasons for implementing DW	Number	Minimum	Maximum	Mean	SD
There is a dearth of reliable information for taking decisions	42	2	5	4.07	0.97
The highly competitive environment created the need to replace the existing systems of decision support	42	1	4	2.59	1.11
The need for more accurate, reliable, relevant and timely information	42	3	5	4.28	0.81
Changes in manufacturing technology, techniques and processes created the need to replace the existing systems of decision support	42	1	5	2.47	1.19
The existing systems of decision support have not been reliable	42	2	5	4.09	1.01
The existing systems of decision support have not provided reliable, useful and relevant information to the process of decision-making	42	2	5	4.24	0.93

Source: The figures are based on the responses to questionnaire.

To measure the success of implementing DW, the respondents, who their firms implemented DW (42 respondents), were solicited for their opinions regarding the derived satisfactions from implementing DW. A seven-point scale from 1 (strongly disagree) to 7 (strongly agree) was used to measure these responses.

Table 4 shows that the great majority of respondents, since the least mean is 5.43, are very satisfied with the derived benefits of implementing DW. As can be seen from these results,most of the respondents believe that DW is useful in making better business decisions (mean=6.69).

TABLE 4.
THE DEGREE OF SATISFACTION FROM IMPLEMENTING DW

Satisfaction and approval of implementing DW	Number	Minimum	Maximum	Mean	SD
The information in your firm's DW is sufficient for taking sound decisions	42	4	7	6.14	0.89
You are content with the benefits of your firm's DW	42	4	7	6.26	0.85
The DW's information meets the requirements of your task	42	5	7	6.17	0.86
DW is a reliable source of information	42	4	7	6.21	0.95
DW's information is beneficial to different areas of decisions	42	4	7	6.19	0.83
DW's information is used in different areas of decisions	42	5	7	6.14	0.81
The DW offers user-friendly query capability to decision-makers	42	3	7	5.83	1.10
DW is a reliable information system	42	4	7	6.02	1.04
DW is a user-friendly information system	42	3	7	5.43	1.32
DW is useful in making better business decisions	42	5	7	6.69	0.66
DW is useful for decision maker's task	42	5	7	6.62	0.62
DW can output information much more quickly	42	5	7	6.33	0.72
The benefits of implementing DW exceed its cost	42	4	7	6.14	0.89

Source: The figures are based on the responses to questionnaire.

Moreover, the figures show clearly that the involved respondents were very satisfied on the grounds that DW is useful for decision maker's task (mean=6.62), DW can output information much more quickly (mean=6.33) and if the users content with the benefits of their firm's DW (mean=6.26).Other high responses include DW's information met the requirements of the respondents' task (mean=6.17), DW's information is beneficial to different areas of decisions(mean=6.19), DW is a reliable source of information (mean=6.21), the benefits of implementing DW exceed its cost (mean=6.14) and the DW's information is sufficient for taking sound decisions (mean=6.14). According to these figures, DW is a user-friendly information system (mean=5.43) and The DW offers user-friendly query capability to decision-makers (mean= 5.83) were the least responses.

Based on these figures, it can be concluded that the implementation of DW (in Jordanian firms) is very useful and have a great positive effect on the process of decision-making. These results are similar to some previous studies' results on DW, for example, [13] and [11].

For the purpose of this study, two hypotheses were formulated. The mean, standard deviation (SD), degrees of freedom (DF), standard error (SE), one sample t-test, p-value and one sample Chi-square test were computed. This assumption led to formulating hypothesis H1. Hypothesis H1: There is a strong association between employing DW in Jordanian firms and improving the process of decision-making. From the data, it was apparent that there is strong evidence of a link between implementing the DW in Jordanian firms and soundness and effectiveness of decisions. According to the statistical analysis, the highest p-value is approximately 0.34%, i.e. 0.0034 and since all the p-values of the variable are less than 0.05 and 0.1 level of significance, the null hypothesis (there is no strong association between employing DW in Jordanian firms and improving the process of decision-making) is rejected. As a result the alternative hypothesis (there is a strong association between employing DW in Jordanian firms and improving the process of decision-making) is accepted.

In addition, the same statistical analysis techniques are used to test hypothesis H2. The results showed that all the variables without exception are the major reasons of implementing DW in Jordanian firms. According to these figures, the highest p-value is approximately 0.28%, i.e. 0.0028 and since all the p-values of the variable are less than 0.05 and 0.1 levels of significance, the null hypothesis, i.e. the variables are not the major grounds of implementing DW in Jordanian firms is rejected. As a result the alternative hypothesis (the variables are the major grounds of implementing DW in Jordanian firms) is accepted.

VIII. CONCLUSION

The evidences, which are obtained by analyzing the data from the questionnaires, reveal exceptionally remarkable facts, first of all and to some extent, the percentage of implementing DW is high (35%) by comparison with other countries. one consequence of implementing DW was the great role of DW's information in enhancing and facilitating the process of decision-making. The results showed that the Jordanian firms benefited greatly from implementing DW. The results also revealed that the DW is a fruitful source of information. Moreover, the implementation of DW proved to be a success through helping decision-makers in taking fact-based decisions. Furthermore, the DW was lauded by the

users for the successful use of its information as a basis for decision-making.

This study has humbly contributed to the field of scientific research in general and the field of decision support systems (DSS) in particular in many ways, first of all, the studies on the implementation of DW were nearly all in developed countries. This study was applied in Jordan, which is one of the developing countries in the Middle East. Therefore, the results of this study made a humble contribution to the existing knowledge in the field of implementing DW worldwide in general and in Jordan in particular. Second, there is a need for evidences that the DW improves the quality and accessibility to information. Therefore, this study practically investigated whether or not the implementation of DW improves the quality and accessibility to information and facilitates the decision-makers' tasks. Lastly, based on extensive literature review, the researchers have identified that firms are often unsuccessful due to a lack of appropriate information. For this reason, this study is one of the few empirical studies which have attempted to examine the effect of DW on decision effectiveness. In addition, previous research has not empirically tested its effectiveness in DSS contexts in Jordanian firms "to the researchers' knowledge".

Despite the usefulness and positive contributions of the study's results, these results should be treated and interpreted with caution. In fact, the study's sample included only the Jordanian firms which are listed on ASE. As a consequence, this might severely restrict the generalization of the results. It is believed that the results of this study might have been dissimilar, if all Jordanian firms have been surveyed. Therefore, prospective researchers are recommended to broaden the scope of their investigation to include all Jordanian firms.

***Abstract*—Knowledge management (KM) is essential for success in global software development. Software organizations are now managing knowledge in innovative ways to increase productivity. In agile software development, collaboration and coordination depend on the communication, which is the key to success. To maintain effective collaboration and coordination in distributed agile projects, practitioners need to adopt different types of knowledge sharing techniques and strategies. There are also few studies that focus on knowledge sharing in distributed agile projects. This research identified the knowledge sharing techniques and strategies applied by the practitioners in distributed agile projects. Challenges faced by the practitioners during knowledge sharing in distributed agile projects are also identified and discussed.**

***Index Terms*—Global software development, knowledge management, knowledge sharing, distributed, agile.**

I. Introduction

Software engineering is a knowledge intensive area. This forces software organizations to manage their knowledge and later use it in smarter, innovative ways to solve problems [46]. It helps software development organizations to acquire and maintain a competitive advantage. KM is crucial for success in global software development [41].

Global software development can be described as "software work which is attempted in different geographical locations across the national boundaries in a coordinated fashion, to involve synchronous and asynchronous interaction" [45]. Software developers work with knowledge and are dependent on each other's work. In global software development this synchronization is dependent on KM. Some studies have identified that knowledge sharing is difficult in distributed agile project due to the lack of face-to-face communication between team members [7,23]. In the agile software development collaboration and coordination depends on communication, which is crucial to successful software development [50]. One of the major objectives of KM is to improve productivity through effective knowledge sharing and transfer [24]. So, the success of agile projects relies on effective knowledge sharing among teams.

This research focuses on exploring knowledge sharing in distributed agile projects. More specifically, this research attempts to identify knowledge sharing techniques, strategies and practices that take place between locally and globally distributed agile teams, and the challenges faced by the practitioners in a distributed agile environment. We are driven by the following research questions:

RQ1: How do team members contribute to knowledge creation in a distributed agile project?

RQ2: How do team members share knowledge in a distributed agile project?

RQ3: What are the challenges faced by the practitioners when sharing knowledge in a distributed agile project?

The rest of the paper is organized as follows. Section II describes a theoretical background of knowledge management in a distributed agile projects is described. In section III we present the research methodology applied and this is followed by validity threats in section IV. A series of semi-structured interviews are described in section V. Results of the different findings are presented in section VI. Discussion of the empirical studies is provided in section VII. Finally, section VIII concludes the paper with a summary of the major findings and future work.

II. Related Work

Software development is considered to be a complex, knowledge intensive and rapidly changing activity, where a number of individuals, teams and organizations are involved infulfilling common goals, interests and responsibilities [13,33]. Technological and strategic knowledge helps developers to communicate; so it is essential to keep the knowledge stored in the organization for the future reuse. Davenport and Prusak [14] define it as "a method that simplifies the process of sharing, distributing, creating, capturing and understanding the company's knowledge". As the size of the organization grows rapidly, it becomes harder to find out where the knowledge resides. Research shows that if the companies manage their knowledge in a better way, they can increase quality, and decrease the time and development costs [44]. To improve the organizational performance, it is important to manage knowledge in a structured way which will help to convey the right knowledge to the right people at the right time. O'Dell and Grayson [37] discussed that, knowledge management is not a vital methodology; it is a framework, a management

978-83-60810-58-3/$25.00

mind-set which is based on past experiences and the creation of new wheels for exchanging knowledge.

To foster dynamic knowledge sharing, improve productivity and coordination in software development teams, agile approaches were introduced. Agile teams share knowledge through several practices [10]: pair programming, release and sprint planning, customer collaboration, cross-functional teams, daily scrum meetings and project retrospectives. But, the authors [10] argue that, these practices are team-oriented and rely on face-to-face interaction between team members. These practices do not facilitate knowledge sharing in distributed agile teams but are effective for collocated and small teams. In one study Dorairaj *et al.* [16] reported that in distributed agile project, team members practice sprint planning, daily scrums, sprint reviews and project retrospective meetings. Distributed agile team members share knowledge through effective use of knowledge management tools like *Wiki*, pair-programming and video-conferencing.

Michael Earl [17] has classified knowledge management (KM) into three categories: technocratic, economic and behavioral. Earl also divided these three categories into seven schools, Technocratic: *Systems, Cartographic and Engineering*, Economic: *Commercial* and Behavioral: *Organizational, Spatial and Strategic*. Both *codification* [20] strategy and *systems school* practice depend on the technology which applies Nonaka's [34] *externalization* conversion technique to convert tacit knowledge into explicit knowledge. Research shows that the technocratic school is closely related with traditional software development and those who are developing software through traditional approaches they are probably benefiting from the technocratic schools [15]. On the other hand, behavioral schools are more related with the agile approaches and agile teams are more benefit more from the behavioral school. A survey in traditional and agile companies shows that agile companies seem to be more satisfied with their knowledge management approaches compared to traditional companies [5]. In agile software development, knowledge sharing happens through the interaction. Developers share knowledge by working together and through close interaction with customers; and more specifically, pair programming, extreme programming, daily scrum meetings, and sprint retrospectives in Scrum. In traditional software development, knowledge management relied primarily on explicit knowledge but in the agile software development KM relies on tacit knowledge [32]. In agile software development, information radiators and collocating teams are related with the spatial school [5].

In traditional software development, knowledge stored explicitly in the documentation, but in the agile development methodology the knowledge is tacit [24]. Extracting tacit knowledge to create explicit knowledge is one of the greatest challenges of knowledge organization [36]. Due to the absence of explicit knowledge in the agile software development, experts need to spend much of their time on repeatedly answering the same questions, knowledge is lost when experienced developers leave project, there is less support for re-usability and there is less contribution to organizational knowledge [24]. In the agile collocated development, informal communication is the key enabler for knowledge sharing but when an agile project is distributed, informal communication and knowledge sharing is a challenge due to low communication bandwidth as well as social and cultural distance [26]. Due to spatial, temporal and cultural factors, communication also becomes aggravated in the distributed settings [21]. Several studies [8,23] also point out that, knowledge sharing in the distributed agile projects is difficult due the challenges in communication, especially face-to-face interaction between team members in different geographical locations. To address these problems, we investigated how shared knowledge creation and transfer activities performed in the distributed agile projects. Along with that, we also investigated what challenges are faced by the practitioners when sharing knowledge among globally distributed agile team members.

III. Research Methodology

Because this research addresses an issue *"How can we retain the benefits that agile practices provide with respect to KM in distributed agile projects"* which is rather under-investigated, this study takes an explorative approach. Exploratory research helps to find out what is happening, seeking new insights and gathering ideas [27,43]. In some qualitative research, data collected through observation or interviews are exploratory in nature. So, extensive interviews are helpful to handle this type of situation [47]. This type of exploratory research was also helpful in achieving our goal through analysis of similarities and differences among the cases [12]. The primary focus of this study was to discover the knowledge sharing activities in distributed agile projects in order to identify techniques, strategies and challenges.

A. Sampling

The selection criteria for these interviewees were based on the kind of company they work at, the experience of the company in distributed agile development (more than 2 years), interviewee role in the distributed team as well as in the company, project duration and project distribution. The participants of this research were project managers, team leaders, software architects, line managers, senior software developers, system developers and Scrum masters in different countries involved in distributed agile projects, located in different countries i.e. Sweden, Norway, Germany, Ukraine, China, India, Bangladesh, USA, and Latvia. To get the rounded perspective of this research phenomenon we included different roles from the agile team.

B. Data Collection

There are three types of interview techniques namely structured, semi-structured and unstructured [18]. Due to the qualitative nature of this study we used semi-structured interviews for conducting a series of interviews in software industries involved in distributed agile projects. According to Robson [42], an in-depth semi-structured interview is helpful in *finding out what is happening and seeking new insights*. *Seventeen*

semi-structured interviews were conducted from *seven* teams in order to identify how practitioners are creating, storing and sharing knowledge related to software development among geographically distributed agile teams. These semi-structured interviews were a combination of both open and focused questions. It helps both interviewer and interviewee to discuss a topic in more details. Before the interviews started, we discussed about overall goal of this research to interviewee. The interview questions were *descriptive* and with the base questions there were follow up questions asked based on the discussion. We were concern about some key terms: *shared knowledge creation, knowledge transfer, strategies and challenges* which later helped us for data analysis and those terms which also evolve with interview questions. We conducted seventeen semi-structured interviews from six different companies. The selected companies are involved with software product development, have different organizational settings and structure and are located in different countries. The duration of these interviews averaged 60 minutes and the interview sessions were tape recorded. Among the seventeen semi-structured interviews, nine were conducted through Skype and eight were face-to-face, depending on distance between interviewer and interviewee.

C. Analysis and Synthesis

In qualitative research, data analysis is the most difficult and crucial aspect due to raw data sets. According to Basit [2], raw data can not help the reader to understand the social world or the participants view unless such data is systematically analyzed. To organize collected data we adopted *thematic analysis* [9] technique during analysis. Thematic analysis is used to identify, analyze and report patterns or themes within data. It minimally organizes and describes data set in detail. In thematic analysis a theme captures data with relation to research questions and represents them in a pattern within the data set [9]. This analysis is performed through a process which maintain six phases to establish meaningful patterns of the data set. Braun and Clarke [9] provides an outline through the six phases of analysis. These phases are: familiarization with data, generating initial codes, searching for themes among code, reviewing themes, defining and naming themes, and producing the final report.

In the *first* stage, we transcribed all the collected interview data into written form in order to conduct a thematic analysis. It helped us to identify possible themes, patterns and to develop potential codes [19]. *Second* phase started with initial codes from the extracted data. There are different types of Coding techniques suggested in different studies such as; *open, axial, selective, descriptive/topic and pattern/analytic* [29,40,48]. In our case, we applied open coding technique and went through all transcribed textual data by highlighting sections of the selected codes. That also helped us to relate coded data with research theme and research questions. In *third* stage, we analyzed broader level of theme rather than codes that helps to sort different codes into potential themes [9].As Braun and Clarke suggested coding as many potential themes/patterns as possible because initially some themes seems to be insignificant, but later they may be important in the analysis process. Later, mind mapping tools were used to represent them into theme-piles. This stage gave us a sense of the significance of individual themes. Stage *four* is reviewing themes. In this stage we identified irrelevant (not enough or diverse) data with relate to different themes and broken down into separate themes. After refining all themes we identified "essence" of each theme and different aspects of the data each theme captures in stage *five*. At the end, in stage *six*, we provided extract data with relate to research questions and present some dialog that connected with different themes in support of results and discussion sections.

IV. Validity Threats

To handle validity threats it is important to identify all possible factors that might affect the accuracy or dependability of the results.

A. Internal Validity

Internal validity for qualitative research mostly relates to the researchers biasness and interpretation of data [6].For finding a similar knowledge level for our interviewees, we went on interviewee profiles on *Linkedin* and their years of experience. After finding out the basic information, the interviewer sent a formal email to the interviewee with an invitation letter about becoming involved with this research. To mitigate the threat of following our own bias, interview questions were designed to have a majority of open ended questions. Every interview started with a similar introduction and some clarification questions. Then the recorded interview was transcribed immediately afterward to reduce the risk of missing some information. Furthermore, researchers sent an interview report to the interviewee in order to check whether interview data was correctly transcribed and to confirm the content indicated participants thoughts, viewpoints, feelings and experiences. In qualitative research it is important to understand the interviewee's inner meaning words. To maintain reliability during data analysis we used a thematic, qualitative data analysis technique, that helped to identify, analyze and report themes within data. The extracted data from the transcribed data was checked twice for any discrepancy by two researchers.

B. External Validity

External validity threat is more applicable to research that are quantitative and which tries to generalize outcome of the research. However, our findings can be generalized only for the agile software development teams which are involved in the development of a shared project from distributed locations.

V. Results

In this section, we describe different findings (techniques, strategies and challenges) from the *seven* cases, that promote effective knowledge creation and sharing activities in distributed agile projects.

TABLE I: Overview of distributed Agile projects

Projects	*Project Distribution*	*Team Size*	*Team Types*	*Agile Position/Roles*	*No. of Interviewees*
Alpha	Sweden-Germany	6-7	Dispersed	Team Leader Developer	2
Beta	Norway-Bangladesh	5-6	Dispersed	Project Manager Developer	2
Gamma	USA-Bangladesh	12-16	Distributed	Head of Engineering Senior Developer Developer	3
Delta	Sweden-Bangladesh	16-18	Dispersed	Software Architect Developer	2
Epsilon	Latvia- Ukraine	11-15	Distributed	Project Manager Developer	2
Zeta	Sweden-China	26-35	Distributed	Line Manager Software Developers System Developer	4

Dispersed teams- **α, β, δ***; Distributed teams-* **γ, ε, ζ***; Hybrid team-* **η**

A. Knowledge Creation: Locally and Globally

We have found that distributed agile project teams practice different types of techniques for both local and global shared knowledge creation. *Pair programming*, *customer collaboration*, *Scrum/Kanban* boards and *community of practice* are explicit practices used by the teams to perform both local and global shared knowledge (see in Table II).

1) Pair Programming: Pair programming is used for both local and global knowledge creation. From the series of semi-structured interviews we have found that both local and remote team members work together in one workstation to solve specific problems. They help each other to share their thoughts and create knowledge through discussion. In two cases, we have found that teams do not perform pair programming for shared knowledge creation among remote team members. In the Epsilon(ε) project, all development team members are in one site, and for that reason they do not need to perform pair programming for global shared knowledge creation. However, Zeta(ζ) project is a collaboration with a Chinese team on the same product, but the development team does not have any dependency. The development teams working on different modules and later core developers merge all modules together for specific release. But the local teams in Zeta (ζ) project perform pair programming.

2) Pre-planning game/customer collaboration: In the development cycle the customer has an important role. Customer collaboration helps teams to build up technical-business collaboration on a project and also helps to set the direction of the project. In agile software development customers are always involved with the development teams by providing project requirements and performing acceptance testing. Through customer collaboration agile teams participate in creating local knowledge. Evidence was also found from different cases that customers are also involved with the remote development teams to create knowledge through continuous discussion and features feedback. We have also found that customers are involved in issue tracking systems, which helps both the project manager and the developers towards early iteration. In two cases (δandε), we found that customer collaboration performed only in the local sites for shared knowledge creation.

3) Scrum/Kanban boards: The are two types of boards used by the office to create knowledge and common understanding. A *Scrum board* is used for teams that plan their work in sprint. A *Kanban board* is used to manage and construct team work in progress. In table II it is shown that, teams use *Scrum* and *Kanban* boards for shared knowledge creation among both local and globally distributed team members. In two cases (γandη), we found that teams are using boards both locally and globally. In Gamma (γ) project, the remote team has a sub-Scrum board, which is replica of the main Scrum board. Along with that, the local team (in γproject) upload pictures of the main Scrum board into a repository every day. But in Eta (η) project, teams use a visual Scrum board to perform shared knowledge creation among distributed team members.

4) Innovation boards: Most innovative ideas are kept in the human mind as tacit knowledge. Due to continuous work

loads, sometimes it is impossible to have a discussion with a team member, or other knowledgeable person. So, rather than talking with someone, people share their ideas through the innovation board in an explicit way. In one interview the researchers found that teams are using innovation boards to share their ideas with both collocated and remote team members.

5) Workshop/Seminars: Weekly or monthly workshops and seminars are arranged through collaboration between business teams, technical teams and customers, in order to share knowledge about projects and the latest technologies. This kind of workshop facilitates common understanding and communication between different team members. Workshops also help to facilitate tacit knowledge sharing through *socialization*. In the studied cases, we only observed *large-scale* teams practicing these techniques locally, to create shared knowledge. Later, the theme of the workshops/seminars was shared among remote team members through repositories.

6) Community of practice: To succeed in agile projects, learning is an important asset for agile teams. Agile teams practice two modes of learning: *peer learning* and *community learning*. In *peer learning*, team members start learning through interacting and collaborating with team members. *Community learning* is accessing and conceiving information that is available in knowledge archives or in discussion forums. We found community of practice within different projects, where it performed to share knowledge creation among local and remote team members.

We also found that to create shared knowledge, teams perform *technical presentations*. But these activities are only performed in the local site and later slides or documents are shared among remote team members. Technical forums are also in practice to perform shared knowledge creation between local and remote team members.

B. Knowledge Sharing: Locally and Globally

Knowledge exchange is always challenging in distributed agile teams due to a lack of face-to-face interaction among team members. Practitioners and researchers are trying to mitigate these challenges by initiating different kinds of techniques and tools. From the studied cases we observed that practitioners maintain different types of tools and techniques to share knowledge among globally distributed teams. Based on the findings, these knowledge sharing techniques are listed in Table III.

All studied projects are concerned with using repositories to share knowledge between local and remote team members. Most of the task and product related knowledge is kept in the repositories, which are easy to access by the remote team members. Different teams also depend on daily scrum, weekly sprints status, discussion forums, online conferences and common chat rooms to share knowledge between local and remote team members. Electronic boards are helpful for sharing knowledge across remote teams. Only one case was found where knowledge is shared between both collocated and distributed teams through electronic boards.

1) Repositories: To share knowledge among distributed sites, local teams used different types of repositories like *Wiki, JIRA, Redmine, Confluence and GitHub etc*. These types of repos- itories provide efficient mechanisms to access codified knowledge. From the gathered data it is evident that (see in Table III) practitioners are most dependent on repositories to share knowledge among both local and distributed team members.

Wiki, according to Ulrike Cress [11], provides new opportunities to learn and use collaborative knowledge building and sharing, through social interaction and individual learning. In different cases we found that *wikis* are helpful for starting new threads and discussing issues with other team members. It is also helpful for new team members as it (the *wiki*) provides detailed information about features, documents and so forth.

Project and Issue tracking: Nowadays, almost all medium and large distributed or dispersed agile teams are using *JIRA/Redmine* to track issues, bugs, tasks, deadlines, codes and hours. As collaboration and content sharing tools practitioners used *Confluence* to share docs, files, ideas, specifications, diagrams and mockups. During the interview one project leader said,

...Most of the time we share tacit knowledge between both local and global teams. After that, the information is converted through Redmine to make it explicit... **Project Leader - Alpha project**.

It is also evident that, in one case we found local teams upload *Scrum* board pictures, slides and workshop information in the repositories, which is codified and easy to access by the remote team members.

2) Pair programming: Pair programming plays an important role in creating and sharing developers knowledge in both locally and globally distributed project. In pair programming, two developers work together at one computer with a common goal [38]. In the studied projects, we found teams are using pair programming techniques to share knowledge among remote team members. Team members use Skype to share screens among remote team members. Along with that we also found that teams use *TeamViewer* and *VPN* services to share the same computer screen with remote team members, in order to perform pair programming.

3) Daily Scrum/weekly sprints status/online conferences: Scrum meetings are a source for sharing project progress information among team members. Usually a Scrum standup meeting is held in collocation. From the gathered data we found that distributed teams practice Scrum standup meetings with Internet Relay Chat (IRC), Skype or other group chatting software. Through daily Scrum/weekly sprints status/online conferences local teams share knowledge with distributed team members. In one case (ζ), we found that due to less dependency, the development team does not need to perform Scrum meetings/weekly sprint status. But team (ζ) maintain online conferences in order to share knowledge among remote team

TABLE III: Knowledge sharing techniques among different sites

Dispersed teams- **α, β, δ***; Distributed teams-* **γ, ε, ζ***; Hybrid team-* **η**

members (if needed). However, apart from Beta(β) project, other projects explicitly maintain *online conferences* globally for knowledge sharing among distributed team members.

4) Common chat room: Common chat rooms are useful for exchanging knowledge among distributed teams. From the empirical findings we observed that for faster and quicker communication among distributed team members, *medium-* and *large-scale* teams maintain common chat rooms.

In one case, a software architect said that *...the Sprint management system handles all task related knowledge but for the domain related knowledge sharing we maintain a common chat room, which helps us to resolve specific problems within a short time* **- Software Architect, Delta project**

But, in another case we found that, it is not an efficient way to communicate among distributed teams due to language barriers, common understanding, technological factors and so forth. Frequently misunderstandings occur and things go wrong. To mitigate these types of problem, practitioners also suggested different types of mitigation techniques.

5) Technical forum: The idea behind a technical forum is *learning through sharing knowledge*. Technical forums are like communities of practice which create a network between technical team members. They are self-organizing groups that consist of individuals who share information, experience and technical skill on a specialized discipline [28]. Technical forums assist distributed teams in quick problem solving and reduce development time since team members do not get stuck on recurring issues. Building trust between team members in the distributed environment is challenging; so knowledge sharing through technical forums can build trust between developers. Technical forums help to create and share both local and distributed knowledge. We have found that large-scale team members practice *technical forum* techniques to share knowledge among remote team members.

6) Electronic board: The office boards hold a lot of knowledge which is difficult to share among distributed teams. The interviews revealed that practitioners are using electronic boards to share and access knowledge both locally and globally. Electronic boards hold the tasks list to perform , latest information and along with that necessary technical and business information are regularly updated in a wiki. Electronic boards help to decrease the communication overhead.

In one case an interviewee said *...I am not satisfied with the current tools; Its tough to describe designs to new team members. Visual aids are helpful during discussions* **- Project Manager, Beta project.**

7) Rotation/Visits: The primary intention of team member rotation between different sites is knowledge sharing. Due to frequent face-to-face interaction with product owners, on-site team members get more business and domain related information than offshore team members [49]. A lack of face-to-face meetings and poor socialization also causes a lack of trust among distributed team members [30]. Rotation between on-site and distributed team members promotes the sharing of business and domain related knowledge across the teams. From the data gathered we found that, both *distributed* and *hybrid* teams visit remote sites and rotate team members to increase the trust and communication bandwidth between team members. But the studied *dispersed* teams never visit and rotate with remote team members.

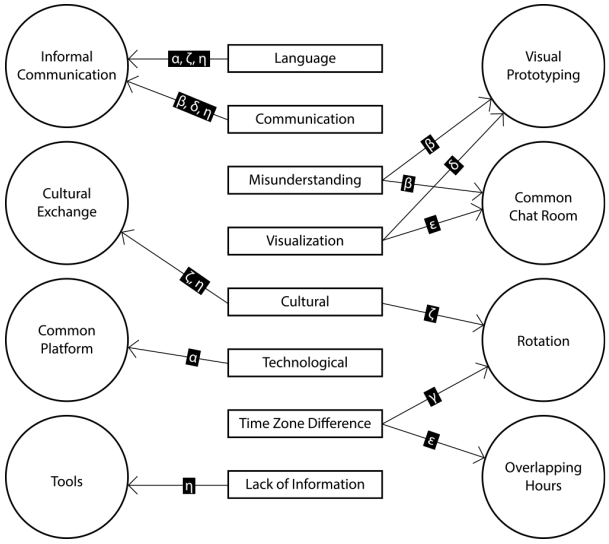
One of the distributed teams line managers said *Visits to remote sites are highly costly. So, we rotate team members and mostly, the duration of the rotation between team members is 3-6 months.* **- Line Manager, Zeta project**

We have also found that teams practice *version control, screen sharing and discussion forums* to maintain knowledge sharing among both local and remote team members.

C. Challenges faced by practitioners during knowledge sharing among distributed teams

In agile software development most of the knowledge is tacit, which resides in the human mind rather than documentation. This codified tacit knowledge is shared among between locally and globally distributed team members through tools. The knowledge sharing approach varies between team members due to experience levels. The types of problem this leads to are search availability and difficulty finding the right knowledge at the right time. We have also found that to share tacit knowledge between remote team members, teams maintain a *common chat room* and *online conference* (see in Table III). In one project

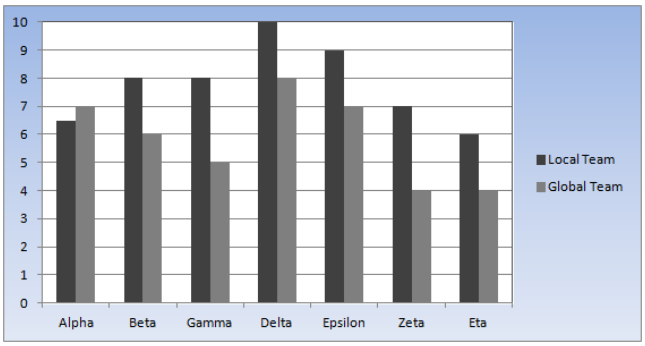
(β), we found that the team does not share tacit knowledge among dispersed team members. But, based on the situation, sometimes the team performs pair programming through screen sharing, to resolve problems. Challenges faced by the practitioners during knowledge sharing among distributed team members are shown in Figure 1. Mitigation techniques applied by practitioners are also shown in the same Figure 1.



Dispersed teams- **α, β, δ***; Distributed teams-* **γ, ε, ζ***; Hybrid team-* **η**

Fig. 1: Knowledge sharing challenges and mitigation techniques

In Figure 1, arrows indicate the mitigation techniques applied by practitioners for a specific challenge. Based on the severity of *communication*, *language* and *cultural* challenges frequently faced by practitioners during knowledge sharing in distributed agile projects (see Figure 1). Distanced teams are also struggling with *misunderstanding* and *visualization* challenges.



Not satisfied (0-3), Satisfied (4-6) and Highly satisfied (7-10)
Dispersed teams- **α, β, δ***; Distributed teams-* **γ, ε, ζ***; Hybrid team-* **η**

Fig. 2: Success of knowledge sharing

Though teams face different types of challenges during knowledge sharing among distributed team members, we identified successful knowledge sharing in both locally and globally distributed agile teams from the seven cases studied. Based on the seven cases the above graph (see Figure 2) has been drawn. An *ordinal scale* is used to map the interviewee satisfaction with their KM activities in both local and global teams. Figure 2 depicts that in project (*Alpha*) interviewees think knowledge sharing activities are more successful among distributed team members than in the local team, due to language barriers (*non-native English speaker*) between local team members. It is also evident from the gathered data that *dispersed* feature teams are more successful in their knowledge sharing among distributed team members than *distributed* and *hybrid* teams.

VI. Discussion

A. Codification of Knowledge

According to Polanyi [39], *Individuals know more than they can say*. Polanyi classified human knowledge into two categories. *Tacit knowledge*, which is very difficult to describe or express: this type of knowledge is transferred through demonstration. Tacit knowledge has an important cognitive dimension which consists of mental models, beliefs and perspectives [3,34,35]. So it cannot be easily characterized by clear expressive language. *Explicit knowledge*, is easily written down and codified. It is easily possible to characterize explicit knowledge in textual or symbolic forms. This kind of knowledge resides in textbooks, memos and technical documents. Codification of knowledge is the conversion of tacit knowledge into explicit knowledge in a written, verbal or visual format. The extraction process of tacit knowledge into explicit is called *externalization*. Tacit knowledge cannot be interpreted fully even by an expert [1]. This type of knowledge is more deeply placed in action and is hard to express in words [22]. Nelson *et al.* [31] conclude that it is impossible to describe all the necessary aspects of organizational tacit knowledge for successful performance. In organizations, most of the tacit knowledge is work related, which is learned informally as the team works [51]. Codification extract tacit knowledge into explicit ; it is a challenging task, so an expert needs to understand the essence of the tacit knowledge in order to increase the degree of explicitness of knowledge. Surprisingly, we found from our results that all studied cases are concerned about knowledge codification. To codify tacit knowledge, teams are using Wiki, JIRA, Confluence etc. In local sites, technical presentations and discussion forums are also taken into account as knowledge codification strategies. Later, teams share codified knowledge among remote team members through repositories and that is helpful for the remote team members to reuse codified stored knowledge.

B. Knowledge Management Strategies in Practices

We found that knowledge management schools are in practice, according to the results in Table II and III. We used Earls [17] framework to select types of strategies,r schools or practices in the different projects that applied to managing

TABLE IV: Knowledge sharing strategies in practice

Projects	**Locally — Globally**

Zeta	+	+	+	+	+	+	+	+	+	-
Eta	+	+	+	+	+	+	+	+	+	+

[+] In practice, [-] Not in practice

knowledge locally and globally.

Based on the evidence from the different cases, we found that knowledge management schools were in use to manage knowledge both locally and globally. It is also evident that *systems*, *cartographic*, *engineering*, *organizational* and *spatial* schools are practiced in distributed agile projects to manage knowledge both locally and globally (see Table IV). Both *commercial* and *strategic* schools are focused on a business perspective (*patent*, *copyright*, *trademark*, *know-how* and *intellectual assets* [17]) and there is also no evidence found within gathered data sets that indicates those schools (*commercial* and *strategic*) are in practice. For that reason those schools are not taken into account in this research.

1) Systems school: This schools philosophy is to codifying knowledge with the help of technology. Organizations use repositories for storing and sharing knowledge. These knowledge repositories usually store domain specific information. The codification of knowledge can be compared with the *externalization* of knowledge by Nonaka [15]. It is easy to realize the benefits of knowledge bases and the systems school is the most researched school [4]. These knowledge bases become richer and more useful over time. As shown in Table IV, the *systems* school is in practice in all cases to manage knowledge locally and globally. Though search functions are a difficult issue in the systems school, practitioners depend on it because across distances this school effectively perform knowledge sharing activities using repositories.

2) Cartographic school: This school focuses on the mapping of organizational knowledge and aims to build knowledge directories by disclosing who knows what [17]. This is sometimes achieved by yellow-pages, which ensure the accessibility to others of a knowledgeable person within the organization for knowledge exchange. Though knowledge maps and directories on company intranets might be helpful for distributed team members to have an idea of who knows what, in distributed projects it seems challenging to put into practice. This is because it needs joint effort and commitment from both local and remote team members. In collocation, it seems easier to find a knowledgeable or experienced person because they knew each other well. In globally distributed projects who knows what and what is where are important issues for effective knowledge exchange. We have found that the *cartographic* school is practiced by different projects (δ,ζ,η) to exchange knowledge both locally and globally. This strategy is also practiced in different companies by introducing the idea of knowledge brokers: this helps other developers to consult with knowledgeable and experienced software engineers [46]. Knowledge brokers are knowledgeable and experienced software engineers who will communicate with other developers, provide them with information or listen to them.

3) Engineering school: This school of knowledge management focuses on business process re-engineering [4] and knowledge flows in organizations. This school has a more empirical attention than other schools, which focuses on managing knowledge about software development processes and improvement of software development processes. More specifically, this school focuses on formal routines, mapping of knowledge flows, project reviews, and social interactions. Software process improvements like CMMI can be regarded as a stimulus for knowledge flow throughout the organization. This school supports explicit knowledge sharing and in distributed projects, temporal distance does not affect this school. In globally distributed projects coordination is one the major challenges and the engineering school focuses on the coordination process and aims to ensure knowledge flows within the organization though shared databases. The processes of using tools *(i.e the installation manual for GitHub or SVN with eclipse)*, quality code writing techniques, testing and reviews are all documented in repositories to share among distributed teams. Practice of this school is found in the studied projects.

4) Organizational school: The philosophy of the *organizational* school is to create a network by collaborating between communities to share or pool knowledge. This school of knowledge management focuses on organizational structure. These structures are often referred as knowledge communities [4]. This is a networking approach for people to communicate and share knowledge. Based on the seven cases, this school is in practice for knowledge sharing both locally and globally.

5) Spatial school: The intention of the spatial school is to encourage socialization (tacit to tacit knowledge) as a means of knowledge exchange [25]. The spatial school is more

concerned with the development and utilization of the social capital which develops from people interactions, formal or informal, repeatedly over time [17]. The spatial school focuses on designing office space to promote knowledge sharing [15]. Organizations use different office settings to promote communication between people. For example, in the case of software organizations agile methodologies may use boards, charts or other tools to create spatial knowledge. Sometimes, even common spaces like conference rooms, dining rooms or places for refreshment and activities are also places where knowledge can be shared. Five cases were found that practice the *spatial* school to manage knowledge locally and only one case (*hybrid team*,η) was found that to practice the *spatial* school to manage knowledge both locally and globally. The *hybrid team* uses visual boards to communicate among collocated and distributed team members.

VII. Conclusion and Future Work

The aim of this research was to discover the knowledge sharing techniques, strategies applied and challenges faced by the practitioners in distributed agile projects.

To perform knowledge management activities in a distributed agile project, different teams practice different types of approaches. But, in general, we found that different types of knowledge creation and sharing techniques are applied by practitioners to perform knowledge management activities in distributed agile projects. Along with that, we also found different types of strategies practiced by the team members to manage knowledge both locally and globally.

For the first research question, we found that:

- To perform shared knowledge creation in a distributed agile project, team members practice: pair programming, customer collaboration, Scrum/Kanban boards, innovation boards, workshops/seminars, learning, technical presentation and technical discussion techniques.
- In globally distributed agile projects, teams practice different types of strategies to perform shared knowledge creation such as: *systems, engineering, organizational and cartographic* schools. We observed that the spatial school is in practice for local knowledge creation but when the project is distributed, this school is used less due to expensive tools.

For the second research question, we found that:

- To share knowledge among distributed sites, team members practice different type of techniques: repositories, pair programming, version control, screen sharing, daily scrums, weekly sprint status, common chat rooms, technical forums, discussion forums, electronic boards, online conferences, rotations/visits etc.
- *Systems*, *engineering* and *organizational* school strategies are explicitly in practice to share knowledge among distributed team members. These strategies foster effective knowledge sharing activities for team members in distributed agile projects. In distributed development, who knows what and what is where need to be known by employees, for effective knowledge sharing: this is associated with the cartographic school. But, in distributed agile projects, this school has is used less due to social-cultural distances. The spatial school facilitates knowledge sharing by using office space but in distributed agile projects this strategy is not explicitly in practice to share knowledge among remote team members.

For the third research question, we found that:

- During knowledge sharing among distributed team members, practitioners faced different types of challenges, such as: language, communication, misunderstanding, visualization, cultural, technological, time zone difference and lack of information.
- To mitigate those challenges, practitioners also apply different types of mitigation techniques, such as: informal communication, cultural exchange, common platform, tools, visual prototyping, common chat rooms, rotation, and overlapping hours.

Through a series of semi-structured interviews from agile practitioners, we investigated knowledge sharing activities in distributed agile projects. Communication, coordination and collaboration are the keys to fostering knowledge sharing between team members in agile software development. However, we have seen knowledge sharing in distributed agile projects is challenging, due to factors such as communication difficulties, language barriers and cultural barriers. To mitigate those challenges and succeed in knowledge sharing within and across borders, practitioners adopt different types of techniques to manage knowledge both locally and globally. Along with these techniques, we have also noticed that, practitioners adopt different types of strategies to manage knowledge both locally and globally. Though systems, engineering and organizational schools are explicitly in practice, the spatial school has less concern with managing knowledge in distributed agile projects. With closer observation between software engineering and schools Bjørnson and Dingsøyr found that there is a heavy focus on the systems and engineering schools [4]. There are also limited number of studies focusing on the organizational school, but no studies in software engineering were found, that focus on the spatial aspect [4]. Agile software development is more related to *socialization*, which includes the spatial schools concepts of knowledge sharing strategies. There is a lot of knowledge residing in the office space and office space fosters knowledge sharing through spatial knowledge management strategy. In the future, it will be interesting to find the spatial school being practiced in distributed agile projects.

VIII. Acknowledgement

We are thankful to our dear supervisor Dr. Darja Šmite, Associate Professor and this paper also published as a Blekinge Institute of Technology's Master thesis, 2013.

***Abstract*—In the dynamic environment, organizations are required to build their competitive advantage not only on own resources, but also on resources commissioned from external providers, accessed through various forms of sourcing, including the sourcing of IT services. This paper presents some of the aspects of information security, in the context of the modern implementation of new IT sourcing methods. IT sourcing solutions are presented, as employed by modern companies, together with potential benefits offered. The main focus is put on the determination of the most important risks involved in information sharing in IT sourcing relations, as well as minimization and reduction of such risks, with particular attention to various cloud computing services on offer.**

***Index Terms*—management, IT sourcing models, cloud computing, information security**

I. Introduction

BUSINESSES are on the lookout for newer and more innovative ways to enhance competitiveness and get ahead of the growth curve. A new generation of advanced technologies – social, mobility, analytics and cloud – have taken the center-stage, promising to transform enterprises and help them do business better. Enterprises that embrace these technologies would be able to seamlessly redesign their business models, strategy, operations and processes to meet the new customer demands.

The business models employed by modern enterprises are increasingly more involved in problems related to the security and protection of information, data, and knowledge, particularly of the classified and undisclosed type.

In a sense, these business models can be viewed as based on knowledge and security. The classified knowledge (technical, technological, design, logistic, etc.) is one of the core competences of large network corporations, such as Renault, Mazda, Opel, Toyota, Deutsche Bank, and others.

The network structure of large corporations, while designed to provide competitive advantage in two areas, namely:

- outsourcing of ancillary functions, support functions, and even primary functions (as in the case of Opel assembly factory in Gliwice),
- centralized investment in R+D and new technologies (patents, inventions, improvements, copyrights),

may also increase the risk of uncontrolled 'leakage' of key undisclosed knowledge (technical, design, technological, financial, trade, etc.) to market competitors. This is a direct result of the increased access to core corporate knowledge offered to cooperating entities.

The most important aspect of this process is the natural outflow of hot knowledge, resulting from transmigration of knowledge agents (managers and long-term employees with unique competences and experience), in both the networked and non-networked systems.

II. New Global Sourcing Models Of Business

In the modern, 'flat' model of economy, networked enterprises build their competitive advantage through careful selection of sourcing agents. One of the most important criteria for such selection is the perceived level of security with respect to uncontrolled and undesired outflow of data, information, and knowledge from organizations to other entities outside their network structure.

Sadly, this particular criterion is rarely perceived as mission-critical. Companies tend to prioritize the aspect of compatibility between core competences of the potential sourcing partner with key competences and resources of the mother company. The increased asymmetry of key competences between sourcing partners may result in the following trends (Fig. 1):

- departure (short-term contracts, rapid capturing of the partner's know-how),
- unification (strengthening the cooperation, balancing the symmetry of undisclosed knowledge, participation in future projects).

New needs of enterprises result in the emergence of new types of global sourcing models, where sourcing can be defined "as the act through which work is contracted or delegated to an external or internal entity that could be physically located anywhere" ([1], p. 2]. Sourcing can also be defined as a comprehensive organizational strategy for distribution of business processes and other functional areas of the enterprise among cooperating partners. For the purpose of this study, sourcing is defined as a notion of superior level to the notions of outsourcing and insourcing ([2], p.17). The main

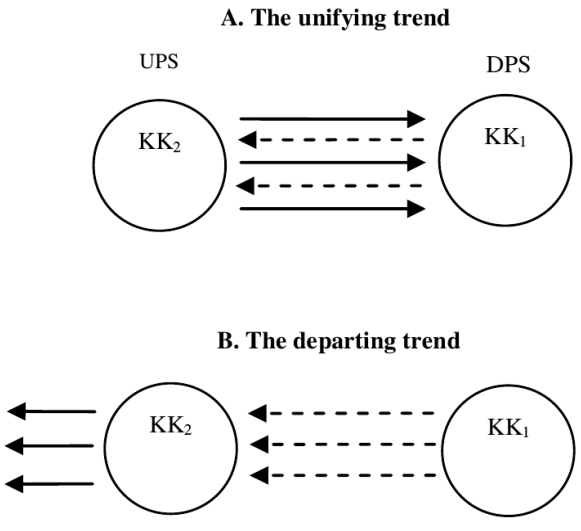

Fig 1. Trends in sourcing cooperation
Source: own research.

differences between sourcing models involve determination of the following factors:

- is the sourced function delegated to a dependent entity or an independent external supplier (or both), and
- is the sourced function performed on-site or off-site, is it performed onshore, nearshore (in a neighboring country) or offshore (in a remote location) ([1], p. 25).

A business model of IT sourcing may comprise the following types/models of sourcing cooperation/relation (own research, based on: [7], pp. 6-16; [1], pp. 26-42; [5], p. 1300; [6]]: facility management, selective outsourcing, tactical outsourcing, transformational outsourcing, transitional outsourcing, Business Process Outsourcing, joint ventures, benefit-based relationships, insourcing (staff augmentation), offshore outsourcing (foreign supplier), nearshore outsourcing (foreign supplier), onshore outsourcing (domestic supplier, "rural sourcing"), cosourcing, shared services, captive models and models based on Internet: cloud computing, software as a service, crowdsourcing and microsourcing. Figure 2 presents a graphic representation of a general model of IT sourcing.

A large number of modern organizations operate simultaneously in two business areas: the real and the virtual. The greater the availability of resources, the greater the potential impact. The more we expand the range of the network (new locations where functions/processes/services of an organization are implemented; greater number of sourcing providers; new areas of service delivery such as cloud computing), the greater the potential opportunities, but also the greater is the risk involved.

A decision to implement a particular sourcing model may be influences by the following factors:

Factors supporting the trends towards IT sourcing (own research, based [7], p.4):

- the global skills shortage,
- a more mobile workforce,
- the mounting cost of in-house developed software,
- the need to move fast, rapidly adopting new technologies and speeding up system development,
- the explosion of Internet technologies and services requiring a wide range of new skills and investments.

For the purpose of this study, the authors focus on the presentation and analysis of one of the most popular Web-based sourcing models – the cloud computing – without going into detailed analysis of other IT sourcing models in use.

Cloud computing allows users to access technology-enabled services on the Web, without having to know or understand the technology infrastructure that supports them. Nor do they have much control over it. It is an innovative new way to boost capacity and add capabilities in computing without spending money on new infrastructure, training new personnel or licensing software.

There are four basic types of clouds: private clouds (operated solely for the use of a single organization), community clouds (operated for a specific group that shares infrastructure), public clouds (which use cloud infrastructure available over a public network) and hybrid clouds (which combine the infrastructure of two or more clouds - public, community, and private).

The increased risk of cloud computing projects has to do with opening up the organization to a whole new space, which is not yet completely examined and "protected". The range of potential risk scenarios is impossible to predict at this moment, since they have yet to be observed in organizational practice. At the same time, the output and the use of the "new space-clouds" can increase the potential added value of using this type of sourcing, compared to more classical forms, such as the generic outsourcing and offshoring models.

New forms of contracting, and – consequently – new resource acquisition methods are required to help modern organizations survive in this age of innovation and strong competition. However, it should be noted that those new solutions, as any new ideas, come with new risks. Some of those risks will be discussed in the following chapters.

III. Information and knowledge security in the IT sourcing models

Information security is one of the key factors to be taken into account in the context of sourcing decisions, particularly those which involve cooperation with external partners. Potential contractors may operate from remote locations, often

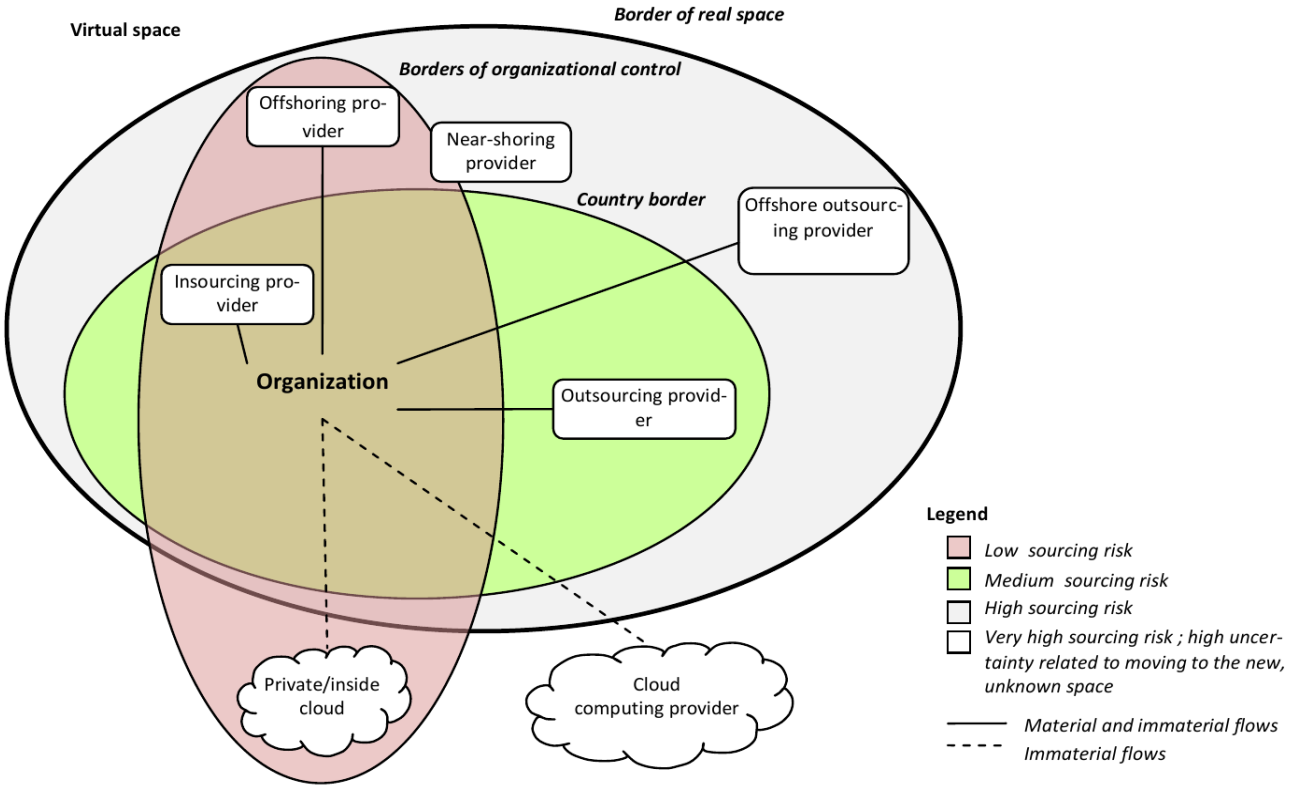

Fig. 2 A general model of IT sourcing
Source: Sobińska 2014

in diverse cultural, political, social, legal, and other settings. The problem of information security is also reported as one of the main concerns for potential cloud computing users and clients.

According to K. Liderman, information security comprises all forms (also verbal) associated with the exchange, storage, and processing of information. It represents the risks involved in information resource loss, as well as misinformation resulting from poor quality of information provided. It must be noted that Liderman makes a clear distinction between information security and 'security of information'. The latter, a subset of information security, is defined as "*justified trust (e.g. based on risk analysis and the adopted risk management procedures) that the organization will not face potential losses as a result of undesired (accidental or intentional) use of information stored, processed, and transmitted within the system, be it information disclosure, modification, removal, or rendering it unfit for processing purposes"* ([4], p. 22). The problem of information security, despite increased publicity in professional literature and media, is still trivialized by managers of many companies. And, while the managerial personnel declare their knowledge of risks involved in this area (as reported in many studies, see: ([11], p.19), in practice they tend to minimize their efforts with respect to information security. The main reasons for negligence are: the financial outlay, and the lack of competences. For instance, not many companies are able to perceive the risk associated with the fact that company information is no longer contained within the 'company perimeter'. Nowadays, information flows freely, and the risk of disclosure is far more pronounced. The lack of informed approach to the risk management process is a fast lane to disaster, since potential incidents may gravely affect the security or company development. *Modern organizations* face the serious challenge of implementing effective security strategies, with proper risk management as one of the main elements of the system [5].

In this context, outsourcing may be seen as a chance to improve information security (and the security of IT systems) by transferring the IT security responsibilities to an external provider with proper specialist knowledge and IT technologies. On the other hand, it may just as well add to the risk, by opening up sensitive company resources to external agents. Those resources may (unwillingly or intentionally) be used to detrimental effects.

Since cloud computing has become a hot topic in IT management, it may be useful to address some of the security issues involved in this form of cooperation. In terms of information security, the main difference between traditional IT structures and cloud solutions is the fact that cloud infrastructure is interspersed and shared among many users. In

addition, certain features of cloud computing, such as the need for continuous optimization, improved access, balancing the computing load across the nodes, etc., bring additional complications to the risk management process.

At present, three main categories of cloud computing solutions can be distinguished, namely: SaaS - Software as a Service, PaaS - Platform as a Service, and IaaS - Infrastructure as a Service. Factors of potential risk to information security include the following ([12], p. 230):

- IT system's resistance to intrusive attacks from outside,
- Resistance to internal attacks (with users able to access and capture information belonging to other users, by exploiting security holes and other vulnerabilities of the system),
- The security verification and encryption methods in use (whether the access codes and passwords are stored in secure, encrypted form, or stored and transmitted in open text).

Each of the above models of cloud computing (SaaS, PaaS, IaaS) employs a specific set of information security solutions ([12], pp.232-233):

- In the SaaS model, users rely on service provider in all matters concerning information security. The provider is responsible for restricting access to sensitive information, as well as supplying proper security measures to prevent intrusion or breakdown. The provider is also responsible for all matters concerning access verification and data encryption. However, the user is rarely able to examine the details of the security measures taken, to make sure that they are up to the desired standard of service.
- In the PaaS model, the service provider may choose to grant the software provider some control over the system security (for instance, the software provider may take on the responsibility of providing their own access verification and encryption systems), but any security issues beyond the application level, such as the security of host machines or network, come under the administration of the service provider. The provider may choose to pass on to the user selected details on the security measures in use.
- In the IaaS model, the software producer has a great deal of control over security mechanisms, since the cloud applications are run on virtual machines, independent and separated from virtual machines used by other users. However, applications in this model take longer to develop, and are decidedly more costly.

The majority of cloud computing service providers offer data backup solutions. This aspect is clearly important from the user's viewpoint, but it must be noted that data backup is not a 100% solution for all security concerns. The SaaS model, in particular, seems the most risky solution in the context of information security. In this model, both the software code and the data being processed are stored remotely (i.e. outside the subscriber's real machine). Consequently, the user has no access to computing operations, and is in no way able to modify it. SaaS offers the potential for server operator to modify the computing software or data processing procedures. Users must upload their data on the server for computing. The result is the spyware effect: the server operator receives user data freely and effortlessly, due to the character of the service rendered, and this gives him the unfair advantage (or even power) over the user. With the IaaS model, on the other hand, it is advisable to refrain from implementing needless functions on virtual machines, as well as making sure that all virtual machine images communicate over encrypted channels, so as to eliminate the risk of data capture on the network infrastructure level.

According to A. Mateos and J. Rosenberg, the security of the cloud computing environment is comparable to that of most internally managed systems, because:

- Most of the potential (and known) risk problems can be eliminated by employing the existing technologies, such as data encryption and virtual local area networks (VLAN), as well as standard tools, such as firewalls and packet filtering (encrypted data stored on cloud may in fact be safer than non-encrypted data used locally);
- Cloud computing solutions may be supplemented by additional controlling and auditing functionality, layered outside the environment of the host. Such a solution offers the user greater security of cloud computing, far better than any locally implemented solution (since the latter require considerable outlay and design expertise);
- Many countries enforce security measures on SaaS service providers, requiring them to restrict transmission of data and other copyright content to the contractor's country of origin ([13], p. 104)

As aptly put by J. Viega, one of the fundamental benefits of a cloud solution is the fact that those structures are fairly unrewarding for willful intruders, since the code – i.e. the most vulnerable element that can be tested for security holes and exploited – is stored on server side, instead of being sent to the client browser ([12], p.230). Data centralization in cloud structures, as opposed to decentralized distribution of data within the company network, allows for vast reduction of leak risk, since users are less inclined to store sensitive resources on their real machines. Furthermore, the access to a centralized resource storage and actual data use can be monitored more closely.

The concern for security of information exchanged in the course of company relations with external service providers, although well-founded, must be examined against any potential benefits offered by this particular type of business model. And the actual informational risk may be largely minimized by employing proper principles of management with respect to relations with external providers – this applies also to knowledge management.

IV. Ways to Reduce the Risk of Knowledge/Information Loss In It Sourcing Models

K. Liderman believes that information security can be enhanced by employing proper documentation of the security

system in use. This task serves the following purposes ([4], p. 120):

- to ensure proper level of protection with respect to information and to those elements of the system which are directly involved in data processing and storing;
- to track (and control) any changes introduced to the system;
- to satisfy the legal requirements that oblige companies to keep and produce on demand certain documents, such as 'security policy guidelines', 'safety instructions and procedures', etc. (the wording used in actual legal standards may vary).

The use of formal documents (information security policies or guidelines) may attest to the company's intent on keeping proper security standards in data protection. It may also help the organization build and maintain trust relations with customers and/or business partners. Lastly, it may also be used to stimulate the involvement of employees in all tasks and procedures related to data/information security.

With respect to basic technical security measures employed for the purpose of maintaining the informational stability of IT and telecommunication systems, Liderman provides the following classification of elements ([4], p. 158-159):

- data backup procedures;
- provision of independent backup power solutions;
- provision of backup solutions for data processing (or even for running the company business, if necessary), in a reasonably remote location from company HQs;
- doubling the key infrastructure: servers, routers, etc., to serve as backup;
- doubling the information packets;
- providing alternative transmission routes (doubling keys and operators);
- use of verified software offering suitable protection of transmitted and stored data (proper data transmission protocols, software-assisted verification of data integrity based on cryptographic methods, etc.);
- protecting the telecommunication and IT systems from unauthorized access – both physical (access to hardware and technical infrastructure) and logical (access to information resources);
- protection from intentional or accidental exposure to hazards (fire, flooding, strong electromagnetic impulses, etc.).

The most advanced security measures used in cloud computing data centers include (own research, based on [13], pp. 104-114):

- physical security – modern centers are often located in unassuming locations and buildings (often in residential areas), with good security and skillful use of barriers (also natural). Security services cover both the immediate area and the access to actual data facilities, using modern CCTV solutions, intruder alert systems, etc. Servers are kept in fortified bunkers, protected by 5-level biometric scanners (hand geometry recognition), round-the-clock patrols and traps (caging intruders in case of unauthorized entry). Physical security is solely in the hands of the cloud computing service provider, and the above measures are required for certification purposes (the SAS 70 Statement on Auditing Standards No. 70).
- access control in public clouds – these apply to verification of users accessing the cloud. The initial registration of a user is a multi-layered procedure, consisting of several overlapping secret questions and answers (e.g. the user's credit card details). Other levels of security verification may include invoice address, call-back verification over the phone (the *out of band* mechanism, based on employing a different channel of communication), login and authorization (the password should be strong), access keys (a good practice here is to provide regular key substitution service), X.509 certificates, paired keys (the latter being the most important element of user verification when working in cloud environment instances)
- network security and protection of data in large clouds. Passing the task on to the experts employed by the cloud service provider seems the best approach, since it may be reasonably assumed that the provider will be faster to respond to a potential intrusion attempt, and that the response will be adequate to the risk at hand. System security in public cloud models is verified at many levels: at the level of the host's operating system, at the level of the virtual machine's operating environment or the host system, at the stateful firewall, and at the level of signed API calls (the cloud application programming interface), with each subsequent level supplementing the capacities of its immediate precursor.
- The role and the responsibilities of the application owner. Cloud users themselves are responsible for security at the level of their host machine accessing the virtual instance. Since the users have full admin control over their accounts, services, and applications, they are responsible for basic security measures, such as the use of strong passwords, safe storage of passwords and private keys, as well as regular key substitution. Data stored in clouds should also be sufficiently protected – for example, by encrypting the resources prior to uploading them to the cloud, to make sure they cannot be read or modified during transmission and storage.

Modern organizations – both the IT customers and IT service providers – should strive to identify and recognize all processes, services and resources considered mission-critical or of key importance from the information security viewpoint. They should also perform a reliable analysis of information risks, and take suitable measures and procedures to minimize the risk over the course of the cooperation with external partners. Thus, irrespective of the security solutions on offer by the service provider, they should employ their own, independent backup procedures with respect to sensitive data – such backup may be of great value if the company de-

cides to withdraw from the contract (in such cases, the provider may refuse access to data stored in their system) or if the provider goes bankrupt.

Companies unwilling to put their trust in external providers, despite numerous obvious benefits offered by cloud computing solutions, can always reach for other models, such as those based on insourcing or the private cloud model.

The insourcing solution is based on internal management of IT services. If need arises, the company may purchase the lacking skills on the market for a limited time, for example by contracting additional personnel for the task. In this model, the organization retains its internal IT personnel and infrastructure, trusting in its ability to free the latent potential of its employees for the purpose of improving its IT services and making them more effective. From the viewpoint of the insourcing model, the internal IT department is formally perceived as a provider of services.

In the case of private cloud solutions, the decision to adopt this particular business model is made on the basis of four fundamental factors: security, accessibility, the size of user population, and the effect of scale (Table 1).

TABLE 1. PREMISES FOR ADOPTING A PRIVATE CLOUD SOLUTION

Factor	Description
Security	Applications require direct control and data protection, for confidentiality and safety reasons (for instance, governmental agencies use dedicated applications for processing of confidential and classified data – it is essential that they be kept from unauthorized access).
Accessibility	Applications require access to a predefined set of processing resources, and this type of access cannot be securely provided in a shared environment.
User population	The organization caters for many users, often in geographically remote locations, and they all require unrestricted access to computational processing resources (private clouds are used, for example, in large telecommunication corporation).
The effects of scale	Data centers and infrastructural resources are readily available, or can be expanded at minimum cost.

Source: own research based on ([13], p.116).

Private clouds offer better control and assurance that the resources will not be used by other customers, since they are not shared in public space. However, as any other solution, the private cloud model has its own limitations, such as (own research, based on [13], pp.119-120):

- limited scale of operation, compared to public clouds,
- the problem of adopting old applications to the cloud structure requirements without redesigning the very architecture of the system,
- limited potential for optimization and innovation of the methods and elements of the system,
- larger operational outlay compared to the public cloud solutions.

Even if the organization does not anticipate any integration with external providers when choosing their outsourcing solution, it may be advisable to keep an open stance in this respect, so that it may smoothly transition to another model if need arises, and not be too restricted with their choice of a potential provider.

V. CONCLUSIONS

New technologies, and the resulting new models and instruments for business, generate new and previously unforeseen risks and threats. Changes in company operating environment, brought about by globalization, increased competition, automation and – most of all – computerization, informatization and virtualization – require a new approach to information security in modern organizations.

As discussed in this paper, new IT sourcing models, especially cloud computing, offer some opportunities, but even if organizations themselves feel "cloud ready," they must anticipate the capacity requirements in the cloud. They must also be aware of new risks, and manage their IT security in accordance with the new operating conditions. The most important risk areas with respect to modern IT sourcing solutions (similarly to those observed in classical outsourcing models) include: the loss of control over the IT environment, inadequate protection of data, overdependence on external suppliers, the loss of potential to switch back to previous (self-contained) IT services, etc. A decision to adopt a particular IT sourcing solution should be based on such factors as: the size of the organization, the scale of operation, risk propensity, the adopted information security policy, the personnel strategy, and the budget.

It seems that migration to a cloud model is a good solution for companies intent on maximizing their profits (cloud computing services are decidedly more cost-effective) while at the same time retaining their high standards of security. What makes the cloud computing particularly attractive for business entities is the fact that they can pass most of the IT system security responsibilities on to the service provider. The providers of cloud computing services, being well aware of the fact that security concerns are the most important factor to restrain companies from choosing the cloud model, make huge investments in security solutions and infrastructure, as a way to emphasize their responsible approach to the security of their clients' resources. Companies which – for a number of reasons – are unable or unwilling to rely on external partners with their data, can reach for other sourcing models, such as the private cloud model or the insourcing model, to improve their IT effectiveness.

Joint Agent-oriented Workshops in Synergy

Joint Agent-oriented Workshops in Synergy is a coalition of agent-oriented workshops that come together to build upon synergies of interests and aim at bringing together researchers from the agent community for lively discussions and exchange of ideas. For the first time JAWS was organized during the 2011 FedCSIS Conference.

Workshops that constitute JAWS in 2014 are:

- MAS&M'2014 - International Workshop on Multi-Agent Systems and Simulation
- SEN-MAS'2014 - 3rd International Workshop on Smart Energy Networks & Multi-Agent Systems

8th International Workshop on Multi-Agent Systems and Simulation

Multi-agent systems (MASs) provide powerful models for representing both real-world systems and applications with an appropriate degree of complexity and dynamics. Several research and industrial experiences have already shown that the use of MASs offers advantages in a wide range of application domains (e.g. financial, economic, social, logistic, chemical, engineering). When MASs represent software applications to be effectively delivered, they need to be validated and evaluated before their deployment and execution, thus methodologies that support validation and evaluation through simulation of the MAS under development are highly required. In other emerging areas (e.g. ACE, ACF), MASs are designed for representing systems at different levels of complexity through the use of autonomous, goal-driven and interacting entities organized into societies which exhibit emergent properties The agent-based model of a system can then be executed to simulate the behavior of the complete system so that knowledge of the behaviors of the entities (micro-level) produce an understanding of the overall outcome at the system-level (macro-level). In both cases (MASs as software applications and MASs as models for the analysis of complex systems), simulation plays a crucial role that needs to be further investigated.

Topics

MAS&S'14 aims at providing a forum for discussing recent advances in Engineering Complex Systems by exploiting Agent-Based Modeling and Simulation. In particular, the areas of interest are the following (although this list should not be considered as exclusive):

- Agent-based simulation techniques and methodologies
- Discrete-event simulation of Multi-Agent Systems
- Simulation as validation tool for the development process of MAS
- Agent-oriented methodologies incorporating simulation tools
- MAS simulation driven by formal models
- MAS simulation toolkits and frameworks

***Abstract*— Agent-Based Simulation (ABS) environments are somewhat of a black box to many modelers in Social Simulation or Economics and their inner workings are often only understood by the computer scientists who developed them. We intend to shed some light into the inner workings of such systems. For this purpose we have developed our own simple ABS environment in C++ using hierarchical state machines. In this paper we provide insight into the design of our ABS environment and then test the performance of it by comparing it to that of an "off the shelf" commercial package. While some programming knowledge is required to understand the paper in all its depth we believe that non programming experts will also benefit from this paper as it provides an insight into the underlying mechanisms operating within an ABS using graphical representations and explanations that avoid heavy technical jargon.**

I. Introduction

An Agent-Based Simulation (ABS) environment is a system in which a population of agents (autonomous objects that behave in a predefined way) are created using a template in order to investigate the consequences of these agents acting together in an environment. The application area that we focus on in this paper is Social Simulation [1] and we use examples from computer games (which are related to Social Simulation but much easier to understand) to describe the agents we created during this investigation. The very simple experiments we conduct help us to understand situations which can otherwise be difficult to replicate. ABS experiments can sometimes yield unexpected results, for example an ABS constructed by Bonabeau [2] revealed that placing a column in front of an emergency exit can improve the flow of people out of the exit in an emergency situation, which is not the first idea which common sense would dictate.

This paper will describe and promote the understanding of the inner workings of an ABS environment that has been developed from the ground up. For the software engineering process (i.e. the development of the ABS environment) we take our ideas from the Multi-Agent Systems field. The models we implement during the validation phase are those typically created in the Agent-Based Modelling community (e.g. by Social Scientists). A good explanation about the relevant differences between both fields can be found in [3].

In order to explore how an ABS system works, and subsequently construct one, it is necessary to first explore the concepts that are involved in creating such a system. Simple ABS systems are generally implemented using finite state machines. Once the behaviour of agents gets more complex the introduction of hierarchical state machines becomes necessary to avoid the over-complication of finite state machines, leading to state machines that can be notoriously difficult to fully understand. Object-oriented design principles will be used in the construction of our tool in order to promote its extensibility, allowing anyone to add features or extend classes where it will benefit them. The Unified Modelling Language (UML) is a graphical notation that is often employed in Software Engineering for conducting object oriented analysis and design. AgentUML is an extension of UML that is specifically used for the development of multi-agent systems [4], as for example mobile agents [5], [6]. However, in the field of Social Simulation it is still rarely used for developing agent-based simulation models that represent social processes [7]. In this paper we use the UML on the one hand to show the structure of the proposed ABS environment (in form of a class diagram) and we use statecharts on the other hand for the design of our agent based models (i.e. to represent the behaviour of our agents) as proposed by [8].

In order to provide the reader with the necessary understanding of all of the topics within this paper we first provide a short introduction to object-oriented methods, agent-based modelling and the concepts of state machines. After this we illustrate the design of the ABS system which we have implemented. Finally we focus on the validation of our system in order to demonstrate that its components adhere to the standards of an ABS system. During the validation process we also take a look at the efficiency of our system compared to an "off the shelf" commercial package in terms of memory usage and runtime.

II. Background

A. Object Oriented Methods

Object-orientation is an important concept for designing software in order to promote extendibility of existing systems. The object model encompasses the core principles of abstraction, encapsulation, modularity, and hierarchy [9].

978-83-60810-58-3/$25.00

It leads to reusable components, wherever possible, rather than the more bespoke solutions which procedural programming often offers. It also breaks programs down into understandable chunks, and by designing software with object-oriented methods in mind it can be more easily extended and fixed when problems arise.

In order to promote object oriented principles in our design we have taken a number of design patterns into consideration while designing our system. A design pattern is a standardized way of implementing a certain feature in a program [10] and makes it easier to reuse successful designs and architectures [11]. This will be discussed in more detail in Section III-A.

UML is a graphical notation commonly used in software engineering for the purpose of object oriented analysis and design. Through UML it is possible to visualise, specify, construct, and document software applications. It acts as a specification language in which we can precisely and unambiguously capture our design decision [12]. Besides the benefits for software design some of the diagrams (e.g. use case diagrams and state machine diagrams) seem to lend themselves particularly well to Agent-Based Modelling (ABM) [13]. Therefore we use the UML notation not only for designing our ABS environment but also for modelling the agents that we use within our system.

B. Agent-Based Modelling

In order to get a good picture of what an ABS environment is, we first need to define what the term agent means, including the principles on which an agent acts and behaves. In the eyes of software engineers agents are simply "objects with attitude" [14] in the sense of them being objects with some additional behaviour added, for instance, mobility, inference, etc. But there are a number of different conflicting views on what an agent is, depending on the situation and discipline for which it is being used [15]. However, often there is a point where the views start to overlap with each other. Castle and Crooks [16] discuss different points of view and merge them together to form a universal definition of an agent, which varying disciplines can agree with. Closely related to their definition we understand an agent to be an autonomous object with some memory, which is able to make individual decisions based on influences from its environment (e.g. messages received from other agents).

The agents which we intend to create have the ability to make decisions based on internal transition trigger rules which might be influenced by the environment they observe. These transition trigger rules which have been programmed into the state machine of the agent and most often fall into one of three categories: condition-based, time-based, or message-based [17]. Details about different transition types can be found in Section III-C.

An agent is often described as having some sort of memory, which comprises of the last state they were in or in the case of composite states, the last super or sub-state they were in. This is the concept of state history, and there are two types: Deep history and shallow history. Deep history goes through multiple levels of composite state, and will return to the last state within a state within a state etc. Shallow history will only return the last state to within a state.

The last major thing to consider with agents is a form of control. As mentioned previously, finite state machines are often used in the creation of agents, as a means to describe the behaviour of an agent, or in other words, a template for how they should act, with conditions specifying when a transition should be made. This leads us onto the topic of Finite State Machines (FSMs).

C. Finite State Machines

A Finite-State Machine (FSM) is conceived as an abstract machine that can be in one of a finite number of states. It can change from one state to another when initiated by a triggering event or condition; this is called a transition [18]. There are different types of FSMs that can be used in a variety of different situations. We distinguish in this paper specifically between deterministic and stochastic FSMs. While deterministic FSMs are based on mathematical formulas and can be formally proven, stochastic FSMs use stochastic rules for deciding about transitions and therefore the exact outcome cannot be predicted; however it may be estimated using models and theories. A turnstile is a good example of a simple deterministic FSM. It can either be locked or unlocked, and there are predefined conditions that determine which state the turnstile is in, and the transitions it can take from each state. Fig. 1 demonstrates this.

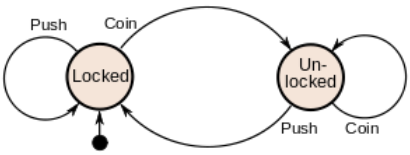

Fig. 1 A simple deterministic FSM (Source: [19])

More complex state machines are often used for economic models [20] and the transition function, which defines the transitions between states, is a lot more complex. For ABM we normally use stochastic FSMs. When behavioural models start to be implemented, FSMs can quickly become complex without some sort of organisation. In such cases Hierarchical State Machines (HSMs) are be introduced in order to keep such a model understandable. In HSMs states may contain other FSMs. This is often programmatically done with nested "if" statements.

D. Hierarchical State Machines

A HSM is similar to the composite state we see in UML state diagrams, and it provides the same functionality. One of the simplest ways to describe a HSM is by showing an example of one of its uses in Game AI design. Non Player Characters (NPCs) must have the ability to act in a complex way in order to give the player a challenge. If all of this behaviour were to be coded with a single if-then-else block, the code would quickly become hard both to manage, and for programmers to read and extend, specifically where the more recent generation of game AI is concerned. Fig. 2

shows the first level of a HSM of a typical NPC enemy in a typical first person shooter game.

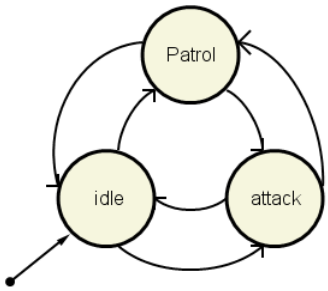

Fig. 2 Typical FSM for an NPC guard in a game

The HSM provides a structural concept for representing behaviour, which can otherwise be complex and resulting in somewhat of "Spaghetti" code when trying to split into logical if statements, in order to structure the functionality into logical categories of behaviour. Fig. 3 shows the hierarchical state "attack" from Fig. 2.

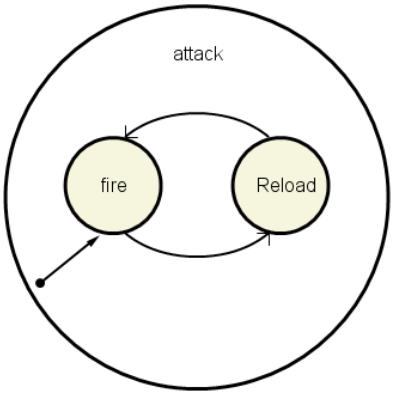

Fig. 3 Hierarchical attack state from NPC guard

Reference [21] talks about an object-oriented software tool that is used for creating the behaviour for NPCs in games by making use of HSMs. The system uses the logical components of a state machine, as well as making use of object-oriented principles such as inheritance and design patterns. This is similar to the work we are conducting, whereby state machines are being used as a template for the behaviour of entities. In our tool, more focus will be placed on the collaboration and communication of agents, unlike NPCs which often have no need to communicate or interact with each other.

E. UML State Machine Diagrams

The UML state machine diagram (also called statechart) is used to depict HSMs. Elements of this diagram are states, transitions, and composite states (which are equivalent to hierarchical states). Fig. 4 shows a UML state machine diagram of an office worker.

The office worker has three main states: "atHome", "elseWhere" and "atOffice". The "atOffice" state shows that while the worker may be at the office, there are still two sub-states that the worker can be in - "working" and "dozing". The statechart entry (the initial state the state machine is initialized into) is represented by the uppermost symbol in

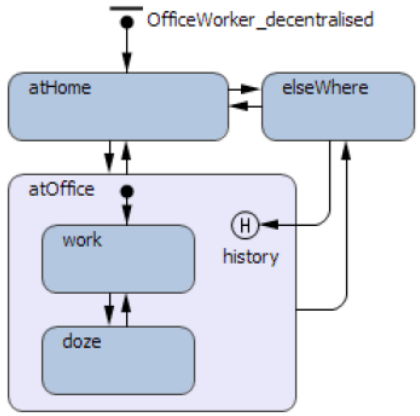

Fig. 4 UML diagram for an office worker (Source: [13])

the state-chart, the circle with an arrow with a line over it. The history state in this example can be described using the following scenario: If a worker was doing work, but then decided to take a break and go elsewhere, they would return to what they were doing before the break. The history state provides this capability. However, if the worker was dozing and then took a break, they would not start at the entry state of working when returning, but instead would return to the dozing state.

III. DESIGN

The design of the finite state machines that run the agents is based on the logical components of a state machine, as is the case in UML, where state machines have states, transitions, and composite states (state machines within states). The agent of this system contains the information relevant to the state machine, which includes the current state, last known state and history states for the super-state it was last in. This is a more memory-efficient way of storing the information, rather than having each agent assigned its own state machine, although the logic behind this is explained later.

A. Design Description

This section will describe the design of the system, including a simple class diagram of the main components of the agent. For the implementation we have decided to use C++ which in some cases has influenced our design decisions (e.g. multiple inheritance is not supported in Java). Fig. 5 shows the classes and initial relationships between each of the classes in our system.

The numbers in Fig. 5 represent the associations between objects, with * representing any number of. For example, the relationship between `Agent` and `StateMachine` is that there is one `StateMachine` to one `Agent`, and the relationship between `StateMachine` and `State` is that one `StateMachine` is composed of one or more `State` objects. The hollow arrowhead represents inheritance, showing that `CompositeState` inherits properties from both a `State` and a `StateMachine`. The `Attributes` of each object are the variables stored within the object, and the `Operations` are a list of methods which are used

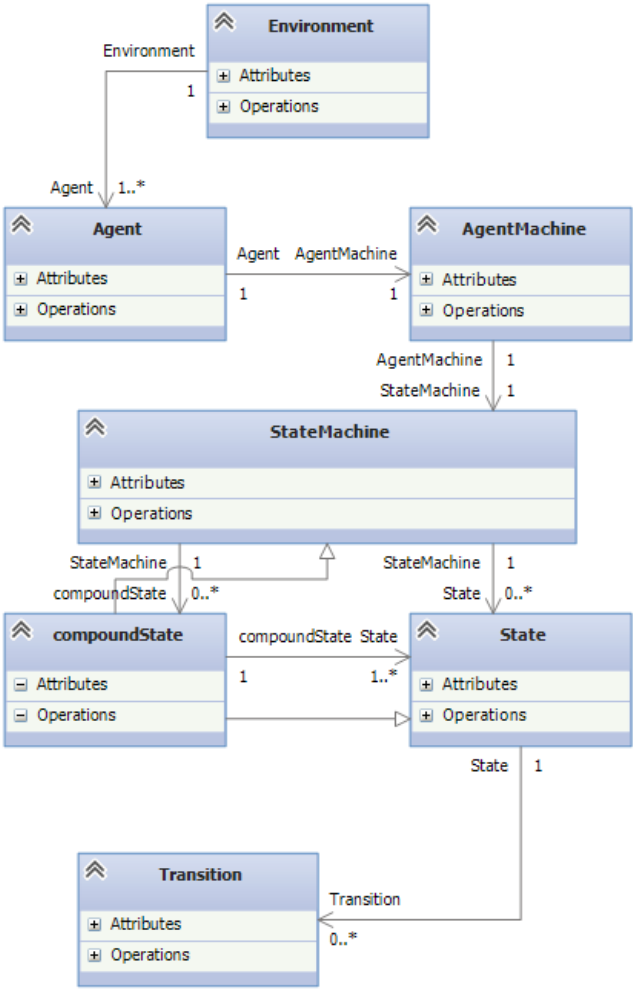

Fig. 5 UML class diagram for our ABS environment

within the object. As such, the object can be accessed as either a `State` or a `StateMachine`. The full class diagram including the methods that are used internally is available upon request.

The way the system is designed ensures object-oriented principles are taken into account so as any one of the objects in the system can be extended. The `CompositeState` class makes use of inheritance to reuse the code from `StateMachine` and `State`, since it exhibits the behaviours of both classes. A number of design patterns such as the Observer pattern, the State pattern, and the Model-View-Controller pattern have been taken into consideration during the design process. For example, the Observer pattern defines a one-to-many dependency between objects so that when one object changes state, all its dependents are notified and updated automatically [10]. In our case the `Agent` class is constructed using the ideas of the observer design pattern, allowing agents to constantly monitor transition conditions and allow them to enact the transitions themselves. This removes the need for the transition conditions to be explicitly checked.

In the following sub-sections we provide some more detailed design strategies for the key elements of our ABS environment. Here we look at the environment and agent design, the state machine design and explain the different time models we used.

B. Environment and Agent Design

The `Environment` in our ABS environment is a container for the agents, which manages their creation and deletion. This class also handles the sending of messages intended for all agents rather than singular agents. The agent class is designed to hold and handle the state machine for the instance of the agent, including telling the state machine to advance a time step in model time. There are two possible ways of controlling the state machine which links to an agent. The first (and simpler) way is to assign a state machine to each agent. The second (more complex) way, proposed by [21], is to use a simplified representation of a state machine without having to create a full machine for each agent; a way which can save a lot of memory. In the latter case the information for the current state of the agent is stored in the agent itself, whilst the state machine stores all of the logic for the states and transitions. The reason for storing information this way, rather than having a machine for each agent, is that even for simple state machines, a high number of objects will take up a lot of memory regardless of how small these objects are. Due to the object-oriented nature of this design, each state machine object requires the creation of every state and transition present in that state machine. The number of objects soon becomes very large, and becomes somewhat of a waste of memory, albeit at the expense of slower processing of state changes. However if a small number of agents were being created or the user were not concerned about memory usage, the gain in state change speed may be preferable.

Let us illustrate this principle with an example. Presume a state machine comprises of a total of 10 states and 10 transitions, and each object takes 1 byte of memory. In order to create 100,000 agents, 1 state machine + 10 states + 10 transitions + 1 agent object will be created for each agent. This totals 22 * 100,000 objects, so 2,200,000 objects in memory. If there is only 1 state machine acting as a template, there are 100,000 agent objects, plus 1 state machine, 10 states and 10 transitions, totalling 100,022 objects in memory. Of course, the larger the state machine is, the more effect it has on the size of the agent. Since we are trying to save memory here, the choice is only logical. We will provide evidence for the memory saving capabilities of this solution in Section IV when we validate our ABS environment.

C. State Machine Design

A state machine has logical components to it, which makes it easy to split up into the objects we talk about in object-oriented programming. The typical state machine is fairly simple and composed of a set of states, and a set of transitions. Composite states however, whilst being regarded as a state within the agent state machine, effectively contain their own state machine. This can be recursive, and there can be many composite states within another state. Fig. 6 shows

a UML diagram similar to the NPC in Fig. 2 but more complex.

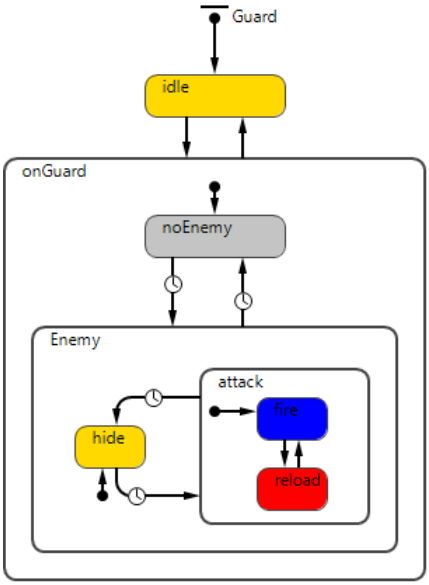

Fig. 6 UML version of a more complex NPC Guard

What we can see in Fig. 6 is that within each composite state there is an initial state pointer. This indicates that a composite state effectively contains a state machine, and so exhibits properties of both, a state machine and a normal state. Therefore it makes sense to reuse both, the state and state machine object, through use of multiple inheritance. Inheriting properties from multiple objects can be a complex problem in object-oriented programming [22]. However, in our case it seems an appropriate solution to the `CompositeState` problem.

Transitions within a state machine have certain conditions which cause the transition to trigger, and in the case of ABM the transitions can be triggered by a number of different things. We have considered the four following triggers which are often associated with transitions: condition; message arrival; rate; timeout. These are quite basic transitions which will cover transitions most people need to implement, however if any other types are needed, the transition class can be extended appropriately.

Condition-based transitions can be specified by the programmer when a certain condition is met. Since this condition could be any number of things (a block of code which can return true or false), there are two feasible ways of implementing such a transition. The first method would be by introducing time steps to the model. This would be using a synchronous time model, and therefore perhaps not the best way to implement things which reflect the real world, in particular in Social Simulation. We as people are not expected to make decisions every arbitrary unit of time, we simply make decisions when they need to be made. Asynchronous time, which does not specify time steps and instead relies on agents doing things when a condition is met, would reflect the real world more accurately, and is also more computationally efficient. One way of implementing such a time model would be to use the observer pattern. This means that once a condition is needed for a transition, an observer will be added to monitor the condition, and when the condition is satisfied, the appropriate object will be notified. In our case, this will be the lightweight object which is used to represent the agent instance of our state machine.

Time-based transitions are based on either timeouts, or a rate at which agents move from one state to another. The method in which this transition can be implemented is similar to Boolean condition based; however an easier way of implementing such a transition in C++ would be simply to set a timer, which notifies the agent instance of a state machine upon expiry. This eliminates the need for an additional observer to be added to the system.

Message-based transitions are the ones which are triggered upon receiving a message. No particular observer is required for this, as messages should be processed upon arrival at an agent. When a message arrives, it will be stored by the agent and a transition from the current state will be triggered if that particular message matches the condition of the agent.

D. Time Models

Agents need to periodically make decisions, which are based on the transitions in the state machine. There are two main ways of doing this: using an asynchronous and synchronous time model. Both ways have their advantages and disadvantages depending on what type of model is being created.

Asynchronous time models are the most commonly used when trying to model real world situations where an agent acts of their own accord at random time intervals [23]. This reflects best what happens in the real world in social systems. It can also be said that typically asynchronous models are more efficient in terms of computational expense, due to the fact that things are only triggered when they need to be triggered, whereas the same model run in asynchronous time will trigger at every time step regardless of whether it is necessary or not.

Synchronous time models on the other hand are where "time steps" are defined, and each time step triggers an agent to perform an action. This action can directly trigger a transition, or it can signal to the agent that it is time to make a decision on whether to make a transition or not. When using synchronous time models, time steps can notify an agent based on probability, effectively imitating asynchronous time models.

In our system we have the choice of which time model to use. Obviously there are advantages and disadvantages for both and it really depends on the application, which time model should be used.

IV. Validation

Our ABS environment has been implemented in Visual Studio 12 using C++ as the programming language. The "off the shelf" commercial package we have chosen for our validation experiments is AnyLogic 7, which is a multi-paradigm eclipse based simulation IDE that supports

graphical model design for all major simulation paradigms (including ABM) [24]. In order to assess run time and memory usage we run the AnyLogic 7 and the C++ implementation on their own with no other processes using significant RAM or CPU time. The experiments were run on the same system to ensure fairness.

For this paper we have conducted two validation experiments which test individual components of the agent, including simple behaviour and composite states. We used the synchronous time model for our tests due to the fact that only time-based conditions were included in the model. We have conducted further experiments using the asynchronous time model as well as all types of transition triggers but due to the limited space we cannot present them here. Results of those experiments are available on request.

A. Overview of Validation Experiments

We have constructed a number of experiments to test the individual components of our system. The purpose of these experiments is to verify that the models running in our ABS environment behave as expected and we also compare the performance (in terms of runtime and memory usage) of our system to that of AnyLogic 7.

With regards to creating the models both simulation systems have a very different approach: Our system requires some basic C++ programming while in AnyLogic you can use drag/drop to create UML charts and then simply set up the transition triggers. The AnyLogic model is then automatically translated into Java code and is ready to be executed from within the AnyLogic environment. For our system, in order to construct the state machines for the experiments, an empty class implementing `StateMachine` is created, first listing each of the states as variables, including composite states. The transitions are then defined, and finally all the states and transitions linked together by using an `addTransition` method.

B. Validation: Experiment 1

The first experiment focuses on testing the simple decision-making capabilities of an agent. The state machine used to control behaviour here consists of two states: `stateRed` and `stateBlue`. When created, each agent initially is in `stateBlue` and based on probability takes a transition that leaves it to a final state `stateRed`. Once in `stateRed` the agent will not change states any more. The UML statechart for the simple agent is provided in Fig. 7. The initial environment was run using 400 agents.

A counter was used in each instance to count the number of agents which are in each state initially, and after 5 time steps. Fig. 8 shows our system after 5 time steps (with 0 representing `stateBlue` and 1 representing `stateRed`), and Fig. 9 shows the counter variables for each state in AnyLogic.

It can be seen that there is a slight difference in the number of agents in each state, due to random number generation in each instance yielding different results. This shows that the agents in our system behave as expected. The

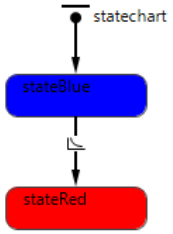

Fig. 7: UML state-chart for a simple state machine agent

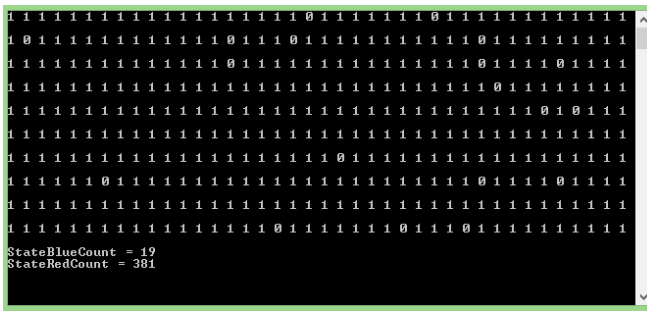

Fig. 8: Our system model after 5 time steps

Fig. 9: AnyLogic model after 5 time steps

experiment was then altered to run in virtual mode in AnyLogic, which simply executes transitions as fast as possible, and was also run without any GUI in our system. The results in each instance are shown in Tables I and II. Since the time taken cannot be easily recorded in AnyLogic, the number of time steps executed in virtual time over 10 seconds was gathered, and averaged per second. The time steps per second on our model was calculated using the time taken for all of the transitions to complete.

TABLE I.
EXPERIMENT 1 RESULTS USING OUR SYSTEM

Agents	Ram	Timesteps
500	0.5 MB	1000 / sec
100,000	14.4 MB	2.92 / sec
250,000	34.1 MB	1.68 / sec
1,000,000	134.5 MB	0.38 / sec

TABLE II.
EXPERIMENT 1 RESULTS USING ANYLOGIC

Agents	Ram	Timesteps
500	90 MB	13063 / sec
100,000	180 MB	19.7 / sec
250,000	320 MB	6.4 / sec
1,000,000	1,260 MB	1.34 / sec

As can be seen in Table I, the number of time steps executed per second is linearly affected by the number of

agents present in the model, and the memory used also grows fairly linearly with the amount of agents when concerned with a large agent population. Table II shows that AnyLogic also exhibits the same linear increase of memory usage with agent population size; however, this memory usage is far higher than our tool. The amount of time steps that is executed per second is also quite drastically affected in AnyLogic when a large number of agents are put into the simulation, although it is faster than with our tool. This could be due to the use of the lightweight state object which is used to save memory, and a performance increase may be obtained with the expense of more memory usage by assigning an individual state machine to each agent. It should be noted that AnyLogic can in fact execute multiple transitions per time step, so the number of transitions taken may be more than the time steps executed. This shows us that an improvement needs to be made to our tool in terms of the speed of the model, focusing on the use of the lightweight `AgentMachine` object used to save memory.

C. Validation: Experiment 2

This experiment implements the idea of composite state machines. In addition to the simple agent behaviour experiment, the `stateRed` state will now contain a clone of the previous state machine. The agent should move into the stateRed state and move between the states within this composite state. The UML statechart for the more complex agent is provided in Fig. 10.

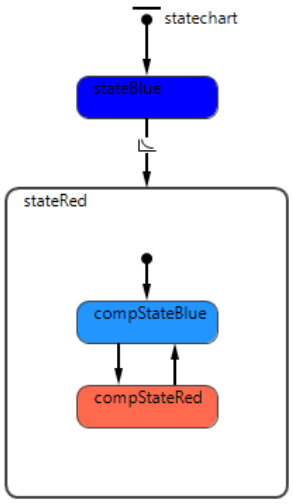

Fig. 10: UML state-chart with a composite state machine agent

As with the previous experiment, a counter was used in both AnyLogic and our tool to count the number of agents in each state. Fig. 11 and 12 illustrate the number of agents in each state after 5 time steps in both, our system and in AnyLogic. In Fig. 11, the numbers 0 and 1 represent `stateBlue` and `stateRed`, respectively, and the numbers 2 and 3 represent `compStateBlue` and `compStateRed`, respectively. As can be seen in Figs. 11 & 12, the number of agents in each state varies between our tool and AnyLogic due to random number being used to determine whether a transition should be made, however the agent behaves as expected with a composite state.

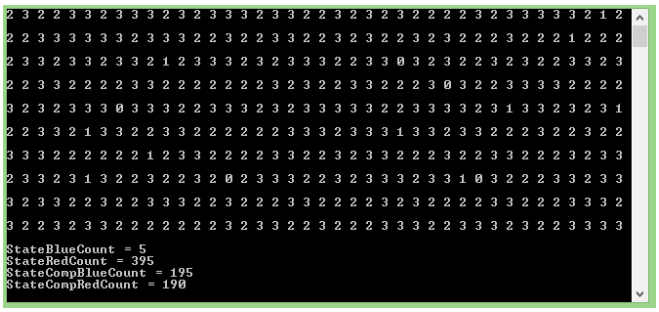

Fig. 11: Our system model after 5 time steps

Fig. 12: AnyLogic model after 5 time steps

As previously, the experiment was then altered to run in virtual mode in AnyLogic, which simply executes transitions as fast as possible, and without any GUI in our system. The results are presented in Table III for our system and in Table IV for AnyLogic.

TABLE III.
EXPERIMENT 2 RESULTS USING OUR SYSTEM

Agents	Ram	Timesteps
500	0.5 MB	1000 / sec
100,000	14.4 MB	2.99 / sec
250,000	34.1 MB	1.22 / sec
1,000,000	134.7 MB	0.29 / sec

TABLE IV.
EXPERIMENT 2 RESULTS USING ANYLOGIC

Agents	Ram	Timesteps
500	75 MB	9135 / sec
100,000	346 MB	16.5 / sec
250,000	540 MB	5.7 / sec
1,000,000	1,615 MB	1.5 / sec

Table III shows that the performance for our system has remained almost the same as in Experiment 1 in terms of memory usage and time steps executed per second. The same is true for AnyLogic in relation to the time steps executed per second, as can be seen in Table IV. However, memory usage has gone up quite significantly. This demonstrates the advantages of our state machine design. One can save potentially a lot of memory when constructing models that feature more complex statecharts.

V. CONCLUSIONS

This paper provides an insight into the often unexplored inside world of ABS environments. We have defined the different components (classes) of such a system, including `Environment`, `Agent`, `StateMachine`, `State`,

`Transition`, and `CompositeState`. For each of these, we have defined what is expected of them in an ABS system, the links between them, and in addition we have explored a variety of different ways in which these can be implemented whilst fulfilling the requirements of an ABS system. We have also designed and implemented some basic tests which showed that the components work as expected.

In Section IV we have compared the performance of our system to that of the "off the shelf" package AnyLogic. The results demonstrate that with a synchronous time model in mind, memory usage of our tool is much lower than that of AnyLogic. This demonstrates the value of our ABS environment when considering larger models where memory usage can be of high importance, and where large agent populations are being implemented. However, there is still much room for improvement in terms of performance, which has become apparent from our experimentation.

We have extensively used object oriented analysis and design principles to create a system that is easy for others to use and extend. This should allow others to easily implement features they might want to include. Through providing UML diagrams we are hopeful that we have helped non computer scientists to understand, perhaps for the first time, how ABS works internally. Through our tests we have demonstrated that our C++ implementation is a promising solution for use within the area of ABS when memory usage is of a higher priority than features.

Currently we are continuing our validation efforts by building more complex real world models in our ABS environment and comparing their performance to the performance of existing models that we have previously built in AnyLogic, e.g. [25]-[27]. With regards to extending the ABS environment we are considering to provide researchers with an easier way of creating simple state machines. XML would be a useful file format to consider for storing models of finite state machines, as all the information on states and transitions could be stored in a structured way, and many tools which are used to draw UML diagrams support the XML file format. Here we follow the idea of [21] where a custom file format is used to interpret HSMs.

Improving the Social Capital of Trust-based Competitive Multi-Agent Systems by Introducing Meritocracy

Antonello Comi, Lidia Fotia and Domenico Rosaci

***Abstract*—A main issue in competitive Multi-Agent Systems is that of allowing self-interested agents to mutually cooperate in those cases where the local agent resources are not sufficient to satisfy user requests. To this end, it is necessary to introduce an internal organization for allowing agents to form suitable friendships and groups facilitating the collaboration. In the past, several approaches have been proposed aiming at forming agent coalitions which maximize the *profit* of the group or the individual agent. However, this viewpoint could introduce some negative side-effects, namely (*i*) it can lead to reward the most *aggressive* agents, also if they have bad social behaviours or (*ii*) it could introduce a sort of social flattening, without taking into account the differences among the agents in terms of merit. To face this issue, in this paper we propose an algorithm for forming friendships and groups which, instead of maximizing individual or global profit, tries to optimize a social capital represented by the mutual trust relationships.**

We theoretically prove that the application of our algorithm leads the competition to reward those agents exhibiting the most *virtuous* behaviours, introducing *meritocracy* in the system, not only rewarding effective agent performances but also encouraging correct behaviours.

I. Introduction

A COMPETITIVE Multi-Agent System (MAS) can be viewed as a virtual community composed of self-interested agents that often need to interact with each other to accomplish complex tasks. Although the introduction of cooperative behaviours seem necessary for obtaining better results, it is not possible for agents to assume that the others will cooperate sincerely, since agents are not interested in global outcome but only their own [4], [1]. For this reason, maybe some of these interactions will be done by some agent with the intention of deceiving its interlocutor, which is also a competitor. Therefore, in these systems, an agent has the problem of accurately selecting its partner, since both incomes and outcomes depend on this choice, and trust-based approaches are a possible solution to face this problem.

The issue of defining and measuring the trust between members of a community has been actively faced in the Social Sciences research field, and a common belief of most of the existing studies is that the concept of trust is strictly linked to the concept of *social capital* [15]. Social capital is a broad concept referring to the collective value associated with a community of individuals, and has been defined as "the density of interactions that is beneficial to the members of a community" [20].

Social capital is widely acknowledged as the most important asset of any social community and, more in general, of any organization. Therefore, the task of measuring trust is of the utmost relevance to understand the benefits a user can draw from her/his membership to a particular social network.

In our scenario, we suppose that the cooperation among agents can be improved by introducing a social organization in the agent community. More in particular, such an organization is realized by allowing that an agent can have some *friends*, collected in a friendship set, and moreover he can join with some *groups*, with the advantage that a collaboration requested to a friend or a member of a common group is obtained for free.

In this scenario the main question is: which is the best organization for the agent community? In our vision, we assume that the best organization is that maximizing the social capital, that we will define as the average advantage, in terms of trust, that the whole community obtains from that organization.

In the past, several approaches [9], [5], [19] have been proposed aiming at forming agent coalitions which maximize the utility of the group or the individual agent. In other words, these approaches have the purpose of optimizing some measure of *profit*. However, this viewpoint could introduce some negative side-effects. In particular, if the approach is based on maximizing the local profit, it can lead to reward the most *aggressive* agents, also if they have bad social behaviours (e.g. misleading or fraudolent agents). Moreover, if the approach tries to optimize a global profit, it could introduce a sort of social flattening, without taking into account the differences among the agents in terms of merit.

To face this issue, in our approach we propose an algorithm for forming friendships and groups which, instead of maximizing individual or global profit, tries to optimize a social capital represented by the mutual trust relationships.

In particular, we will provide two main contributions. First, we theoretically prove that our algorithm leads to continuously increase the social capital of the community. Then, enough interestingly, we also prove that the application of our algo-

This work has been partially supported by the TENACE PRIN Project (n. 20103P34XC) funded by the Italian Ministry of Education, University and Research.

rithm leads the competition to reward those agents exhibiting the most *virtuous* behaviours, i.e. those that the community perceives as the most competent and honest. In other words, our approach introduces meritocracy in the system, not only rewarding effective agent performances but also encouraging correct behaviours.

The plan of the paper is as follows. In Section II we describe a reference scenario for competitive agents. Then, in Section III we introduce our trust model while Section IV present the FGF algorithm we propose for forming friendships and groups. Next, in Section V we provide two important results related to FGF algorithm. In Section VI we discuss some related work and, finally in Section VII we draw our conclusions and discuss our ongoing research.

II. The reference scenario

Let U be a set of users and let A be a set of agents competing for satisfying the users' requests. In particular, each user $u \in U$ can submit to an agent $a \in A$ a service request r_γ falling in the category $\gamma \in C$, where C is a set of pre-defined categories. The user u will pay a fixed price p to the agent a, after the service has been provided.

Each agent a is provided with an expertise $e_a(\gamma)$ for each category $\gamma \in C$, where the expertise represents the agent's capability to correctly providing a service falling in γ. The expertise $e_a(\gamma)$ is a value ranging in the interval $[0..1]$, where $e_a(\gamma) = 1$ (resp. $e_a(\gamma) = 0$) means that a provides services falling in γ with the maximum (resp. minimum) quality of service. When the service has been provided, the user u returns a feedback f to a, where f is a value falling in $[0..1]$, such that $f = 0$ (resp. $f = 1$) represents the minimum (resp. maximum) satisfaction perceived by u for the service provided by a.

Each agent a has a set of *friend agents*, denoted by F_a, where $F_a \subseteq A$. Moreover, some groups of agents can be formed in this scenario. Let G be the set of these groups, where each group $g \in G$ is a set of agents, such that $g \subseteq A$. The names of agents and groups are registered in a Directory Facilitator (DF), as it is usual in multi-agent systems. The DF also provides a mapping $agents(g)$ receiving as input a group $g \in G$ and returning the set of the agents which are members of g.

In order to satisfy a service request concerning the category γ, the agent a can request the *contribution* of another user b, that can accept or refuse the contribution request. If b accepts, a price cp must be paid by a to b after the contribution has been provided by b. However, if b is a friend of a or a and b are in the same group, i.e. $b \in F_a \bigvee \exists g \in G : a, b \in g$, then b will accept the request and will provide the contribution for free.

In our scenario, we suppose that an agent can request a maximum number of $cMax$ contributions.

Moreover, in order to select those agents that are the best candidates for requesting contribution, the agent a can require the opinion of the other agents. In particular, a can send to an agent c a request for obtaining a recommendation $rec_b(\gamma)$ about the expertise $e_b(\gamma)$ of b in a given category γ. In other words, $rec_b(\gamma)$ is an estimation of $e_b(\gamma)$ provided by c. The recommendation request can be accepted or refused by c, and in the case of accepting, a price rp is paid by a to c. However, if c is a friend of a or a and c are in the same group, i.e. $c \in F_a \bigvee \exists g \in G : a, c \in g$, then c will accept the recommendation request and will provide the recommendation for free.

In our scenario, we suppose that an agent can request a maximum number of $rMax$ recommendations.

III. Trust measures: reliability, reputation and honesty

We assume that in the scenario described above it is possible that misbehaviours are adopted by some agent. In particular, an agent b that has been requested for a contribution by a could provide a service with a quality lesser than that corresponding to his actual expertise. Analogously, an agent c that has been requested for a recommendation by a about the agent b could indicate a value for the expertise of b different from the value that c really knows.

In order to manage these possible misbehaviours, the agent a associates three trust values to each agent b with which he interacted in the past. The first value, denoted by $rel(b, \gamma)$ is called *reliability* of b with respect to the category γ, and represents how much a trusts in the capability of obtaining good contribution from b in service falling in category γ.

When a receives from a user a feedback f for a service, he computes for each agent b which provided a contribution for that service, the component of the feedback associated with b. This component f_b will be obtained by considering the feedback f and possible additional information i_b that a has about the actual contribution provided by b. Formally, we define a mapping h such that $f_b = h(f, i_b)$. For example, assume that the service provided by a is represented by an integer value p. The user u when receiving p as the response to his request, will provide the feedback f as the percentage error with respect to the correct answer r. Then, in this case, f_b can be computed as the percentage error associated with the contribution r_b provided by b with respect to the correct answer r. In the case we do not have any additional information i_b, we assume that each feedback component $f_b = f$. In other words, in this case the agent a entirely transfers the responsibility of his feedbacks to his contributors. The reliability $rel(b, \gamma)$ is defined as the arithmetical mean of all the feedback components associated with b, related to feedbacks that a received from users for services falling in the category γ.

The second trust value, denoted by $hon(b)$, is called *honesty* of b when providing a recommendation. This value is computed by considering, for all the l feedback components f_c^1,..,f_c^l that a received from users and that are related to services which have been provided by a contributor c recommended by b, the percentage difference between f_c^l and the recommendation r_l provided by b and related to c (i.e. we compute $diff_l = \frac{|r_l - f_b^l|}{r_l}$). The value $hon(b)$ is defined as the arithmetical mean of all these $diff_l$ values.

Finally, the third value, denoted by $rep(b, \gamma)$, is called *reputation* of b with respect to the category γ, and represents how much the agents interrogated by a estimate the capability of b in the category γ. The reputation $rep(b, \gamma)$ is obtained as the weighted mean of all the recommendations that other agents provided to a about b in the category γ, where the weight of each recommendation provided by an agent c is considered equal to $hon(c)$.

For all the agents b that a did not contact in the past for requesting contributions in category γ, $rel(b, \gamma)$ is set equal to $crel$. Analogously, for all the agents b that a did not contact in the past for which a did not receive recommendations in category γ, $rep(b, \gamma)$ is set equal to $crep$. Finally, for all the agents b that a did not contact for requesting recommendations in the past, $hon(b)$ is set to $chon$. The values $crel$, $crep$ and $chon$ are cold start values associated with the agent a.

As a synthetic measure of trust for an agent b in the category γ, a considers the measure $trust(b, \gamma)$=$W_{rel} \cdot rel(b, \gamma) + (1 - W_{rel}) \cdot rep(b, \gamma)$ where W_{rel} is a weight ranging in [0..1] representing the importance that a assigns to the reliability with respect to the reputation.

IV. The friendship and group formation (FGF) algorithm

As described in Section II, for an agent a is preferable to ask for a contribution or a recommendation a friend or a member of one of his groups, since in this case he will not pay any cost. The difference between a friend fr and a group member m, from the viewpoint of a, is that fr has a direct connection with a, in the sense that a and fr mutually accepted in the past to become friends. Instead, m could not be a friend of a and thus he is available to give contributions and recommendations to a for free due to the fact they belong to the same group.

At each instant of time and for each category γ, the agent a can compute a set of *γ-preferable contributors* PC_a^γ, containing the agents b with which a interacted in the past for obtaining a contribution related to the category γ, and having (*i*) the highest $cMax$ trust values $trust(b, \gamma)$ and (*ii*) a trust value greater than a fixed threshold tc. The agents belonging to PC_a^γ are those that a would prefer to contact to have a contribution. Analogously, the agent a can compute a set of *preferable recommenders* PR_a, containing the agents b with which a interacted in the past for obtaining a recommendation, and having (*i*) the highest $rMax$ honesty values $hon(b)$ and an honesty value greater than a fixed threshold th. The agents belonging to PR_a are those that a would prefer to contact to have a recommendations.

In order to obtain the maximum performances, a would desire to have in his set of friends F_a, or in some group $g \in G_a$ with which he is joined, only the agents belonging to the sets of γ-preferable contributors PC_a^γ (for all the categories γ) and the set of preferable recommenders PR_a. In other words, he would desire to achieve the following goal:

$$\bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a = F_a \bigcup_{g \in G_a} g \tag{1}$$

However, it is possible that (*i*) some agents that do not belong to $\bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ there exist in $F_a \bigcup_{g \in G_a} g$ and (ii) some agents that belong to $\bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ are not present in $F_a \bigcup_{g \in G_a} g$. Both these situations imply a disadvantage for a, that must be available to satisfy for free possible requests coming from the agents that belongs to $F_a \bigcup_{g \in G_a} g$ without balancing this cost with the possibility to have in its turn the best interlocutors for obtaining contributions and/or recommendations.

In the situation (i) the disadvantage for a can be represented by the percentage of the agents $b \in F_a \bigcup_{g \in G_a} g - \bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ (w.r.t. the number of agents present in $F_a \bigcup_{g \in G_a} g$), since each of these agents will not never contacted for requesting help while they can contact a obtaining help for free.

In the situation (ii) instead, the disadvantage for a can be represented computing, for each agent b of $\bigcup_{\gamma \in C} PC_a^\gamma$ that is not present in $F_a \bigcup_{g \in G_a} g$, the difference between $trust(b, \gamma^*)$ and $trust(alt_b, \gamma^*)$, where γ^* is the category in which b is one of the preferred agents (in case b is the preferred agents in more categories, γ^* is the category associated with the highest trust value) and alt_b is the best alternative to b among the agents of $F_a \bigcup_{g \in G_a} g$, i.e. the agent of $F_a \bigcup_{g \in G_a} g$ having the best trust value in category γ^*. Analogously, it is necessary to cmpute for each agent b of $\bigcup_{\gamma \in C} PR_a^\gamma$ that is not present in $F_a \bigcup_{g \in G_a} g$, the difference between $hon(b)$ and $hon(alt_b)$, where alt_b is the best alternative to b among the agents of $F_a \bigcup_{g \in G_a} g$. The whole disadvantage can be considered equal to the average of all these contributions.

In other word, at each time the disadvantage of a will be expressed by this formula:

$$D_a = \frac{P_1 + P_2 + P_3}{3} \tag{2}$$

where:

$$P_1 = \frac{\| F_a \bigcup_{g \in G_a} g - \bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a \|}{\| F_a \bigcup_{g \in G_a} g \|} \tag{3}$$

$$P_2 = \frac{\sum_{b \in \bigcup_{\gamma \in C} PC_a^\gamma - F_a \bigcup_{g \in G_a} g} trust(b, \gamma^*) - trust(alt_b, \gamma^*)}{\| \bigcup_{\gamma \in C} PC_a^\gamma - F_a \bigcup_{g \in G_a \|} g \|} \tag{4}$$

$$P_3 = \frac{\sum_{b \in PR_a - F_a \bigcup_{g \in G_a} g} hon(b) - hon(alt_b)}{\| PR_a - F_a \bigcup_{g \in G_a \|} g \|} \tag{5}$$

Obviously, if the equality 1 holds, the disadvantage D_a will be equal to 0 (minimum value), while if (*i*) all the agents belonging to $F_a \bigcup_{g \in G_a} g$ are not preferred contributors or recommender, and (*ii*) all the alternative agents introduce a trust difference equal to 1, therefore the disadvantage D_a will be equal to 1 (maximum value).

The algorithm we propose is executed by the agent a for minimizing D_a during several *epochs*, such that in each epoch some preferred agents are joined to the set $F_a \bigcup_{g \in G_a} g$ replacing those agents having the worst trust or honesty values.

The period of time between two consecutive epochs is equal to a pre-fixed value T.

At each epoch, the algorithm is composed by the following two tasks, the former (called active task) dedicated to manage the requests that a sends to the other agents, the second (called *passive task*) managing the requests coming from the other agents:

A. Active task

The agent a executes this task in order to obtaining the friendship or the presence in a group of G_a of those agents belonging to $\bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ but which do not yet belong to $F_a \bigcup_{g \in G_a} g$. To this end, the strategy of a is that of (*i*) first requesting the friendship of each missing agent b; (*ii*) if the missing agent b does not accept the friendship, then requesting to join with some group that contains b; (*iii*) if any group containing b does not accept the joining request, then trying to forming a new group that in the future could attact b, requesting the participation of other agents having similar necessities.

More in particular, this task is composed by the following steps:

1) The set $\bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ is computed.
2) For each agent $b \in \bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a - F_a \bigcup_{g \in G_a} g$, a request of friendship is sent to b.
3) If the friendship request is accepted by b, then b is added to F_a. Moreover, if $b \in PC_a^\gamma$, then the agent $k \in F_a$, $k \notin \bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ having the worst trust value $trust(k, \gamma)$ is removed from F_a. Otherwise, if $b \in PR_a$, the agent $k \in F_a$, $k \notin \bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ having the worst honesty value $hon(k)$ is removed from F_a.
4) If the friendship request is not accepted by b, then the agent a requires to the DF the set $GROUP_b$ of all the groups containing b as a member. For each group $g \in GROUP_b$, the agent a computes the disadvantage D_a^* that would derive if the group g is added to G_a, using the Formula 2. If $D_a^* < D_a$, then a sends a joining request to g.
5) If the joining request is accepted by g, then g is added to G_a. Moreover, analogously to the previous step, if $b \in PC_a^\gamma$, then the agent $k \in F_a$, $k \notin \bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ having the worst trust value $trust(k, \gamma)$ is removed from F_a. Otherwise, if $b \in PR_a$, the agent $k \in F_a$, $k \notin \bigcup_{\gamma \in C} PC_a^\gamma \bigcup PR_a$ having the worst honesty value $hon(k)$ is removed from F_a.
6) If the joining request is not accepted by g, then a sends a *call for a new group* to all the agents belonging to $F_a \bigcup_{g \in G_a} g$.
7) When some agent affirmatively responses to the call for a new group, the new group is formed and registered to the DF.

B. Passive task

The purpose of this task is that of managing the requests of friendships coming from other agents, as well as the requests of joining that other agents send to groups with which a is joined. In particular, this task is composed by the following steps:

1) When a friendship request coming from an agent b arrives to a, then a will accept it if the insertion of b in the set F_a (with the consequent removing of an agent following the rules described in step 3 of the active task) implies a decrement of the disadvantage D_a. Otherwise, the request will be refused.
2) When a joining request coming from an agent b arrives to the administrator of a group g with which the agent a is joined, a voting is requested from the administrator to all the agents belonging to the group g. Each vote can be positive or negative. If the the majority of the votes is positive, then the joining request of b is accepted, otherwise it is refused. The agent a will give a positive vote if the insertion of b in the set F_a (with the consequent removing of an agent following the rules described in step 3 of the active task) implies a decrement of the disadvantage D_a. Otherwise, the vote of a will be negative.
3) If a call for a new group arrives from an agent b, then a accepts the proposal to join with the new group if the addition of b to $F_a \bigcup_{g \in G_a} g$ does not increase the disadvantage D_a.

V. Theoretical results

We define *Social Capital* SC of the whole multi-agent system the mean value of all the contributions $(1 - D_a)$ given by each agent a. In other words, the social capital represents the *average advantage* associated to a given internal organization of the MAS in friendships and groups.

Definition 1: The Social Capital of a MAS is defined as:

$$SC = \frac{\sum_{a \in A}(1 - D_a)}{\|A\|} \tag{6}$$

In this section, we provide two important results related to the FGF algorithm. First, we prove that at each iteration of the FGF, the social capital SC increases. In other words, we show that FGF achieves the purpose of creating relationships among agents tending at optimizing the global social utility.

Theorem 1: The social capital SC increases at each new iteration of the FGF algorithm.

Proof: At each iteration, each agent a performs only actions that can either (i) increase each D_a, in the case some preferred contributor or recommender accept his joining request or (ii) maintain unvaried D_a, if any agent does not accept hos joining request. However, D_a can decrease due to actions performed by other agents, as the cancellation of a preferred contributor or recommender from F_a or from a group of G_a. However, let b a preferred contributor in a category γ^* or a recommender that cancels himself from F_a or from a group of G_a. Then, the disadvantage D_a will increase for the necessity to replace b with the best alternative alt_b, and the increment will be equal to $trust(b, \gamma^+) - trust(alt_b, \gamma^*)$ (or $hon(b) - hon(alt_b)$ in the case of a recommender), that is lesser than 1. However, b cancels himself from F_a of

from a group of G_a only if a is not one of his preferred contributors or recommenders, thus the cancellation implies a decrement of D_b equal to 1. Overall, the sum of D_a and D_b will decrement of 1-$(trust(b,\gamma^*) - trust(alt_b,\gamma^*))$ (or $1 - (hon(b) - hon(alt_b))$. From this observation, we directly derive that the sum of all the agent disadvantages decreases at each iteration, and consequently the sum of all the contributions $(1 - D - a)$ increases. This proves the theorem. ■

In order to characterizing the global trustworthiness that an agent a receives from the whole community in a given category γ, we define the notion of *merit* μ_a^γ, as follows:

Definition 2: The merit μ_a^γ of an agent a in the category γ is defined as the number of agents that consider a as a preferred contributor or a preferred recommender.

Moreover, we define also the notion of *expected gain* of an agent a, for characterizing how much the agent a can expect to increment his bank amount at a given step of the competition. Denoting as $P_a(i)$ the probability distribution of the bank amount increment for a, i.e. the probability that the bank amount increment is equal to i, we have that:

Definition 3: The expected gain δ_a of the agent a is defined as the expected value of the probability distribution $P_a(i)$

Finally, we consider valid the following *mirror assumption*:

Assumption 1: Let a, b be two agents, such that at a given iteration $\mu_a^\gamma < \mu_b^\gamma$. In this situation the number u_a of users contacting a for a service request in the category γ will be lesser than the number u_b of users contacting b.

This assumption appears reasonable considering that if $\delta_a^\gamma < \delta_b^\gamma$, then the global satisfaction of the agent community for the performances of a is lesser than the satisfaction for the performances of b. Since the global satisfaction of the agent community is constructed based on the feedbacks received by the users, it is reasonable to think that in this situation also the users will prefer to contact a instead of contacting b. In other words, this assumption means that the users' choices specularly reflect the agents' choices. This will be particularly true if the trustworthiness of a, represented by the number of agents that consider a as a preferred interlocutor, actually capture the expertise of a. Obviously, the more the trust models of the agents are built strictly based on the users' feedbacks, similarly to the case of the trust model presented in Section III, the more the mirror assumption can be considered as valid. Furthermore, the more the adopted trust model is able to capture the actual expertises of the agents, the more the assumption above will reflect the real situation.

Theorem 2: At each iteration, for each pair of agents a, b such that $\mu_a^\gamma < \mu_b^\gamma$, the expected gain δ_a will be lesser than the expected gain δ_b.

Proof: Let a, b be two agents, such that at a given iteration $\mu_a^\gamma < \mu_b^\gamma$. Supposing as valid the mirror assumption, the number u_a of users contacting a for a service request related to γ will be lesser than the number u_b of users contacting b. Moreover, in this situation, the probability PI_a that a is contacted by other agents for a contribution or a recommendation related to γ is lesser than the corresponding probability PB_a, and therefore the expected number of the agents i_a contacting a for a contribution or for a recommendation related to γ is lesser than the expected number i_b of those contacting b. In the same way, the expected number of agents o_a contacted by a in the category γ is greater than the expected number of agents o_b contacted by b, due to the high probability that the expertise of a is smaller than that of b. Thus, also supposing for simplicity that both the price of a contribution or a recommendation is equal to p^*, the expected gain δ_a at the end of the current iteration is $u_a \cdot p + i_a \cdot p^* - o_a \cdot p^*$, that is smaller than the corresponding gain δ_b for the agent b. ■

VI. Related Work

This section discusses some previous work related to the issues of partner selection and collaboration among self-interested agents. Partner selection plays an important role in filling the deficit of distributed agents. Research on partner selection generally proposes various types of evaluation metrics for selecting appropriate partners. Local decision with local modeling [12], [16] takes into account the local model about potential partners and finds the most appropriate partners, for example, according to trustworthiness, reputation or quality of provided services. These models are constructed either by direct observation or communication with other agents. In social control research, agents need to evaluate other agents or the services provided by other agents in order to realize a distributed but secure control over the interactions among agents [8].

The negotiation-based approach involves explicit peer-to-peer communication for negotiation. The Contract Net Protocol (CNP) [21], [6] provides a mechanism for finding the best partners who provide necessary services at the least cost. The Adaptive Decision Making Framework (ADMF) [2] also deploys a negotiation-based partner selection scheme. Recently, the use of trust in competitive agent systems has been widely emphasized [17], [11]. In this context, trust measures have been exploited for forming clusters of agents [10], [3] and for generating recommendations in social network contexts [7]. The problem of detecting group of actors in a competitive social community based on trust has particularly been faced in [13], [18], [14]. None of the aforementioned approaches faces the issue of improving the social capital of the agent community by introducing meritocracy. Instead, those approaches try to use trust measures for recommending to an agent the best agents to contact as promising interlocutors, without the purpose of introducing a social advantage for the whole community. Instead, our approach is capable of achieving such an advantage, also realizing it through a meritocratic approach, that encourages the social actors to assume correct behaviours for increasing their social reputation.

VII. Conclusion

The problem of introducing a convenient organization into a community of self-interested agent is central in the context of allowing agents to collaborate for increasing the individual capability of providing services to users. If in the past the

most of the proposed approaches face such a problem trying to maximize the profits of the single actors or the whole community, however it is important to remark that these kinds of proposals lead to important negative effects as, for instance: (*i*) encouraging deceptive or fraudolent behaviours in the case the goal of the approach is that of rewarding the most aggressive agents or (*ii*) introducing a social flattening that does not take into account the different merits of individual agents, in the case the approach is focused on the optimization of the profit associated with the entire community. In this work, we argue that a possibility to avoid the above problems is that of using as objective function to maximize a measure of social capital, depending on the trust relationships existing among agents. In other words, in our vision the social capital of the community is represented by the strength of these trust relationships in the friendship lists and in the groups formed into the community. As a consequence, in this vision, those agents that are perceived as the most trustworthy are rewarded by our approach, thus introducing a form of meritocracy in the community. Our paper gives the theoretical demonstration that, at each iteration of the FGF algorithm (*i*) the social capital SC increases and (*ii*) for each pair of agents a, b such that $\mu_a^\gamma < \mu_b^\gamma$, the expected gain δ_a will be lesser than the expected gain δ_b. This second result has been proved under the *mirror assumption*, valid in the case the behaviour of the users when selecting the agents reflects the behaviour of the agents when selecting their collaborators.

Our ongoing research is now devoted to test the FGF algorithm in complex situations, characterized by large sets of agents, and in real cases when agents operate on the behalf of human users. In particular, we are planning to develop an application in the domain of grid/cloud services, that appears as a promising possibility of profitably using our approach for introducing a convenient organization in the service system.

***Abstract*—It is well known that the multi-agent system paradigm is well suited for modelling and developing simulations of complex systems belonging to several application domains. Simulation study aims at developing simulation models useful for representing, studying and analyzing entities and their behavior in a system according to specific purposes. With our work we are trying to understand what are the right elements to be considered and included in the description of a simulation problem. In order to root our resulting metamodel in the state of the art of multi-agent simulations we started from the study of twelve papers dealing with four different application domains: Crowd Dynamics, Traffic and Transportation, Electricity Power Engineering and Supply Chain and Logistic. From this study we obtained a metamodel that may be used by an analyst as a guideline and concept repository for facing a new system design. The metamodel is the result of a well defined approach that is described together with the obtained results consisting in one core metamodel containing elements that are common to all the four application domains and some domain extension contents. These latter contain the elements that are specific of each of the studied domains and are not present in the others.**

I. Introduction

MULTIAGENT system paradigm is well suited for modeling and developing simulations of complex systems belonging to several application domains. As Klügl says in [1], multiagent simulation is considered a killer application of agent-based technology. But an engineering approach for developing simulation models is still lacking and several issues are still open. Moreover the author says "*a categorization of models with respect to relevant design concepts would be a good starting point advancing the knowledge on what is relevant for multiagent simulations* "[1]. This future research is suggested to address the challenge about: *which design concepts are relevant for which type of model?* Due to the wide variety of domains in which multiagent simulations are employed, our question is: *which concepts are relevant for which type of agent based simulation problem?* Answering to this question, in our opinion, helps to find a solution to the proposed challenge.

The main aim of our research is to develop a complete methodological approach for conducting simulation studies. Our approach will be composed of: *(i)* the phase devoting to describe the features of the simulation problem, *(ii)* the phase for verifying if the simulation model adheres to the real system and then *(iii)* the phase for defining experiments and implementing them in the simulation framework. The development of a specific MAS resides inside the whole simulation methodology.

In this paper we focus on the first part of our project, the one related to the first activities of a simulation study. Simulation study aims at developing simulation models useful for representing, studying and analyzing entities and their behavior in a system following specific purposes. Activities in simulation studies are mainly performed by the analyst and the model designer that have to create a model of the world starting from the description of the problem. But what are the right tools for them to build the simulation model that best fits their needs? And above all, agent simulation is used in several application domain presenting very different features that affect the creation of simulation models, so how may the model designer identify the elements helping him to construct the simulation model?

This starting point is very demanding, several authors in literature agree on that and propose different solutions. In this work we propose a preliminary work for solving this problem by focusing on the problem statement, our aim is to create a metamodel of all the elements and their relationships that we have to find in the problem description of a simulation study. As we said, several different simulation studies greatly differ for the application domain they refer to, so in order to be as much general as possible in the creation of the metamodel, we analyzed and studied papers by four different application domains (Crowd Dynamics, Traffic and Transportation, Electricity Power Engineering and Supply Chain and Logistic) in order to retrieve common and specific elements.

In other words, the contribution of this paper is in the identification of what elements are commonly used for describing some simulation problems and, moreover, what elements are used in specific application domains. From this study we obtained a metamodel that may be used by an analyst as a guideline and concept repository while describing a new problem. We do not claim that all situations may be faced

978-83-60810-58-3/$25.00

(or have to be faced) with the proposed metamodel but we think that if the elements we list in that have been frequently used in papers dealing with similar problems, it is likely that such elements may be useful again in the same context or in a similar one.

The rest of the paper is organized as follows: in section II we detail the motivations for our work against the related works in literature, in section III we show the process for bundling the metamodel and then in sections IV and V some discussions and conclusions are drawn.

II. Motivation and Related Works

Simulation is the discipline for designing a model of actual or physical systems. It abstractly represents a real system involving the elaboration of models where system behavior is reproduced following a set of hypothesis used to define different scenarios. Multiagent simulation focuses on the study and description of distributed behavior in a dynamic context [2] and consists in identifying simulation models where entities (such as agents), their behaviors, their interactions among themselves or with the environment in which they are situated, are described. Hence simulation studies prescribe to work with models of the problem and not with the problem itself.

Simulation results are used in place of experimentation over the actual or real system. If the model were not the closest approximation of the actual system then it might lead to erroneous considerations, faults and costly decisions.

The question we want to answer is: which are the activities to made in order to build adequate simulation models?

In [3] and [4] the life cycle of a simulation study is illustrated, it prescribes ten phases organized in a quite iterative way. Briefly, the first step is *communicating the problem* and *formulating it*, then defining the system objectives, creating the conceptual model and finally designing experiments. Defining and setting the objectives of the study is a very important step that may lead to the identification and the definition of the right simulation model to use for investigating a specific problem and analyzing its results.

In [5] the author investigates how to build a valid and credible simulation model. He does not describe a real and complete methodological approach, rather he presents a set of techniques for building a valid model. Law's approach starts with the identification of a set of steps to do for formulating the problem, these steps sound like advises more then techniques, indeed he say "Problem of interest is stated by the decision-maker. It may not be stated precisely or in quantitative terms. An iterative process is often necessary" and still "a kickoff meeting is necessary for discussing the overall objectives of the study, the scope of the model, the performance measures, etc.". Nothing is said, in Balci's, Nance's and Law's works, about *how* to perform these activities in order to retrieve the most useful elements for creating simulation models starting from problem description.

It is clear that the description of the problem, or of the domain under study, greatly affects the production of simulation models. The risk of influencing the result of simulation study is high. The model developer and then the decision maker have to be sure to work with problem domain description where useful elements are described. From a literature review and above all from [6] we can highlight the following elements: entities of the domain exposing behavior, the objective of the simulation, the parameters to be tuned for evaluating results, the interactions among entities, possible rules or constraints for interacting, resources and services from which entities take data for implementing their behavior.

Balci and Nance in [7] presented an high level procedure for guiding the analyst during problem formulation; he identified the need of formulating the problem in objective terms and distinguished between problems requiring prescriptive or descriptive solutions. The procedure he proposed is very detailed and is followed by a formulated problem verification activity and the measurement of the formulated problem. The overall approach may be resumed in fifteen very detailed tasks that, we may say, influenced all the successive work in problem domain description and from which the previous said elements may also be abstracted.

In the agent oriented context Garro et al. [8] propose a methodology for guiding domain experts from analysis to modeling. Our approach mainly focuses on the problem formulation and, starting from the same considerations of Balci and Nance, does not "still" propose detailed guidelines for problem statement description but instead provides the set of elements and relationships among them, a metamodel, that we abstracted from several works presented in literature. This metamodel is the base for obtaining the sequence of activities to do for building the most correct problem statement for a specific problem.

Today, it is quite usual that existing software engineering design methodologies start with the assumption that the Problem Statement document is already available, it is usually presented in the form of a text document, sometimes delivered using techniques such as interviews or ethnographic approaches [9] as often as not it is presented as an unstructured document containing a free description of the problem.

Our aim is to pose the base for creating guidelines for writing problem statements as a useful input for an agent-based simulation methodology and we want to answer to the following questions:

- *How the problem statement has to be done?*
- *Which are the essential elements it has to present?*
- *How to describe the specific problem that should be solved by the model in the simulation study?*

First of all, we considered that if the Problem Statement has to serve as a basis for obtaining a simulation model it has to contain and make explicit elements such as the entities involved in the real system, their behavior and interaction with the environment but also elements representing the objectives of the simulation and a fair set of parameters settings and measures.

This is very different from a common problem statement, for instance from the one devoted to illustrate elements useful for obtaining an object model (of a object-oriented methodology).

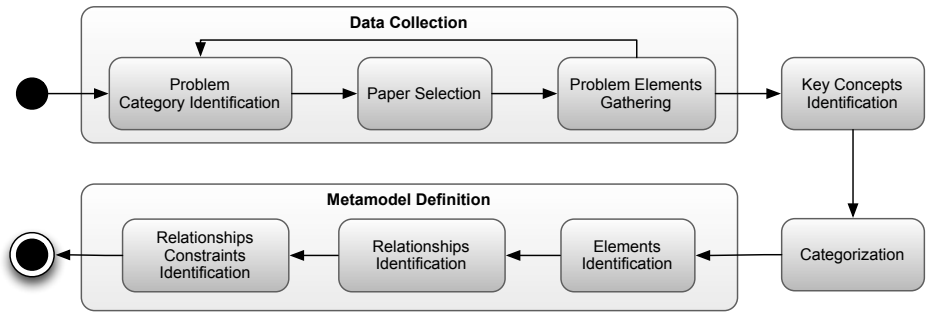

Fig. 1. Metamodel Building Process

In what does a simulation study differ from an agent based methodology? May differences be reported on the structure (or on how to build) of a problem statement? In order to answer to these questions we decided to explore and analyze the research products of several fields in which agent-based simulation is used in order to retrieve the common elements in use and to create a metamodel for supporting the creation of problem statements for agent-based simulation systems.

We analyzed literature from the fields of Financial Market, Urban Development, Traffic and Transportation, Crowd Dynamics and Logistic and Supply Chain Management in order to identify the shared elements in all these categories of problems and to conduct a generalization process that is detailed in the following section.

The reason for which we create a metamodel for representing abstract simulation study elements lies in the deep experience we have in creating and documenting design methodologies [10], [11], [12], [13]. Indeed, in the PRoDe approach [14], elements and relationships among them are used for representing dependencies among elements and establishing the right sequence of tasks/activities to do for reaching a design result. This is what we mean to do with the problem domain, once having determined the elements and their relationships that have to be present in a problem statement we might be able to determine the set of activities for instantiating them. This results, in the context of our complete building-in- progress methodology, in a set of guidelines to be used for writing the most useful problem statement for a specific need.

III. METAMODEL DEFINITION

A critical point for a simulation study is to accurately formulate the problem to be addressed in order to obtain a high-quality simulation model. Problem statement is the first activity by which the addressed problem is translated into a well formulated one that is sufficiently detailed for allowing specific modeling activities. Several studies have highlighted that agent-based simulations seem to be more suited in the field of socio-economic systems, which covers a wide range of problem domains. These domains share some common concepts but differ from some others. Hence, for answering the question *"which concepts are relevant for specific types of agent based simulation problems?*", we are leading a systematic analysis of several scientific papers in order to determine: (i) what are the domains of simulation problems commonly faced with an agent-based approach; (ii) what is the set of shared concepts useful for describing such problems and (iii) what is the set of concepts that differ among domains of agent based simulation problems.

As we previously said, we are working on the development of a methodology that covers the entire life cycle of a simulation study starting from the problem statement activity. In this paper we propose a preparatory study whose aim is building a metamodel that may be applicable in different agent based simulation studies for supporting the problem statement creation activity.

In the following we show the process we performed for building such metamodel and its preliminary results.

A. Metamodel Building Process

In order to build the metamodel for agent based simulation problems, we followed the process shown in Fig.1. The first three steps allow us to collect data and information that will be the starting point for our analysis. Then, a key concepts identification, followed by a categorization activity, enables us to make some reasoning useful for determining the metamodel. In the following we show the results of these steps.

a) Data Collection Phase: Firstly, we performed a literature review for identifying problem categories addressed by means of agent based simulation approaches. The preliminary results of this research highlighted that agent based simulations are applied to solve problems in the following domains (and not only[1]): *(i) Financial Markets* [15], [16] where simulations are used for studying the behavior of individual investors, the dynamics of markets, trading mechanism and so on; *(ii) Urban Development* [17], [18] that studies models for urban planning, city dynamics, individual residential behaviors; (iii) *Traffic and Transportation* [19], [20], [21] dealing with simulation models for transportation planning, design and operations; (iv) *Crowd Dynamics* [22], [23], [24] that studies the behaviors of individuals, groups in several critical scenarios often with the

[1]This research is not intended to be exhaustive. The results we present are only preliminary. We are doing further researches in order to obtain more accurate results.

aim of buildings design; (v) *Social Networks* that studies the evolution and dynamics of networks [25], [26]; (vi) *Logistics and Supply Chain Management* that studies processes inside different nodes of supply chain or the whole supply chain in order to find the best organizational structure for collaborative companies working together [27], [28], [29]; (vii) *Electric Power Engineering* [30], [31], [32] deals with the generation, transmission, distribution and utilization of electric power as well as the electrical devices connected to such systems.

The second step in the Data Collection phase was papers selection for each of the previously identified categories. The selection was based on two criteria: details of the simulation problem description and its relevance/impact of the paper. Finally, we analytically gathered elements from each paper. Such elements were opportunely ordered according to their semantic and functional similarity.

So far, we have examined only four problem domains: Traffic and Transportation [19], [20], [21], Crowd Dynamics [22], [23], [24], Electric Power Engineering [30], [31], [32], Logistics and Supply Chain Management [27], [28], [29]. In this preliminary work we selected 12 papers, three for each domain.

The results of this phase are sets of domain dependent concepts. All the common concepts of each domain have been grouped by analyzing the text describing each domain in the papers. Each element has been identified firstly looking at its explicit presence in sentences, the same was made for relationships, and secondly analyzing the whole domain description text in order to find unexpressed implicit knowledge.

b) Key Concepts Identification and Categorization: The key concepts identification (see Fig.1) is the conceptual activity we performed for processing sets of domain dependent concepts coming from the previous stage. Our aim was to infer a set of "higher level" abstraction categories that can be more widely applicable to generic agent based simulation problems (see Fig.2). For instance, in the domains we studied, we found concepts like room, road and city that may be represented, at an higher level, by the "spatial position" concept.

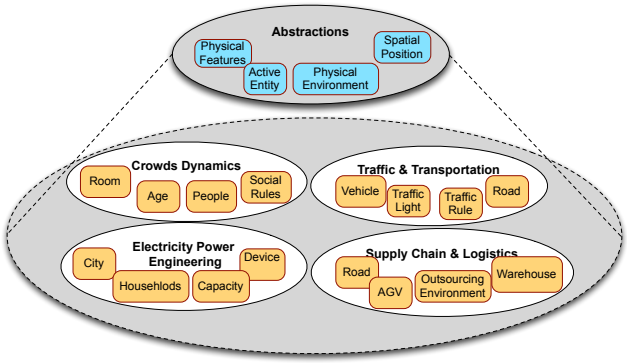

Fig. 2. Identification of higher level abstraction categories for the problem description metamodel.

The results of this activity are listed below:

1) A problem statement of an agent based simulation study describes active entities. For representing such entities, each domain uses concepts such as: (i) people, persons, pedestrian, individuals, human beings in the field of crowd dynamics; (ii) cars, drivers, buses, vehicles, people, AGVs, trucks etc... in the domain of traffic and transportation; (iii) electric cars, devices, households, electricity sellers, buyers, players etc... in the domain of power engineering; (iv) companies, suppliers, production, customers, resources,organization etc... in the domain of logistic and supply chain management.
2) Active entities may be located in a physical space. Their local position could either be a geographic position or a particular place (for example a room, a corridor, a road, in a station and so on);
3) Active entities are described by means of features and behaviors. The kinds of features we discovered in our domains are: physical, psychological and technical features. To give some examples in the domain of Crowd Dynamics a problem statement may contain sentences such as: "*Agents in a hurry will not respect others' personal space . . . More polite agents will respect lines and wait for others to move first. . .*" [23]; "*Agents are given different psychological (e.g., impatience, panic, personality attributes) and physiological traits*" [23]; "*Human individuals are different from each other by age, body dimension, mobility and personality*"[33]. Examples in Power Engineering are: "*The market operator manages the pool using a market-clearing tool to set market price and a set of accepted selling and buying bids for every negotiation period*" [30]. "*Room air conditioning Schedule time on: 15 min Schedule time off: 35 min, Power: 221 W . . . The simulated vehicles are able to move to and between different cities and recharge from time to time*"[31]. In the domain of Traffic and Transportation, typical features are described with sentences such as "*Each driver or pedestrian is assigned an agent's profile that includes height, width, velocity steering . . .* " [21]. In the Logistic and Supply Chain domain we may find sentences such as *"...forest is harvested by small-size entrepreneurs responsible for felling trees, for cross cutting them into appropriate length logs, and for hauling then to roadside"* [34].
4) The problem statement includes a description of a real world portion (physical or abstract). The represented environment may contain active entities, static and dynamic objects, groups of entities. Some examples: "*Each smart city starts with a number of households, vehicles and power stations. . . . Its area is placed at the origin of a coordinated system or as a neighbor to an existing reference city e.g. on north, south, east or west*" [31]. "*The electricity market environment typically consists of a pool that players submit their bids to, which can be symmetric or asymmetric, and a floor for bilateral*

contracts" [30]. "*Ten thousand agents that fill a corridor that is 300m long*" [22]. "*The floor plan contains a number of office spaces organized along hallways and corridors. There are two egress exits, exit A on the west and exit B on the south*" [33]. "*The static structure of a bus network is composed of four elements: itinerary, line, bus stop and bus station*" [20]. *"is a warehouse consisting of: number of Gates where the articulated lorries leave their containers waiting to be unloaded; number of Sorting Area with twelve Sorter Places (where the pallets are left in order to be addressed toward next destination)..."* [29].

5) The problem statement describes the dynamics occurring in the real world portion. These dynamics are expressed in terms of actions and interactions of active entities. They can also be constrained by some regulations. To give some examples: "*When people are crossing portals, care must be taken to avoid intersection between agents leaving and agents entering*"[23]."*High truck A is stopped in the lane closest to the sidewalk and obscures the pedestrian's view. Vehicle B approaches the crosswalk from the second lane and the view of the driver is obscured too*"[21]. "*Players negotiating on the pool must prepare a bid for the 24 periods of the spot market . . . The market operator must assure that the economical dispatch accounts for the specified conditions, which might imply removing entities that have presented competitive bids but whose complex conditions were not satisfied*" [30], *"a network of facilities is responsible for orchestrating all operations from the forest to the customers, including the operations of many sawmills" "Once dried, bundles are disassembled to be planed, cut to length, sorted, and graded according to standard rules or customer specifications"*[34]. "*In a normal situation(non-panic), people will respect lines and wait for others to walk first*" [23]. "*People movement can also be restricted due to environmental constraints imposed by the spatial geometries*" [33]. "*The length of time that elapses during an assembly depends on a specified manufacturing delay parameter. It also depends on whether the assembly is performed in parallel or sequentially*" [28].
6) The problem statement may contain information about entity groupings and roles of the entities. Examples: *"Members in a hierarchically structured group (such as families) tend to stay together and follow the leader*"[33]. "*Each household belongs to one city and it is randomly placed within the city area. Households have a number of appliances that consume and/or produce energy*" [31].
7) The problem statement defines the objectives of the simulation study. Examples taken from the examined papers are: *"Egress Analysis for building design"*[33]. *"Traffic analysis for support decision for example road safety"* [21]. *"Efficient management of electricity network"*[31]. *"The goal of both simulations was to service customer orders at or near 100%, based on the three day requirement"* [28].
8) The problem statement defines parameters to be tuned in order to reach simulation objectives. These parameters may refer to the system as a whole or to its entities. Some examples of system parameters: *different spatial distribution of the occupant* [33], *density of crowd* [22], *changing supplier or add a distribution center* [35]. Examples of entity parameters are: *distance to obstacles*[23], *vehicles velocity and distance from cross walk* [21], *inventory levels, lead time and transportation time at different locations to better understand the dynamics of the supply chain* [35].

TABLE I
KEY ELEMENTS AND THEIR MAPPING WITH THE ANALYZED DOMAINS.

			PROBLEM DOMAINS			
			Crowd Dynamics	Traffic & Trasportation	Power Engineering	Logistics & Supply Chain

After Key Concepts Identification, the Categorization of Concepts is carried out in order to find high level concepts as explained in Fig. 2. Two work products result from this activity, one describing the concepts (see Table I) and one describing the relationships discovered into the analyzed domain(see Table II).

In Table I we represent the set of high-level concepts resulting from this activity grouped according to a more general category they are related to. In particular, a total

mapping (x) means that the concept has been encountered in all the papers we examined for the specific domain. Partial mapping (v) means that only some papers of the same domain use the concept the cell refers to. No mapping is represented by (-).

For space constraints, we only show an excerpt of the work product related to the relationships (see Table II). This is a table where the kind of relation discovered between two concepts is reported. The values of darker cells are the same of their symmetric cells. Only to name a few, we have detected the following relationships: *(i)* an active entity interacts with active entities; *(ii)* the behavior may be constrained by behavioral rules; *(iii)* physical environment may contain static object; *(iv)* a static object may be located on a physical space and many others.

c) Metamodel Definition: The study of the simulation problems under analysis, Table I and Table II highlighted that, although the problem domains are quite different, they share some high level features and differ for some others. For instance, looking at the table's columns, we may see that Abstract Environment is not present in the Crowd Dynamics and Traffic and Transportation domains and it is only partially present in the other two. The Physical Environment has always been found in the Crowd Dynamics and Traffic and Transportation domains and only partially in the Power Engineering and in the Logistics and Supply Chain management domains. So, we may say that the problem statement metamodel for the simulation study of a specific domain may be composed of a core metamodel, where common elements for all the studied domain may be found, and extensions where some specific and particular elements are shown (Fig. 3).

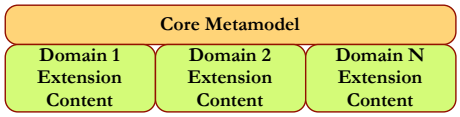

Fig. 3. Metamodel Scheme

Hence, the *Core Metamodel* contains all the elements we identified derived from the set of concepts that are shared among all domains under analysis. As a consequence, the role of the *Core Metamodel* will be to provide a minimum set of elements to be described in a problem statement for a non specific agent based simulation study. The *Domain Extension Contents* are collections of metamodel elements that allow for defining "more specific and domain dependent" contents for a

problem statement of agent based simulation studies belonging to a particular domain.

The resulting *Core Metamodel* is shown in Fig. 4. It aims to support the definition of an agent based simulation problem by identifying those elements that, once defined in the problem statement, will provide a shared starting point for the development of an agent based simulation model. The *Domain Extension Contents* for Traffic and Transportation and Power Engineering domains are shown in Fig. 5 and Fig. 6 respectively. As concerns, the *Domain Extension Content* for Crowds Dynamics domain, it entirely overlaps with that Traffic and Transportation Extension Content. For space constraints, we do not show the Logistics and Supply Chain Extension Content.

In particular, Table I, along with other considerations arisen from the activities we performed, helped us to define the elements of the metamodel. Whilst, Table II helped us to define the relationships among elements of the metamodel. The total or partial mapping also provided us information to define the cardinality of the metamodel relationships. For instance, from Table I we defined the metamodel elements: Active Entity, Behavioral Rule, Social Rule, Structural Constraint and Behavior. In Table II, we can see that these elements are linked by the following relationships: *(i)* Active Entity follows Behavioral Rules; *(ii)* Active Entity respects Social Rules; *(iii)* Behavior is constrained by Structural Constraints. Hence, we chose to model these relationships in our metamodel by introducing an abstract element named *Rule* whose Structural Constraints, Behavioral Rules and Social Rules are specializations. This choice allowed us to model the aforementioned relationships with only one link between Behavior and Rule labeled *is constrained by*. The Active Entity is related to Rule by means of its Behavior. In the same way, we deducted some other relationships and elements of the metamodel that do not explicitly appear in the tables.

In the following we describe the Core Metamodel elements showing also, when present, the related elements of the Domain Extension Contents.

Looking at Fig. 4, a generic *Simulation Problem Statement* is composed of a *System to be simulated* and *Simulation Purposes*. The *System to be simulated* in an agent based simulation study can be described by means of a set of interacting entities (i.e.: *Active Entities*) that own some distinctive attributes concerning their individuality (i.e.: *Features*) and that show particular *Behaviors*. A *Physical Feature* is a particular kind of *Feature*. It allows to describe the body properties of the entities (i.e: weight, height, etc...). The *Feature* may also be *Psychological* (i.e: impatient, polite, etc...) and *Technical Feature* (i.e.: energy consumption, capacity, etc...), we found the first in the description of the Crowd Dynamics domain and in the Traffic and Transportation domain (see the Extension Content in Fig. 5) whereas we found the second in the description of the Active Entities in the domain of Power Engineering (see the Extension Content in Fig. 6). Whilst, the *Behavior* is constrained by *Rules*. Rules can be *Behavioral Rules* (see Fig.5), *Structural Constraints* and *Social Rules* (see Fig. 5). A *Behavioral Rule* is an explicit statement or principle governing the functionality, the conduct or the procedures within a particular domain, commonly prescribing what is possible or allowable. *Social Rules* and *Structural Constraints* are defined in the following.

Commonly, the primary purpose of a simulation study is to analyze the behavior of a system under some conditions. Thus, the simulation purpose is defined by identifying the *Questions* to be answered and by determining what are the *Parameters* to be investigated from which the resulting simulation model will depend on. In this context, a Parameter denotes a measurable factor that can be varied during simulation experiments and may characterize the system and/or determine its behavior (i.e: *System Parameter*). *Parameters* are related to each *Active Entity* present in the system so, since *Active Entities* own *Features* and show *Behaviors*, parameters may also characterize or determine *Behavior* and may be related to *Features* through the *Entity Parameter*. For instance the velocity of a vehicle is a physical feature described together with the related active entity, so, in this case, a physical feature may also be realized by an *Entity Parameter*.

Moreover, the *System to be simulated* concerns a *Real-World Portion* that includes *Active Entities* and passive entities (i.e.: *Objects*). These latter do not exhibit behaviors but contribute to the description of the *System to be simulated*. The *Real-World Portion* is a *Physical Environment* in the domains of Crowd Dynamics and Traffic and Transportation and it may impose several *Structural Constraints* (see Fig. 5) derived by its physical configuration. Whilst, it can be also an *Abstract Environment* like it is in the domain of Power Engineering (see Fig. 6) for electricity markets.

In the same way, *Objects* may be *Static* or *Dynamic Objects* in the Crowd Dynamics and in the Traffic and Transportation domain but only static in the Power Engineering domain[2] (see the Extension Contents in Fig. 5 and Fig. 6 respectively).

Moreover, *Active Entities* and *Objects* are located on a *Spatial Position* when the problem concerns a *Physical Environment*.

For describing the *System to be simulated* it is also necessary to identify *Scenarios* to be investigated. A *Scenario* is a description of the *Interactions* that occur among entities and/or the *Actions* individually performed by *Active Entities*. A *Scenario* describes a way in which the *System to be simulated* behaves in specific situations.

Finally, the *System to be simulated* may be further described by means of a *Social Structure*. The *Social Structure* describes the way the *System to be simulated* is organized according to specific *Roles* played by *Active Entities*. A *Role* describes what an active entity is able to do. It expresses a set of behaviors showed by an Active Entity when it is involved in a social

[2]We would like to point out again that these considerations are the result of a preliminary work. We think to be likely that Dynamic Objects can be found in the Power Engineering Domain, but at the moment this does not emerge from the examined papers. Whether the element *Dynamic Objects* should be present also in the domain of the Power Engineering, then both elements, *Dynamic Object* and *Static Object*, will be moved within the Core Metamodel.

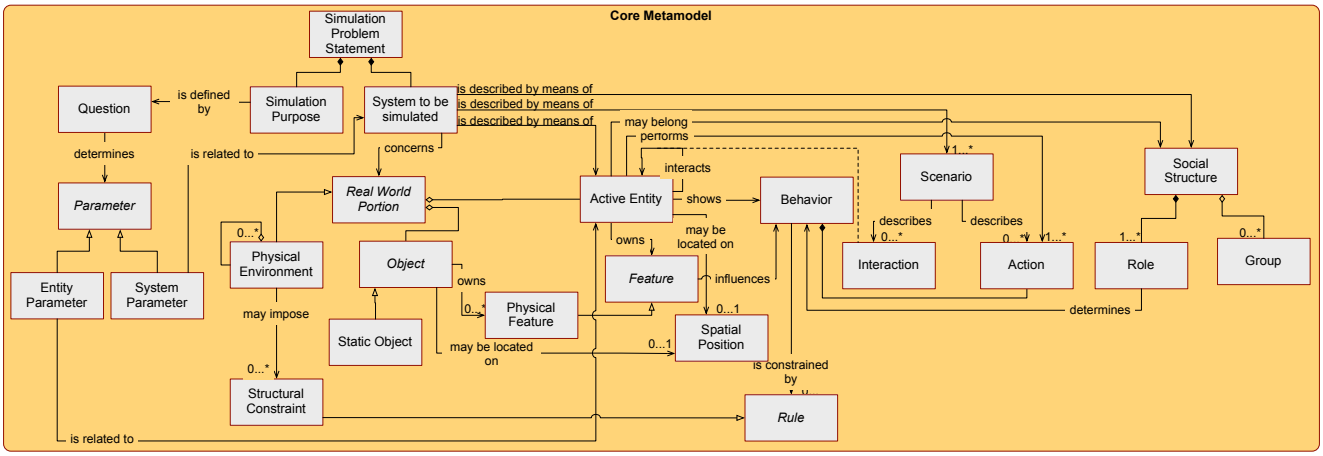

Fig. 4. The Core Metamodel derived from the domain under analysis.

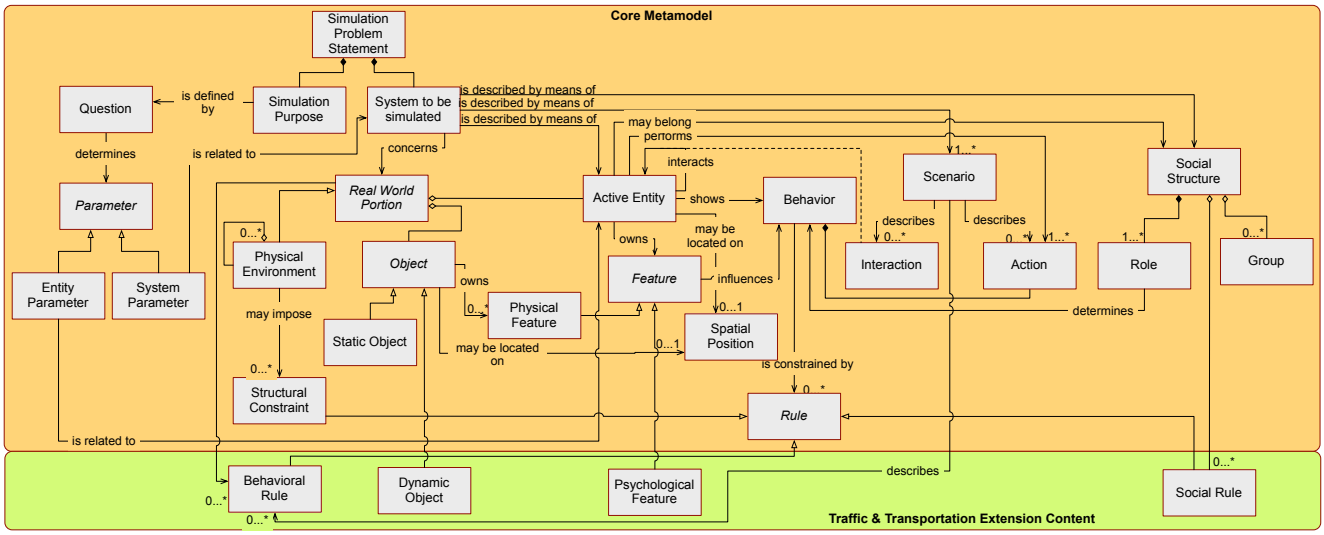

Fig. 5. Core Metamodel along with Traffic and Transportation Extension Content.

pattern. A *Group* defines an aggregate of active entities that can be together in the same place or that can be connected by some shared behavior or feature. A *Social Rule* has the same role of a *Behavioral Rule* but it is shared and followed by the members of a *Group*.

IV. Discussions

The focus of the Problem Statement Activity is to acquire all the necessary knowledge of the real-world system to be simulated and to point out the issues that the simulation studies have to address. In particular, without a definitive statement of the specific questions of interest to be addressed, it is impossible to decide on an appropriate level of knowledge detail useful to build an appropriate simulation model. A method to clearly define what type of the knowledge about the problem is relevant may be useful in order to avoid missing important parts of the problem description. The metamodel resulting from our study allows to handle two levels of knowledge at the same time. A knowledge related to the system to be simulated as a whole. It concerns aspects of the system that are not directly related to the individual entities and it helps to build the so-called environment model[3]. A knowledge relating to specific aspects of single entities that will be suited for building the agent models. Moreover, preliminary results we have obtained give us some suggestions about the knowledge to be included in a problem statement and how to describe it in a systematic way. The Core Metamodel highlights that the formulation of a simulation study may ground on five key aspects:

[3]An agent based simulation model is in many cases composed of two basic components. They are an agent model that focuses on each single agent and its behavior and an environment model that focuses on the structure and features of the real world portion in which agents act.

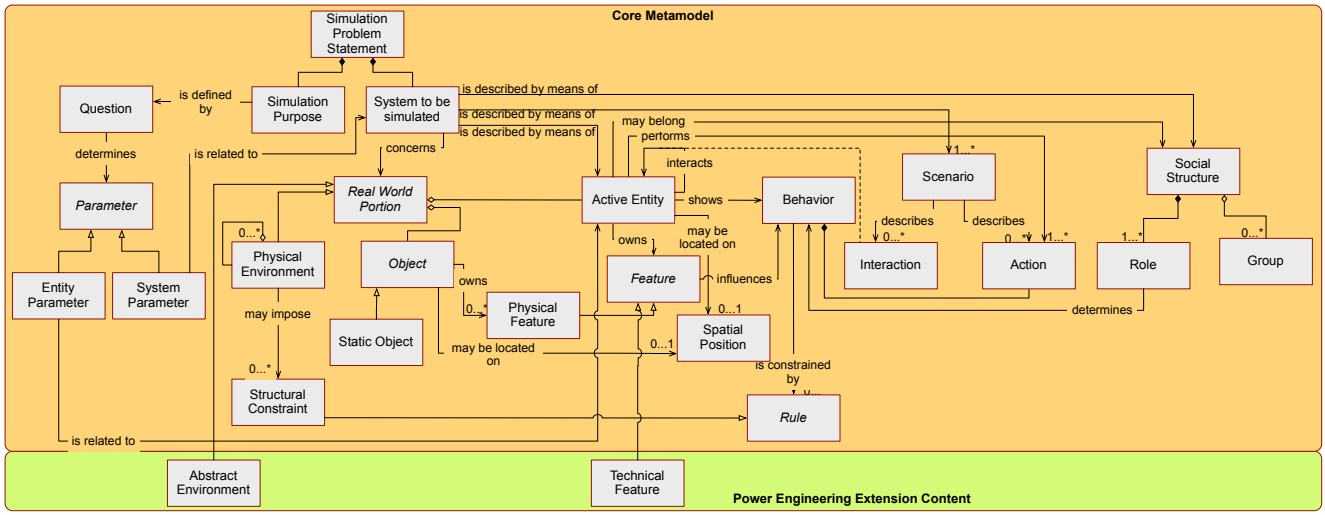

Fig. 6. Core Metamodel along with Power Engineering Extension Content.

1) the *issues* to be addressed by the simulation study made explicit by means of the metamodel element named *Simulation Purpose*. Instantiating this metamodel element means to formulate the questions to be answered that coincide with the definition of goals of the simulation study. As a consequence, this leads to associate goals with information that define them operationally and that has to be considered during the definition of the simulation model.
2) the *structural aspect* of the system to be simulated defined by its constituting parts. It is made explicit by instantiating the metamodel element named *Real World Portion*. This means to collect the knowledge necessary to describe the real-world part involved in the system to be simulated according to the issues to be addressed. Commonly, this concerns the description of the physical configuration of the real-world system under analysis (i.e: its components). As the Core metamodel shows, components may be static objects of the portion of the world enclosed by the system or active entities that are someone/something performing actions;
3) the *dynamical aspect* of the system to be simulated caused by processes taking place in the system. It is captured by defining actions and interactions that are performed by someone/something in particular operative scenarios.
4) the *organizational aspect* (if any) which refers to the social structure captured by defining the groups and sets of roles that may be present in the system to be simulated.
5) the *normative aspect* (if any) given by regulations that commonly constrains the dynamics or physicality of the system. It refers to any kind of regulations such as procedural rules, legal regulations, social norms, structural rules or physical laws. Usually, only some kinds of norm affect the system, this strongly depends on the particular domain. For example, in a simulation study concerning a manufacturing system normally the system is subjected to procedural rules and legal regulations. Vice versa, if the simulation is about the citizen of a town during an event then, probably, social norms could affect the system.

These key aspects may provide a first guideline about the kind of knowledge that can be managed during the problem statement activity. Moreover, basing on such a metamodel we are able to establish a starting point for the construction of a systematic approach for performing the problem statement activity by choosing the order that should be used for instantiating the metamodel elements. We already explored such an approach with the PRoDe method for developing software design processes starting from the underlying metamodel [14].

V. Conclusions and Remarks

Multiagent simulations are employed in several domains and for several simulation purposes. Finding a uniform way to address the problem description for a simulation study is an open issue. The work proposed in this paper is a preliminary step toward an ambitious objective: the definition of a complete methodological approach to obtain high quality simulation models for generic agent-based simulation studies. Such an approach will cover several activities starting from the problem statement to the results analysis trough the model validation. At the moment, we are addressing some questions related to the problem statement activity and in this paper we present our preliminary results.

As well as in many engineering contexts, we think that an accurate problem formulation is the first step to be accomplished in order to obtain a high-quality agent based simulation model. To do this, we are defining a metamodel-based approach in order to perform the problem statement

activity. The metamodel aims to guide the problem formulation highlighting the main elements and relationships that have to be made explicit. In this paper we present the rough metamodel we have already defined. This metamodel is composed of elements belonging to a shared level among several simulation problem domains useful for formulating generic simulation studies and several domain extension contents that allow us for detailing specific domain simulation studies.

***Abstract*—We explore the on-line problem of coverage where multiple agents have to find a target whose position is unknown, and without a prior global information about the environment. In this paper a novel algorithm for multi-target search is described, it is inspired from water vortex dynamics and based on the principle of pheromone-based communication. According to this algorithm, called S-MASA (Stigmergic Multi Ant Search Area), the agents search nearby their base incrementally using turns around their center and around each other, until the target is found, with only a group of simple distributed cooperative Ant like agents, which communicate indirectly via depositing/detecting markers. This work improves the search performance in comparison with random walk and S-random walk (stigmergic random walk) strategies, we show the obtained results using computer simulations.**

I. Introduction

THE PROBLEM of finding multiple targets whose positions are unknown without a prior information about the environment is very important in many real world applications [1]. Those applications vary from mine detecting [2] [3], search in damaged buildings [4] [5], fire fighting [6], and exploration of spaces [7] [8], where neither a map, nor a Global Positioning System (GPS) are available [9]. The random walk is the best option when there is some degree of uncertainty in the environment and a reduced perceptual capabilities [10] because it is simple, needs no memory and self-stabilizes. However, it is inefficient in a two-dimensional infinite grid, where it results in an infinite searching time, even if the target is nearby [11], it results also in energy consumption and malfunction risks. To deal with these limits, some effective ways to coordinate multiple agents in their searching task need to take place. Recently many researchers have investigated bio-inspired coordination methods [12] [13], in which agents coordinate on the basis of indirect communication principle known as stigmergy.

Complexity of multi-target search solutions depends on simplifications considered over idealized assumptions, such as: perfect sensors [14], stationary environments [15], unlimited direct communication [16]. Even if these assumptions are far from real world applications, they provide first basic solutions. The algorithm presented in this paper avoids such type of assumptions. It makes the following contributions:

1) it is of very low computational complexity, in which agents have a very low-range of sensors;
2) it executes a search in nearby locations first by adopting spiral turns around the starting cell and around agents each other;
3) agents use stigmergic communication via digital pheromone;
4) it can be executed on known or unknown static obstacle-free environments or obstacle environments.

The rest of this paper is organized as follows. Section 2 discusses some related work. Section 3 describes the problem statement and formulation. S-MASA algorithm is described in detail in Section 4. Performance evaluation is given in Section 5. A comparison with the random walk and S-random walk strategies are given in Section 6 and Section 7 concludes the paper.

II. Related Work

The problem of searching a target may be considered as a partial area coverage problem that constitutes a key element of the general exploration problem [17] where coverage can be done by a single or multiple robots, with on-line or off-line algorithms. In the on-line coverage algorithms, the area and target positions are unknown, and are discovered step by step while the robot explores the environment, whereas, in the off-line algorithms, the robot has a prior information about the environment, target and obstacles positions, so it can plan the path to go through. Different approaches have been developed in the literature to solve area coverage using single or multiple robots. In this section, a brief overview of techniques that are used to solve the coverage problem using both single and multiple robots is presented. The single robot covering problem was explored by Gabriely and Rimon [18]. One of the most popular algorithms is the Spanning Tree Coverage (STC). In an STC algorithm, the robot operates in a 2D grid of large square cells. It aims to find a spanning tree for such grid, and allow the robot to circumnavigate it. This algorithm covers every cell that is accessible from the starting point, and it is optimal because the robot passes through each cell at least once [19]. Spiral STC is an online sensor based algorithm for covering planar areas by a square shaped tool attached

978-83-60810-58-3/$25.00

to a mobile robot. The algorithm incrementally subdivides the planar work into disjoint D size cells, while following a spanning tree of the resulting grid. The spiral STC covers every subcell accessible from the starting point, and covers these subcells in O(n) time using O(n) memory [20]. In this new version of STC, the spanning tree is stored in the onboard memory, which results in a dependency of the search area on memory size. With the aim of resolving the memory problem, Gabriely and Rimon propose in [21] the ant-like STC which forms the third version of the basic STC algorithm, that uses markers on visited cells. D-STC is introduced in [21] to solve the problem of uncovered partially occupied 2D-size cells, by visiting the previously uncovered cells, which results in worst-case scenarios, a twice coverage of the environment area. A generalization of STC to multi-robots is given in [22], the MSTC, in which a spanning tree is computed, and then it is circumnavigated by each robot. Another spanning tree construction using multiple robots based on approximate cellular decomposition is proposed in [23]. Another approach developed in [1], where the environment is subdivided into n concentric discs, each disc is covered by one robot, when the entire disc is completely covered, the robot move to the next disc not yet covered; an extension of this algorithm that uses heterogeneous robots is given in [17]. Instead of focusing on the on-board resources, some part of robotics literature use a single ant or a group of robots to cover an area robustly, even if they do not have any memory, do not know the terrain, cannot maintain maps of the terrain, nor plan complete paths. They use environmental markers such as pebbles [24], [25], [26] or pheromone like traces [27] or greedy navigation strategies [28].

Whether we deal with coverage, multi-target search as foraging task, we need at the first stage to search the corresponding area. A search is defined as the action to look into the area carefully and thoroughly in an effort to find or discover something [29]. In most search strategies based on random walk, the agent tends to return to the same point many times before finally wandering away, because it has no historical information about visited regions. But when time and energy consumption are determinants, it will be efficient to guide the agent to not visited regions and repulse it from visited ones. In [30] a cooperative and distributed coordination strategy (IAS-SS) is proposed, it is applied to exploration and surveillance of unknown environments. It is a modified version of the artificial ant system, where the pheromone left has the property of repealing of robots either than attraction. A guided probabilistic exploration strategy for unknown areas is presented in [31], it is based on stigmergic communication and combines the random walk movements and the stigmergic guidance. The paper [32], provide a simple foraging algorithm that works asynchronously with identical ants, based on marking visited grid points by pheromone. It lacks robustness to faults. Authors in [33], propose a swarm intelligence based algorithm for distribute search and collective clean up. In this algorithm, the map is divided into a set of distinct sub-area and each sub-area is divided into some grid. Each robot decides individually based on its local information to which subarea it should move. A direct communication via WIFI model is used between robots and their neighbors. The paper [11], introduce the ANTS (Ants Nearby Treasure Search) problem, in which k identical agents, initially placed at some central location, collectively search for a treasure in a two-dimensional plane, without any communication between them. A survey of online algorithms for searching and exploration in the plane is given in [34]. S-MASA is a simple search algorithm that uses pheromones to guide the search process, agents are reactive and do not need any memory. It can locate nearby targets as fast as possible and at a rate that scales well with the number of agents, so it operates as some animal species that search for food around a central location, known as central place foraging theory [35]. Table I gives a comparison between our algorithm and some of the related works according to the search process used.

Even if chemical substances [36], electrical devices such as Radio Frequency Identification Devices (RFIDs) [37] [38] [39] [40] are examples of real implementation of stigmergic communication in real world experiments, it is still important to understand and improve pheromone-based algorithms in simulations. By understanding the optimal conditions required for pheromone-based coordination, the real world implementations can also be better directed [31].

III. Problem Statement and Formulation

In a collective multi-target search task, there are a lot of targets randomly distributed in an area. The agents (robots) should find as fast as possible the targets and, after that, remove them, if we deal with a cleanup task, or transport them to a nest, if we deal with a foraging task. In this paper, a new search algorithm is proposed that enables a group of agents, each with limited perception capabilities to search quickly the targets. The algorithm presented here uses the principle of pheromone-based coordination where each agent deposits pheromone on its environment to inform the others about already visited areas. The finish time of the collective search is when all targets have been found. This section defines and clarifies some key terms which will be used in this paper.

- *Environment:* we assume that agents move in an N X M grid-based environment. It is divided into N X M cells. Each cell can be an obstacle, target or the base station, and can also contain an agent.
- *Agent:* simple reactive agents, with limited range sensor (can only perceive the four neighboring cells), have no memory and use the environment as their shared memory. Each agent has an initial position and heading (0, 90, 180 or 270).
- *Pheromone:* has a numerical meaning. It is represented by a color. The intensity of the pheromone at time t is set to arbitrarily chosen value c which is a small positive constant. It evaporates with time with a coefficient p fixed to 0.075 using equation 1 to avoid accumulation of pheromone.

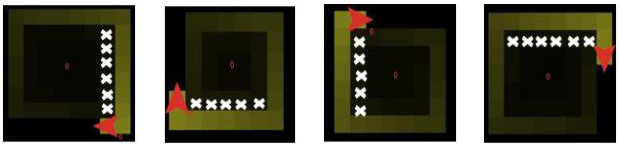
- *Motion policy:* each agent chooses the next cell to visit using a motion policy that is function of the presence of pheromone trail and obstacles. This policy helps the agent to decide where to go next.

IV. Design of the S-MASA Algorithm

The idea behind proposing this algorithm is to reproduce the behavior observed in water vortex dynamics. The vortex is a region in which a fluid flow is mainly a rotary movement about an axis, rectilinear or curved. So each agent tries to turn around the base station and around the other agents. Doing this with agents only is difficult and needs a great number of agents, but using pheromone to repulse agents from visited cells was very helpful to reproduce the structure of a vortex.

A. Basic S-MASA

In S-MASA, each agent started from an initial given position and oriented toward a given heading. To turn around the base station and around each other, each agent checks on his right cell if it is visited or not. If it detects a pheromone (Figure 1), it indicates to the agent that it is about to enter to a visited cell and therefore the agent keeps going forward its current heading, else the agent changes its heading and moves toward a new heading. S-MASA is further detailed in Algorithm 1.



(a) (b) (c) (d)

Fig. 1: S-MASA coordination principle: (a) Changing heading from 180 to 270 (b) Changing heading from 270 to 0 (c) Changing heading from 0 to 90 (d) Changing heading from 90 to 180, where white crosses represent already visited cells

Algorithm 1 S-MASA

Input: position and heading for each agent,
Output: iteration number,

```
while number of targets and boundaries are not reached do
    Move
    Lay pheromone
    Update Pheromone
end while
```

Move function is the motion policy. Each agent has initially a given heading (0, 90, 180 or 270) that allows it to move up, right, down or left in the four neighboring cells. The agent checks always its right cell which is the *up* cell if the heading is 270, the *down* cell if the heading is 90, if no pheromone is there it can change his heading to the new one using the move function and goes forward in that new heading. The move function is detailed in Algorithm 2.

Algorithm 2 Function Move

```
if (pheromone is detected in right cell) then
    go forward
else if (heading = 270) then
    set heading to 0
else
    set heading to heading + 90
end if
```

Update pheromone function is used for pheromone evaporation, using the equation

$$\Gamma_i(t+1) = \Gamma_i(t) - p * \Gamma_i(t) \quad (1)$$

Where: p is a coefficient which represents the evaporation of trail between time t and $(t+1)$ and is set to 0.075 to avoid unlimited accumulation of pheromone. S-MASA can be applied to environment with or without obstacles, the agent executes the function avoid obstacle to avoid obstacles, where

the agent follows in this case the obstacle boundary until a not visited cell is encountered, which means that agents are going around the obstacle in the direction of visited cells to guarantee the completeness of the algorithm.

B. S-MASA Extensions

The proposed algorithm allow to cover gradually the environment starting from the base station and reproducing by the way principle of central place foraging theory [35]. Although, this algorithm generates very efficient search results based on relatively simple motion rules, it can be extended to deal with dynamically changing environments, and with coverage problem in known or unknown environments.

V. Performance Evaluation

We used Netlogo framework [41] to evaluate the performance of our algorithm in two scenarios. In the first scenario we evaluate the algorithm by varying the number of agents from 5 to 30 agents in two environment configurations: obstacle-free environment and obstacle environment. In the second scenario, we evaluate the algorithm by varying the size of the environment from 20 X 20 cells to 100 X 100 cells. Obstacles in the two scenarios were defined in two ways: (i) given a desired percentage, cells were randomly designated as obstacles (ii) obstacles were specifically designed by hand. Then, one possible extension on S-MASA is discussed and related simulation results are illustrated. To evaluate average performance, each simulation is repeated 20 times, where time is defined as the number of iterations required by the agents to discover all the targets.

A. Scenario 1: Influence of Number of Agents on Performance

Agents start from initial given positions and each agent has a heading, we vary the number of agents from 5 to 30. The environment consists of a square of size 40 X 40 cells shown in Figure 2, free or with obstacles, with four targets distributed randomly. An example of execution of S-MASA on a group of 5 agents, 30 agents on obstacle-free environment, a group of 30 agents on obstacle environment (obstacles are uniformly distributed) and a group of 5 agents on obstacle cluster environment (where the distribution of obstacles in the environment gives a cluster or line shapes either than the uniform distribution) are illustrated in Figure 2.

Table II shows the performance of the algorithm in scenario 1 while the number of agents is varying from 5 to 30. It is represented graphically in Figure 3. The search time becomes dramatically faster with an increase in the number of agents. Note that there is no direct communication between agents, the only communication tool is the pheromone deposited in the environment. The standard deviation of the number of iterations reflects the impact of the random distribution of the targets between simulations. There is a linear decrease in the iterations number.

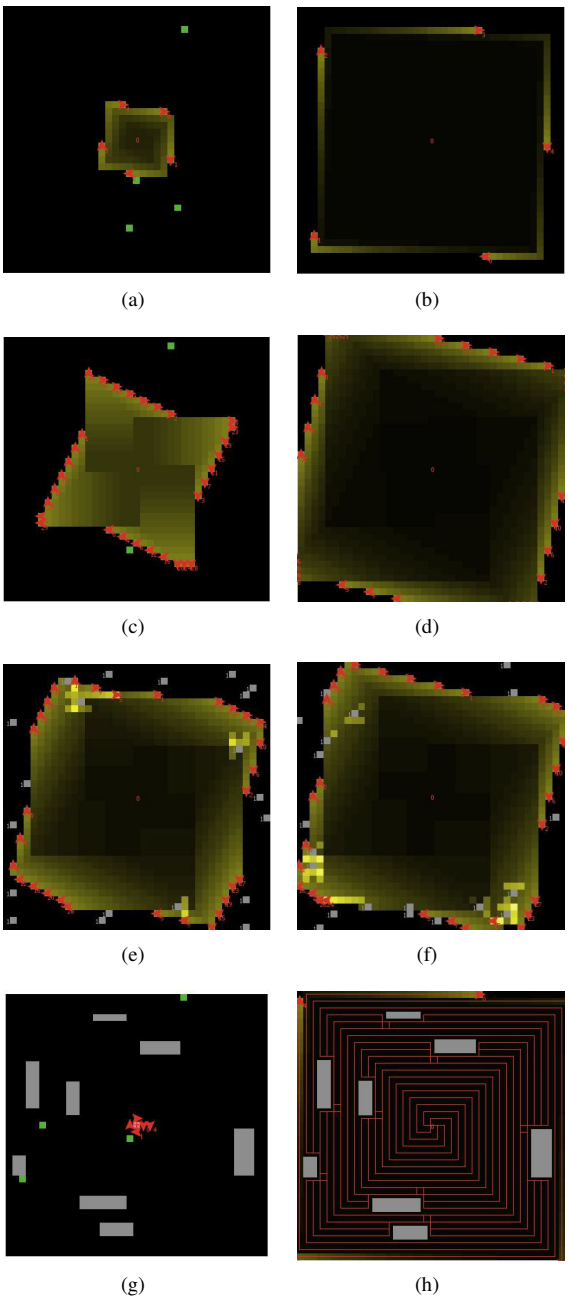


Fig. 2: The evolution of search achieved by S-MASA: (a), (b) Initial and final position of the 5-agents group in an obstacle-free environment. (c), (d) Initial and final position of the 30-agents group in an obstacle-free environment. (e), (f) Initial and final position of the 30-agents group in an obstacle environment. (g), (h) Initial and final position of 5 agents group in an obstacle cluster environment.

TABLE II: Effect of agent number on performance

	5	10	15	20	25	30
Iterations in free env	242,85	122,2	78,85	63,5	54,8	43,9
STD Deviation	46,62	24,84	17,87	14,15	11,35	10,15
Iterations in obstacle env	289,85	143,35	114,15	93,55	71,8	69,55
STD Deviation	56,76	36,93	18,29	18,58	22,97	22,24

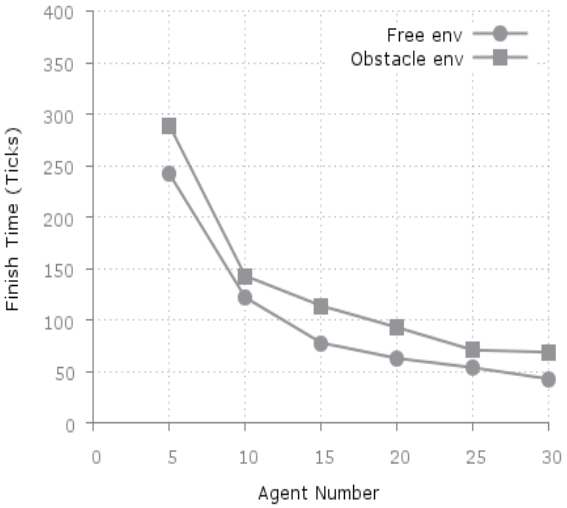

Fig. 3: Effect of agent number on performance in obstacle-free and obstacle environment

B. Scenario 2: Influence of Environment Size on Performance

We now show how the size of the environment affects the performance of the algorithm when the number of agents is set to 20. Also here we used an obstacle-free environment and an obstacle environment, just varying the size of the environment from 20 X 20 cells to 100 X 100 cells.

Table III shows the performance of the algorithm in scenario 2. It is represented graphically in Figure 4. The search time increases by increasing the size of the environment which is evident because the number of cells increases. The results show a difference in iterations number, S-MASA is robust to obstacles but this increase in number of iterations is due principally to the avoidance of obstacles that takes at least four iterations more, to go around a simple obstacle.

TABLE III: Effect of environment size on performance

	20X20	40X40	80X80	100X100
Iterations on free env	16,2	63,4	254,8	366,15
STD Deviation	3,28	13,48	50,47	101,03
Iterations on obstacle env	24,5	92,2	315,3	449
STD Deviation	8,06	23,37	71,49	131,06

C. Extension 1: S-MASA for Coverage Problem

Simulations presented in this section show that by changing the finish condition of the algorithm, the agents can achieve

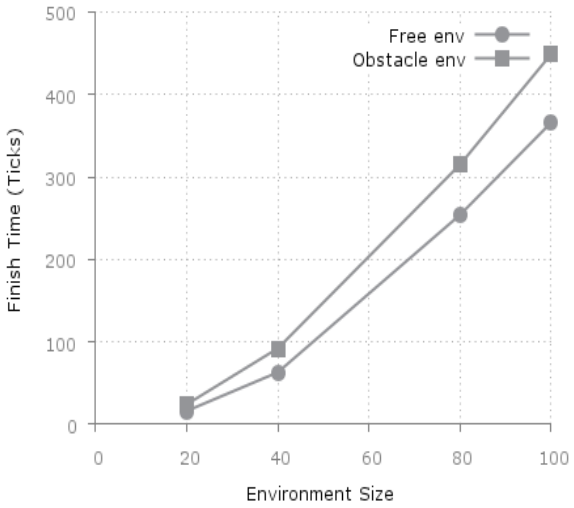

Fig. 4: Effect of environment size on performance in obstacle-free and obstacle environment

coverage mission as well as search one. The S-MASA algorithm can be applied for instance to known or unknown static environments, free or obstacle environments. Each simulation is repeated for 20 times in obstacle environments, because the obstacles are disseminated randomly in the environment and according to their position the agent take more or less iterations to go around the obstacle. Figure 5 represents the two simulations in obstacle-free and obstacle environment. As in scenario 1 and scenario 2, we test the performance of the algorithm on coverage problem by varying the number of agents and by varying the size of the environment in the two types of environments. Table IV and Figure 6 show the obtained results when varying the number of agents. There is a linear decrease in number of iterations when increasing the number of agents, and there is a difference between iterations in obstacle-free environment and obstacle environment, which are similar to Scenario 1 results. A possible reason is the random distribution of targets, so if there is one target close to boundaries, the search will be very close to coverage task and in the two tasks the number of iterations will be very close.

TABLE IV: Effect of number of agent on performance

	5	10	15	20	25	30
Iterations in free env	320	171	120	89	80	68
Iterations in obstacle env	354,25	206,7	164,3	138,6	126,25	111,55

Table V and Figure 7 show the obtained results when varying the environment size, because here there is no random distribution of targets or there are no targets, the coverage time in obstacle environment is greater than the coverage time in obstacle-free environment, but there is always an increase in the number of iterations in the two cases of simulations.

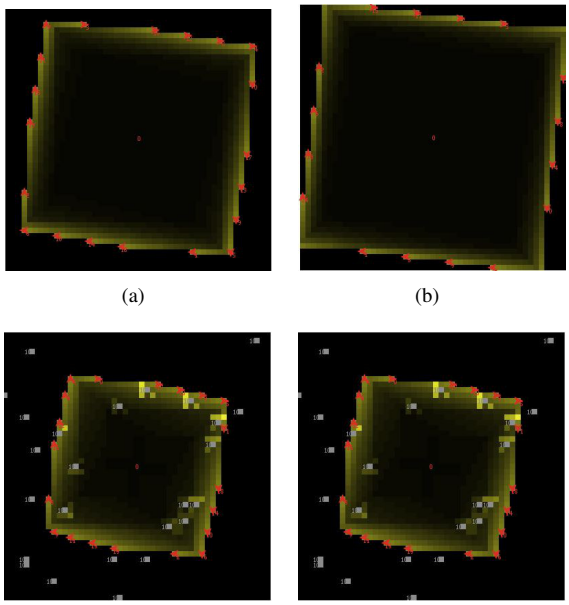

Fig. 5: The evolution of coverage achieved by S-MASA: (a), (b) 20-agents group in an obstacle-free environment in iterations 78 and 101. (c), (d) 20-agent group in an obstacle environment in iterations 44 and 108.

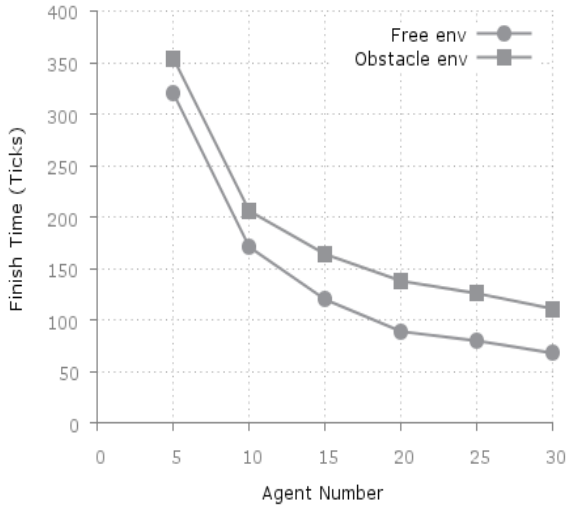

Fig. 6: Finish time of coverage in free-obstacle and obstacle environment when varying the number of agents

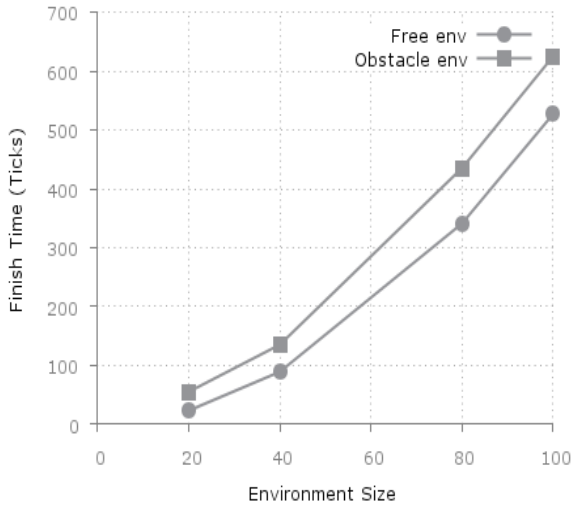

Fig. 7: Finish time of coverage in free-obstacle and obstacle environment when varying the environment size

VI. Comparison results

We compare S-MASA algorithm with two search strategies: the random walk, in which the agent chooses randomly one of the four neighbors even if it is already visited, that causes a increase in the global finish time; and the S-random walk, in which the agent chooses one of its four neighbors that are not visited yet, at each step the agent deposit a pheromone to mark already visited cells. Tables II and VI show the obtained results with S-MASA algorithm, random walk and S-random walk respectively when varying the number of agents from 5 to 30 in free-obstacle and obstacle environment where obstacles are uniformly distributed (2 *(e), (f)*). Figure 8 represents a comparison between these strategies according to Tables II and VI. Our algorithm performs much better than the random walk and the S-random walk, when the number of agents is less than 15. The results of the three strategies are close when the number of agents is more than 15, but our algorithm gives the best results.

TABLE VI: Effect of agent number on performance in random walk and S-random walk

	5	10	15	20	25	30
random walk free	2536,3	1365,65	932,6	567,05	508,7	487,3
STD Deviation	2021,98	1014,65	811,29	271,43	242,56	340,66
random walk obs	673,5	313,6	218,35	164,7	111,45	105,35

STD Deviation	653,18	343,38	87,74	129,71	99,00	66,57

Tables III and VII show the obtained results with S-MASA algorithm, random walk and S-random walk respectively when varying the size of the environment from 20 X 20 cells to

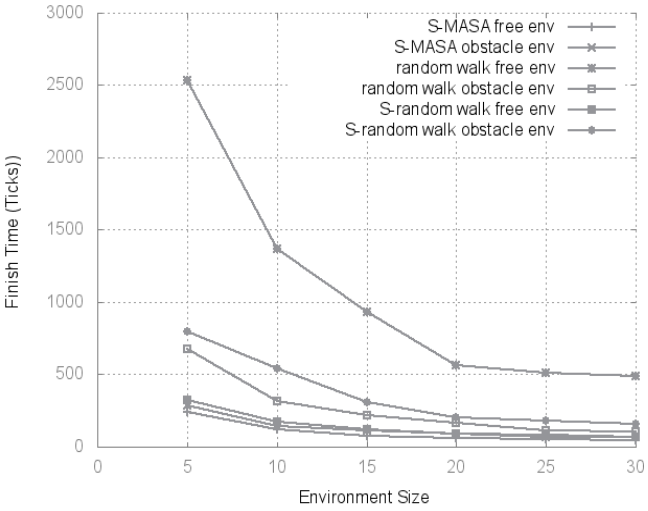

Fig. 8: Comparison of S-MASA with random walk and S-random walk when varying the number of agents (uniform distribution of obstacles)

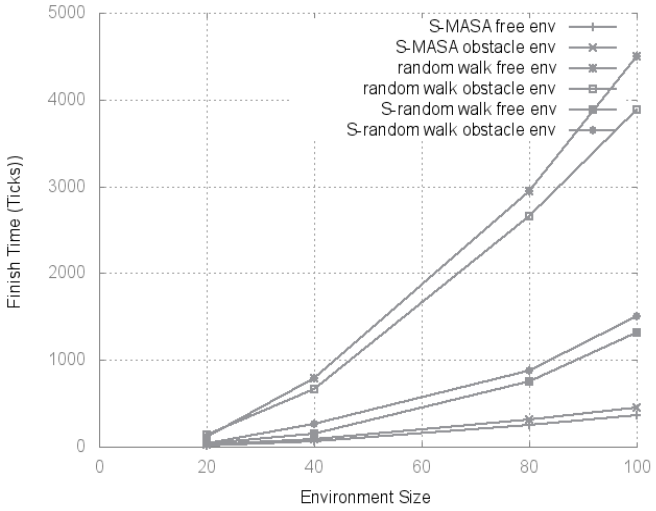

Fig. 9: Comparison of S-MASA with random walk and S-random walk when varying the environment size (uniform distribution of obstacles)

100 X 100 cells in free-obstacle and obstacle environment where obstacles are uniformly distributed (2 *(e), (f)*). Figure 9 represents a comparison between these strategies according to Tables III and VII. When the size of the environment is equal to 20 X 20 cells , the three strategies provide very close results. By increasing the environment size from 40 X 40 cells to 100 X 100 cells, our algorithm outperforms the two others.

TABLE VII: Effect of environment size on performance in random walk and S-random walk

	20X20	**40X40**	**80X80**	**100X100**

VII. Conclusion

A multi-target search algorithm called S-MASA is presented in this paper. This algorithm reduces overall finish time without any direct communication between agents. Simulation results demonstrate the higher performance of our algorithm in comparison with the S-random walk which is guided by pheromones to repulse agents from visited areas and with random walk strategy. We believe that future work improvements should reduce searching time, consider more complex, dynamic and unknown environments in the context of foraging problem.

3rd International Workshop on Smart Energy Networks & Multi-Agent Systems

The emerging smart infrastructure in energy networks represents a major paradigm shift in resource allocation management with the aim to extend the centralised supply management model, towards a decentralised supply-and-demand management that is expected to enable more efficient, reliable and environment-friendly utilisation of primary energy resources.

Together with this vision, there are new and complex tasks to manage, in order to ensure safe, cost-reducing and reliable energy network operations. This includes the integration of various renewable energy systems, like the photovoltaic or the wind energy, which are able to reduce the greenhouse gas emissions but that are working under greater uncertainty; as well as the interaction of transport and storage systems for energy that are envisioned through techniques like 'Power to Gas' and fuel cells, which are using the electrical and the gas transportation network.

Further tasks can be found in the fact that the market participants (e.g. simply households) are becoming more autonomous and intelligent through technologies like smart metering, which requires a coordinated demand side management for millions of producers, consumers or, if this applies, prosumers by means negotiations and agreements.

Information and communication technologies are key enablers of the envisioned efficiencies, both on the demand and the supply sides of the smart energy networks, where the agent-paradigm provides an excellent first modelling approach for the distributed characteristic in energy supply systems. On the demand side they aim at supporting end-users in optimising their individual energy consumption, e.g. through the deployment of smart meters providing real-time usage and cost of the energy and the use of demand-response appliances that can be controlled according to the user preferences, energy cost and carbon footprint. On the supply side they aim at optimising the network load and reliability of the energy provision, e.g. through active monitoring and prediction of the energy usage patterns, and proactive control and management of the reliable energy delivery over the networks. It is also envisaged that they will be able to influence the demand through the dynamic adjustments of the energy price in order to influence the end user behaviour and energy usage patterns throughout and across the energy networks for electricity, gas and heat.

Although a significant effort and investment have been already allocated into the development of smart grids, there are still significant research challenges to be addressed before the promised efficiencies can be realised. This includes distributed, collaborative, autonomous and intelligent software solutions for simulation, monitoring, control and optimization of smart energy networks and interactions between them.ion plays a crucial role that needs to be further investigated.

Topics

The SEN-MAS 2014 Workshop aims at providing a forum for presenting and discussing recent advances and experiences in building and using multi-agent systems for modelling, simulation and management of smart energy networks. In particular, it includes (but is not limited to) the following topics of interest:

- Experiences of Smart Grid implementations by using MAS
- Applications of Smart Grid technologies
- Management of distributed generation and storage
- Islands Power Systems, Microgrid Applications
- Real time configurations of energy networks
- Distributed planning process for energy networks by using MAS
- Self-configuring or self-healing energy systems
- Load modelling and control with MAS
- Simulations of Smart Energy Networks
- Software Tools for Smart Energy Networks
- Energy Storage
- Electrical Vehicles
- Interactions and exchange between networks for electricity, gas and heat
- Stability in Energy Networks
- Distributed Optimization in Energy Networks

***Abstract*—Dynamic and volatile grid conditions caused by the growing amount of renewable energy producers require the operation of large-scale distributed Demand-Side Management (DSM) applications. This is one of the tasks of the aggregator role in smart grid operation according to the Smart Grid Architecture Model (SGAM). For the optimization of distributed demand-side loads under such conditions, Multi-Agent Systems (MAS) have been shown to provide an appropriate paradigm to model, simulate and deploy automated operating components.**

In this paper, we address an engineering problem that is still a matter of concern, namely the construction of efficient distributed optimization algorithms in conjunction with a generic software architecture. For this purpose, a distributed Multi-Agent architecture is presented with a generic consumer model and an energy exchange market as well as further roles and components. Ant Colony System Optimization is shown to effectively optimize consumers in a nature-inspired, self-organizing way.

The applicability of the proposed approach will be demonstrated in a use-case study where a group of heterogenous consumers optimize their runtimes in order to map their demand to the energy generation of a wind power plant in a self-organized fashion.

I. Introduction

THE DEVELOPMENT of small, affordable and profitable energy generators as well as the desired growth of renewable energy resources leads to an increasing decentralization and heterogeneity in the smart grid. The capacity and availability of the decentralized energy resources often depends on environmental influences so fast-reacting conventional power plants and energy storages will be needed to compensate such fluctuations.

The utilization of the demand-side potential, the *Demand-Side-Management* (DSM), could be an additional planning option which becomes achievable and affordable through the increasing degree of automation and information- and communication technology (ICT).

The management of both demand and production side can be more efficient and safer with planning and forecasting, but will require predictable and intelligent devices and appliances for domestic households as well as industrial applications. Those devices should be able to coordinate and optimize their schedule in order to achieve pre-qualification for markets or to lower their runtime costs. While in the energy domain no real quality of service, like frequency- or availability services, can be sold, demand-side orientated business models must focus on the flexibility and planning potential of the devices with dynamic pricing or stock exchange models. The scheduling and optimization of the highly heterogeneous and distributed devices needs adaptive solutions. It seems to be likely to use these intelligent embedded devices themselves for this task, because of their computational- and communication-capacities. So a lightweight and simple optimization algorithm and a distribution concept with a minimum of shared information are required.

Because of the distribution- and autonomy-properties Multi-Agent-Systems (MAS) are suitable as a paradigm for the logical representation of grid entities. Even the current top-down modus operandi of the grid could be considered as a distributed MAS-architecture regarding the distribution of loads, substations etc. Therefore, the architectural approach in this paper utilizes the MAS-paradigm towards the distributed optimization of consumers for DSM applications.

The remaining paper is structured as follows: Section II provides an overview on the related literature and covers different aspects of todays grid development towards an emerging DSM integration. In Section III a description of the distributed MAS-Architecture for DSM and optimization is provided. Section IV describes the reference implementation of an adapted Ant Colony System - Algorithm for distributed optimization. In Section V the applicability of the proposed approach is demonstrated in a use-case study where a group of heterogenous consumers optimize their runtimes in order to map their demand to the energy generation of a wind turbine in a self-organized fashion, before Section VI concludes the paper and gives an overview about future work.

II. Related Work

Energy supply particularly on the field of electricity currently experiences a profound change. Due to the availability and the versatile ways of use, electricity has become one of the most important energy sources. New applications and potential uses as well as laws, standards, guidelines and social developments generate new requirements for the energy generation, the grid-infrastructure and also the consumer-side. This Section introduces current laws and standards of the energy domain, it gives a brief overview about the situation on the energy markets and presents current grid-infrastructures

978-83-60810-58-3/$25.00

before an overview about related work on DSM and MAS-Simulation concludes the Section.

A. Laws and Standards

In the USA the development of energy distribution has mainly arisen from the oil crisis. Until today the *National Energy Conservation Policy Act* (NECPA) from 1978 regulates the energy consumption in the United States. Contrasting to California, where the electricity-demand has been stabilized by the 1972 decree on device efficiency, building regulation and energy efficiency for energy suppliers, which was manifested as a law in 2006 [1], the power consumption in the rest of the USA has risen steadily [2]. This led to the 2007 *Energy Independence and Security ACT* (EISA) as an extension of the NECPA. In 2000 Germany applied a law[1] to regulate the favored input of electricity from renewable energy resources and to guarantee a fixed buyback price for the next 20 years. Until 2020 the amount of electricity generated from renewable resources should have reached at least 35%, rising up to at least 80% in 2050. In 2013 this amount had already reached 23,4% [3]. Because of the volatility of renewable energy resources, the favorable input of such unsteady resources conflicts with the classical modus operandi and requires highly dynamic and regulable power plants to compensate energy deficiencies respectively the establishment of corresponding storage capacities as required by the Energy Industry Act[2]. This law demands that the security and reliability of the energy grid is secured through net- or market-based measures in case of disturbances or compromises. Besides the duties on the producer side, the law also permits the detailed acquisition of performance data and load balancing measurements on the consumer side through load- and time-depended tariffs.

In order to deal with this situation almost all parts of the grid from the producer to the consumer must be automated in the future. This requires a new role- and domain-model as defined by the *NIST-Framework-Roadmap* [4]. It is established as a quasi-standard for further publications in this area. European organizations and research facilities have adopted the model and extend it for local requirements, e.g. with the extension of the distributed energy resources (DER) domain as part of the *European Smart Grid Reference Architecture* and the *Smart Grid Architecture Model* (SGAM), a layered-architecture for smart grids representing the communication and information layers [5].

B. Energy Markets

Today's electricity market in Europe is highly regulated in order to maintain operational safety. Due to the big trade volume it is mainly accessible for large producers and consumers. The most important energy markets in Europe are the *European Energy Exchange* (EEX)[3] respectively the *European Power Exchange* (EPEX SPOT)[4] as power-based spot market located in Leipzig, Germany. In 2011 the German net-agency (Bundesnetzagentur BNetzA) reformed the bidding conditions for secondary and tertiary control by reducing the minimum submission size, enabling aggregation and allowed deliverance guarantees by third parties. Through the low investment risk and short amortization times both small and medium-sized energy producers as well as DER have gained increasing attractiveness in recent years [6]. But not without creating new challenges: Due to the increasing distribution of energy producers their coordination becomes more and more complex. Also because of their low production rate DER are not able to participate directly at the energy markets. A possible solution is the grouping of DER to larger entities, the so called *Virtual Power Plants* (VPP) [7], [8].

C. Communication Infrastructure

Many projects from the energy domain facilitate internet-technology like the TCP/IP protocol as communication infrastructure for their applications because of the well-defined standards and their wide dissemination [9]. Another interesting infrastructure approach for domestic household automation is given by the *OGEMA-Project* [10]. It deals with the connection of household devices via a gateway-interface to a coordination centre and allows the automated control of consumers depending on variable power prices. Alongside to the OGEMA-project, *OpenADR* is an established system for automated demand-response, focusing on top-down business models controlled by a system operator [11]. According to [9] there is still a lack of a common communication standard for demand-side management. [12] points out the need for a registry for DER and consumers which provides information about all available energy services. Therefore, the area-wide facilitation of DSM capacities is still a topic of current research areas.

D. Demand-Side Management and Multi-Agent Systems

Demand-Side Management (DSM) is defined by [13] as planning and implementation activities of utilities and operators in order to influence the consumer's demand so that the intended consumer-behavior is achieved. A study of the US *Federal Energy Regulatory Commission* [14] comes to the conclusion, that in the USA the peak-load will rise from 775 GW in 2009 to 900 GW in 2019. That would require 2000 new power plants. Here DSM is seen as a measurement to limit this growth to 800 GW and to stabilize it in order to deal with the increasing costs and environmental impacts [15]. Apart from energy savings also the purposeful use of volatile effects from the renewable energy resources is a significant DSM use-case in Germany [9].

Multi-Agent Systems (MAS) are an established technology in order to simulate different DSM applications in smart grids. Due to their distribution and autonomy properties they can be developed relatively similar to real infrastructures and grid entities. Almost all approaches share the fact, that agents are used to represent consumers or net-entities. Most approaches utilize the demand-side for feedback control and secondary

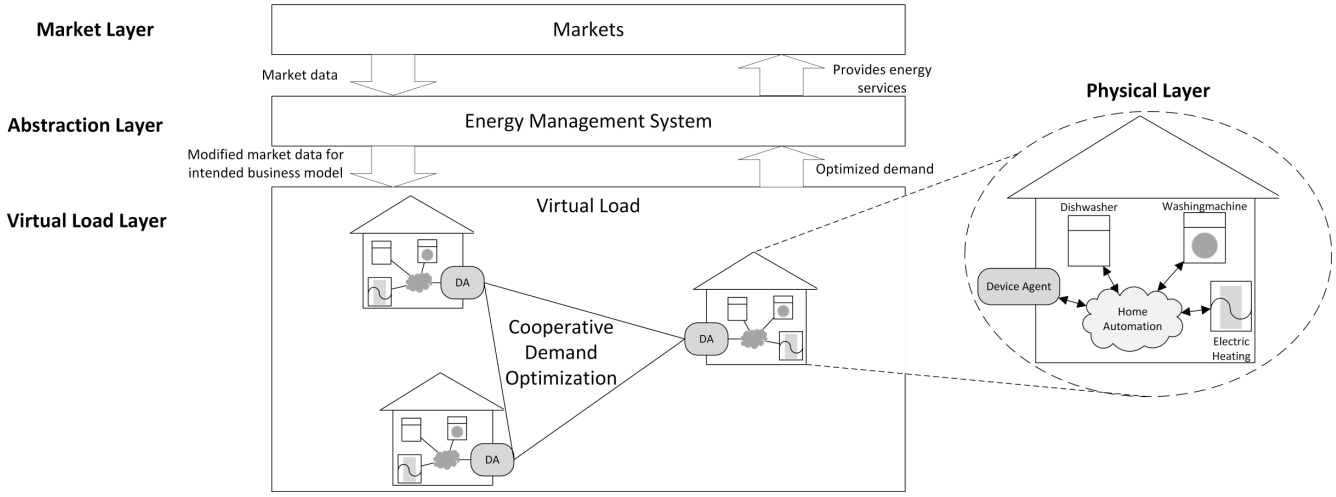

Fig. 1. Architectural model for the distributed optimization system.

and tertiary control energies. Hereby, the examined time frame ranges from near real-time applications as presented in [16] to applications like *PowerMatcher* [6] which focus more on day ahead planning. The simulation systems mainly differ on how the DSM is achieved. Here it can be differentiated between direct and indirect control. Direct control focuses on the used protocols and signaling, whereas indirect control approaches can be further differentiated between approaches based on price signals, auctions and optimization on the consumer-side. An example for the direct control of load is presented in [17] where the joint control of loads is researched. The advantage of this approach is the reliable system response for defined signals, as the connected consumers have to act accordingly to specified signaling. Additionally, the according service provider or operator has complete control over the loads. But this mode of operation implicates hard constraints on the consumer-side concerning the conditions under which load can be switched centrally. Thereby, the coordination centre requires detailed information about the controllable loads and time frames, in order to anticipate the effects of the according control signals. This approach seems to be more interesting for industrial consumers due to the complexity and heterogeneity of domestic household devices and appliances.

In the area of indirect load control very different approaches have been researched. Close to direct control is the use of price signals as described by [18]. It is based on the familiar top-down communication of price signals through a central control centre and therefore, a consequent enhancement of existing tariff models. But simple price minimization may cause peak-loads for automated consumers. Therefore, a real time observation is required so that the operator is able to counteract. Common are also auction-based approaches, where the consumer either bargains directly with the distributed energy resources or via aggregation agents [6], [16], [19]. All this approaches have in common, that the generator and load respectively the prices are tuned and negotiated in a bilateral way. A common challenge hereby is the a priori agreement on price barriers and acceptance levels for each DER or load through the producers and consumers. The last class of approaches focuses on the optimization on the consumer-side in order to generate an optimal degree of efficiency related to the according business- or operational-model. Both [20] and [21] describe exemplary use-cases with regard to specific business-models.

The usage of MAS for the aggregation of DERs to microgrids, modern, small-scale versions of the centralized electricity systems is described in [22], [23]. In [22] the aggregation of DERs and loads together to an autonomous entity a microgrid is described. Here a MAS approach as a branch of distributed artificial intelligence methods is introduced for DERs control in the microgrid. Similar work has been undone in [23] where a MAS for energy resource scheduling of an islanded power systems with DER is presented. It monitors, controls and operates an energy system consisting of a set of microgrids and lumped loads.

An interesting overview about the lastest applications of MAS in the smart grid context is given in [24].

III. Distributed Multi-Agent Architecture

Demand-Side applications usually contain large numbers of dynamic and inhomogeneous loads and thus require a distributed architecture with loose-coupled entities and generic models in order to handle the system-immanent complexities. Multi-Agents-Systems are a good metaphor for modeling and simulating such distributed grid components.

The abstract MAS architecture designed for such demand optimization problems shown in Figure 1 consists of four layers. The first layer is the market layer containing exchange markets for generation and energy services (see [4]). On a physical layer, each domestic household acts like an agent, monitoring the own environment through sensors, trying to achieve interests and goals (like a low energy price), while handling the system immanent restrictions (e.g. maintaining

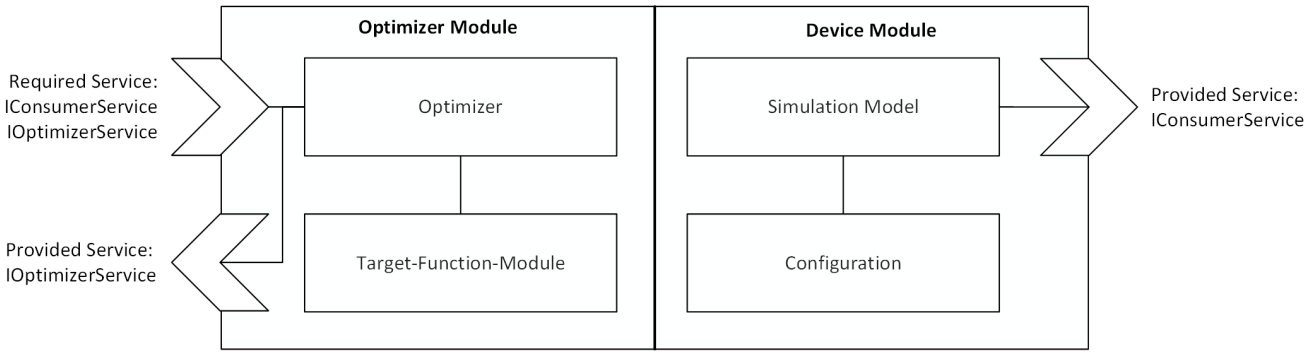

Fig. 2. Modular structure of the Device-Agent.

TABLE I
CLASSIFICATION OF LOADS

Class	Description	Control	Examples
User-driven loads	Loads that satisfy the users demand directly	User-controlled	Light, TV
Program-driven loads	The user starts the device but it may not run immediately	semi-automatic	Washing machines, dishwasher
Fully-automated loads	These devices have actors and sensors to maintain a certain state	Automatic, parameter driven	Electric heating or cooling (fridge)

a certain temperature in the household). This behavior, represented through Device-Agents, could be used by the Energy Management System as a virtual (and distributed) load to provide grid services to the market.

The **Device-Agent** (see Figure 2) is the most important entity in this energy system. Its role is to make the underlying physical layer transparent for the optimization system. With the Device-Agent as a gateway interface to the smart grid, it could abstract $1 : n$ physical devices and appliances, providing the accumulated DSM-potential of the underlying physical layer (like load-shifting). The Device-Agent needs actors and sensors to control the physical devices as well as an intrinsic simulation model in order to anticipate the runtime constraints of the physical devices connected to it.

The load of the Device-Agent is described by:

$$L\{\tau_1, \tau_2, \ldots, \tau_{n_m}\} = \sum_{i=0}^{n_m} \mathcal{L}(t - \tau_i), \tag{1}$$

with n_m as the variable number of starting times for the device, $\mathcal{L}(t-\tau_i)$ as the load of the agent, and τ_i as the discrete starting times of the loads.

An optional second module of the Device-Agent is the optimization module for the distributed, cooperative optimization of the loads. It implements a distributed lightweight optimization algorithm (described in Section IV) that optimizes the starting time of all participating Device-Agents utilizing the described iterative planning approach.

As stated in Table I loads could be classified into three groups [17]. The first class is only relevant for long term DSM efforts like strategic conservation [13]. The second and third classes can be planned iteratively using the provided *IConsumerService* of the related Device-Agent. An optimizer requests the first possible starting time vector from a Device-Agent and receives it as an integer array, then chooses one starting time and commits it back to the Device-Agent. Depending on the chosen starting times the Device-Agent calculates the next possible runtime-vector with the simulation model. This will be repeated until the Device-Agent returns an *end-of-planning*-flag. Program-driven devices require just one planning step, as the first vector contains all possible starting times from the earliest to the latest. Under the assumption that every planning step of a fully-automated-device depends on the previous condition of it, the iterative planning provides a generic way to plan such devices. Thus, the optimizer is able to plan the device without domain-specific knowledge and the whole simulation and planning logic remains at the device for security reasons and separation of concern.

The **Energy-Management-Agent (EMA)** is the domain specific representation of the control component. It is responsible for planning and operation tasks and therefore, requires knowledge about the intended *modus operandi* and the current status of the associated Device-Agents. The role of the EMA in the Smart Grid could be a versatile one. For example, the EMA could aggregate Device-Agents all over the balancing zone for secondary or tertiary control. Focusing more on local business models, the EMA may optimize the load of domestic households towards the available power provided by DERs in a local grid.

The infrastructure domain is subdivided into two parts: The infrastructure represented by a simple TCP/IP-network supporting the service-based communication of the agents and a **Registry-Agent**. The latter one provides and manages information about the Device-Agents to the EMA as an additional ancillary service, so it is able to find suitable Device-Agents

for the intended business model.

The **Energy Market** is a reactive agent or entity that provides a platform for an energy exchange. Here DERs can offer their generated power with the according prices, so consumers can evaluate and accept the offers.

At application runtime each Device-Agent has to register at the Registry-Agent giving information about its runtime capabilities, consumption capability, optional optimizer capability and some additional information (geographical or logical position in the grid). A User (Operator/Service Provider) defines the business plan parameters of the EMA i.e. the user group, markets or system targets. The EMA requests suitable Device-Agents at the Registry, reserves the control capability of the Device-Agents, defines a subset of optimizers out of the set of Device-Agents and parametrizes them (e.g. announces which Device-Agents are in the user group, which are the active/optimizing agents and which the passive ones). The optimizing Device-Agents iteratively plan the runtimes of all participating Device-Agents in the group and transmit the result to the EMA. The EMA then parametrizes every devices with its planed runtime.

IV. Implementation of a distributed optimization algorithm

In order to optimize the starting times of the devices, every starting time vector submitted by a Device-Agent could be interpreted as a set of nodes in a directed graph (see Figure 3). Thus, each optimizing Device-Agent receives the same ordered list of Device-Agents to be optimized from the EMA, so they are all traversing the identical graph. The edges of this graph are weighted with the operational price.

This interpretation of the problem domain allows to apply several meta-heuristics for combinatorial optimization. Furthermore, to enable the consumer-side and to use the potential of the embedded-systems, the applied algorithms must be distributable, lightweight and scalable for different environmental conditions. Thus, Meta-heuristics like Evolutionary Algorithms (EA) with their population-based concepts seem to be suitable for such load planning problems.

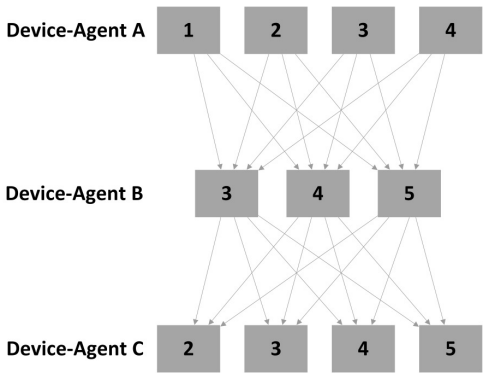

Fig. 3. Runtime vectors of three Device-Agents (A, B, C) interpreted as graph

A. Definition of the optimization problem

The optimization problem for load planning based on a power exchange market can be defined as the cost-minimization of the whole system:

$$I = min \sum_{t=0}^{T} \sum_{j=1}^{A} I_j(t) P_j(t), \tag{2}$$

where T is the number of time slots in the optimization period. Typically it ranges between 96 for quarter hour time slots and 1440 for minute-based time slots. A denotes the number of offers for the prices $I_j(t)$, and $P_j(t)$ the amount of power bought from that offer. A constraint is: $P_j(t) \leq P_{j,MAX}(t)$, meaning that the power bought may never exceed the offered amount.

The bought power is defined as:

$$\sum_{j=1}^{A} P_j(t) := L_N\{\tau_n\}(t) \tag{3}$$

with

$$L_N\{\tau_n\}(t) := \sum_{m=0}^{M} L_m(\tau_1, \tau_2, \ldots, \tau_{n_m})(t) \tag{4}$$

where M is the total number of devices and $L_N\{\tau_n\}(t)$ as the total consumption over all devices participating.

Propagating this problem to the virtual load by the EMS, the Device-Agents of the virtual load try to find cooperatively an optimal scheduling for price-minimization.

B. The distributed ACS

As a reference implementation an adapted version of the Ant Colony System (ACS, see [25]) was used. ACS is an algorithmic metaphor for food-searching ants, placing pheromones on their trail to indicate the shortest path between colony and food-source.

The problem described as a directed graph can be interpreted as a path-finding through the graph, a task ACS originally was designed for. In Figure 5 the global behavior of the optimizing module is illustrated. After the initialization phase, a Device-Agent (Master) with an optimizer module dispatches a certain number of Ant-Agents (Slaves) as its local colony. The local number of Ant-Agents and their serial or parallel execution (see [26]) depends on the properties and restrictions of each participating platform. Besides the nodes, the pheromones were also stored locally at the corresponding Device-Agent. Therefore, each Ant-Agent has to call the Device-Agent's service at least two times, one for the available nodes and one for the corresponding pheromone vector.

An Ant-Agent requests the initial vector of possible starting times from the first Device-Agent in the corresponding ordered list and randomly chooses the first staring time out of the vector and adds it to a temporary vector, before going iteratively through the following steps:

1) It requests the next possible starting time vector and the pheromone vector from the Device-Agent, transmitting the previously chosen starting time.
2) If the vectors are available, the Ant Agent chooses the next node based on the costs of operation (edge-weight) and the according pheromones on the trail.
3) If the Agent receives an *end-of-planning*-Flag it proceeds to the next Device-Agent in the ordered list (if available) and executes step 1.

Every optimizing Device-Agent has its own colony. After every full iteration, e.g. after each of the local Ant-Agent has traversed the graph once, the Master-Agent chooses the best-so-far path and places pheromones at the other Device-Agents along the path through service calls. Because of the different computational speeds of the Device-Agents the pheromone adjustment happens asynchronously. Further synchronizing efforts are not required but fast optimizers may place pheromones more often than slower ones.

In a reference scenario with 100 domestic households, the ACS performs best compared to a basic Ant-System implementation [27] and a greedy algorithm. (see Figure 4).

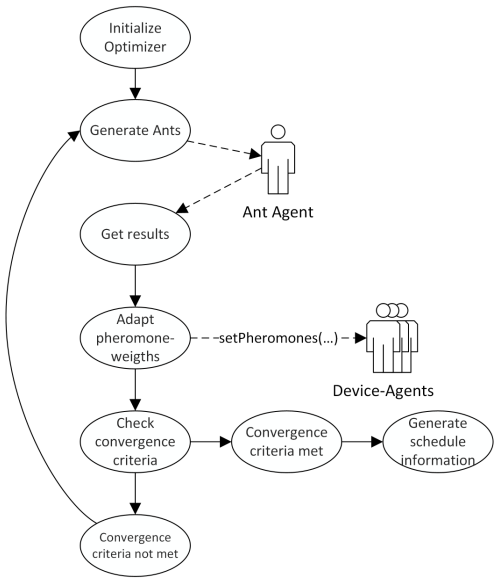

Fig. 5. Behavior of the device-agent optimizing the loads of other device agents.

V. Use-Case: Planning of wind energy resources

A typical use-case for consumer optimization is the day-ahead optimization of predictable and controllable loads for a given load profile. It is often necessary to plan the power consumption according to the optimal utilization of volatile DERs to achieve a higher efficiency. Based on weather forecasts it is in many cases possible to predict the electricity generation capacity of wind turbines with a sufficient accuracy one day ahead. Energy generated by such plans is keen available, as the operation does not require any additional resources and thus the marginal costs are low. Therefore, if the demand is planned accordingly to the generated energy the users may save money through the efficient use of the resource as only a low amount of external (and often expensive) control energy has to be bought in addition.

For this use case example the generated energy of a 330 kW Enercon E-33 wind turbine is used to meet the demand of flexible consumers in a reference scenario. Although the DSM-potential of domestic households is often to be considered relatively low, the results can be easily transferred and compared, as industrial applications have often very specific requirements and constraints. The considered property consists of 100 active domestic households. Accordingly to the dispersion in Germany 92% of them have a washing machine, 62% a dish washer and 4% an electrical heater. This results in 158 program-driven and 4 full-automatic Device-Agents representing and simulating the electrical consumers and appliances. The program-driven agents were statistically parameterized with regard to the *Smart-A Project-Study* [28]. The European-wide mean runtime probability of both washing machines and dish washers based on studies of the University of Bonn (Germany) were evaluated and implemented in the agent models. In order to calculate the runtime flexibility, the usage of power-up delays for the devices as described by the *Smart-A Project-Study* was analyzed. In case of the washing machines 56% of the users chose a power-up delay time period of 0 to 3 hours and 28% a time period of 4 to 6 hours. Therefore, by considering flexibilities up to six hours approx. 84% of the user preferences are considered in this use-case.

The study also shows the general acceptance of power-up delays for these type of devices. The broad degree of utilization alternates between approx. 38% in Sweden up to 81% in Italy in which the actual usage of power-up delays for every stage of washing program goes to approx. 43%. The situation for dish washers is similar. In 2007 39% of them were equipped with a power-up delay capability and 27% of the users were actually using it [28]. It can be assumed that the degree of usage and acceptance will increase further if the distribution of such power-up capabilities grows and more profitable DSM use-case utilizing this function will arise.

The fully-automated-device representing the electrical heater was parametrized with a temperature corridor of 1.0°C around the standard room temperature of 21°C. The heater can be turned on and off again in 15 minute intervals. The outside temperature based on temperature data from the Hamburg's air quality control net for September 15th 2013.

The turbine's power generation was simulated with the Greenius-Tool[5] based on weather data for the same day and scaled to the controllable power demand of 100 households in the reference property. So 10% of the turbine's nominal capacity can be used to meet the requirements of the flexible consumers. The wind power generation simulated here is extremely atypical for the property, where most of the energy is required in the evening hours due to the high amount of program-driven consumers. Therefore, even an optimized

[5]http://freegreenius.dlr.de

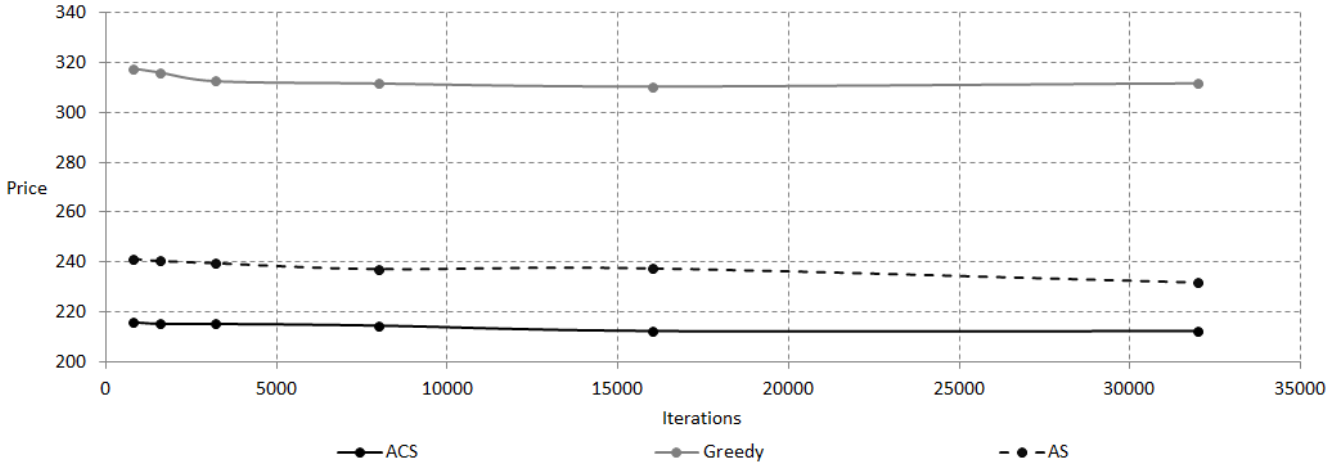

Fig. 4. Comparison between ACS, AS and a greedy algorithms.

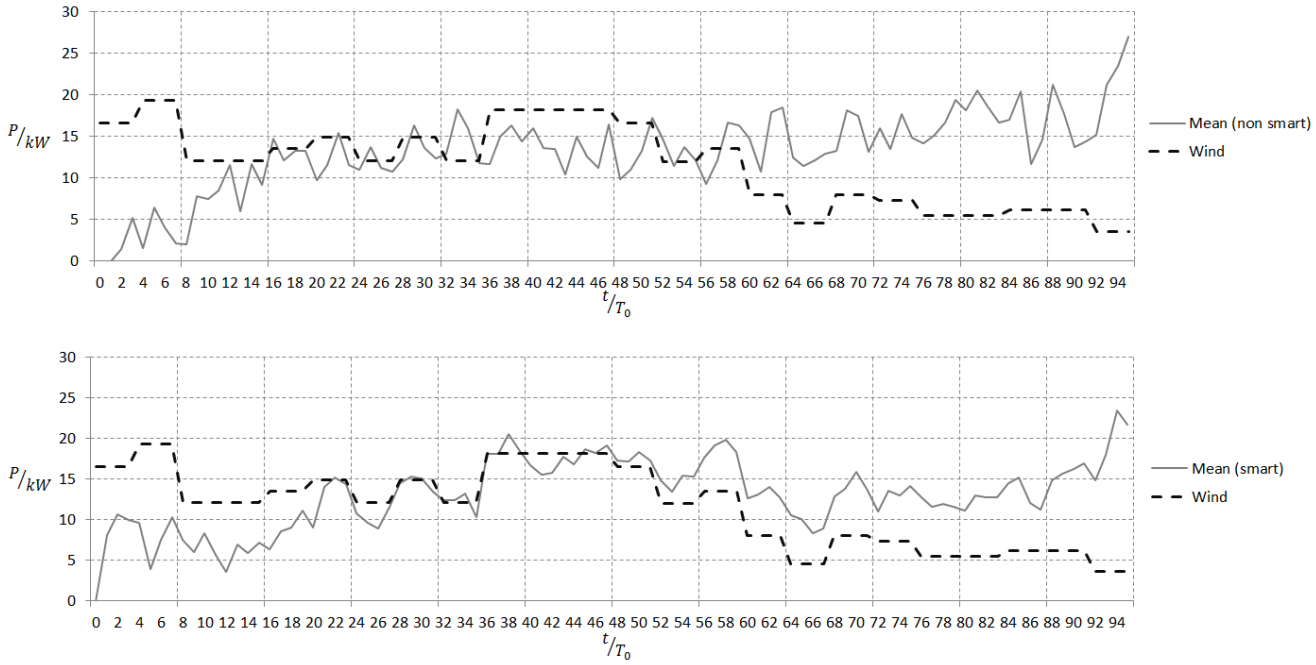

Fig. 6. Use-Case: Comparison of smart load control (below) and uncontrolled energy consumption (above).

schedule will not be able to utilize the available energy completely. But by utilizing the degrees of freedom of the four fully-automatic Device-Agents a significant energy saving can be achieved.

Figure 6 shows the aggregated results for 10 simulation runs. The upper chart shows the results for the uncontrolled energy consumption while the lower one displays the results of the ACS-based smart load optimization. For the latter parts of the day the energy consumption excels the generation as expected, but the optimized load control demands a significant lesser amount of external energy and utilizes especially earlier time slices better. The uncontrolled case utilizes 78,5% of the generated energy, while the controlled case uses 85,6% (+7,1%). This implies that for the uncontrolled case 100,0 kWh of external energy have to been bought in addition, while the optimized scenario requires only 78,5 kWh (-21,5 kWh). The addition of more fully-automated consumers, e.g. refrigerators or freezers should lead to further, significant improvements.

VI. Conclusion and Future Work

In this paper a Demand-Side-Management oriented Multi-Agent-System for distributed optimization was presented. The approach focusses on the automated use of flexibility potentials on the consumer-side. Through the use of a lightweight

and distributed optimization concept the demand-side was integrated into the electricity market. The defined generic Device-Agent supports the planning of both program-driven and fully-automated devices without requiring domain specific knowledge about the optimizing agents. The exchange market model allows the application of many different use-cases, including e.g. *flexible tariffs*.

The implementation of *Ant Colony System* (ACS) as a meta-heuristics for the optimization was described as well as the developed distribution concept of the algorithm. The presented use-case study includes 100 active domestic households with 158 Device-Agents and a wind turbine. The Device-Agents of the households optimized their demand towards the predicted power generation of the wind-turbine. It could be shown that the optimized planning lowered the demand for external energy about 21,5 kWh, even as the generation was extremely atypical for the normal load curve of the property.

Future work will cover several topics of the developed system. First, grid restrictions (avalanche-effect protection, see [20]) will be considered, which includes also the further development of the exchange market and its capabilities. A second aspect is to integrate a wider range of distributed optimization algorithms. Evolutionary Algorithms like Genetic Algorithms or other state of the art techniques of modern Operations Research like combined Branch-and-Cut and meta-heuristics will be examined as first tests have shown that ACS finds very good solutions but leaves room for performance improvement. Also specification for regional market layers as well as generic energy-service descriptions of the typical use-cases could be defined. Furthermore, field tests and the integration of the proposed system as extension into systems like OGEMA or OpenADR can be targeted.

***Abstract*—Power distribution systems worldwide are entering one of the biggest transformations since their inception. The Smart Grid has become a strategic term, which is associated with promising technology enhancement on one hand, but also high investment risks on the other hand. To maximize the former and minimize the latter, power distribution companies are searching for methods and tools to simulate and compare different Smart Grid design alternatives and deployment scenarios.**

In this paper, we draw upon our involvement in the modelling and simulation of the Smart Grid in the Czech Republic, and elaborate possible directions of Smart Grid modelling and analysis research to reach the "quality by design" before the actual Smart Grid realization. The discussion then details a specific design challenge together with its context within the design of the Czech Smart Grid.

I. Introduction

THE CURRENT generation of power distribution networks faces new requirements that stimulate discussion on its future transformation. Some of the strongest triggers that the current power grid fails to keep pace with are the transition to a distributed power generation [1] and demand response optimization [2], whose both rely on mature information exchange and control. This stimulated the integration of the power distribution and information technology domains into the concept of a Smart Grid. The Smart Grid is an electricity network that can cost-efficiently integrate the behavior and actions of all users connected to it—generators, consumers and those that do both—in order to ensure economically efficient, sustainable power system with low losses and high levels of quality and security of supply [3]. The Smart Grid relies on an Advanced Metering Infrastructure (AMI) [4], [2] with a bi-directional communication channel which allows the control of electricity demand at customer level by directly or indirectly (e.g. by on-line adjusting electricity prices) controlling household appliances [2].

The deployment of Smart Grids is becoming a strategic act for many countries, forced by their legislation [5]. European Commission calls in its mandate M411 [6], released in 2009, for the standardization in the area of Smart Metering. The standards should enable interoperability of utility meters (water, gas, electricity, heat), and allow mass production of Smart Meter devices at the competitive European market. The mandate is aligned with the OPEN meter project [7], which ended in June 2011 and delivered open and public standards for smart metering, and consequent OpenNode project [8] with similar endevour regarding low-voltage monitoring.

The transition to the Smart Grid represents heavy investments (in orders of hundreds of millions of Euros) into technology that was never before deployed in such a large scale. To minimize investment risks and maximize benefits, power distribution companies are seeking new ways of Smart Grid modelling and simulation to evaluate and compare different Smart Grid architectures and deployment scenarios. This initiatives aim in each national context at a cost- and quality-effective validated solution, before mass investments into Smart Grid deployment.

Goal of the paper: In this paper, we draw upon our involvement in the modelling and simulation of the envisioned Smart Grid in the Czech Republic, and elaborate a discussion on the possible directions of Smart Grid modelling and analysis to reach the "quality by design" before the actual Smart Grid deployment.

Paper structure: The paper is organized as follows: Section II overviews the history, context and key terminology of the field; Section III discusses the specific research questions related to the modelling, simulation and analysis towards Smart Grid design; Section IV elaborates a specific research question concerned with the communication strategy discussed in the specific context of the Czech Smart Grid design; and Section V concludes the paper.

Related work: Although numerous overview papers have been published in the Smart Grid domain, the discussion of research questions and challenges towards mature Smart Grid design is not receiving systematic attention. The existing surveys instead focus on the goals, impact, benefits, risks and undelaying technology principles (architecture, communication technologies) of the Smart Grid, usually influenced by national research and deployment [4], [9], [2], [10]. The source of the information are hence the research papers elaborating individual research questions in isolation, such as for instance the papers on multi-agent approaches in a distributed Smart Grid [11], [12], [13], security-driven Smart Grid design [14], [15], [16], survivability analysis and Smart Grid self-repair [11], [17], or demand response optimization [18].

II. Background

One of the first large network utilities was built by Thomas Alva Edison in 1882 in New York. Edison promoted direct current for electric power distribution, despite the disadvantages of this approach, namely in short distance between a power plant and its customers (2.4 km was the limit of effective distance), which meant that small power plants needed to be built in customer areas. New research in Europe and America has brought electric motors and transformers working with alternating current and with the help of Edisons major opponent George Westinghouse, the previously used direct current was replaced with the alternating current, which persisted till today. Alternating current could be efficiently transmitted over long distance and hence allowed power plants to be built outside inhabited areas, closer to input resources.

The process of power transmission nowadays involves step-up transformers that transform electricity into very high voltage to decrease transmission losses. Electricity is then transmitted over hundreds of kilometers of transmission network. Before distribution to end customers, the voltage is decreased by a series of step-down transformers, which act as gates between high voltage *power transmission* and low voltage *power distribution networks*.

In the Czech Republic the *power transmission network* consists of power plants, first-level substations and high-voltage power lines. The first-level substations and power plants are connected using 400 kV and 220 kV lines. There is high flow of energy and therefore very high voltage is used to lower the electric current, which leads to lower losses during transmission. The first-level substations produce also 110 kV intended for power distributors.

The Czech *power distribution network* consists of 110 kV lines, second-level substations transforming 110 kV to 22 kV or 35 kV for connected third-level substations. Multiple third-level substations are situated in towns and produce well-known 230V/400V used by end customers.

The current generation of power transmission and distribution network has been designed for centralized electricity generation in a small number of large power plants. Nowadays, this concept is being replaced with a more distributed electricity generation thanks to an increasing amount of predominantly renewable energy sources. European Union supports renewable energy sources in its Energy and Climate Change Policy [20] with the goal to achieve 20% renewables share in the European energy mix until 2020.

The new approach, however, brings up serious issues: (1) Since the grid load changes along the day and since there is no efficient way to centrally store the surplus of generated electricity for later use or to rapidly increase the demand of electricity, power plants have to adjust their electricity production to meet the expected demand. Immediate production change is very complicated for most types of power plants, so both the consumption and the production of the renewables have to be predicted in advance, which brings additional risks to the whole process of electricity production and distribution. Moreover, thoughtless connection of many uncontrolled renewables (e.g. photovoltaic panels) may (2) damage the current grid or (3) cause significant technical losses, because the amount of generated electricity may in specific areas exceed its demand and overload the related part of the grid.

The first step towards effective management of power distribution is Smart Metering, which measures and collects power consumptions of individual customers. In particular, the deployment of Smart Metering can provide the following inputs for smart power distribution management:

a) Collection of power consumption data: Without deployment of Smart Meter units, the power consumption measurements are automatically collected only during electricity transmission in large substations. In the Czech Republic, moreover, only very large customers have similar devices already deployed. Collection of more data from individual consumers and all substations is a necessary condition of reliable predictions, which can help to locally balance the grid load.

b) Early fault detection: Current generation of power grids can only detect failures in substations that are connected via computer network to a control center that monitors the grid. It is also possible to detect broken high-voltage wires. But when it comes to individual customers, it does not provide means to detect power outages at individual customer level, because such an outage cannot be detected directly from the substation. In the Czech Republic, this type of outage is usually reported by the customer via a phone call at distributors service line. Nowadays, to detect this type of outage automatically, each monitored customer needs to be equipped with a device that periodically sends hearth beat signals to the substation. Smart meter measurements sent to a substation can substitute the hearth beat signaling.

The current state of the practice in power transmission and distribution implies numerous challenges for the Smart Grid design and deployment, many of which could be adressed with multi-agent approaches. The next sesion discusses these challenges and related research questions in detail.

III. Smart Grid modelling, simulation and analysis

To minimize the risks associated with the Smart Grid deployment and maximize its quality across multiple quality attributes, possible modelling and simulation techniques to evaluate and compare different Smart Grid design alternatives before the actual deployment are becoming of high interest to power distribution companies. This section summarizes the specific research questions towards Smart Grid design that we identified with our industrial partners, and aims at opening the discussion on the newly establishing research field of Smart Grid design support, to which the computer science, and multi-agent research in particular, can strongly contribute. The areas include:

Fig. 1. Map of the Czech transmission network, where red labels are the major power plants, red lines are 400 kV lines, purple dots are large substations and blue lines are 220 kV lines [19].

A. Prediction of the expected consumption
B. Load control
C. Energy backup and storage
D. Hardware infrastructure design
E. Smart grid topology design
F. Decision on the types of information to be exchanged and transferred
G. Evaluation of Smart Grid communication strategies
H. Quality assessment of different Smart Grid design options

A. *Prediction of the expected consumption*

Smart metering can significantly contribute to the creation of a new global power consumption model, recording power consumption even at an individual customer level. Such a model can be used for the prediction of expected electricity consumption. As mentioned in [2] a valid consumption-prediction model is much more complex than it used to be before, because of customer life style change. Also, a need to predict locally-dependent consumption and ability to react on lower electricity prices arises together with the requirement on local load-balancing.

We identified the following research questions associated with this topic:

- How to predict power consumption in both normal and crisis situations?
- What is the appropriate level of detail on which the consumption should be studied? How to cluster the Smart Grid architecture into consumption-relevant levels for analysis?
- What trends and technologies may significantly affect the validity of current prediction models? How to predict the consumption associated with the increasing use of electric automobiles?

B. *Load control*

The goal of the load control is to lower the gap between the base load and the daily peak load in each locality. This can be achieved by shifting power usage to off-peak hours, in particular to balance production of local renewables. There are multiple advantages of this approach: (1) It decreases the maximum power generation and transition capacity required to avoid blackouts; (2) It avoids extensive stopping and starting of power generating units by shaping the power usage to remain relatively constant over time [2]; (3) It helps avoiding electricity overflow from low voltage to high voltage and related problems mentioned above. This can be achieved either manually by motivating the customers to shift their power usage via variable pricing models or automatically by remote power distributor signaling that controls customer equipment.

In the Czech Republic, a combination of both mechanisms is used for households with water boilers which are controlled remotely via HDO signals[1]. The signals are broadcasted together with a code of the controlled area, so that only HDO switches in the targeted area are affected. Nevertheless, since these groups are fixed, one cannot smoothly control the load-balance, hence this solution works only partially and cannot be considered sufficient for the uprising problems with local renewable energy sources.

[1]HDO is a shortcut that stands for “Massive Remote Control” in Czech.

There are algorithms that can optimize the power demand at the customer level based on the electricity price. One of them is described and validated in [18]. However, to validate such a demand response model in a global context, we need to step-up in the hierarchy and model many interconnected customers in the grid and mainly the behavior of the distributor, who sends impulses (in form of real-time price or direct control of appliances) to increase or decrease the demand.

The research questions that could be answered with the help of a complex demand response model are:

- Are the current communication channels suitable for reliable control of customer appliances or real-time delivery of the price? How does the system behave in case of a broken communication line?
- How effective is the proposed demand response model in terms of lowering the gap between the base load and the peak load? What is its response time?
- What is the overall reliability and safety of the proposed solution? What happens if the load control mechanism misbehaves? E.g. intelligent agents start to spread invalid information to other agents in the grid which leads towards a snowball effect? What protection needs to be implemented to ensure grid survivability in such a case?

C. Energy backup and storage

One of the consequences of high difference between the base and peak load in current power grids can be the need for large-scale (to balance the whole grid) and small-scale (to balance individual areas) energy storage. As for the large-scale energy storage, according to Electric Power Research Institute the pumped-storage hydroelectricity provides more than 99% of bulk storage capacity worldwide [21] with the efficiency that varies between 70% and 80%.

Another approach to energy storage is the agent based micro-storage introduced by Vytelingum et al. [22]. This approach models the use of small capacity batteries (4 kWh) deployed in households and accompanied with an intelligent agent, which may be an integral part of a Smart Meter. The agent buys electric energy when it is cheap and stores this energy in batteries for its use during peak time when energy price increases. According to the study, this system can achieve savings of up to 13% for an average customer using a 4 kWh battery. Moreover, in case of power outage, the system can work as an energy backup. Other approaches involve electromobile batteries or local hydrogen production.

The research questions associated with this domain are:

- How to predict required energy storage capacity in case of successful Smart Grid deployment?
- Shall households employ local small-capacity energy storage? Will their deployment affect the overall demand-response strategy? Should they be strictly controlled by the utility provider or should they autonomously react on incentives (lower energy prices)?
- How will the demand response problem be affected by growing share of electro vehicles which are charged mostly over night or during working hours? Should be the chargers controlled remotely? How to balance the need of the user to charge the vehicle and the need of the grid to govern the demand? How to predict electric vehicle usage and its recharge power consumption?
- How to solve the problem of energy surplus when the demand response mechanism fails?

D. Hardware infrastructure design

The goal at least in the Czech Republic is to minimize hardware infrastructure investments and construction costs, and hence reuse as many existing infrastructure elements as possible when transiting to the Smart Grid. The suitability of every reused component should be individually assessed together with its parameters such as component dependencies, reliability, replacement costs and other associated limitations comparing to modern alternatives. Such an evaluation process, which is in fact multi-objective optimization, may be very slow and complex when done manually. Therefore, it is beneficial to employ a Smart Grid model with all relevant components modelled together with their dependencies and parameters. The model can be then used for semi-automatic or automatic evaluation of different versions of hardware components and their associated risks and benefits. The automation of this process may lead to more complex analysis of the model in a larger scale, which may identify previously hidden solutions that can be easily validated with running simulation on top of the grid models.

This approach is suitable for the modelling and validation of Smart Meter features, communication elements, and data concentrators. Even control and data-processing software can be evaluated in this way.

The most relevant research questions are:

- What design strategies can be used to maximize the quality of the Smart Grid under the constraint of legacy infrastructure?
- What hardware infrastructure changes will imply the highest ratio of quality increase to implementation costs (i.e. quality/cost)?

E. Smart grid topology design

The overall Smart Grid quality and behavior depends not only on the hardware components, but also on their organization into the grid topology. The topology, which determines the logical architecture of the grid, can take advantage of different levels of centralization (e.g. customer data from a given region managed through a single substation), hierarchical structure (e.g. substations governed by parent substations) and redundancy (to minimize the critical chain effects and maximize grid survivability in case of local outage).

The relevant research questions towards the logical architecture of a Smart Grid are the following:

- What shall be the level of centralization within the Smart Grid?

- Shall the substations and other grid components be organized in a hierarchical manner? If yes, how many levels should be used?
- What level of homogeneity/heterogeneity (with respect to the smart logic within the grid nodes) is most beneficial?
- What are the critical chains of the Smart Grid with respect to the consequences of their outage?
- What is the level of grid robustness and survivability? What are the most cost-effective topology improvements that significantly increase robustness and survivability? What is the expected benefit of self-repair mechanisms comparing to their implementation costs?

F. Decision on the types of information to be exchanged and transferred

The concept of a Smart Grid relies on the transfer of various information between grid components. The Advanced Metering Infrastructure (AMI) needs to transfer measurement results collected from Smart Meters for processing purposes, substations need to report their state to a parent substation in case of hierarchical infrastructure or broadcast their state to other substations in case of multi-agent processing.

To minimalize the traffic among Smart Grid components, the information value of different types of data needs to be understood and used to drive the identification of needless data, whose transfer should be limited. On the other hand, the critical information types shall be prioritized in the communication.

The relevant research questions include:

- How to identify and model importance of collected measurements for later processing in the Smart Grid? How this process can be automated?
- What is the ideal collection frequency of measurements from Smart Meters to satisfy the legislation needs, ensure sufficient precision of prediction models and help load balancing on one hand and lower the communication line load on the other hand?
- How to efficiently identify dependent information for producing complex measurements across more elements in the grid?
- What is the acceptable age of particular type of information for a given stakeholder?

G. Evaluation of Smart Grid communication strategies

Modelling of different communication strategies in the Smart Grid is essential for the evaluation of grid behavior in different situations. Identification of a suitable communication strategy is often hindered with a set of constraints that must be fulfilled. For instance, one of the primary restrictions in the Czech Republic is the employment of existing communication infrastructure, because significant rebuild of the infrastructure would unacceptably increase the Smart Grid deployment costs. When following the physical structure of the grid described above, we need to transfer measurements from Smart Meter units placed at customers electrical connections to a datacenter for processing, and control commands back to the elements of the grid. The problem is that a Smart Meter cannot be usually connected directly to the computer network to send all required data securely over the Internet.

Employment of the Internet connection of the customer for direct connection of the Smart Meter to the Internet would be a solution, but in terms of its availability, reliability and the legal complexity, it is merely impossible to deploy it nationwide.

There are two available groups of technologies that can be used in Smart Grids to transfer data between the elements of the grid—data transfer over power lines and wireless data transfer. Possible use and issues associated with these technologies in the Czech Smart Grid are examined in Section IV.

Relevant research questions for this area are:

- Can network modeling and network simulation tools be used in large scale as Smart Grid modeling and validation requires? What optimizations need to be done prior their use?
- What level of precision in a network simulation is required for trustworthy validation of the communication strategy?
- What communication channels and communication strategies are suitable for control channel? What are the requirements that control channels need to meet?
- Is it better to transfer raw measurements or pre-processed data? Where does the processing take place?
- How can we increase the reliability of the line? How can we get cost-effective line redundancy?

H. Quality assessment of different Smart Grid design options

The quality evaluation, prediction and optimization during Smart Grid design are critical cross-cutting concerns to all the research issues discussed above. The Smart Grid quality is typically understood in terms of the grid reliability, security and efficiency, and considered along with its environmental and energy sustainability and cost.

The reliability engineering in the Smart Grid domain aims at incorporating autonomous control actions to enhance reliability by increasing resiliency against component failures and natural disasters, and by minimizing frequency and magnitude of power outages subject to regulatory policies, operating requirements, equipment limitations, and customer preferences [23]. This includes the techniques for automated failure detection, isolation and restoration (FDIR), and terms such as grid survivability and robustness.

The security requirements for a Smart Grid are mainly the authenticity, integrity, and privacy of metering data, along with the safety and availability of the grid [24]. The Smart Grid design shall aim at resiliency against malicious attacks through better physical security and cybersecurity, to protect the infrastructure, energy asset and data of the grid.

The efficiency of a Smart Grid refers to the infrastructure utilization on both the energy-transfer and data-transfer level. The new research questions emerge mainly in the context of data-transfer efficiency, which is specifically concerned with

the level of utilization of communication channels and latency of data delivery.

The research questions concerned with the quality assessment and optimization include:

- Which of two or more Smart Grid design options is better with respect to a specific quality attribute?
- How shall a specific Smart Grid design alternative be changed to optimize a specific quality attribute (under given constraints, such as the cost)? E.g. to optimize the time needed for failure detection, isolation and grid restoration.
- What is the quality trade-off of different quality-related strategies? E.g. what is the security improvement and efficiency degradation of a specific security strategy?
- What is the context (characteristics of the settings) in which a specific quality-improving strategy yields highest benefits?
- Can the Smart Grid reach a specific unsafe condition (i.e. a state violating safety specification)?
- What are the critical components of the Smart Grid with respect to a specific quality attribute? E.g. what are the most critical components with respect to grid security or survivability? What communication links have the highest impact on data-transfer latency?
- What is the level of satisfaction of individual stakeholders, including the energy distributors, customers and public organizations?

Following on from these research questions the next section describes in detail various communication strategies that are being currently evaluated by Czech power distribution companies for potential deployment in their Smart Grid projects.

IV. Situational study of the communication strategy for the Czech Smart Grid

Together with our industrial partner, the Mycroft Mind company, which is a leading expert in the field of Smart Grid simulation in the Czech Republic, we are researching new ways of Smart Grid modelling, simulation and analysis that can be integrated into their analytical tool called Grid Mind.

One of the biggest challenges in Smart Grid deployment in the Czech Republic is the communication strategy. The Advanced Metering Infrastructure (AMI) produces waste amount of data that needs to be transferred to a datacenter of the power distributor for processing. Every day the grid of the CEZ power distributor is expected to produce more than 340 Million measurements. The key concern is that the current communication channels will not be able to transfer the measurements in time. Another challenge is to process the measured data at real time, which is necessary for effective demand response optimization. Last, there is a concern that the control channels will not be able to deliver the control commands with the necessary level of reliability.

Our colleagues at the Faculty of Informatics, Masaryk University, Brno, were involved in the research examining what transfer characteristics can be expected with different versions of GPRS. We now look at this problem in a broader way. Together with Mycroft Mind we are building a modelling and simulation environment that is planned to be used for modelling, simulation and validation of various communication strategies in the Smart Grid, whose key characteristics are elaborated in the rest of this section.

There are two available groups of technologies that can be used in a Smart Grid to transfer data between the elements of the grid—data transfer over *power lines* and *wireless* data transfer.

The Power Line Carrier (PLC) technology stands for a family of communication protocols and technologies that transfer data over *power lines*. Different PLC technologies vary in frequency ranges used as transport medium for data: NPL (Narrow Power Line) uses frequencies between 3 KHz and 148.5 KHz, BPL (Broadband Power Line) uses higher frequency range between 2 MHz and 50 MHz. The quality of the data transfer is significantly dependent on the properties of the power line, such as the path attenuation and noise in case of medium voltage lines connecting primary to secondary substations. The number of parameters that need to be evaluated increases when low voltage lines that connect secondary substations and Smart Meter devices are used. More detailed characteristics of PLC technologies can be found in [25].

In the low voltage network there are two types of devices: central low voltage unit (CLU) and remote low voltage unit (RLU). CLU is located at low voltage substations usually with a few hundreds of connected customers. RLU is built into a Smart Meter and may act also as a repeater in order to extend the action radius of the PLC signal. The PLC communication medium is composed of sub networks defined by CLU. To avoid collisions, access to PLC medium has to be controlled, therefore CLU controls all the traffic and RLU are allowed to communicate only in case they respond to CLU's request.

PLC was chosen as a suitable technology for centralized collection of measurements from Smart Meters. The benefit is that it uses existing power lines which decreases deployment costs and provides sufficient communication channel for collection of power consumption measurements. The deployment of this technology is currently being validated using almost 40,000 Smart Meter units deployed in four Czech towns [26]. The problem is how to transfer the collected data from substations.

The latter group of technologies usable for data transfers in the Smart Grid is *wireless* transfer. There are many available wireless communication technologies that can be effectively used for measurements transfer to a data center for processing. We discuss some of the technologies usable over large distance and explain their advantages and disadvantages below.

a) 2G GPRS/EDGE: In the Czech Republic, the coverage of public cellular networks is approaching 99% of area. 2G cellular networks provide data services in the speed of kbps or tens kbps. These data services are optimally tailored for automated meter readings. Mobile operators offer data-only SIM cards for industrial use with lower communication priority. No investments into network infrastructure are needed

for cellular network-based AMI solutions. Transferring data over 2G cellular network from each individual Smart Meter unit would not be cost effective in terms of running costs paid to mobile operator, therefore we propose to use this technology to transfer collected data from substation. It is necessary to model such a situation and validate if the transfer speed of 2G networks is sufficient.

b) 3G UMTS: 3G cellular networks are extending the functionality of traditional 2G networks, allowing data transfers at significantly higher speeds. With HSPA extension peak data rates up to 14 Mbit/s in the downlink and 5.75 Mbit/s in the uplink are supported. Data rates of 3G networks are fully sufficient for AMI purposes. In the Czech Republic, most of the 3G coverage is in densely populated areas. According to the data provided by the Czech Telecommunication Office, the mobile operator with the best 3G signal coverage covered at the end of year 2012 only 48% of the Czech Republic [27]. Substations in uncovered areas will have to rely on slower 2G networks.

c) 4G LTE: LTE cellular network rapidly increases transfer speeds up to 100 Mbit/s. Mobile operators started to deploy this communication technology in the Czech Republic at the end of 2013. The Vodafone mobile operator selected this technology as a complement to their 3G network which will not be extended anymore. They would like to primarily upgrade 2G EDGE connection in places uncovered by HSPA to cover 93% of the Czech population with 3G or 4G connectivity until December 2014. Such a rapid deployment of LTE as a replacement of 2G network should be considered in evaluation of Smart Grid communication model in case of 2G networks insufficient speed.

d) WLAN/WiFi: Broadband wireless technologies based on the IEEE 802.11 standard have found broad acceptance worldwide for wireless area networking. The use of WLANs for AMR has been frequently reported. In the US, several cities (e.g. Santa Clara, CA) already use WLANs to automatically collect readings from electricity, gas, and water meters [28]. Using 802.11s technology supporting mesh may provide a technically attractive solution for AMR [28]. Use of public WLAN in municipalities, if available, may solve problems with connection availability at substations, but considerable number of substations is out of reach of WLANs. Using WLAN as primary connection technology for measurements collection is less reliable than PLC.

e) WiMAX: Worldwide Inter-operability for Microwave Access is a wireless broadband access technology which has been designed to provide transfer speeds up to 72 Mbit/s in both directions. Communication range varies between few kilometers in case of non-line of sight conditions and 50 km in case of line of sight conditions. Deployment of a dedicated WiMAX network solely for the purpose of an AMI likely cannot be justified. In those areas where public WiMAX services are available (e.g. municipal networks), WiMAX may principally be an option [28].

f) ZigBee: ZigBee standards-based protocols provide infrastructure for wireless sensor network applications. ZigBee is capable of creating a mesh network, which provides additional capabilities—increased redundancy, self-configuration and self-healing. Situation of building nationwide dedicated network using ZigBee is the same like in case of WiMAX. Possible use of ZigBee wireless network in terms of Smart Metering is connection of individual sensors where the power line does not meet quality requirements of PLC based protocol. Another use may be peer-to-peer connection between substations to increase redundancy or capacity of Internet connection (e.g. EDGE).

g) Satellite systems: Satellite system are suitable for sending measurements in areas where no suitable terrestrial infrastructure is available. Today, there is a number of satellite operators offering data transfer services. For instance Iridium service, which uses low earth orbit satellites or SpaceChecker that uses geostationary satellites. Deployment in areas covered by other communication infrastructures needs to be evaluated, because costs are expected to be significantly higher than use of other terrestrial communication technologies.

The infrastructure that is currently examined in the Czech Republic combines PLC technology to transfer measurements from Smart Meters to a substation. Each substation is collecting data usually from a few hundreds Smart Meters. The data concentrator unit, which is deployed at substations, can process data locally which opens new possibilities in building more decentralized solutions. Each data concentrator is equipped with a cellular network modem, in the Czech Republic usually EDGE technology, and sends data to a data center. This approach brings significant improvement in terms of connection costs reduction but increases the demands on speed and reliability of Internet connection available at substations, because more collected data needs to be transferred from a single point.

We were provided with the operational measurements of data transfer speed and latency of currently used GPRS communication channel in the test deployment of Smart Grid in the Czech Republic. The used low-priority industrial SIM cards can utilize only 10% of the communication capacity of a mobile base transceiver station (BTS), therefore under heavy load they operate only at the speed of few Kbits per second. Provided measurements show problems with connection handling across different levels of the network stack. If there is a network connection that is not used for a longer period of time, this connection is disconnected by the BTS at the physical level, but the TCP connection remains open. Any later attempt to transfer data via this broken TCP connection results in a communication failure and a need to reopen the connection which takes a few seconds to establish. The discussed problems illustrate the need to build a valid simulation model of the network communication in the Smart Grid. To be able to handle the high complexity of this model, we propose together with our industrial partner Mycroft Mind decomposition of this model into three interconnected simulation models. The

first model describes the simplified behavior of the physical layer, the second model describes the simplified version of the transport protocol and the third model describes used application protocols. The Grid Mind simulation environment utilizes the discrete event simulation and proposed models to evaluate different communication channels, protocols and communication strategies.

Constraint in a form of available Internet connection at the locality of the substation is one of the key problems that needs to be evaluated using correct modelling and simulation approaches.

V. Conclusions

To minimize the risks associated with the Smart Grid deployment and maximize its quality across multiple quality attributes, possible modelling and simulation techniques to evaluate and compare different Smart Grid design alternatives before the actual deployment are becoming of high interest. In this paper, we elaborated a discussion on the possible directions of Smart Grid modelling and analysis to reach the "quality by design", and presented specific research questions towards Smart Grid design that we identified with our industrial partners. One of the research questions, concerned with the communication strategy, was then discussed in detail and linked to the specific situation in the Czech Republic. The communication strategy evaluation is at the same time our ongoing research aim, which will be in the future extended in the direction of the research questions discussed in this paper.

Acknowledgement

We would like to thank our industrial partners, especially the Mycroft Mind company and its head Filip Prochazka, for the fruitful discussions and valuable inputs that made this paper possible.

***Abstract*—The increasing pervasion of information and communication technology (ICT) in energy systems allows for the development of new control concepts on all voltage levels. In the distribution grid, this development is accompanied by a still increasing penetration with distributed energy resources like photovoltaic (PV) plants, wind turbines or small scale combined heat and power (CHP) plants. Combined with shiftable loads and electrical storage, these energy units set up a new flexibility potential in the distribution grid that can be tapped with ICT-based control following the long-term goal of substituting conventional power generation. In this contribution, we propose an architectural model and algorithms for the self-organization of these distributed energy units within dynamic virtual power plants (DVPP) along with first results from a feasibility study of the integrated process chain from market-driven DVPP formation to product delivery.**

***Index Terms*—Smart Grid, Virtual Power Plant, Agent-Based Control, Self-Organization.**

I. Introduction

DISTRIBUTED energy resources like photovoltaic (PV) plants, wind turbines or small scale combined heat and power (CHP) plants entered the energy market in many European countries, especially Germany, with the financial security of guaranteed electrical feed-in tariffs. With their share in the market still rising, a concept is needed to integrate them into the very same regarding both real power and ancillary services to reduce subsidy dependence and follow the goals as defined by the European Commission.

Virtual power plants are a well-known concept for the aggregation of distributed energy resources (DER) to deliver both energy products and ancillary services [1]. Besides the control of generation by distributed energy resources like e. g. photovoltaic plants, shiftable loads like heat pumps, water boilers or air conditioners can be controlled to adapt the load profile regarding different optimization targets. Electrical storage may additionally be a new player in this scene, delivering even more flexibility for the optimized use of distributed generation. To address these three aspects, generation, load and storage, we will refer to distributed energy units (DEU) for the rest of this paper.

Parts of this work have been funded by the Lower Saxony Ministry of Science and Culture through the 'Niedersächsisches Vorab' grant programme (grant ZN 2764) within the project cluster Smart Nord.

In this contribution, we present an architectural model and algorithms for conjoint distributed aggregation algorithms using flexibility modelling and distributed scheduling heuristics. We present the evaluation environment that will be used for the evaluation of these conjoint processes within dynamic virtual power plants (DVPP) for the use case of active power delivery on current energy markets like the European Power Exchange (EPEX SPOT), along with first results from a feasibility study implementing these processes. In developing the integrated process shown here, we followed the Smart Grid Algorithm Engineering (SGAE) approach described in [2].

To tap the full flexibility potential of all energy units in the distribution grid we set up the following domain-driven paradigms for DVPPs (cf. [3]):

- Distributed energy units have to trade their services on markets, for both active power products, and ancillary services (as far as possible; see e. g. [4] for the position of the German Federal Network Agency regarding this topic).
- To dynamically adapt to current power system operational states and handle the vast amount of DEU in the distribution grid, an approach based on self-organization principles is used. By this means, characteristics like robustness, scalability and adaptivity of the overall system should be gained.
- DVPPs should be set up on a per-product base, thus allowing for optimal aggregation of energy units regarding the products needed. The paradigm of a dynamic VPP with respect to the product obligation is completely different from current virtual power plant concepts. It has to be evaluated, if more flexibility can be extracted from the distribution grid with such a highly dynamic approach.
- The potential of DVPPs for power system control lies in their units' flexibility. Therefore a generic representation of these flexibilities is needed, building the foundation for all DVPP mechanisms concerned with DEU scheduling.
- For active power delivery on energy markets, the operation of DEUs is controlled using operation schedules for all different types of units. The resolution of the DEUs' operation schedules should reflect current schedule resolutions by indicating mean active power values

978-83-60810-58-3/$25.00

for each 15 min. time interval. This is different to the current handling of renewable energy sources – current systems work with prognoses and use schedules only for controllable generating electricity units.
- To deliver ancillary services with locality constraints (like voltage control), DVPPs have to be able to reflect the grid topology. Therefore grid topology should be an optional parameter in the aggregation process and within the operation of DVPPs.

Within this context, the objective of this contribution is to introduce a seamless process chain for day-ahead based active power provision by means of DVPPs. We present an integrated multi-agent system (MAS) realizing the aggregation algorithm, the scheduling heuristic as well as the flexibility modelling used for DVPP management. For this, we start with an overview on the state of the art regarding distributed control in energy systems in Section II and show why this control scheme is appropriate for DEU interaction on energy markets. In Section III we introduce the use case of active power delivery on day-ahead markets in detail. In Section IV the algorithms for the aggregation of agents to dynamic VPPs are explained, showing how grid topology is a guidance in this process without yielding hierachically restrained static aggregation schemes. The scheduling of DEU is depicted in Section V. In Section VI the generation of surrogate models to represent DEU flexibilities is explained. The integrated agent model with respect to the generation and usage of this surrogate model is shown in Section VII. The evaluation architecture and first results from a feasibility study are presented and discussed in Section VIII. We finish this contribution with a conclusion and an outlook on future work in Section IX.

II. Distributed Control in Energy Systems

The operational management of energy systems involves a number of complex tasks ranging from technical aspects like supervisory control and data acquisition (SCADA) to organizational measures performed by business management systems (BMS). These are coupled within an energy management system (EMS) based on information and communication technology (ICT). Traditionally, the EMS is implemented as a centralized control system. However, given the increasing share of DEUs in the distribution grid today, the evolution of the classical, rather static (from an architectural point of view) power system to a dynamic, continuously reconfiguring system of individual decision makers endangers the feasibility of such centralized control schemes. In the seminal work of Wu et al. [5], the need for decentralized control has been identified as follows: "Control centers today are in the transitional stage from the centralized architecture of yesterday to the distributed architecture of tomorrow. [...] To summarize, in a competitive environment, economic decisions are made by market participants individually and system-wide reliability is achieved through coordination among parties belonging to different companies, thus the paradigm has shifted from centralized to decentralized decision making." In line with this vision, the International Energy Agency (IEA) describes a possible transition to decentralized control in three steps [6]:

1) **Accommodation.** Distributed generation is accommodated into the current market with the right price signals. Centralized control of the networks remains in place.
2) **Decentralization.** The share of DG increases. Virtual utilities optimize the services of decentralized providers through the use of common communications systems. Monitoring and control by local utilities is still required.
3) **Dispersal.** Distributed power takes over the electricity market. Microgrids and power parks effectively meet their own supply with limited recourse to grid-based electricity. Distribution operates more like a coordinating agent between separate systems rather than controller of the system.

The concept of a *virtual utility* mentioned therein was introduced in the late nineties and describes a "[...] flexible collaboration of independent, market-driven entities that provide efficient energy service demanded by consumers [...]." [7] Virtual power plants (VPP) have been studied extensively as a derivation from this concept with a number of successful realizations [8]. Additionally, different operational targets have been defined and implemented for VPPs, like aggregating energy (commercial VPPs) or delivering system services (technical VPPs) [1]. These VPP concepts form a basis for the decentralization stage in the transition path above. However, such VPPs usually focus on the long-term aggregation of generators (and sometimes storages) only and are each still operated in a centralized manner. For an implementation of the dispersal stage in the transition path, a more flexible concept is required. In the last years, a significant body of research emerged on this topic. For instance, [9] surveys the use of agent-based control methods for power engineering applications. Exemplary applications can be found in [10], [11], [12]. Finally, a research agenda in this context was proposed recently in [13].

In contrast to the work referenced above, the concept of DVPPs explicitly takes the current market situation into account for the process of forming aggregations of DEUs: DVPPs form with respect to concrete products at an energy market, and will dissolve after delivering a product. Additionally, fully distributed control algorithms are being used, as will be shown in the following sections, building the foundation for the dispersal stage in the mentioned transition path. A preliminary description of the concept including a detailed differentiation from related approaches was given in [3].

III. Dynamic Virtual Power Plants

To introduce the concept of dynamic virtual power plants and show which tasks have to be performed by the software agents, we refer to the use case of active power products traded on the day-ahead power market, where product trading is based on an auction mechanism as described in [3] (see Fig. 1). From the market perspective, three different phases have to be distinguished. In the first phase, bids can be placed in the so-called order book for predefined product types. Once the

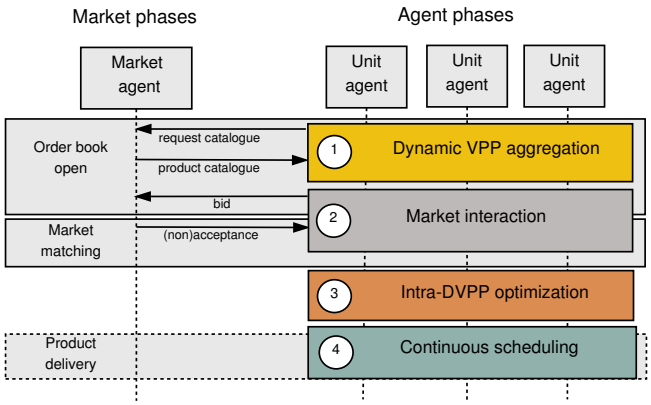

Fig. 1. Simplified use case of a dynamic VPP delivering energy products on a day-ahead market

order book is closed (e. g. at 12 a.m. for active power products traded day-ahead in Germany at EPEX SPOT) a matching mechanism clears supply and demand bids to set up the market price. In the last phase, these products have to be delivered, but no distinct market actions are entangled with this phase: the surveillance of product delivery and associated actions for balancing are subject to balancing group management.

To implement this process with regard to DVPPs, unit agents are set up to represent distinct DEUs within a multi-agent system. Four sequential phases within these unit agents are needed for active power delivery on day-ahead markets, as can be seen on the right hand side of Fig. 1:

1) **Dynamic VPP aggregation:** First, energy units have to be appropriately aggregated to DVPPs with the goal to deliver active power products. Grid topology has to be an optional parameter in this phase.
2) **Market interaction:** In the second phase, DVPPs place their active power products on the market by means of a *representative* agent for each respective DVPP and are informed about acceptance after market matching. Thus, after market matching the units' obligations regarding their power contributions are known.
3) **Intra-DVPP optimization:** Within a third phase, an intra-DVPP optimization is performed, taking into account these obligations and updated prognoses regarding the units' operational states.
4) **Continuous scheduling:** The last phase is concerned with continuous energy scheduling to ensure product fulfillment. In case of an incident endangering product delivery a rescheduling of the units has to be performed.

In Fig. 2 the same process is shown from a more detailed perspective regarding the software agents. An exemplary energy unit is shown on the left hand side that is controlled by a unit agent. To the right of this unit agent, one additional unit agent is shown with less details as example for all other unit agents. Last, a market interaction agent is shown. Details on the different agent roles during DVPP setup are given in Section IV.

In the first phase of dynamic VPP aggregation, the agent *unit_agent_1* identifies relevant market products via an interaction with the market agent. With this information, it starts the VPP aggregation process. The result of this process is a (product-specific) DVPP consisting of a set of unit agents, with a designated *representative* and a DVPP schedule mapping the DEUs to operation schedules in such a way that the product can be fulfilled.

In the next phase (market interaction), the *representative* bids at the market. After market matching, it is informed about the product to be delivered. The *representative* communicates the needed contributions to all other unit agents within the DVPP. A unit agent might have proposed active power delivery of his unit in several DVPPs (e. g. for adjacent hourly time intervals, i. e. different power products). As all obligations are known to all unit agents within the DVPP after market matching, an optimization can use remaining flexibilities. For all DEU within the DVPP, updated forecasts and measurements can be used to optimize product delivery in this step, before configuring the units with these optimized schedules.

All unit agents have to follow the same task in the last phase, from unit schedule configuration until the product delivery is finished: They have to ensure the delivery of the DVPP active power product. Therefore, the unit agents continuously (e. g. on a minute base) check the unit's operational state and check it for schedule compliance. If a unit is not following the desired schedule and if the overall DVPP active power contribution will not fulfill the defined product as a consequence, a rescheduling is performed within the DVPP agents.

In the following sections we will focus on the algorithmic details of the aforementioned steps.

IV. Dynamic Aggregation

The problem of dividing the unit agents into several DVPPs can be generally described as coalition structure generation (CSG) problem. Goal of CSG is to find an optimal partition of a given set of agents A, referred to as coalition structure (CS). The elements of a coalition structure are coalitions (C) and can be evaluated using a value function $v(C)$, where the value of a coalition structure, $V(CS)$, is calculated as the sum of values of all comprised coalitions. Goal of a CSG algorithm is to maximize $V(CS)$. There are different algorithmic solutions for CSG problems, including dynamic programming, anytime optimal solution strategies and heuristic approaches [14]. The dynamic aggregation process described in the following provides a heuristic solution to the CSG problem. For a detailed description of the considered setting see also [15].

The dynamic aggregation of energy units takes place within a defined market area which is represented by a power grid comprising a set of connected DEUs. Each DEU is supervised by a unit agent as described in the previous section. General goal of the aggregation process is an optimized provision of active power on a global level. To this end, agents are generally able to cooperate in order to form coalitions and aggregate the capabilities of their supervised DEU. The purpose of each coalition is the provision of a day-ahead active power

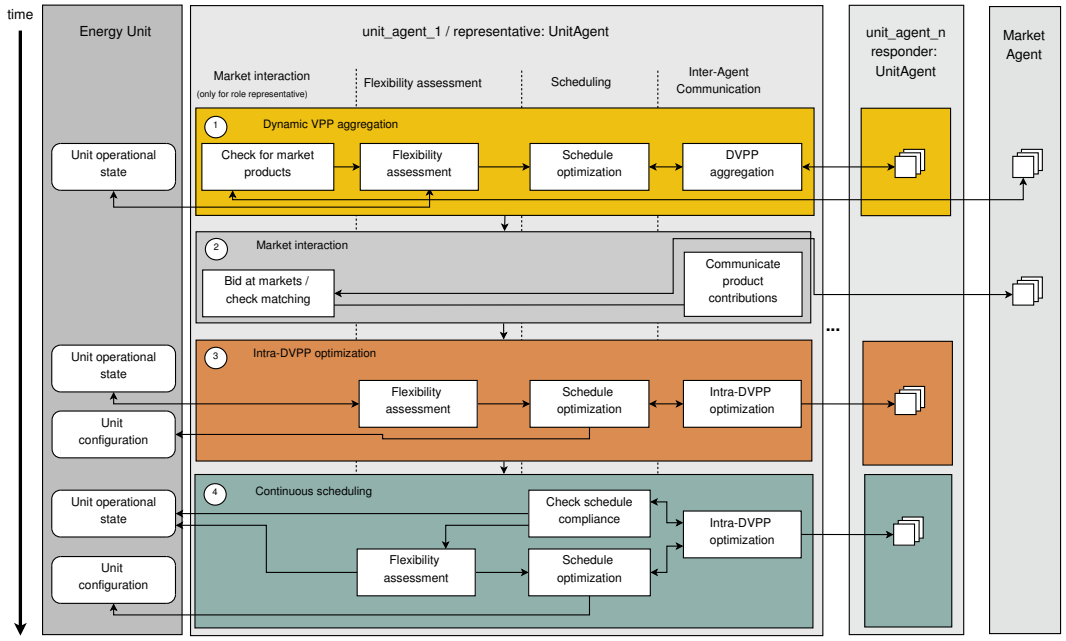

Fig. 2. Agent tasks for DVPP setup, market interaction and product delivery

product which is intended to be supplied within a corresponding product horizon reflecting the time of fulfillment. Thus, the process of DEU aggregation directly corresponds to the one of forming coalitions of supervising unit agents. Each agent contributes to an aspired power product by providing an amount of electrical energy according to the operational potentials of its energy unit. As optimization criteria, agents take the aspired target product as well as the respective costs of provision into account.

In accordance with the requirements and paradigms described in Section I, our proposed mechanism for unit aggregation is based on the principle of self-organization where agents form coalitions without external control of a superior instance. Moreover, aggregation takes place in a fully distributed and temporally flexible fashion, meaning that the organizational binding resulting from common product procurement is restricted to the provision of a provided product only and coalitions dissolve after their fulfillment. The mechanism is an iterative process, each cycle consisting of four activities which are carried out by each agent with the goal of forming coalitions with other unit agents and thus aggregating respective operational capabilities of their supervised energy units:

1) **Product portfolio generation:** In the course of the first activity an agent creates an individual product portfolio comprising a set of target products which it is generally willing to trade on the market. These target products satisfy all operational constraints of its supervised unit (like minimum operation time) as well as the product constraints obliged by the market (like maximum price/kWh). Generally, in this step several markets of same or different kind (like active power or reserve control markets) could be integrated into the decision making process in order to optimize benefit. However, our current work is restricted to a single day-ahead active power market only.
2) **Neighbourhood formation:** Given the set of target products as well as a distance function quantifying physical distance between DEUs in the grid, agents start forming neighborhoods which comprise potential cooperation partners for forming coalitions given the constraint that their supervised units are located within a specified range of physical proximity. This second activity allows unit agents to initially reduce communication and computation costs in the course of the actual aggregation process. Moreover, by taking the grid topology into account, coalitions are generally able to provide grid-sensitive power products within a specified area of the grid and thus to procure respective system services like redispatch capacities for congestion management.
3) **Coalition formation:** As third activity, agents start unit aggregation by forming coalitions within their afore defined neighborhoods in order to collectively fulfill common target products. In case an agent is not able to find a suitable coalition within its current neighborhood, it iteratively goes back to the second step and extends the scope of its neighborhood in order to include more potential cooperation partners.
4) **Payoff division:** Finally, after unit aggregation has finished and a coalition's product was accepted on the market (e. g. after clearance on an exchange), agents enter the last task and divide the payoff received from common product fulfillment among each other based on agreed criteria like contributed energy amount or reliability of procurement. To allow a fair division, the

payoff is distributed based on game-theoretic concepts [16].

V. Scheduling of Units in Planning and Operation

The scheduling of energy units within DVPPs can be regarded as 0-1 multiple-choice combinatorial optimization problem. In this type of problems, multiple sets or classes of elements (i. e. feasible operation schedules in our use case) are given, from which each exactly one element has to be chosen to form a solution. The goal is to find a solution that minimizes (or maximizes) a given objective function (e. g. power product fulfillment).

Many problems solved by multi-agent systems are modeled as distributed constraint optimization problems (DCOP). According to [17], in a DCOP, a number of independent agents each control the state of (a subset of) the variables in the system, with the joint goal of maximizing the global reward for satisfying constraints. If global constraints affect a larger subset of agents and the problem should be solved in a distributed manner though, classical DCOP methods are not feasible. Hence, in our concept, we use the Combinatorial Optimization Heuristic for Distributed Agents (COHDA) for all scheduling aspects throughout the process (see [18] for details including an overview on and discussion of alternative solutions for this problem).

A. Intra-DVPP optimization

In the considered use case of day-ahead power provision, there will be a significant time span between market matching and product delivery (e. g. 12 hours for the EPEX SPOT in Germany). This available time span will be used for an internal optimization within a DVPP prior to product delivery. Here, updated prognoses and measurements for each DEU can be utilized in order to tap the full potential of the unit's flexibility, which allows for optimizing the unit's schedule with respect to accuracy and reliability. For example, the operational state of a combined heat and power plant in combination with new measurements of e. g. the water temperature for an attached hot water storage are used to recalculate the unit's flexibility (the modelling of a units' flexibility is described in Section VI). With this new information, a rescheduling for the units within a DVPP is performed: The obligation of a DVPP is given in the form of a power product that comprises an active power profile for a defined planning horizon (e. g. the next 24 hours) as a series of constant amounts of active power (e. g. hourly intervals, as is common for the EPEX SPOT). The optimization goal in this phase is to find a schedule for each DEU of the DVPP such that the sum of all schedules matches the power product as close as possible. However, each unit agent must be permitted to decide itself which schedule it contributes. This way, economically or ecologically rooted soft constraints can be taken into account as secondary optimization goals while preserving privacy and autonomy of the participating units. Thus we employ the self-organizing heuristic COHDA as described in [19], [18] for this task as follows.

The key concept of COHDA is an asynchronous iterative approximate best-response behavior, where each unit agent reacts to updated information from other agents by adapting its own selected schedule with respect to the power product. In order to reduce the communication overhead of this distributed optimization problem, the unit agents are placed in an artificial communication topology (e. g. a *small world* topology), such that each unit agent is connected to a non-empty subset of other unit agents. To compensate for the resulting non-global view on the system, each $unit\ agent_i$ collects two distinct sets of information: on the one hand the believed current configuration γ_i of the system (that is, the believed current schedules of all unit agents), and on the other hand the best known combination γ_i^* of schedules with respect to the power product it has encountered so far. Recall that an agent initially only knows its own flexibilities, and the difficulty of the problem is given by the distributed nature of the system in contrast to the task of finding a common allocation of schedules. Thus, the agents coordinate via message exchange. Beginning with the *representative* of the DVPP, each $unit\ agent_i$ executes the following three steps, cf. [18]:

1) **(`update`)** When a $unit\ agent_i$ receives information from one of its neighbors (say, $unit\ agent_j$), it imports these information (γ_j and γ_j^*) into its own knowledge base by updating γ_i and, if better, replacing γ_i^* with γ_j^*.
2) **(`choose`)** If γ_i or γ_i^* has been modified in the previous step, the agent adapts its own schedule according to the newly received information, while taking its own local objectives into account. If it is not able to improve the believed current system configuration γ_i, the configuration γ_i^* will be taken instead. The latter causes $unit\ agent_i$ to revert its current schedule to the one stored in γ_i^* (note that γ_i^* contains a schedule for each agent in the system and $unit\ agent_i$ takes its own of course).
3) **(`publish`)** If γ_i or γ_i^* has been modified in one of the previous steps, the agent finally publishes its knowledge base (γ_i, including its own selected schedule, and γ_i^*) to its neighbors. Local objectives are not published to other agents, thus maintaining privacy.

The algorithm terminates when for all agents γ and γ^* are identical. At this point, γ^* is the final solution of the heuristic and contains exactly one schedule for each unit in the DVPP. With this information, the unit agent configures its respective DEU by setting the schedule.

B. Continuous scheduling

Once the internal optimization has finished, operation schedules for each DEU are known to the unit agents. These schedules can now be transferred to the respective DEU of each unit agent as set values.[1] However, incidents of several types may have rendered the chosen operation schedules

[1] Appropriate communication technology choice and information modeling is not subject of this paper. For example, data can be modelled using state-of-the-art international standards and protocols like OPC UA and CIM [20].

infeasible, like DEU breakdown, updated forecasts or the operation of the DEU for unforeseen services like system services. Therefore a rescheduling is needed in those cases, where the summed deviations of the DVPP's energy units enhinder product fulfillment. To detect this behavior, the unit agents continuously monitor their DEU. If product fulfillment cannot be guaranteed anymore, rescheduling is triggered. The scheduling heuristic COHDA described in Section V-A is used for this application as well, but additional constraints and optimization criteria have to be considered beside the target product to be delivered:

- **Local DEU contraints:** As the DEUs are already in execution of a given operation schedule, reconfiguration of the unit should take care of the DEU's current operational state. In the algorithmic framework presented here, surrogate models are used to cover this task: A simulation model is initialised with the current operational state of the DEU to deliver feasible sample schedules. Thus local constraints are covered by each operation schedule retrieved from this surrogate model.
- **Robustness:** The schedules generated during internal optimization may still hold severe uncertainty regarding their feasibility. With the product delivery period approaching or even started, robustness of a DEU for a chosen schedule becomes more important, as a repeated rescheduling by the agents and resulting reconfiguration of the DEU may result in suboptimal overall system performance. Therefore the weighting of robustness may increases over time depending on the specific facets of robustness important in the context of DEU scheduling, i. e. soft constraints within the operation of DEU and power grid feasibility margins.
- **Cost:** As long as there is still enough time left until product delivery, the cost of the schedules is the most important optimization criterion. A bad robustness value can be compensated by rescheduling. When product delivery has started though or not enough time is left for rescheduling, robustness can outbalance the costs if product delivery is threatened and thus other costs (e. g. for balancing energy) would severely cut the DVPP profits. Therefore the weighting of costs decreases over time.

The optimization function for continuous rescheduling therefore has to be formulated as time-dependent optimization function, where these factors are convexly combined and given hard constraints like product fulfillment and other criteria (e. g. power grid related criteria) are taken as side conditions. The details on this are subject to current work.

VI. Representing flexibilities with surrogate models

Real world scheduling problems often face nonlinear constraints. This set of constraints defines the shape of a region within the search space (a hypercube defined by operation parameter limits) that contains all feasible solutions. This feasible region might be arbitrary shaped or discontinuous and defines the region where to pick feasible solutions from. Several techniques for handling constraints during optimization have been developed. Nevertheless, almost all are concerned with special cases of non-linear programs or require a priori knowledge of the problem structure in order to be properly adapted [21]. A good overview can be found in [22] or [23].

At the same time, support vector machines and related approaches have been shown to have excellent performance when trained as classifiers for multiple, especially real world problems. Tax and Duin developed the support vector domain description as a one-class support vector classifier that is capable of modeling the region that is defined by some given training data [24]. We adapted this concept for integrating constraints into optimization in a way that allows for efficiently navigating the feasible region. The basic idea is to construct a mapping from the whole, unconstrained domain of the problem (the hypercube) to the feasible region to be able to automatically repair infeasible solutions during optimization. In this way, the scheduling problem is transferred into an unconstrained one by mapping any arbitrary solution onto a nearby feasible one.

Information about the flexibility of a DEU, i. e. the capability to alter energy production or consumption, is indispensable for coordinating processes within a DVPP. Planning for a product specific adaption of operations demands for a detailed model of a unit's scope of action. Taking into account all feasible alterations of operation, flexibility can be represented as the set of realizable (operable without violating any constraint) schedules. Unfortunately, a full assessment of this set is in general intractable. Depending on the time resolution of the schedule and possible operational settings of a unit, the number of theoretically realizable schedules can be in the order of some 10^{100}. Each unit has to obey individual technical, economic or user defined constraints in their operation that restrict the set of feasible schedules resulting in an individually shaped feasible region. Thus, the search space that defines feasible solutions of each unit forms an individually shaped feasible region. A mathematical model of the flexibility has to be derived repeatedly on demand as it depends on the current setting (e. g. operation state) and on recent forecasts (e. g. on thermal demand). Furthermore, because a DVPP continuously re-organizes in our approach, a mathematical optimization model for a DVPP cannot be determined statically in advance. Thus, with a newly formed DVPP the model for scheduling has to be re-built according to the participating units and their individual current flexibility. Hence, we use surrogate models for a unit's flexibility as proposed in [25]. The core of the model for the set of feasible schedules is a one-class support vector classifier trained with a set of operable example schedules. This flexibility model works as follows: Given a set of sample schedules, a description of the inherent structure of the feasible region of a unit is derived. After mapping the data to a high dimensional feature space by means of an appropriate kernel, the smallest enclosing ball in this feature space is determined. When mapping back this ball to data space, the pre-image of the ball forms a set of contours (not

necessarily connected) enclosing the given data sample (in our case: the feasible schedules of the respective DEU). The result of this procedure is a decision function that in general allows deciding on an arbitrary data point whether it belongs to the same region that contains the other data or not. In our use case, it allows testing a schedule wether it can be operated by the DEU or not.

But, for a controlled construction of solutions we have to go one step further, as we want to have a means for a goal-oriented search that allows us to systemetically find feasible schedules. In this way, we need a means that guides any algorithm where in the search space to look for feasible schedules. The advantage of our model is that it allows to generate a decoder that transforms the problem of distributed active power planning into an unconstrained one [26]. In general, a decoder is a constraint handling technique that imposes a relationship between feasibility and decoder solutions in order to give an algorithm hints on how to construct a feasible solution [23]. The flexibility of a unit is represented as pre-image of a high-dimensional ball. This representation has some advantageous properties. Although the pre-image might be some arbitrary shaped non-continuous blob in $\mathbb{R}^d$, the high-dimensional representation is still a ball and thus geometrically easier to handle. The relation is as follows: If a schedule can be operated without violating any constraint, it lies inside the feasible region. Thus, it is inside the pre-image (that represents the feasible region) of the ball and thus its image in the high-dimensional representation lies inside the ball. An infeasible schedule lies outside the feasible region and thus its image lies outside the ball. Additionally, we know some relations: the center of the ball, the distance of the image from the center and the radius of the ball. Hence, we can move the image of an infeasible schedule along the difference vector towards the center until it touches the ball. Finally, we calculate the pre-image of the moved image and get a schedule at the boundary of the feasible region: a repaired schedule that is now feasible. We do not need an explicit mathematical description of the feasible region or of the constraints to do this. Working with this decoder concept comprises two successive stages:

1) **A model/decoder training phase:** During the training phase (flexibility assessment) the decoder is build out of an set of example schedules derived from a simulation model of the unit.
2) **A successive planning phase:** Once the model is built, it can be (re-)used for assessing the feasibility of arbitrary schedules and for systematically generating feasible schedules with the decoder.

The latter is the main use case for the flexibility model: Whenever a prospective schedule is generated as a candidate solution to a specific unit, the decoder is used to convert this schedule into a similar schedule that is guaranteed to be operable by this DEU. The feasible version is used for scheduling. At the same time, performance indicators characterizing individual schedules with respect to different optimization goals are automatically preserved with this method [27]. Thus, after mapping a schedule (even with wrong or no associated performance indicators) to a feasible one, evaluation with respect to multiple criteria is possible. For distributed problem solving, the decoder can serve as a substitute for an often (particularly with regard to a fully automated generation in dynamic environments) hardly derivable mathematical model of a unit. The flexibility model automatically derives a means for generating feasible solutions from an unknown (to the agent) technical model. Hence, in our use case the flexibility model allows the agent for always working with operable schedules and thus with feasible solutions during coalition formation and scheduling without a need for a unit specific agent implementation.

VII. Agent model

In order to manage the repeatedly executed tasks of the four phases (DVPP aggregation, market interaction, intra-DVPP optimization, and continuous scheduling) the automaton depicted in Fig. 3 is guiding each agent through the process. Once started, the agent first executes the flexibility assessment task by querying the current state of the controlled unit and simulating possible flexibilities with its parameterization. The flexibility model and the decoder are built and provided for reuse in successive tasks. If the agent is not yet part of a DVPP, the agent takes part in the aggregation process that as a result assigns the agent to a newly formed DVPP. After forming the DVPP each agent participates in a continuous optimization process that aims at assigning a schedule to each agent's unit such that correct delivery of the product is ensured as reliable and at the same time as efficiently as possible. To do this the described optimization process is executed. The first execution is started at latest directly before product delivery. In case of an event that invalidates the current flexibility model due to changed assumptions or technical problems, the flexibility assessment has to be started again. With this new flexibility model, the optimization process may then be executed for rescheduling as a reaction to the event. The rescheduling may be triggered without a new flexibility assessment in case it is triggered due to the invalidation of another agent's flexibility model. After product delivery the DVPP's existence comes to an end and the cycle starts again.

VIII. Feasibility study

A. Simulation Environment

The purpose of distributed control concepts as described in this work is to realize an agent-based control of distributed energy units according to a current market situation, the current energy unit's state and the power grid's operational state. As a consequence, purpose of the evaluation system is to evaluate the effect of these distributed control concepts on the energy units and (for some applications) the power grid. Therefore a Smart Grid simulation has to be performed, following requirements regarding the reuse of existing models, a convenient and easy to reuse scenario specification, a well-defined API to real-world components and a synchronization concept and implementation between the multi-agent system

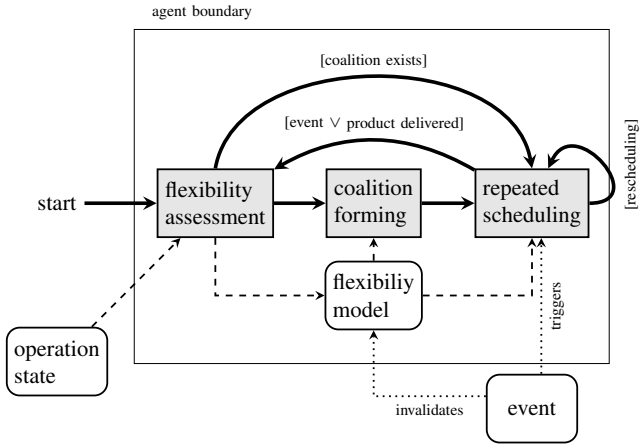

Fig. 3. Flow chart of the agent model with control flow (solid), data flow (dashed) and trigger (dotted)

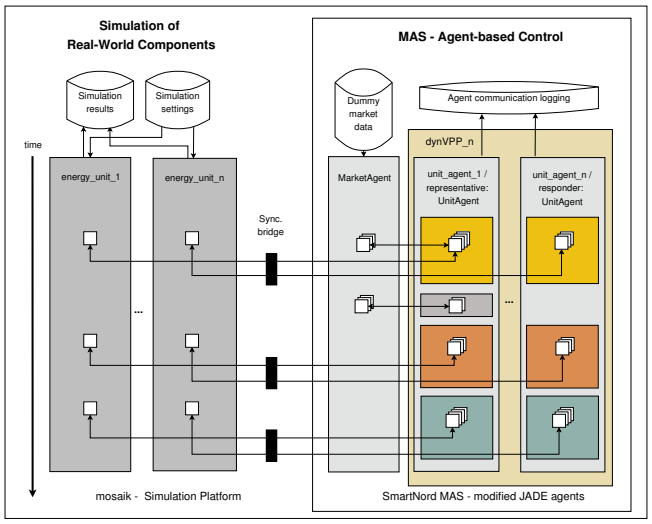

Fig. 4. Evaluation system with unit simulation using mosaik, multi-agent system for control of the VPP and synchronisation agent.

and the Smart Grid simulation. We use mosaik [28] as Smart Grid simulation framework that was built to meet these requirements. The chosen Smart Grid simulation framework has to be coupled with the distributed control technology framework chosen. In our case, we chose JADE [29] with some modifications.[2]

In Fig. 4 an overview on the evaluation system is given. Smart Grid simulation and agent-based control are completely separated. On the left hand side, the Smart Grid simulation with all simulation models for DEU is shown. On the right hand side, the MAS is shown. Within this part of the MAS, the agent-based control of the simulated real-world components (that is DEU in the use case chosen here) is realized. During simulation, the unit agents have to access the simulated energy units to set schedules and retrieve current measurement values. This access is realized using a synchronization bridge (depicted in in the middle of Fig. 4) offering a JADE interface. Besides data transfer, the bridge handles the sychronisation between Smart Grid simulation and MAS. The agents cannot distinguish being run in a simulation environment or in a real-world application. Within mosaik, the bridge allows to handle the MAS as an additional simulation component. In our system, dummy market data serve as input for the market agent to define products and realize the market matching once the order book is closed. The output data of both Smart Grid simulation and multi-agent system are stored in two HDF5-databases.

[2]As JADE schedules events in real-time, parts of the agent framework JADE had to be rewritten to realize this synchronization, thus allowing to run JADE as a MAS-simulation.

B. Experimental setup and results

To give an illustrative example for the integrated process chain within a feasibility study, we setup a scenario with 38 combined heat and power plants combined with thermal storage connected to households in a low-voltage grid. As product to be realized by the DVPPs we defined a product of 25 kWh from 2 p.m. to 3 p.m. on January 2nd, 2013, i. e. 15 min. time intervals 56 to 59 on day 1. The simulation was run from January 1st, 2013 (day 0) to January 2nd, 2013 (day 1) to cover the day-ahead market use case defined in Section III. The Smart Grid simulation was run with a stepsize of one minute, taking into account the weather conditions on the chosen simulation days.

We expected the following phases when running the MAS in the coupled simulation with mosaik: (1) Day-ahead flexibility assessment for all units and DVPP formation for defined product for day 1, and (2) Intra-day pre-delivery flexibility assessment for DVPP units and rescheduling of units for day 1.

We started the process of DVPP setup at 0 a.m. on day 0. Reassessment of flexibilities and rescheduling was started at 0 a.m. at day 1. In this setup, grid topology is reflected within DVPP setup as defined by the neighbourhoods (cf. Section IV).

In Fig. 5 the sample schedules for the initial flexibility assessment are shown for one energy unit ($unit_1$). For each sample schedule, the mean power value is plotted for all 96 operation schedule intervals. The distribution of power values over time is quite uniform. In the surrogate model trained with these samples (cf. Section VI), very different operation schedules can be found for the product horizon starting at interval 56 (2 p.m.). During DVPP formation, energy units aggregate to coalitions if their potential contributions fit the product needed (cf. Section IV). In the example given here units should aggregate to deliver a 25 kWh hourly product. For reasons of clarity, we only illustrate the product setup of one DVPP from this scenario. For the example DVPP chosen, 5 unit agents jointly deliver the defined product. On the left hand side of Fig. 6 the active power contributions of all energy units within the DVPP are shown as stacked chart over time for the product horizon (2 – 3 p.m.). The energy that would be delivered by the DVPP following these schedules is depicted on the right hand side. The product target of 25 kWh is not reached due to the tolerance settings within coalition

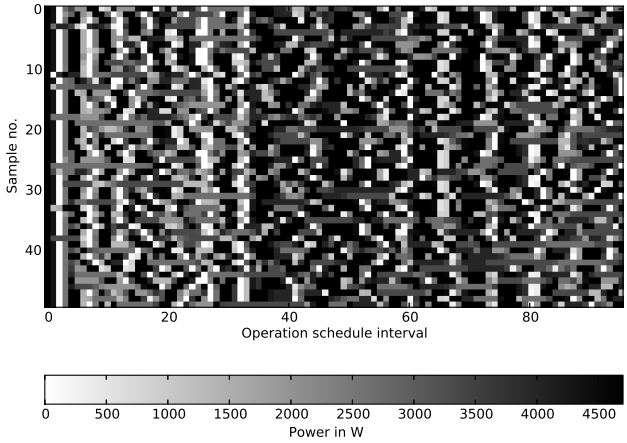

Fig. 5. Day-ahead sample schedules for $unit_1$

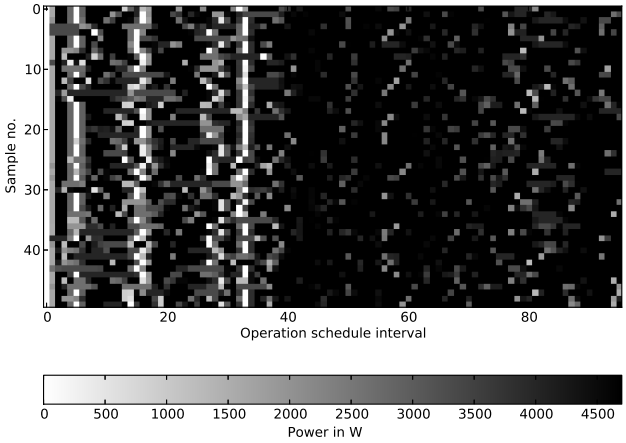

Fig. 7. Intra-day sample schedules for $unit_1$

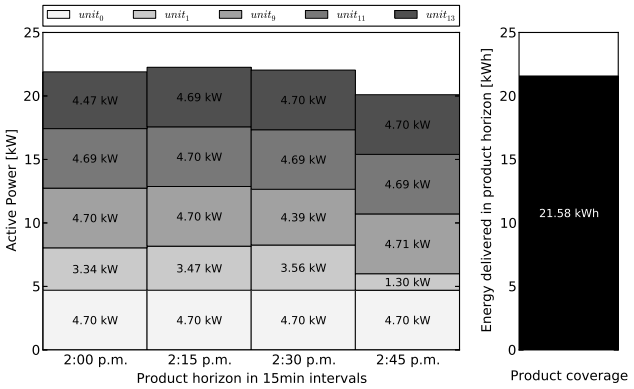

Fig. 6. Cluster schedule and product coverage after DVPP setup

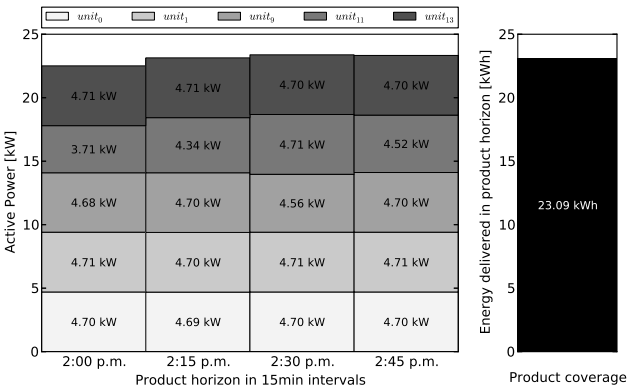

Fig. 8. Cluster schedule and product coverage after rescheduling

formation; these can be adapted individually for each product.[3]

A second flexibility assessment was triggered at 0 p.m. on day 1. Fig. 7 shows the samples taken from the simulation of the unit at that simulation time. If compared with the initial samples (Fig. 5), a much darker region can be detected at the product horizon (time intervals 56 – 59). Obviously, flexibilities in unit operation have narrowed down (e. g. due to the current capacity of the thermal storage or updated weather prognoses). The surrogate model trained with these samples will not produce schedules with power values lower than 3000 W in the chosen time horizon. We now take a closer look on the results of the planning phase using the surrogate models trained by the sample schedules from the second flexibility assessment.

In Fig. 8 the schedules after rescheduling using COHDA (cf. Section V-A) are shown. As can be seen, the product is now fulfilled better (23.09 kWh). One reason for this might be the changed surrogate model of $unit_1$: In the original plan, this unit has been scheduled with a contribution of 1.3 kW for time interval 59 (2:45 p.m.). This active power range cannot be retrieved from the surrogate model trained with the samples shown in Fig. 7, as an active power value lower 3000 W is not within the set of feasible schedules. Therefore, a new solution has been found by COHDA following both the updated flexibilities (modelled within the surrogate models of the energy units) and the target product tolerance margins.

[3]The evaluation of an optimal setting of these margins is part of a later evaluation of the overall system.

IX. Conclusion

In this paper we presented an agent-based control method for dynamic virtual power plants self-adapting their unit set and operational plan to be able to trade products on a power market. The three coordination steps of aggregation, schedule optimization, and continuous scheduling for DVPP control are integrated into the behavior of unit agents. These agents interact with each other and with the power market. Aggregation as well as scheduling of DVPPs is based on self-organization methods to achieve adaptivity to a changing set of units and new products traded on the market. So, DVPPs are self-coordinating, self-optimizing, and – within certain limits – self-healing. A cross-sectional technology for representation of the units' flexibilities is provided by a

surrogate model allowing to integrate new types of units easily into the coordination mechanism of DVPPs.

A simulation-based demonstrative example of the interaction of the coordination steps of a DVPP has been given in this contribution. Based on the current state of knowledge, DVPPs are a very promising approach to exploit flexibilities of decentralized units in a future power grid to support the integration of renewable energy resources. More and particularly more complex scenarios have to be studied to evaluate the performance, stability and dynamics of this control method. This will be a significant goal in our ongoing project cluster Smart Nord.

ACKNOWLEDGMENT

We thank Steffen Schütte and Stefan Scherfke for the technical support in setting up the coupled simulation environment using mosaik.

***Abstract*—Power balancing is an important issue when microgrids in island mode are considered. It requires active, real-time decision making to minimise the imbalances. El Farol Bar and Potluck problems are artificial problems designed to challenge the decision making process in a situation of limited information. They are theoretical, ill-defined problems designed to show that rational decision making in a situation of scarce information can give worse results than non-rational behavior. Potluck problem can be compared to electric power balancing in microgrids. But due to reduced complexity and constraints of theoretical problems and differences in goal functions the approach has to be in each case different. The study of these differences in this paper shows the importance of exchange of information between participants (or agents); it also suggest what type of information are necessary in what conditions. The amount of information that needs to be exchanged depends on the relation between participants (agents): the less cooperating their relation is, the less information they are willing to exchange.**

I. Introduction

THE POWER grids enter a new era, where the ecological impact and power security are playing an important role in their development. The introduction of relatively cheap micro sources has created a concept of microgrids: a localized part of the power network that usually is equipped with micro power sources and can be disconnected from the external power grid (operate in island mode). With new technologies, new challenges appeared, and among them management of power in the microgids. This task is difficult due to a relatively large changeability of production and consumption of power in small scale grids. The problem of power balancing became especially important for the development of microgrids operating in island mode. In such case, imbalances can lead to an ineffective system, to waste of power or even to damages of the devices. This problem is a subject of many research, where various methods have been developed for balancing and for minimizing the imbalances.

The power management can focus on the consumption side, and is called the demand side management [1] or demand response [2]. The idea behind it is to convince the power users to adjust their behavior patterns according to the energy situation in the grid or to allow some information system to do it automatically. An alternative is the supply side management, which requires managing the operating point of power sources, including switching on and off power production devices, to compensate for non-controllable production from renewable power sources. In this work, only supply side management will be considered.

Enumula and Rao described the Potluck problem in [3] and pointed out its similarity to the balancing of electric power. Both problems deal with equalizing supply and demand in an iterated way, where the supply can be only approximately assessed and balancing depends on decisions of many suppliers. The theoretical Potluck problem is claimed to be a generalization of El Farol Bar problem described in [4], where it is shown that, when there is lack of information, the inductive reasoning gives better results than rational reasoning. The theoretical Potluck problem is very constrained and does not allow any flow of information between participants, which make the problem ill-defined. An inductive reasoning based algorithm provides an acceptable solution to the Potluck problem, in the sense that the solution oscillates around the desired outcome. For energy balancing, such a solution is not good enough: it implies that the system is constantly experiencing imbalances. Relaxing the constraints of the Potluck problem allows for a more exact solution to be found using a rational method; the analysis of which constraints need to be relaxed in the Potluck problem provide valuable information to develop a scheme in which balancing in a microgrid can be solved.

In this article, a comparison of the balancing problem, the El Farol Bar problem and Potluck problem is presented. Although it is claimed that they are similar, there are major differences that require different approach to each of them. In section II a description of the power balancing and its importance is presented. Section III explains the theoretical El Farol and Potluck problems. In section IV a comparison of the problems is presented. Section V deals with real life approaches to the power balancing issue. The final section VI concludes the paper.

II. BALANCING ELECTRIC ENERGY IN MICROGRIDS

High voltage grids, unlike low-voltage microgrids, have different properties. Large grids require an approach where power flow dynamics are considered, as the power in large grids have to travel large distances and the power loses are significant. Such networks have also much more inertia and delays in changing the operation levels. When a node of such grid is not balanced (there is either an overproduction or a deficit of power) it affects all connected nodes and a number of nodes have to compensate, as the power disturbance can travel through the network, even to distant nodes. Microgrids are smaller and react faster to control requests, so they are manageable in an easier way, without considering the effect of distance, induction of power in the grid or power losses.

A microgrid is a part of an electric grid that potentially can be disconnected. Very often, microgrids are equipped with power sources (such as e.g. gas microturbines, micro wind turbines, photovoltaic panels) or power storage (e.g. batteries, flywheels) and can work in an island mode. In the island mode operation, in a microgrid it is necessary to balance the production and consumption of power to maintain the quality factors of the electric current; these guarantee the safety of the devices in the microgrid. A symbolic picture of microgrid elements is presented in Fig. 1. If a microgrid has an abundance of power production, then energy has to be wasted and/or production limited; in case of shortage of energy, some of the consuming devices should be switched off according to importance or preference. The difficulty is that a decision has to be made and it should follow the constantly changing conditions in the grid. The faster the decision is made, the less power is wasted and the safer the devices are. Power produced by some renewable sources (especially micro sources, which might lack the ability to manage their operating point) fluctuates dynamically due to sudden changes in e.g. wind and solar irradiance. Predictors, to some extent, can forecast the production and help minimizing the imbalances, but the predictions are not perfect. Consumption of energy is also very changeable and often unpredictable, especially in small microgrids, where a single device can make a noticeable difference in overall power usage. That means that the actions of a single human being can make a noticeable disruption from a typical daily power usage profile.

Balancing should make the amount produced ($s(t_k) = \int\limits_{t \in t_k} s(t)dt$), for a given time ($t_k$), equal to the amount that can be consumed ($d(t_k) = \int\limits_{t \in t_k} d(t)dt$) at that time. The real energy balancing is a continuous process, but from the operational point of view it can be quantified to a number of short time periods t.

$$\sum_{i=0}^{n} s_i(t_k) = \sum_{j=0}^{m} d_j(t_k) + L(t_k),\ t_k \in T \qquad (1)$$

where $n \in N$ is the number of active producers and $m \in M$ is the number of active consumers. The losses of power during transmission ($L(t_k)$) are not considered: they are relatively small, their amount depends on network structure and their absence does not influence the theoretical solution, but allows for a simplification of the model.

Balancing is possible due to the existence of controllable devices (their operation point can be changed by the energy management system) and the ability of switching off or on a part of the consumption. In most real life installations, a microgrid is connected to an external power grid, which can provide or absorb a large amount of power. In large power grids, a constant reserve of production power is kept in order to cover occurring imbalances. Due to the high costs of this type of installation, small microgrids usually do not have such a reserve.

The presence of the power storage units, e.g. batteries, can facilitate the balancing, as they provide a time and power buffer for the management system. Power storage units are generally much faster than controllable power sources when it concerns changing the amount of taken or given energy. Extremely fast operating storage units such as flywheels can smooth the sudden peaks of power and compensate for short power loses. Large enough capacity of power storage devices in the microgrid can solve a lot of issues, even completely eliminating the imbalances. Detailed analysis of influence of power storage can be found in [5]. Storing the power unfortunately results in loses of power, a high cost of installation of storage units and, in some cases, a necessity of replacing them relatively often. In microgrids, large capacities of storage units are not common due to high costs. The most frequently considered devices are batteries, flywheels and superconductors.

The problem of balancing a microgrid is of interest to many research teams. General architectures of energy management systems might be found in [6], [7] and [8]. Details of the algorithm of the market based short-time balancing can be found in [9].

A microgrid in general can consist of producers, consumers and prosumers. Each of these can be controllable or uncontrollable. Uncontrollable devices are those which are not manageable by computer system, to this category are included most of the power consuming devices and small renewable power sources (in which power production depends on weather conditions). The balancing problem reverts to a decision problem of setting the operation point of controllable devices in the microgrid, so that supply and demand equal according to equation (1). To simplify a model, all uncontrollable devices can be aggregated to a single value: this value is either 0 (perfect balance of uncontrollable devices), positive (behaves as producer) or negative (behaves as consumer). Here, the aggregated device is assumed to be a consumer, in order to avoid a situation of overproduction by uncontrollable producers. Such situation needs special actions (e.g. removing an uncontrollable producer, wasting power, etc.), which are not common situations in the typical balancing problem.

The power sources have physical limitations: a minimal and maximal operating point, a time necessary for changing the operation point, etc. Managing a controllable power source

means deciding if the device will be active in the next time period ($s_i(t_k)$), and if so, determine the amount of power it will provide.

Limited information about the amount of consumption and production is a problem for balancing. The consumption is changeable in time: it is the sum of consumption of a number of small devices, where each of them may have different usage patterns. While patterns and cycles, such as daily or weekly, are usually visible in the amount of power usage, the exact amount can only be roughly predicted.

The production is the sum of the decisions of all producers which operate in the microgrid. They may or may not know how many producers are present in total and decide to participate in balancing, but in any case they can only estimate the amount of power produced by all other sources. The information shared between producers is a property of a used scheme, which can depend on the level of cooperation, the size of the microgrid or other factors, such as cost of power production, ownership, regulations, etc. In microgrids with one owner, there can be full cooperation with full flow of information; allowing for central balancing to be used. When the competition of producers is present, the flow of information may be constrained to the minimal level that is necessary for the process. When a microgrid is really small, it is helpful to know the physical limitations of the units to predict the amount of produced power.

Other factors also play important roles. When for instance the cost of operation of a power source is considered, some sources are more profitable than others. Preference to a source can be modeled by introducing the cost, which does not necessarily match the real world cost, but allows for a preference ordering that can be dynamically adjusted. Such value in market schemes is sufficient for achieving effective balancing as presented in [9]. In microgrids operating in the synchronous mode (with connection to an external power provider) the costs and profits usually dominate the decision about the production – the balancing is not the main goal of the system but becomes a constraint. In extreme cases, a certain level of imbalance might be tolerated even though it means cutting off selected consumers from the grid. Such a solution is not considered in this article. Here the microgrid is considered to be in an island mode only.

Amount of public information and what information are being exchanged is an important problem. For various reasons, as e.g. safety, competition, willingness to make profit, the producers tend to keep certain information private. The lack of information exchange can make it impossible to perform balancing. Such situation was considered by Arthur in [4], where a method to deal with such ill-defined problem is suggested. The extension of this problem, the Potluck, considers the supply and demand equalization with almost lack of information exchange.

III. El Farol and Potluck Problem

A. Agents and communication

To achieve common understanding of the term agent in this article, an explanation is required. In the computer science, an agent is an autonomous programmable unit that interacts with its environment and tries to fulfill given goals. Agent can be also understood as a representative of an entity, that takes decisions to achieve given goals. These two definitions are similar – both underline the autonomous decision making feature. In this article, the term agent is used in more general sense – as an entity that can make decisions. In this context, any exchange of information can be called communication, without further description on how such communication is made.

B. El Farol Bar Problem

The El Farol Bar problem (or Santa Fe Bar Problem) was introduced by Arthur in 1994 [4]. The problem was inspired by a real bar in Santa Fe, which was very popular during Thursday nights. But if too many people decided to go to the bar to enjoy the music, it was too crowded. Arthur defined the problem as follows. If there are not more than 60 people in the bar, the people inside enjoy being there. Otherwise they feel better at home. This problem is illustrated in Fig. 2(a). So a participant is considered a winner if she/he goes to the bar while it is not crowded, or if she/he stays at home when the bar is crowded. In the El Farol Bar problem, the participants' goal

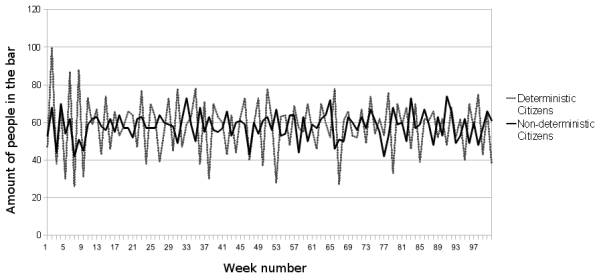

Fig. 3. Attendance to the El Farol bar of deterministic and non-deterministic citizens.

is to win as many times as possible, where the goal function $g_i(t)$ of i-th participant in the t-th night is defined by:

$$g_i(t) = \begin{cases} 1 & \text{if (go to the bar and the bar not crowded)} \\ & \text{or (not go and the bar is crowded)} \\ 0 & \text{if (not go and the bar not crowded)} \\ & \text{or (go and the bar is crowded)} \end{cases} \tag{2}$$

The participants do not know how many of them are in the city, they are not communicating with each other and they have no idea what other people want to do. The only information available to them is the historic attendance: each participant knows how many people were in the bar during the last weeks. In a such defined problem there is no win-win solution - when in the bar is 60 people, the ones remaining at home loose, when there is 61 people in the bar, this 61 people loose.

In this situation, there is not enough data to make a deductive, rational decision, which makes the problem ill-defined. In [4], an inductive reasoning scheme is proposed. This is an idea taken from psychology: people are very often facing ill-defined problems and humans cope with this situation by looking for patterns and similarities in other situations. If a person would be asked the reason for going to the bar, possible answers could be: 'last week it was empty so this week it will be the same', 'last week it was full, so this week it will be empty' or just 'because I want to go'. From the game theory and mathematical analysis point of view these answers are not reasonable, but due to lack of information they are as good as any other. Humans often do not analyze all possible actions deeply, but make shortcuts and take non-optimal decisions, sometimes due to undefined reasons. It is logical from the evolution point of view, as taking decisions fast has been more crucial for survival, than being indecisive and not performing any actions. Arthur (in [4]) assumed that each person has its own way of predicting the attendance in a bar – they have a set of simple predictors. The predicted attendance might be: an average of the last few weeks; the same as last week; the same as 3 days ago (cycle detector) or assumption that the bar will always be half empty. Each person also knows the attendance from few last weeks. So a going or not-going decision depends on the known history of attendance and ones own hypothesis. What is more, participants can choose their predictors from a pool, according to the success rate of a considered predictor (how many times it gives a good advice). Surprisingly, the simulations show that the attendance in the bar is oscillating around the chosen maximal comfortable number of the participants in the bar. An example of the bar attendance in this problem is presented in Fig. 3. Arthur called it inductive reasoning method and defined it as follows. When there is a lack of knowledge to take a reasonable decision, one should use simple models that worked best in the past, and after each iteration of the process evaluate the models.

An interesting feature of this approach is that starting from some defined conditions and following totally deterministic rules, the outcome is a sequence of attendance that resembles a stochastic process. The amount of people in the bar is oscillating around 60. It is explained by the fact that citizens choose the predictors that performed best, this creates a self-regulating system where the number 60 is a natural attractor.

It is worth to notice that if the citizens know how many of them are in the city, they can solve the problem quite easy by coming to the bar in cycles. This solution was described in [10].

C. Potluck Problem

The Potluck problem was described and defined in [3]. A potluck is a party where every guest brings some food for everyone to eat. If the food is in an excess, the guests feel uncomfortable, as their food has to be thrown away. On the other hand, if there is a deficiency of the food, guests are hungry and unhappy. The perfect situation would be to have the exact amount of food, but the appetites of the guests depend on many factors and can vary between parties. So, without communication guests have to guess the total amount of food they have to bring, not knowing what strategy other guests will adapt, see Fig. 2(b) for an illustration.

In the Potluck problem, the goal function is to balance the supply and demand. Assuming that demand is something out of control, the goal function of l-th guest can be defined as, see [3]:

$$g_l(t) = \begin{cases} 1 & \text{if } \sum_{i=0}^{n} s_i(t) = \sum_{j=0}^{m} d_j(t) \\ 0 & \text{if } \sum_{i=0}^{n} s_i(t) \neq \sum_{j=0}^{m} d_j(t) \end{cases} \tag{3}$$

The notations are explained in Table I. A guest is in the winning position when the sum of supply is equal to the sum of demand. But a guest has no means to communicate with other guests to inquire about the amount of food they plan to bring or the food they want to eat. This lack of information makes the problem ill-defined, where the rational reasoning does not help in winning of any of the guests. Enumula and Rao ([3]) define rational reasoning as applying the best strategy in given situation, that is with the assumption that the consumption level will be the same in future as in the last time. This show that it leads to increased oscillation of supply. If all guests make this assumption, they will take similar decisions, which will lead to an exaggerated change in the supply of food and the balance is never reached. The way to prevent it is by introducing different strategies for each

of the participants, hoping that at least to some extent the undersupply and oversupply will balance.

A method to deal with this problem is presented in [3]. It is a non-rational approach similar to the inductive reasoning described in [4]. As was mentioned before, rationality, according to Enumula and Rao [3], is to apply the best strategy according to the present knowledge. In the Potluck problem, the rational action is to act as if the supply has not changed since the last party. The non-rational approach is to allow participants to take an action that is assuming a certain change in the future supply (usually not explained by analysis of the problem). Participants have a set of simple predictors with assigned weights, that forecast the level of consumption. The decision is made on the basis of a weighted sum of predictors response (weighted majority algorithm). After each party, the predictors are evaluated and weights are adjusted accordingly. Enumula and Rao [3] called it a non-rational learning algorithm. In the cited article prediction of supply side is not considered.

Enumula and Rao claim in [3] that the Potluck problem is a generalization of the El Farol Bar one. But actually the points of view of decision-makers and the goal functions are in both problems different. The personal goal function in the El Farol Bar problem is given by equation (2). It is clearly an egoistic goal, which does not consider the well-being of other participants. Decisions of a participant are influenced by the actions of others, which can be interpreted as influencing the decision-maker, but it is not done intentionally. A participant has no intention to make the bar full or not, because in both situations there is a possibility of winning. Arthur [4] underlined that participants are independent agents, that are following their goals, even not being aware how many of participants are in the system.

In the Potluck problem, the goal function is to balance supply and demand, as described by equation (3). The goal can be defined as a global goal function which means that it is a type of a social welfare function. Unlike the El Farol Bar problem, it does not consider a personal gain or loss, but the sum: all participants win or lose. In the El Farol problem, if the bar is crowded, the people in the bar loose, but the people that did not go to the bar win. An analogy to social welfare in the El Farol Bar problem would be the situation where the citizens are trying to reach 60 people in the bar every week, and in case when there are more or less attendees everyone looses.

The question arises if these problems are really equivalent although the goals of the participants are different. The methods of approaching them are similar, but the problems complexity is changing in them when some exchange of information is introduced. In case of a personal goal, adding knowledge about the decisions of others (by communication) only introduces complications in decision making: the agent has to actively make effort to be in the winning position. To clarify this statement a following scenario can be considered: there are 100 participants in the El Farol bar problem, but just 99 of them has some media of communicating their decisions, e.g. announcing it on the social network. None of them knows

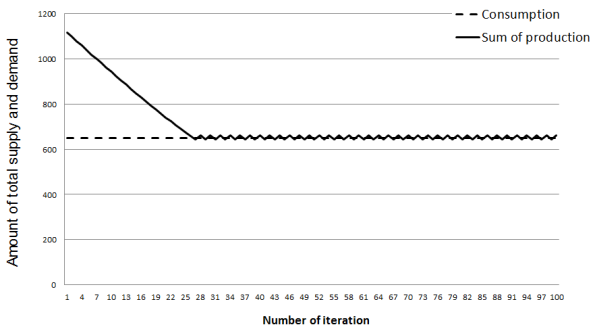

Fig. 4. Potluck problem simulation with linear consumption, with n=100.

what the 100th participant will decide, and this participant does not know the decisions of others. By communicating each other, the participants can agree to perform a schema that will ensure fair amount of winnings for each agent. They can agree that 59 of them are going to the bar and 40 staying home (the agents that are going to the bar can change every week, which would mean introducing going to the bar in cycles). This is a solution where the winner group is the largest, independent of the decision made by the isolated person. But it requires of participants to make concessions for some kind of social fairness. In the original problem agents are assumed to be myopic and egoistic, which does not allow them to cooperate. So, seeing the situation, participants staying home will be willing to change their decision. If this happens, the situation will change again and the decisions of the participant will also change. That would trigger a set of changes that would lead to an apparently chaotic behavior. A stopping condition may be applied, e.g. it might be the time (an hour of going to the bar is defined) or the number of decision changes. When the decision making process is closed the number of citizens in the bar is very likely to be not optimal. The outcome will show pseudo stochastic oscillations around the number of 60 people going to the bar, even when almost everything is known. In the Potluck problem the behavior in this scenario is different. Information about the amount of food brought by 99 out of 100 people suggest their predicted consumption level and all participants try to minimize the error of prediction. After a number of iteration the 99 participants can predict the production level of the 100th participant and consider his decision. Imbalance is still present, but the oscillations are relatively smaller. Socially aware agents are more likely to cooperate, make concessions and negotiate their decisions. Introduction of communication to the problem makes it possible to reason rationally.

IV. From Potluck to power balancing

Table I presents a comparison of the theoretical El Farol Bar problem, the Potluck problem and a practical problem of power balancing. The problems seem very similar, but a quick analysis shows main differences which cause that distinct methods of facing these problems have to be considered. The theoretical problems are very simplified and constrained. The

TABLE I
COMPARISON BETWEEN PROBLEMS OF EL FAROL, POTLUCK AND POWER BALANCING.

Symbol	El Farol Problem	Potluck Problem	Energy balancing
T	set of weeks	set of weeks	set of time periods
N	set of participants	set of guests	set of suppliers
M	equal to 1	set of consumers	set of energy consumers
$s_i(t)$	binary decision of going or not	amount of brought food by i-th guest	amount of energy produced by i-th supplier
$d_j(t)$	constant	amount of food expected by consumer j	amount of energy demanded by consumer j in time t
$S(t) = \sum_{i=0}^{N} s_i(t)$	total attendance in the bar in a week t	amount of food brought to the party	amount of energy produced by all suppliers
$D(t) = \sum_{j=0}^{M} d_j(t)$	constant	total demand of food	total consumption
$P_i(t)$	prediction of the attendance to the bar in a week t	prediction of the amount of total consumption in a week t	prediction of total consumption in time t

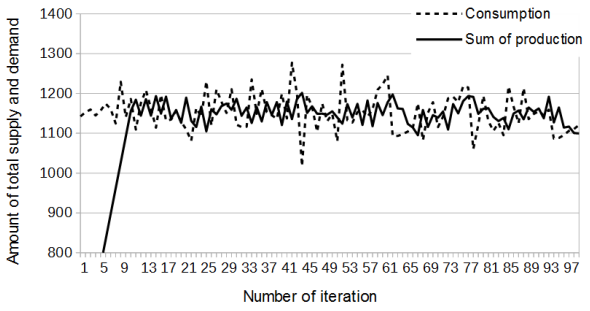

Fig. 5. Potluck problem simulation with random consumption, with n=100.

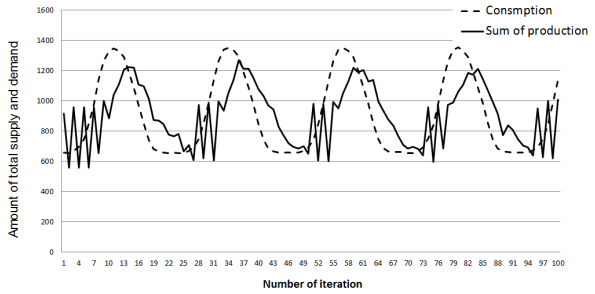

Fig. 6. Potluck problem simulation with sinusoidal consumption, with n=100.

most limiting constraint is that agents are banned from exchanging information. The Potluck problem can be expanded with additional constraints that resemble physical limitations that are present in the power balancing problem (e.g. minimal operating point, maximal operating point, latency of operating point change, etc.), but these do not significantly change the problem considered: it is still an ill-defined decision problem, the additional constraints do not simplify nor complicate it.

In the Potluck problem, lack of information about power production is equally problematic as lack of knowledge about its consumption. Tests have been made using a non-rational learning algorithm with different consumption patterns: the performance of the algorithm with a random consumption is shown in Fig. 5, with a fast changing sinusoid consumption in Fig. 6 and with a linear consumption in Fig. 4. Several categories of predictors have been used in the calculations:

- average demand over the last k periods,
- randomly chosen value of demand from the last k periods,
- choosing the demand from $t - k$ period, this predictors are cycle detector, it can detect cycles of 2, 3, 5 periods,
- mirror image around the average of the last k periods,
- the same as the previous period,
- trend over the last k periods,
- median of the last k periods,
- weighted solution over the last k periods - the random k weights are chosen: $w_1, w_2, \ldots, w_k$, where $\sum_{i=1}^{k} w_i = 1$ and the prediction is calculated as: $\sum_{i=1}^{k} D(t-i)w_i$.
- the smallest value of demand out of the two last periods,
- the larger value of demand out of the two last periods.

It is clear that a less changeable consumption makes it easier to reduce imbalances, as predictors work better. However, even for linear consumption agents could not fully balance demand and supply. The oscillations are still visible.

The reason for this is that suppliers use the same algorithm and therefore take similar decisions based on the same information, which in turn leads to overcompensation. This is logical, as a supplier has no knowledge of other suppliers and tries to solve the imbalance by itself. In some situations (e.g. the oscillations in the linear case) the result can be improved by introducing additional conditions to the agents' logic, but such specialization would decrease overall performance in the general case. A better solution is to allow for communication between the suppliers.

There are many ways in such communication can be introduced. The simplest case considers publishing information for all agents. One way to prevent big oscillations is to limit the number of suppliers that can change their decision, such that not all suppliers will react to the imbalance. This automatically limits the total change. It can be achieved by introducing tokens to tell a supplier that it is allowed to change its output, and publishing which agents have the tokens in the given iteration. Preferring certain suppliers over others becomes a

matter of a central body that has to decide how the tokens are distributed. Another way of preventing big oscillations is by introducing direct communication between the suppliers. This can lead to bilateral and multilateral negotiations, which permit for rational reasoning. In a similar way, a solution with an ordering of suppliers can be introduced, and the agents higher in hierarchy would be privileged to change their supply. In both last approaches, preference of a supplier can be decided by all the suppliers, using the information they share, without a central decision body.

Realistically, a rotation of the suppliers should be introduced, based on various factors, such as e.g. the cost of supply. To dynamically adjust the ordering, a market scheme can be adopted: prices will introduce a certain order. Exchanging information about the price and defining a cost of imbalance (the bigger the difference between supply and demand the higher the cost) is a simple market based scheme for balancing. Considering such approach requires concessions from participants, but also allows for rational decision making and leads to almost perfect balancing.

The goal function in real life power balancing is much more complex than in the artificial, theoretical problems. Comparing the goal functions (equations (1) and (3)) can give impression that they are the same. But in many of the described models the criterion is to maximize the profit or minimize the cost of producing energy ([9], [11]), where achieving balance is just one of the conditions. Often only these microgrids are considered that have connection to the external power network. Such a reserve (external network is not a constraining factor in this case: it can supply or receive any amount of power) is ensuring that the balance can always be achieved, which facilitates the decision making. In such conditions, the problem of balance is not the primary one and the goal function focus usually on profitability of the power production. The concept of a microgrid is fairly new. Pointing out that it can generate a revenue can motivate further development of this technology and construction of microgrids. When the island mode operation of the microgrid is considered, the power balancing becomes crucial for safety of the devices and the network itself.

In the Potluck and the El Farol problems decisions must be taken in discrete time intervals and need many iterations to allow the learning algorithms to adjust the predictors. After each iteration the outcome is calculated – the amount of people in the bar or amount of food on the party. The power balancing problem is in reality a continuous process, but it is often quantified to allow computer algorithms to cope with. The shorter the quantification time, the more small changes can be balanced, leading to smaller loses and better security of the grid. However, shortening of the balancing time has also its limits; as the change of the operation point of the devices requires time. Different devices have varied times of reactivity regarding their operation point change, which makes it impossible to derive the optimal minimal length of a time period in general. It can be approximated when the real set of devices that are installed in the defined microgrid is known. At present, for energy management system, the time periods may be 10 minutes, 5 minutes, but seldom less than 1 minute. Of course, the minimal physical time depends on the set of devices, but that can be evaluated only experimentally.

V. Methods of power balancing

The problem of power balancing is slightly different on each level of the power grid. Balancing power in the high voltage network can benefit from big aggregation of consumption. There the daily and weekly cycles dominate [12] and the inertia of the grid is much larger. In microgrids, the changes in consumptions still have visible cycles, but the random behavior plays a bigger role and the inertia of devices is smaller. This requires fast decision making regarding changing the operation point of sources and consumers in the grid. That poses a computation challenge, especially when the number of nodes is large and an energy management system has to balance the energy in all nodes, considering also all the physical limitation of the devices within a defined time period.

Effective balancing requires some kind of communication or a schema of cooperation between the producers of energy. The most straightforward schema is the centralized management: it is then possible to have one predictor of demand (e.g. that which gives the smallest errors), based on which the plan for production is made and the system distributes the power production. Centralized systems offer possibility of optimal production distribution [11], possibly considering multicriteria decision making. Centralized systems unfortunately have a number of different disadvantages: sensitivity to central controller failure, poor scalability, and requirement of full control over the sources. Full control may not be a problem in microgrids with a single owner, but may be unacceptable in a general situation. A centralized system might also not be able to consider specific preferences of the source owners or might give unacceptable results when a source owner happens to actively make decisions on its own (although that should not happen in a well designed system).

Non-centralized solutions have been also developed and showed promising results. Agent-based power balancing systems are quite popular approach. Due to the intrinsic characteristics of the agents, these system are distributed. A classification of different energy management schemes for agent-based systems can be found in [13]. Agents can represent single devices, nodes in the power grid, subsets of nodes or even single microgrids. The presented categories of management schemes are central-hierarchical control structure, distributed-hierarchical control structure, and decentralized control structure (peer-to-peer relation). The hierarchical organization of agents introduces an order and defines agent's functions in optimization and decision making. This can speed up the processing of the data, by dividing and distributing the tasks for calculation. The hierarchy can handle power distribution in a similar way as centralized systems. Completely decentralized control structures are extremely robust to failures and can quickly adapt to changing conditions, but because there is a larger exchange of data and negotiation, such systems tend

to operate slower, which might be the source of additional imbalances.

The last group of control systems are the ones based on market structures. The market is the central element of the balancing process, but the participants decide what kind of offer is placed on the market. In such approaches, money and cost functions play the role of ordering the power from most desired sources (i.e. cheapest and most efficient) down to the sources that are used only in emergency (i.e. more expensive power systems). Presentation of market based energy control systems can be found in [6], [9], [14].

VI. Conclusion

The power balancing problem in microgrids is especially important when the island mode operation is considered.

There are many methods that approach this problem with success, by using well known concepts such as markets. However, question arises whether other and perhaps simpler schemes might also be successful and more performent. This problem is adressed in the paper.

Practical power balancing has a lot of different limitations, which are very difficult to model: profitability, physical limitations, long term contracts for power, interaction between sources, delays in changing operation point, etc. Despite of this, theoretical models of the grid can give many useful information about the behavior of the real world system in an extremely controlled environment. The Potluck problem is very simplistic, but it touches the core of balancing: distributed decision making, in a situation of insufficient knowledge about demand and supply. Unfortunately, the problem is ill-defined and there are simply not sufficient data to create a rational-learning algorithm. The inductive learning and non-rational approaches give results that are oscillating around the ideal solution which is acceptable for theoretical problems but is unacceptable in power balancing.

In the Potluck problem, it is clear that the uncertainty is on both supply and demand side. The power balancing problem is different, as the demand can be predicted and a quick adjustment of the supply can be done in order to compensate the errors of the prediction. The inertia of the devices defines a time in which this adjustment has to be made: the faster the managing algorithm is, the smaller are the imbalances that occur, and the better it is for the grid devices.

The Potluck problem further shows that, when demand is constant and known to the suppliers, autonomous decisions made by the suppliers can actually result in a big oscillation of supply. Having the same set of information (even true and exact) cannot help if all suppliers are taking rational decisions, but do not consider decisions of other suppliers.

This also applies to the power balancing. Certain willingness to cooperate and to make concessions is needed to assure that the balancing works, with minimal oscillations. Reactiveness to the current situation and to other participants turns out to be more important than historic data about power usage and production. As shown in the experiments, knowledge about behavior of other producers is more important than historical knowledge of consumers. More accurate predictions help to improve the situation, but as human behavior is quite unpredictable, not much improvement can be made. The Potluck problem can be solved with a rational solution, if certain constraints are relaxed. Relaxing the constraint pertaining information sharing between suppliers, which we consider to be in a form of communication, is sufficient. In this situation, the Potluck problem closer resembles the power balancing one, where communication or sharing of information between producers is also sufficient to achieve a balancing within the time in which the devices need to react.

Moving from traditional grids to microgrids in the island mode is a huge modification and poses new technological challenges, not only in the physical structure, but also in the management and underlying schemes. Communication between controllable producers is anyway becoming a standard in modern power grids. This evolution gives enough information to develop a management scheme for a microgrid in the island mode, where proper balancing can be achieved within the limits of available production and consumption.

Don't step on the Distribution's Tail!

Investigating the impact of random fluctuations on efficient resource utilization

***Abstract*—It is sometimes assumed that the total amount of a resource being consumed is the key consideration when attempting to devise the most efficient management strategy. We explore a case in which the rate and timing of resource utilization are also susceptible to impact on performance and illustrate how bringing random fluctuations under control can help maximize efficiency in a simple client-server scenario. The role of self-organization and distributed control methods in achieving this goal is briefly discussed.**

***Index Terms*—random fluctuations; resource management; performance optimization; client-server architecture**

I. Introduction

MUCH has been said about demand side management [1], the so called smart grid [2] and about intelligent infrastructure [3]. Intuitive results are often generalised and the important little exceptions are sometimes overlooked. This short paper aims to invite the reader to follow the authors on a interesting, empirical result based investigation.

We simulate a server farm under a capping constraint, as it is commonly discussed in the literature when e.g. considering the use of renewable energies to power some infrastructure. By comparing two scenarios and assuming a cost for the deviations from the norm for both, we can compare the impact either strategy has on the cost efficiency of the operation. This led us to a result which we consider worth sharing.

II. Background

Efficient resource management is fast becoming one of the most critical features of almost any human activity. Whether this is the case seems clear to us, why this is the case we would rather leave to a philosophical debate. On a very abstract level, this is arguably because we have been so successful as a species that we have reached a limit above which the planet is no longer capable to sustain our wasteful habits. There was a time when we could afford to be oblivious of how much water, food, energy etc. we were using, simply because our impact was negligible, the environment was able to replenish the stocks of whatever resource we needed as quickly as it was consumed. But is no longer the case, and has not been the case for some time.

A. The problem

For better or worse, we have entered an age in which we will have to act more responsibly, to use only what is needed when it is needed, under penalty of seeing our global society descend into conflicts and service disruption as we are forced to compete ever more aggressively for dwindling supplies. The *we* here can be understood as the societal *all of us*, but also as the managerial *our company* or even the personal and cost aware *I* in every day live.

The most visible aspect of this requirement is that we must seek to limit the total amount of a resource that is consumed in the process of achieving a certain goal. There are countless examples of this today, from designing more fuel-efficient vehicles to engineering crops that require less water or nutrients. There is however another, perhaps less obvious angle to this quest for efficiency: notwithstanding how much of a resource is consumed in total, when and at which rate it is being used can also have a critical impact on its availability (and cost). While this seems an obvious fact, it is often overlooked, or lost in abstraction.

B. Example

A good example of such a resource is renewable power. Imagine that a solar plant producing 1 MW for 10 hours a day is used to power a community that consumes a total of 10 MWh over 24 hours. If some power is used at night or if the load ever exceeds the available output from the solar plant during the day, even if the aggregate supply as well as consumption total for the day is still exactly identical (i.e. 10 MWh), some provision for this "mismatch" between supply and demand will need to be made, in the form of an additional power source or storage facility. On the contrary, if the demand could be exactly mapped to the output of the solar plant over time, then it could be met locally and efficiently (with fewer losses). This is of course widely discussed in the recent literature, and techniques to shape the load so as to better approximate the available supply are collectively known as "Demand-Side Management" or DSM [4].

There is a slightly different but related and very common special case of this problem: what if the average demand for a resource is constant and known but instantaneous consumption fluctuates randomly and unpredictably? If a facility (or supply) is dimensioned so as to accommodate the average requirement, then it will necessarily be sometimes under-, sometimes over-used. Moreover, depending on the characteristics (amplitude, symmetry, . . .) of the fluctuations, the time spent in either state (over-utilization and under-utilization), as well as the deviation from the average, may vary greatly.

978-83-60810-58-3/$25.00

C. The issue with statistics

In practice, it is often assumed that, because fluctuations statistically cancel each other out over time, this is no cause for concern and so not a relevant field of study. But this view is contradicted by the realization that the rate and timing of resource utilization can impact on efficiency (as illustrated by the above example). Similarly, the commonly held view that in a large enough population of consumers, deviations from the global average will be negligible is also a simplistic one. Indeed, there is no guarantee that the costs incurred by such deviations grow linearly. If they don't, then even small deviations can have a significant impact and large ones, although extremely rare, could have a disastrous effect.

D. Aim of this paper

In this paper, we experiment with a set of conceptual tools designed to quantitatively measure the influence of random fluctuations on performance in a simple client-server scenario. Specifically, we compare the case in which no upper bound is imposed on the number of active servers to that in which there is such a constraint. In effect, we propose a cost/benefit analysis of two strategies: cutting the upper-end tail of the distribution (which creates execution delays) versus "stepping on it" (which may incur extra costs).

III. Model and simulations

A. The model

We used Monte Carlo simulations to approximate the dynamics of a group of servers. On every time-step, all identical servers have a fixed probability `P` to receive a new job, the duration of which is comprised between 1 and (2 $\times$ `avg` 1) time-steps (where `avg` is the average duration of a job). `P` is chosen in such a way that, statistically, slightly less than 1 out of 8 servers is expected to be busy at any time.

On every time-step, the number of servers in the "busy" state is recorded. In the default scenario (no constraints), this value is allowed to exceed the 1:8 ratio. In the other scenario, no more than 1 out of 8 servers are allowed to be active simultaneously. If random fluctuations in job arrivals / duration would cause the system to exceed this limit, the execution of a corresponding number of jobs (randomly selected) is temporarily suspended (i.e. the servers processing them are put on stand-by).

In the default scenario, performance degradation is measured by the number of server-time-steps falling above the 1:8 target and incurring extra costs. In the constrained scenario, it is the cumulative delay (total number of time-steps) suffered as a result of imposing a cap on the number of active servers (QoS (quality of service) penalty).

B. Simulations

Data-centers were modelled to operate between 1000 and 4000 servers (by increments of 500) and were simulated for 512 time-steps. The average job duration was 8 time-steps (i.e. flat distribution between 1 and 15). There were 1000 realizations for every size and for each scenario, totaling 14000 independent simulation runs.

A control simulation (simulating batches up to 1024 time steps was run to confirm the results presented in the next section. The results from this investigation confirmed that the system was at, or very close to, its steady state at t=512.

IV. Results

A. Frequency distribution

Fig. 1 shows the frequency distribution of simulation outcome for 4 different server population sizes. As expected, for the "constrained" scenario, there is a sharp peak corresponding to the 1:8 ratio (125, 250, 375 and 500 servers respectively) since the whole tail of the distribution has "collapsed" onto this single value. Note that the remainder of the distribution closely follows the Gaussian profile found for the default scenario, apart from in the case of smaller populations, where capping also seems to negatively affect the height of the normal peak.

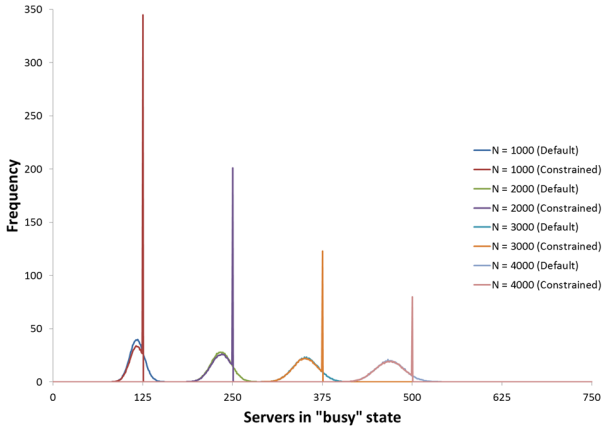

Fig. 1. Frequency distribution of system state as a function of the number of active servers, for 4 different population sizes and for the two possible scenarios ("Default" vs. "Constrained"). 1000 runs per set of parameter values.

The values reported in Fig. 1 consider only the values for the last 128 (out of 512) time-steps, when the system is at or very close to steady state. The motivation is that the initial values would be too much affected by the build up, but after $3/4^{th}$ of the steps we can assume that the overspill from previous steps has normalised (especially since the individual duration can not exceed 15 and we are not including the first 384 steps).

B. Aggregated QoS violation

Fig. 2 shows the evolution of the average delay (QoS penalty) incurred over all processed jobs, for increasing system size and for both scenarios. As expected, this value is unaffected by system size in the default case, where a delay only occurs when a job is submitted to a server before it has completed the execution of its predecessor. By contrast, in the constrained scenario, a QoS penalty is also incurred when the overall workload exceeds the processing capacity of $1/8^{th}$ of the population.

The main finding is that the average delay converges quickly for both cases as system size increases. This is due to the amount of time spent above the cut-off limit in the default scenario being inversely proportional to the number of servers involved; thus capping becomes proportionally less frequent in the constrained scenario (illustrated by the decreasing height of the sharp peak corresponding to 1:8 limit, see Fig. 1).

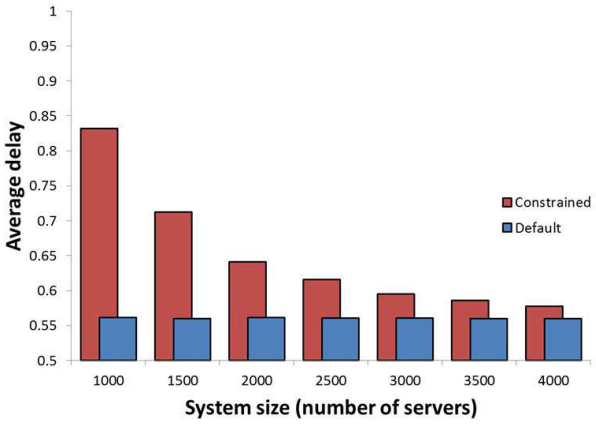

Fig. 2. Evolution of the average delay per job as a function of population size (workload proportional to the number of servers). The larger the system, the lower the QoS penalty resulting from enforcing the 1:8 cap.

C. Comparative QoS violations

Although to some extent these results are merely intuitive and can be anticipated from known statistical properties [5], they can also be interpreted in a different and more surprising way. For instance, the fact that, in the default scenario, the absolute number of server-time-steps falling inside the high-end tail of the frequency distribution shown on Fig. 1 (i.e. above the 1:8 limit) exhibits a maximum (see Fig. 3) clearly suggests that the capping strategy would yield most benefits within a finite range of system sizes.

D. Potential benefit analysis

Table I illustrates how the potential benefits of using the capping strategy would vary as a function of system size, under the arbitrary assumption that every server-time-step over the 1:8 target incurs an extra £0.01 cost (e.g. because of higher server rental cost) and every time-step delay incurs a £0.01 penalty fee (e.g. as compensation for breaching the service-level agreement).

TABLE I
POTENTIAL SAVINGS FROM APPLYING A CAPPING STRATEGY (ARBITRARY PENALTY COSTS). NOTE THE PRESENCE OF A MAXIMUM FOR N = 3000.

N	Cost Breakdown		
	Cost Differential (default-constraint)	*QoS Penalty (constraint-default)*	*Net Savings*
1000	£33,792	£21,251	£12,541
2000	£41,238	£12,687	£28,552
3000	£43,052	£8,160	£34,892
4000	£39,187	£5,562	£33,625

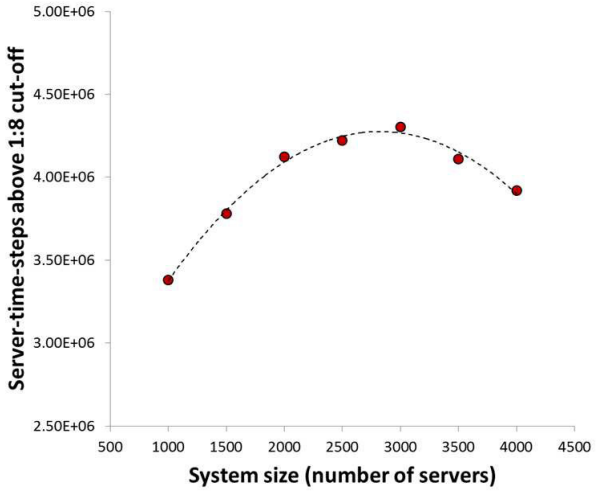

Fig. 3. Total (absolute) number of server-time-steps falling above the 1:8 cut-off limit in the default scenario, as a function of population size.

V. CONCLUSIONS

These preliminary findings confirm that there are realistic applications for which limiting the total amount of a resource being consumed over a period of time is not enough. Preventing the instantaneous load from exceeding a predetermined value can be beneficial and contribute to improving efficiency.

Moreover, relying on statistical effects, either over time or over a large population, to ensure a smooth demand profile may be a high-risk strategy as it is possible that even small or rare deviations from the average incur a severe penalty.

In this context, it seems important to investigate control methods that would permit to regulate the aggregated demand from a population of resource consumers so as to prevent them from exceeding a certain target. Because a central mechanism for achieving such a goal may not be feasible (due to scalability problems, limits on information availability or even ownership boundaries), we argue that a form of collective intelligence capable of supporting self-management is required. The investigation of a candidate technology for implementing such a distributed resource controller will be the subject of future work.

***Abstract*—Resource allocation is a task frequently encountered in energy management systems such as the coordination of power generators in a virtual power plant (unit commitment). Standard solutions require fixed parametrised optimisation models that the participants have to stick to without leaving room for tailored behaviour or individual preferences. We present a modelling methodology that allows organisations to specify optimisation goals independently of concrete participants and participants to craft more detailed models and state individual preferences. While considerable efforts have been spent on devising efficient control algorithms and detailed physical models in power management systems, practical aspects of unifying several heterogeneous models for optimisation have been widely ignored – a gap we aim to close. As a by-product, we give a formulation of warm and cold start-up times for power plants that improves existing power plant models. The concepts are detailed with the load-distribution problem faced in virtual power plants and evaluated on several random instances where we observe that a significant number of soft constraints of individual actors can be satisfied if considered.**

I. Constraint Optimisation Problems in Power Systems

RESOURCE allocation and scheduling are difficult problems that occur frequently in energy systems, be it the coordination of power generation [1], demand-side management, or building control software. In a producer-based view, supply needs to meet the demand as accurately as possible in order to guarantee stability and avoid costs incurred by corrective measures. Similarly, consumers may try to find cost-minimising schedules for processes required throughout a day with respect to time-dependent energy prices. Current initiatives[1] are based on the assumption that *groups* of prosumers (i.e., energy producers and/or consumers) can form and team up to achieve better prices or production rates for their participants. We also adopt the notion of *agents*, indicating that the prosumers are in principle autonomous entities, even if they surrender the decision about their power output to the group.

A straightforward solution (see, e.g., [2], [3], [4], [5]) to this resource allocation problem is to model the decision making process (e.g., distributing the load in a virtual power plant (VPP) or scheduling energy-consuming domestic processes in a consumer coalition) as a mathematical optimisation problem such as a mixed integer program (MIP), a linear program (LP) or as a constraint satisfaction and optimisation problem (CSOP) as done by industrial distributed energy management tools such as Siemens DEMS [6] or PLEXOS Integrated Energy Model [7]. DEMS is used, e.g., by the municipal utility of the city of Munich for controlling a VPP [8]. In essence, the problem is specified in terms of (decision) variables, their associated domains, and constraints that regulate which assignments are valid. The task accomplished by the respective solvers is then to assign values to all variables such that no constraint is violated and an optimisation objective is minimised (or maximised).

Typically, such tools (DEMS in particular) offer a predefined range of agent types such as energy generators, storages, or controllable loads. Users may then specify the topology of their energy system to calculate optimized power schedules. A concrete power generator is thus essentially represented by *one tuple* in a data repository containing the parameters defining its behaviour. Consequently, the provided models constitute a static *one-for-all* solution that needs to encompass all supported characteristics of power generators, including, e.g., time-dependent properties such as inertia.

Clearly, power generators show varying characteristics such as change rates, cool or warm start-up times or power boundaries depending on, e.g., the power plant type or manufacturer. *Parametrised models* as described above cannot support this variety. At some point the model has to be fixed for all participants and individual variables necessary to model a certain constraint cannot be added. To overcome this limitation, we suggest to synthesise an optimisation problem from several *individual models*. Such *synthesised models* allow for individual preferences (typically in the form of knowledge acquired by power plant operators such as economically optimal production ranges or limited ramp-up or -down of a generator) and separate modelling of the organisational optimisation problem and physical models of individual participants – properties that are attractive for organisations as more clients can be served as well as for individual participants as they can influence the assigned plans. This methodology is not only nice to have in multi-agent systems, where optimisation problems result from a combination of several sub-problems – it is *necessary*.

Our contribution leads to a methodology that offers:

1) support for heterogeneous prosumers requiring specific sets of variables;
2) isolated modelling of physical components;
3) clean separation of the organisational aspects such as

[1] cf. https://www.energiekosten-stop.at/ for consumer alliances or http://www.swm.de/geschaeftskunden/effizienz-umwelt/virtuelles-kraftwerk.html for virtual power plants

978-83-60810-58-3/$25.00

objectives or fairness constraints from physical models;
4) incorporation of individual preferences into the optimisation routine of a coalition to increase and incentivise the participation.

We exemplify model synthesis with the problem of creating schedules in a virtual power plant and show how to integrate custom behaviour in the form of cold and warm start-up times that are specific to certain power plant types as well as individual economical preferences. While we demonstrate the modelling and synthesis approach for a single organisation, these concepts can be incorporated to solve hierarchical resource allocation problems as described in [9], which focused on the abstraction of constraint models.

The paper is structured as follows: Sect. II introduces a formalism to express preferences with the help of constraint relationships while Sect. III shows the general approach to power plant scheduling within a virtual power plant. Both approaches are used in Sect. IV to synthesise individual models within a group of power plants. Sect. V then instantiates the general framework for use with IBM ILOG CPLEX. Our experimental results and the findings drawn from them are discussed in Sect. VI. We conclude the paper with a discussion of future research directions.

II. Constraint Programming with Constraint Relationships

As we suggest a modelling methodology for constraint satisfaction and optimization problems (CSOPs, see, e.g., [10]) to solve resource allocation problems, we briefly revisit the core model elements as well as the definition of constraint relationships [11] that we use to denote individual preferences of single agents. A CSOP $\zeta = \langle \mathcal{X}, \mathcal{D}, \mathcal{C}, f \rangle$ consists of a set of decision variables $\mathcal{X}$ that take values from the domain $\mathcal{D}$ where consistent assignments $\theta \in (\mathcal{X} \to \mathcal{D})$ are regulated by the set of constraints $\mathcal{C}$. We write $\theta \models c$ if the constraint c is satisfied by an assignment θ. The objective function $f : (\mathcal{X} \to \mathcal{D}) \to \mathbb{R}$ measures the quality of a solution and effectively imposes an ordering over the assignments where we seek the best one.

However, not all constraints need to be hard requirements and some may also be violated if no assignment simultaneously satisfies all constraints [12]. We call these constraints *soft* and denote them by $\mathcal{C}_s$ as opposed to hard constraints $\mathcal{C}_h$ with $\mathcal{C}_h \cup \mathcal{C}_s = \mathcal{C}$, $\mathcal{C}_h \cap \mathcal{C}_s = \emptyset$. A set of *constraint relationships* for the soft constraints C_s of a CSOP ζ is given by a binary asymmetric relation $\mathcal{R} \subseteq \mathcal{C}_s \times \mathcal{C}_s$ whose transitive closure $\mathcal{R}^+$ is a partial order relation. We write $c' \prec_{\mathcal{R}} c$ or $c \succ_{\mathcal{R}} c'$ iff $(c, c') \in \mathcal{R}$ to define c to be *more important* than c', analogously for $\mathcal{R}^+$. If $c' \prec_{\mathcal{R}} c$ we call c' a *direct predecessor*, if $c' \prec_{\mathcal{R}^+} c$ a *transitive predecessor* of c. Moreover, we refer to the *constraint relationship graph* as the directed graph spanned by $\langle \mathcal{C}_s, \mathcal{R} \rangle$. Figure 1 shows a toy example of a CSOP with constraint relationships.

The binary relation over soft constraints needs to be lifted to sets of soft constraints that are violated by an assignment. Such a *violation set* is denoted by capitalizing the letter used for the assignment; i.e., for some assignment $t \in (\mathcal{X} \to \mathcal{D})$ its violation set is $T = \{c \in C_s \mid t \not\models c\}$. We propose different dominance properties $p \in \{\text{SPD}, \text{TPD}\}$ where SPD (single-predecessor-dominance) indicates that one constraint may only dominate a single predecessor and TPD (transitive-predecessor-dominance) defines that a single constraint is more important than *all* of its predecessors (corresponding to the relative importance among constraints) – we refer to [11] for more details. We write $T \longrightarrow^p_R U$ to denote that the violation set T *worsens* to U with dominance level p and use the following rules:

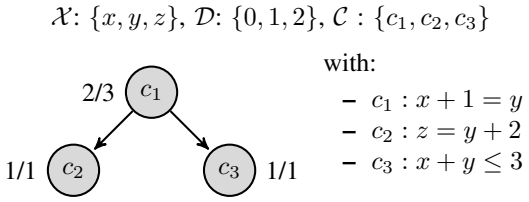

Fig. 1. Not all three constraints can be satisfied simultaneously, e.g. c_2 forces z to be 2 and y to be 0, conflicting with c_1, We can choose between solutions satisfying $\{c_1, c_3\}$ or $\{c_2, c_3\}$. Weights are given in the form "SPD / TPD".

$$T \longrightarrow^p_R T \uplus \{c\} \tag{W1}$$

$$\frac{T_1 \longrightarrow^p_R U_1 \quad T_2 \longrightarrow^p_R U_2}{T_1 \uplus T_2 \longrightarrow^p_R U_1 \uplus U_2} \tag{W2}$$

$$T \uplus \{c\} \longrightarrow^{\text{SPD}}_R T \uplus \{c'\} \quad \text{if } c \prec_R c' \tag{SPD}$$

$$T \uplus \{c_1, \ldots, c_k\} \longrightarrow^{\text{TPD}}_R T \uplus \{c'\} \quad \text{if } \forall c \in \{c_1, \ldots, c_k\} : c \prec_{R^+} c' \tag{TPD}$$

Finally, we define a partial order over solutions, denoted by $t >^p_R u$ and to be read as "t is better than u", using $T \ (\longrightarrow^p_R)^+ \ U$ (meaning repeated sequential application of the rules) for the selected $p \in \{\text{SPD}, \text{TPD}\}$. To use them in a CSOP, we calculate weights for the constraints that respect the partial order $>^p_R$ where we summarise the weights of violated constraints as the *penalty* of a solution:

$$w^{\text{SPD}}_R(c) = 1 + \max\{w^{\text{SPD}}_R(c') \mid c' \in \mathcal{C} : c \succ_R c'\}$$
$$w^{\text{TPD}}_R(c) = 1 + \sum_{c' \in \mathcal{C}_s : c \succ_R c'} (2 \cdot w^{\text{TPD}}_R(c') - 1)$$

Consequently, we define an objective based on $p : (\mathcal{X} \to \mathcal{D}) \to \mathbb{N}$ as:

$$\underset{\theta}{\text{minimize}} \ \ p(\theta) = \sum_{c \in \mathcal{C}_s, \theta \not\models c} w(c) \tag{1}$$

III. Scheduling Power Plants within a Virtual Power Plant

Our approach to synthesise individual models is exemplified with the problem of finding schedules for power plants in a virtual power plant that we described in [9] and [13]. This problem is also known as economic load dispatch (ELD) [14] or unit commitment (UC) [15]. In essence, the task is to

```
int lastSimStep = 10;
range TIMERANGE = 0..lastSimStep;
{string} PowerPlants = ...;

tuple PowerPlantData {
  float minimal; float maximal; float fixedRamp;
};

PowerPlantData plants[PowerPlants] = ...;
float demand[TIMERANGE] = ...;

dvar float+ production[PowerPlants][TIMERANGE];
dexpr float totalProduction[t in TIMERANGE] =
            (sum( p in PowerPlants ) (production[p][t]));

minimize
  sum ( t in TIMERANGE )
     abs(demand[t] - totalProduction[t]);

subject to {
  forall (p in PowerPlants, t in 0 .. (lastSimStep - 1)) {
    production[p][t] >= plants[p].minimal;
    production[p][t] <= plants[p].maximal;
    abs(production[p][t] - production[p][t+1])
        <= plants[p].fixedRamp;
  }
}
```

Listing 1. A minimalistic, *parametrised* model of a load distribution problem

distribute a given load (for a certain time window) to a set of power generators in such a way that their capacities as well as inertia between consecutive time steps are respected. We present this basic scheduling problem as a CSOP (which we will refine to accommodate additional model aspects):

$$\begin{aligned} \underset{P_t^a}{\text{minimize}} \quad & \sum_{t\in\mathcal{W}} |P_t - \mathcal{D}_t|\,,\ P_t = \sum_{a\in\mathcal{A}} P_t^a \\ \text{subject to} \quad & \forall a \in \mathcal{A}, \forall t \in \mathcal{W} : P^a_{\min} \le P_t^a \le P^a_{\max}, \\ & v^a_{\min}\left(P^a_{t-1}\right) \le P_t^a \le v^a_{\max}\left(P^a_{t-1}\right) \end{aligned} \tag{2}$$

where P_t^a are the decision variables representing the production of plant $a \in \mathcal{A}$ at time step $t \in \mathcal{W}$, the scheduling window. The demand is given as the vector $\mathcal{D}$ and basic properties about the constraints of each power plant include minimal and maximal production values, $P_{\min}$ and $P_{\max}$ and functions denoting minimal and maximal production given the current output $v^a_{\min}, v^a_{\max} : \mathbb{R} \to \mathbb{R}$ to incorporate inertia and model the ramping behaviour of power plants [16]. To make this example more concrete, we assume that a power plant is described by its production boundaries as well as a fixed ramp up rate between two consecutive time steps (taking the role of $v_{\min}$ and $v_{\max}$) depending on the nameplate capacity as, e.g., given in [17]. We can then formulate the optimisation problem from Eq. 2 in IBM's optimisation programming language (OPL) as in Listing 1. OPL is used by IBM ILOG CPLEX [18] which in turn can be employed by both DEMS and PLEXOS.

The listing shows the shortcomings of a *parametrised* model: All power plants are described by the *same* set of parameters and constraints are defined uniformly for all power plants and time steps. Hence, the possible variety is severely limited.

TABLE I
DIFFERENT COLD AND HOT START-UP TIMES FOR POWER PLANT TYPES. A COLD START OCCURS IF A PLANT IS DOWN FOR MORE THAN 48H, A HOT START IF IT IS DOWN FOR LESS THAN 8H. TAKEN FROM: [17], [21]

Plant type	Cold start-up (h)	Hot start-up (h)
Black coal	4 – 5	2
Brown coal	6 – 8	2 – 4
Gas turbine	0.5	0.25
Photothermal	4 – 5	2

In order to achieve feasible schedules, a number of different types in constraints are usually employed in power plant models. While the models presented within the scope of this work are far from complete and much more detailed models exist (see, e.g., [14], [15], [16]) these types are common and therefore representative. In addition, the more complex and heterogeneous models found in the literature only emphasise the need for a methodology to incorporate these diverse descriptions of physical and economic limitations with organisational aspects. The types of constraints considered here are:

Minimal up/down times: a generator is required to run (or be switched off) for a certain number of steps before being switched off (or turned on) [15].

Ramp up/down rates: usually, a fixed amount of production change between two consecutive time steps is assumed [19], especially in thermal power plants in which physical boundaries for heating and cooling the system have to be captured (as used in Listing 1). Alternatively, the possible change can be specified as a relative quantity denoting the percentage of the current output that a power plant can adapt.

Cold/warm start-up times: a power plant may need a certain number of time steps to ramp up from 0 to its minimal production level as modelled by [16]. However, for some plants, this start-up duration depends on the downtime as "cold starts" differ from "warm starts" (see Table I for sample values). We show how to formalise these start-up times in a MIP-framework using the transition system in Fig. 2. We consider the actual duration of a start-up as opposed to the costs which can be approximated with exponential functions [20].

Please bear in mind that *not all* power plants feature the *same* constraints. Consider, e.g., a power plant where the ramp up/down rates are high enough to regulate from minimal to maximal production in just one time step (say 15 minutes). Then, the model may not contain such a constraint [19]. If we want to consider this constraint in a parametrised model, *all* power plants would have to include model elements (e.g., ramp up rates). The problem becomes even more obvious when we consider minimal off times. As we demonstrate in Sect. IV-A, we need *additional* decision variables for the current off time

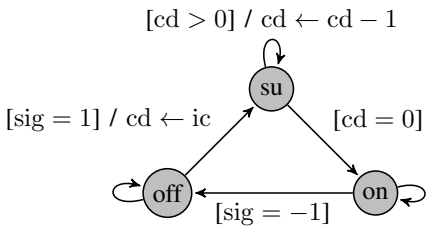

Fig. 2. Transition system to model adaptive start-up times depending on down time. The signal (sig) takes values from $\{-1, 0, 1\}$ where 1 shows a start-up, 0 is the default, and -1 triggers a shut-down. A countdown is initialised with ic as a result of a function of the down time and has the plant stay in the state *su* (start-up) for ic steps. A plant can only contribute in the state *on*. Expressions in brackets contain guards and other annotations at the transitions denote actions manipulating local variables.

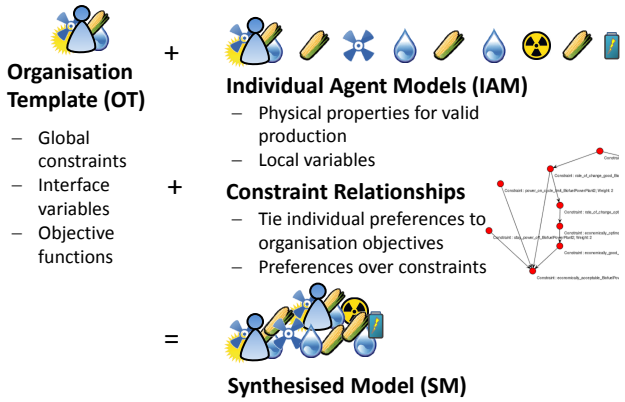

Fig. 3. Overview of the synthesis process

to adequately model these constraints. A parametrised model would again introduce these variables for *all* power plants including those that do not show minimal off times. For them, dummy values allowing to ignore certain constraints (e.g., a fixed ramp up rate of $P_{\max}$) would be required.

From an engineering perspective, it thus makes sense to model these aspects separately. Variants of these constraints can also be specified as preferences, if, e.g., a ramp up of 15 % is technically possible but it is more desirable to limit ramp up to 10 % to save expenses and material. We will use these exemplary constraints to create individual, heterogeneous power plant models to be used in synthesised models.

IV. Synthesis of Coalition Models

In light of the presented problems we can distinguish two aspects that are intermingled in Eq. 2:

Individual Agent Models (IAM) describe the properties of *one* agent representing a physical entity in terms of constraints for the available production. Constraints can be formulated depending on the internal state (being on/off, production levels etc.) independent of other agents. This model needs to be provided by the agent designer, e.g., the power plant manufacturer, possibly with customisations by its operator. An IAM defines the feasible production or consumption range of an agent but also regulates possible transitions between different time steps. Moreover, preferences (such as those avoiding high ramp-up rates) can be specified with constraint relationships to further constrain feasible schedules.

Organisational Templates (OT) represent the specific goals of an organisation or a coalition formed by the organisation. We consider organisations to be entities that exist independently of their specific agents and are therefore modelled separately [22]. The template captures the optimisation criterion and provides so-called *interface variables* that each IAM needs to incorporate. Additional (soft) constraints can impose policies of the organisation such as "prefer agents of type X" or "distribute resources in a fair manner".

Model synthesis is concerned with creating a CSOP from a set of agent models including their individual preferences and an organisational template as Fig. 3 shows. Aside from the generally required parameters of the individual agent models introduced in Listing 1 such as possible contributions, the power plant models exhibit varying characteristics regarding feasible schedules given by the constraints presented in Sect. III. Recall that to formalise these properties, we might need additional decision variables such as number of time steps a power plant has been switched off to capture the down time. As only *some* power plants may need these for modelling their start-up behaviour, we call them *local variables*. IAMs constitute a possible refinement of *option models* in the context of *Energy Agents*, a unifying framework for agent-based energy systems [23].

In our VPP example, the interface *decision* variables are the scheduled production values of all power plants over all time steps. Similarly, $P^a_{\min}$ and $P^a_{\max}$ need to be specified by each power plant a to calculate load percentages. Thus, the interface variables model the *homogeneous* parts of all considered agents as opposed to the *heterogeneity* introduced by custom behaviour in local variables: To accommodate minimal up/down times, we need variables $\top_t$ and $\bot_t$ that represent for how many time steps a power plant has been up or down, respectively, at time step t. For convenience, we further define $\nu_t \leftrightarrow P_t > 0$. A minimal up time of $\top^{\min}$ is expressed by the following constraint:

$$\forall t \in \mathcal{W} : \nu_t \wedge \neg\nu_{t+1} \rightarrow \top_t \geq \top^{\min} \tag{3}$$

For start-up times that depend on down times we need a countdown variable that regulates the time steps the power plant has to be in the start-up state shown in Fig. 2. We will further discuss how to formulate this constraint but first describe the general steps required for model synthesis.

A. Components of Model Synthesis

We first formally illustrate the ingredient models of our synthesis approach and give an implemented example using OPL in Sect. V. For doing so, we assume an organisation λ that controls a set of agents, $\mathcal{A}^\lambda$, along with their IAMs that consist of the interface variables $\mathcal{X}^\lambda$ and local variables

$\widehat{\mathcal{X}}^a$ for each agent a. In our example, modelling downtime limitations, $\mathcal{X}^\lambda = \{P_{\max}\} \cup \{P_t \mid t \in \mathcal{W}\}$ and $\widehat{\mathcal{X}}^a = \{P^*_{\min}, P^*_{\max}\} \cup \{\top_t, \bot_t, \nu_t \mid t \in \mathcal{W}\}$ would be a suitable choice. We need $P_{\max}$ to specify load factors later on and can technically distinguish $P_{\max}$ from P_t since the former are indeed constants and not decision variables as their value is fixed for a power generator. However, for ease of presentation we assume $P_{\max}$ to be just a decision variable with a domain consisting of only one value and treat all variables alike. The same holds for $P^*_{\min}$ and $P^*_{\max}$ that locally specify preferred ranges of operation. Then, the valid scope for all constraints within a single IAM of an agent a is $\mathcal{X}^\lambda \cup \widehat{\mathcal{X}}^a = \mathcal{X}^a$. The set of individual constraints $\mathcal{C}^a$ consists of both hard and soft constraints, $\mathcal{C}^a_h$ and $\mathcal{C}^a_s$ where $\mathcal{R}^a$ represents the constraint relationships defined over $\mathcal{C}^a_s$. We illustrate how to tie the auxiliary local variables in $\widehat{\mathcal{X}}^a$ to the interface variables with the vector denoting whether a plant is running:

$$\forall t \in \mathcal{W} : \nu_t \leftrightarrow P^0_t > 0$$

This expression helps in defining additional constraints and can be implemented by a decision expression in OPL directly. An individual preference for a certain production subrange $[P^*_{\min} P^*_{\max}]$ is specified by the soft constraint:

$$\forall t \in \mathcal{W} : P^*_{\min} \leq P^a_t \leq P^*_{\max}$$

To summarize, IAMs are specified as constraint satisfaction problems and represented as $\langle \mathcal{X}^a, \mathcal{D}^a, \mathcal{C}^a, \mathcal{R}^a \rangle$ with suitable choices of domains.

Next, consider the organisational template (OT). It provides at least the interface variables for *all* its subordinate agents – i.e., in contrast to a single IAM which specifies in terms of variables $x \in \mathcal{X}^\lambda$, the OT consists of a set of interface variables $\mathcal{X}^{\mathcal{A}^\lambda} = \{x^a \mid x \in \mathcal{X}^\lambda, a \in \mathcal{A}^\lambda\}$ for every agent a. These variables have to be provided in every IAM so the OT can use them for defining the organisational goal. Note that this would certainly not be true for local variables. It is not possible to specify, e.g., $\top^a_t$ indexed by a as it does not have to be defined in every model – contrary to a parametrised scheme. For unit commitment, the objective is taken from Eq. 2:

$$f = \underset{P^a_t}{\text{minimise}} \sum_{t \in \mathcal{W}} \left| P^\lambda_t - \mathcal{D}_t \right|,\ P^\lambda_t = \sum_{a \in \mathcal{A}} P^a_t$$

where $\mathcal{D}_t$ are constants representing the demand at time steps t and P^λ_t can either be seen as an additional decision variable in OT restricted by the constraint to be the sum of all agent productions or directly as a decision expression that is fully determined by the value of its associated decision variables (P^a_t). A soft fairness constraint for a VPP could be that no power plant should produce less than 40 % of its nominal capacity, $P_{\max}$, if possible. We call this organisational constraint oc1:

$$\text{oc1} : \forall a \in \mathcal{A}^\lambda, t \in \mathcal{W} : P^a_t \geq 0.4 \cdot P^a_{\max} \tag{4}$$

Similarly, we could impose a soft upper bound (oc2) for the load factor to prefer schedules that do not rely on few power generators providing all energy. All together, an organisation template is given by $\langle \mathcal{X}^{\mathcal{A}^\lambda}, \mathcal{D}^\lambda, \mathcal{C}^\lambda, \mathcal{R}^\lambda, f \rangle$ – the interface variables instantiated for each agent and their domains, a set of organisational hard and soft constraints with optional constraint relationships and an optimisation function f.

B. Steps of Model Synthesis

Synthesis takes a set of IAMs $\langle \mathcal{X}^a, \mathcal{C}^a \rangle$ for agents $a \in \mathcal{A}^\lambda$ and an organisation template to create the synthesised model (SM) for λ, a CSOP $\zeta = \langle \mathcal{X}, \mathcal{D}, \mathcal{C}, \mathcal{R}, f \rangle$, the construction of which we discuss step-by-step.

Step 1: First we make sure that local variables do not clash when combining several agents by renaming them to a unique identifier. A substitution operator $\{x_1 \mapsto x_2\}$ replaces all occurrences of the variable x_1 by the variable x_2 in a constraint or optimisation function. We then write x^a for a variable $x \in \mathcal{X}^a$. Note that this intentionally connects the interface variables $\mathcal{X}^\lambda$ used in an IAM with the counterpart in the OT, $\mathcal{X}^{\mathcal{A}^\lambda}$. The set of variables of ζ is then defined as $\mathcal{X} = \mathcal{X}^{\mathcal{A}^\lambda} \bigcup_{a \in \mathcal{A}^\lambda} \{x^a \mid x \in \widehat{\mathcal{X}}^a\}$ (furthermore, constraints keep their original domains to form $\mathcal{D}$).

The constraints $\mathcal{C}$ then consist of all hard and soft constraints of the organisational template and the constraints in all IAMs after substituting variables by their labelled counterparts. Hence:

$$\mathcal{C} = \mathcal{C}^\lambda \cup \bigcup_{a \in \mathcal{A}^\lambda} \{c\{x \mapsto x^a, \forall x \in \mathcal{X}^a\} | c \in \mathcal{C}^a\}$$

Constraint relationships for the synthesised model can be formed under the assumption that organisational constraints have a higher priority than individual preferences.

Step 2: As Fig. 4 shows, we then impose artificial edges that specify that all constraints in the OT are more important than all soft constraints of IAMs that do not have constraints that are deemed more important. However, this is a design decision as it might not be desirable for all problems to strictly prioritise organisational constraints. It should be noted further, that constraint relationships of different IAMs all have a disjoint scope – the respective $\mathcal{X}^a$ sets – and that the constraint relationships are subject to the variable renaming as well.

$$\mathcal{R} = \mathcal{R}^\lambda \cup \bigcup_{a \in \mathcal{A}^\lambda} \mathcal{R}^a \cup \{(x, y) \mid x \in \mathcal{C}^\lambda_s, y \in \mathcal{C}^a_s, \nexists z : z \succ_{\mathcal{R}^a} y\}$$

Step 3: Finally, as the optimisation function is defined in terms of the instantiated interface variables, $\mathcal{X}^{\mathcal{A}^\lambda}$, we can keep f as the objective of ζ. This yields two possibly conflicting objectives regarding the satisfaction of individual and organisational soft constraints versus meeting the original objective f. We could then use an existing multi-objective optimisation technique such as utopia search [24] but propose an alternative three- stage optimisation to strongly favour the organisational objective f while still optimising p if possible.

C. Multi-objective Optimisation with Constraint Relationships

During synthesis, constraint relationships are responsible for combining soft constraint priorities as well as establishing a

connection to organisational constraints. Fig. 4 shows how agents have different preferences on soft constraints that only affect their individual performance, e.g., *economically optimal* states that prescribe that production should better be in this range whereas other values are technically feasible. Optimizing the SM $\zeta = \langle \mathcal{X}, \mathcal{D}, \mathcal{C}, \mathcal{R}, f \rangle$ with respect to the original objective *and* soft constraint satisfaction (as defined by the penalty function p in Eq. 1) can be achieved as follows (w. l. o. g. we restrict ourselves to minimization problems):

1) Let $\hat{f}$ be the optimal result of ζ (with the original objective f).
2) Find an upper/lower bound f^* for the objective such that $f^* = \delta_f \times \hat{f}$ for some x, where $\delta_f \geq 1.0$ for a minimisation problem. Note that for a non-negative minimisation objective, $\delta_f \times \hat{f} = 0$ so the bound collapses to a single point, 0 such that any valid solution has to be optimal if at least one is.
3) Impose a constraint to restrict $f(\theta)$, $\theta \in (\mathcal{X} \rightarrow \mathcal{D})$. Let ζ' be the problem that minimises the violation of penalties with respect to the bound f^*: $\zeta' = \langle \mathcal{X}, \mathcal{D}, \mathcal{C} \cup \{c' : (f(\theta) \leq f^*\}, \mathcal{R}, p \rangle$.
4) Solve ζ' and let $\hat{p}$ be the minimal sum of penalties of violated constraints.
5) Impose a restriction on the sum of penalties to be less than or equal to $\hat{p} \times \delta_p$ and solve for the original objective: $\zeta'' = \langle \mathcal{X}, \mathcal{D}, \mathcal{C} \cup \{c'' : (p(\theta) \leq \hat{p}\}, \mathcal{R}, f \rangle$. This step is necessary as otherwise a solver might just lie within the tolerance of f^* even if better solutions in terms of f (having the same penalty sum) exist.

Appropriate choices for δ_f and δ_p have to be found specific to a problem but so do weights of a single combined objective function commonly employed in a global criterion method [24]. This approach can certainly be costly if the optimisation problems themselves are hard and time-consuming to solve – but if the coalitions are sufficiently small and organised (as, e.g., in a hierarchical system [9]) the benefits of finding solutions that are attractive to the individual participants outweigh the expensive optimisation runs. Moreover, the solutions found in previous steps can be used as starting points in subsequent runs to speed up the optimisation and other multi-objective optimisation approaches such as utopia search require several optimisation runs as well.

V. Implementing Synthesis in CPLEX

We exemplify the synthesis process with an example of a VPP consisting of three power plants with heterogeneous constraints modelling the requirements presented in Sect. III. For each power generator, we formulate the individual constraints and explain the usage of local and interface variables. The problem is comparable to the parametrised model presented in Listing 1. The models are directly presented in the Optimisation Programming Language (OPL) used in CPLEX [18] to provide a prototype even though our concepts do not rely on any specific CPLEX features such that the models could equivalently have been presented in a pseudo-code for CSOPs. Extensions to OPL regarding soft constraints are therefore implemented using the keyword *SOFT-CONSTRAINTS* in comments. We do not describe entire models (which are provided online[2]) but rather highlight the most important aspects.

A. Organisational Template

We start with the organisational template as it contains the core optimisation problem to be tackled. The first section indicates the identifier of the set consisting of the agents' identifiers (*plants* in our case) as well as generally needed constants such as the time series and load curve.

```
{string} plants = ...;
range TIMERANGE = 0..5;
float loadCurve[TIMERANGE] =
  [200.0, 250.0, 230.0, 247.0, 349.0, 551.0];
```

The set of *plants* needs to be filled with the identifiers of actual power plant models. *TIMERANGE* and *loadCurve* are furthermore examples of interface variables that individual agents may use to define their local variables and constraints. Additional decision variables and expressions common to all agents are described in the next section. *Production* for different time steps are the decision variables in this example and we require each agent to provide its maximal output (nameplate capacity) such that we are able to define the load factor of each plant. Note that these decision variables are indexed by the set of child agents ($\mathcal{X}^{\mathcal{A}^\lambda}$). Decision expressions primarily are syntactic tools to facilitate the formulation of optimization functions and constraints. They have to be fully determined by the value of the decision variables but offer to aggregate a set of decision variables using the *sum*, *min*, or *max* constructs. The presented expressions serve to provide a formulation of the constraint presented in Eq. 4.

```
float P_max[plants] = ...;
dvar float+ production[plants][TIMERANGE];
dexpr float totalProduction[t in TIMERANGE] =
  sum(p in plants) production[p][t];
dexpr float loadFactor[p in plants][t in TIMERANGE] =
  production[p][t] / P_max[p];
dexpr float minLoadFact[t in TIMERANGE] =
  min(p in plants) loadFactor[p][t];
dexpr float maxLoadFact[t in TIMERANGE] =
  max(p in plants) loadFactor[p][t];
```

Violation takes the sum of the absolute values of the deviation between the aggregated production and the load curve. It is the quantity that we aim to minimize.

```
dexpr float violation = sum(t in TIMERANGE)
  abs(totalProduction[t]-loadCurve[t]);

minimize violation;
```

We can explicitly request that all productions are below the nameplate capacity as a *hard* constraint. Furthermore, this organisational template provides for two soft constraints regarding distributions of load — denoted by $\mathbf{oc1}$ and $\mathbf{oc2}$. They indicate that the load factor of the individual agents should not

[2]Please refer to footnote 4

vary too much if possible thereby avoiding a highly skewed resource allocation. In particular, power plant operators might expect to have their generator contribute at least to a certain extent to generate revenue. Indifference between **oc1** and **oc2** is expressed by not modelling a relationship.

```
subject to {
  forall (t in TIMERANGE) {
    oc1: minLoadFact[t] >= 0.4;
    oc2: maxLoadFact[t] <= 0.6;
    forall (p in plants) {
      production[p][t] <= P_max[p];
    }
  }
};

/* SOFT-CONSTRAINTS
oc1
oc2 */
```

Compared to Listing 1, we only require a subset of the homogeneous aspects (the maximal power). However no restriction in terms of rates of change and other, inertia-based constraints are imposed as they are part of the individual agent models.

B. Individual Agent Models

We describe three types of power plant models consisting of the constraints presented in Sect. III. These are implemented independently from the organisational template but also contain definitions for the interface variables to be tested in advance. The first type, **A**, does not implement a warm and cold start-up and does not foresee minimal up and down times. Thus, it corresponds to a power plant that can be started up fast enough for the considered time step durations [19]:

```
float P_min = 50.0; float P_max = 100.0;

float rateOfChange = 0.15;
dvar float production[TIMERANGE];
dexpr int running[t in TIMERANGE] = !(production[t] == 0);

subject to {
  forall (t in 0..TIMERANGE) {
    running[t] => production[t] >= P_min;
    rate_of_change: (running[t] == 1) && (running[t+1] == 1)
     => abs(production[t] - production[t+1])
          <= production[t] * rateOfChange;
    c1: (running[t] == 1) && (running[t+1] == 1)
     => abs(production[t] - production[t+1])
          <= production[t] * 0.07;
    c2: (running[t] == 1) && (running[t+1] == 1)
     => abs(production[t] - production[t+1])
          <= production[t] * 0.10;
  }
};
/* SOFT-CONSTRAINTS
 c1 >> c2 */
```

During synthesis, the system automatically distinguishes between *P_max* being an interface variable and *P_min* being a local variable. Some power generators such as hydro power plants could be throttled down to no production at all, whereas others can enforce a minimal operation production as modelled in this example. The decision expression *running* helps syntactically to distinguish between these states. Note that here, *production* is not indexed over any agent set, so an individual agent model only has access to its own decision variables. We furthermore have two constraints reflecting a preference for small rates of change which aim for operational stability.

The second type, **B**, is used to express minimal uptimes [15]. We need additional decision variables to capture the number of time steps a plant is running consecutively at a particular time step. Based on these, we can decide whether a transition from on to off is feasible. And for the sake of the argument, assume that no relative rate of change but rather a fixed rate of change at every production level is given (we omit variables already discussed). We also assume three ranges of different economical preference that can be expressed with soft constraints:

```
int minUpTime = 2;
float fixedChange = 20;

dvar int+ consRunning[TIMERANGE];
 [...]
forall (t in TIMERANGE) {
  c1: production[t] >= 22 && production[t] <= 25;
  c2: production[t] >= 20 && production[t] <= 30;
  c3: production[t] >= 18 && production[t] <= 33;

  fixed_change: (running[t] == 1 && running[t+1] == 1) =>
    abs(production[t] - production[t+1]) <= fixedChange;
  cons_run: (running[t+1] == 1 &&
              consRunning[t+1] == (1 + consRunning[t])) ||
            (running[t+1] == 0 &&
              consRunning[t+1] == 0);

  min_up_time: (running[t] == 1 && running[t+1] == 0) =>
                (consRunning[t] - minUpTime) >= 0;
}
/* SOFT-CONSTRAINTS
 c1 >> c2
 c2 >> c3 */
```

Note that it becomes apparent that a parametrised model would now be severely limited. To support minimal up times within a MIP framework, we need those variables (or implement custom constraints and propagators for a constraint solver) but would have to offer these variables for *all* plants.

Finally, our third type, **C**, incorporates hot and cold start-up times based on the down time (with down time being defined analogously to up time in the previous model). In essence, we provide a MIP formulation for the transition system presented in Fig. 2 implementing start-up times that respect the data shown in Table I. We use a stepwise function that returns 2 time steps duration for down times of less than 3 and 4 time steps for longer down times. A decision variable *signal* stores when to initiate a start-up process and we need to enforce that those signals are only sent when a plant is in the appropriate state (e.g., sending a start-up signal only when in the *idle* state). Additionally, we also have three soft constraints (c1, c2, c3) regarding economical ranges and rates of change.

```
int IDLE = 0;
int STARTING = 1;
```

```
int STOPPING = 2;
int UP = 3;
stepFunction startUp = stepwise{ 2->3; 4 };

dvar int+ countdown[TIMERANGE];
dvar int+ powerPlantState[TIMERANGE] in 0..3;
dvar int+ consStopping[TIMERANGE];
dvar int+ consRunning[TIMERANGE];
dvar int+ state[TIMERANGE] in 0..3;
dvar int signal[TIMERANGE] in -1 .. 1;
 [...]
forall (t in TIMERANGE) {
 c1: production[t] >= 300.0 && production[t] <= 350.0;
 c2: production[t] >= 280.0 && production[t] <= 370.0;
 c3: abs(production[t] - production[t+1]) <= 20;

  signal_states : signal[t] == 1 => state[t] == IDLE &&
                  signal[t] == -1 => state[t] == UP;
 state[t] == IDLE =>
        ( state[t+1] == IDLE ||
        ( state[t+1] == STARTING &&
          signal[t] == 1 &&
         (countdown[t+1] == startUp(consStopping[t ]))));

 ( state[t] == STARTING && countdown[t] >= 1) =>
        ( state[t+1] == STARTING &&
          countdown[t+1] == countdown[t] - 1);
 ( state[t] == STARTING && countdown[t] == 0) =>
          state[t+1] == UP;
 state[t] == UP => (state[t+1] == UP ||
       ( state[t+1] == IDLE && signal[t] == -1));

}
/* SOFT-CONSTRAINTS
 c1 >> c2
 c1 >> c3 */
```

This model is significantly more detailed than the previous ones and indicates how future realistic models could be integrated to achieve more accurate schedules.

C. Synthesised Model

Combining these three individual agent models with the organisational template results in one CPLEX model where constraints, local variables and interface variables are replaced as described earlier. In contrast to the formal definition (where x would just be replaced by x^a), we can however distinguish interface from local variables in the synthesised model. This is due to the fact that it can come in handy to have interface variables indexed by plant identifiers (e.g., for defining the expression `totalProduction`). As we cannot assume local variables to be available for every individual agent, we add the plant identifier to the variable name, such `rateOfChange` would become `rateOfChange_a` for a plant `a`. The individual constraint relationship graphs are combined with the organisational template yielding a synthesised graph as depicted in Fig. 4. We give some snippets that show parts of the synthesised model.

```
{string} plants = {"b", "c", "a"};
float P_max[plants] = [35.0, 400.0, 100.0];
dexpr float totalProduction[t in TIMERANGE] =
  sum( p in plants ) production[p][t];
 [...]
```

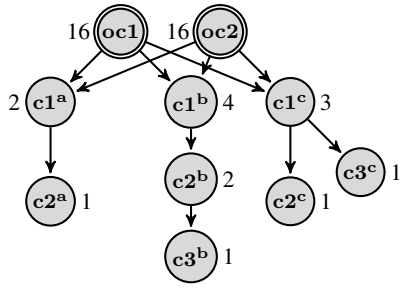

Fig. 4. Synthesised Constraint Relationship Graph with weights presented for TPD

```
float rateOfChange_a = 0.15;
float fixedChange_b = 5;
dvar int+ consStopping_b[TIMERANGE];
 [...]
subject to {
  forall (t in TIMERANGE) {
   c1_b: production["b"][t] >= 22 && production["b"][t] <= 25;
  }
   [...]
};
/* SOFT-CONSTRAINTS
oc1
oc2
oc1 >> c1_b;
oc1 >> c1_a;
oc2 >> c1_a; */
```

The last step to acquire a solvable model is then to transform the constraint relationships into weights and add decision variables and expressions to incorporate these weights as penalties to come to a scalar objective function. Essentially, all soft constraints are collected and used to index a vector of penalties and a reformulation is performed for each soft constraint $c \in \mathcal{C}_s$:

$$c' : (c \wedge p_c = 0) \vee (\neg c \wedge p_c = w(c))$$

which leads to the following changes in OPL:

```
{string} softConstraints = {"c1_b", "c1_c" ,[...]};
dvar int+ penalties[softConstraints][TIMERANGE];
dexpr float penaltySum = sum(t in TIMERANGE,
                             c in softConstraints) penalties[c][t];
 [...]
c1_b: (production["b"][t] >= 22 && production["b"][t] <= 25
       && penalties["c1_b"][t] == 0) ||
      (!( production["b"][t] >= 22 && production["b"][t] <= 25)
       && penalties["c1_b"][t] == 4);
```

We then have `penaltySum` as the expression to minimize the violation of soft constraints.

VI. Evaluation

Evaluating our approach at this stage is not straightforward as to the authors' knowledge, no public benchmark library containing unit commitment models is available. In addition, the described synthesis is primarily a methodology to incorporate heterogeneous models, not a concrete algorithm, thus performance issues are not yet in the focus of development. To

still get a quantitative (and as objective as possible) evaluation about how well individual preferences can be considered, we performed synthetic randomised experiments based on the constraints presented in the paper and power plant data[3].

The source code of both the experiments and the example discussed in Sect. V are available online[4] to facilitate replication of our experiments.

A. Experimental Design

We first generate a pool of 400 power plant models based on the types presented in Sect. V taking into account existing data of gas turbines and biomass power plants to capture plant-specific properties. We then perform a number of optimisation runs by picking a set out of these power plants randomly, synthesising them into one model and running the three-stage-optimisation with the *synthesised model*. The following parameters characterise one experiment:

- n the number of power plants
- δ_v the delta applied to the first optimum in the three-stage-optimisation as a tolerance
- δ_p the delta applied to the penalty in the third step
- d the dominance level SPD or TPD
- r the number of runs that are conducted

Several measurements are taken to evaluate properties of the synthesis and averaged over the r runs:

- v_1 – v_3 the violation (discrepancy between demand and production) for the three optimisation steps
- p_1 – p_3 the same holds for the aggregated penalties
- $\overrightarrow{v}$, $\overrightarrow{q}$ measures the relative improvement or worsening of v_1 to v_3 and p_1 to p_3 to show how the objectives change when considering penalties: $\overrightarrow{v} = \frac{v_1}{v_3}$, $\overrightarrow{p} = \frac{p_1}{p_3}$
- **#pred** is the average number of predecessors per violated constraint as a measure for how more important constraints are treated
- **#vc** sums up the total number of violated soft constraints relative to the number of all soft constraints (with $\overrightarrow{\#\text{vc}}$ denoting the relative improvement from the first optimisation step to the third)

Note that #pred and #vc are evaluated for the final result returned by the three-stage-optimisation. Some runs failed to provide a correct solution within a threshold of 3 minutes. We excluded those results from the evaluation as our focus is not yet on performance and robustness issues.

B. Experimental Results

We examine questions of interest and present the results of the experiment runs.

a) Solution quality: How does taking into account individual preferences affect the solution quality? We want to obtain an impression about how the choice of the parameters δ_v and δ_p affect the solution quality. For all choices of parameters, we found that allowing a small tolerance regarding the mismatch of demand and production allowed for comparable, substantial improvements in the satisfaction of soft constraints as Table II shows. If a violation tolerance of 10% was imposed, the solver still managed to reduce the number of violated soft constraints by half from the optimal solution to the final one while staying within a range of 1 % optimality. As expected, increasing the violation tolerance leads to better reductions in terms of penalties and soft constraints.

TABLE II
COMPARISON OF DIFFERENT DELTAS REGARDING THE SOLUTION QUALITY. MEASUREMENTS REPRESENT AVERAGES OVER 50 RUNS FOR 9 TIME STEPS WITH $n = 5, d = \text{SPD}$ AND STANDARD DEVIATIONS.

(δ_v/δ_p)	1.1/1.2	1.2/1.2	1.2/1.1	1.3/1.2
$\overrightarrow{v}$	1.0039	1.0161	1.056	1.022
	(0.0076)	(0.0286)	(0.044)	(0.034)
$\overrightarrow{p}$	0.599	0.546	0.534	0.527
	(0.116)	(0.142)	(0.142)	(0.148)
$\overrightarrow{\#\text{vc}}$	**0.555**	**0.502**	**0.486**	**0.487**
	(0.132)	(0.152)	(0.181)	(0.163)

TABLE III
COMPARISON OF DIFFERENT DOMINANCE LEVELS. MEASUREMENTS REPRESENT AVERAGES OVER 50 RUNS FOR 9 TIME STEPS WITH $\delta_v = \delta_p = 20\%$ AND STANDARD DEVIATIONS.

(n/d)	5/SPD	5/TPD	10/SPD	10/TPD
$\overrightarrow{v}$	1.022	1.0001	1.027	1.0
	(0.027)	(0.0009)	(0.038)	(0.0005)
$\overrightarrow{p}$	0.595	0.7484	0.45	0.774
	(0.169)	(0.15)	(0.085)	(0.168)
#pred	**2.905**	**2.541**	**3.23**	**2.76**
	(0.406)	(0.2569)	(0.41)	(0.281)
#vc	**0.34**	**0.468**	**0.283**	**0.462**
	(0.12)	(0.138)	(0.064)	(0.123)

b) Influence of dominance property: How does the selected dominance property affect the number of violated soft constraints? The dominance property influences how much more important a single constraint is with respect to its dominated constraints. In the case of single predecessor dominance, a constraint is only more important than one of its predecessors, not a whole set. Therefore the weights lie more closely to each other and no strong "hierarchical" difference is imposed. Choosing the property, however, is not straightforward as this substantially influences the number of soft constraints that are "dropped" by a solver in favour of more important ones. We observe this behaviour in Table III: The percentage of violated soft constraints is significantly higher when using TPD than SPD for both 5 and 10 power plants while the average number of predecessors per violated constraint (measuring its importance) is lower when using TPD. TPD semantics lead to an average dissatisfaction of about 40% of all soft constraints, whereas SPD only dissatisfies 30% albeit returning slightly worse solutions (about 2% higher demand violations when 20% higher were allowed). It is thus a relevant question for preference elicitation and requirements engineering to find out whether the system's constraints are more hierarchical or egalitarian. Constraint hierarchies correspond to TPD semantics [9] and we argue

[3]see http://www.energymap.info/ and http://www.lew-verteilnetz.de/
[4]https://github.com/Alexander-Schiendorfer/synthesisenergycoalitions

that there are certainly circumstances where having more soft constraints fulfilled is more desirable than just satisfying the most important ones and no others.

VII. Conclusion and Outlook

Although there is a vast body of literature on efficient models and algorithms for unit commitment problems (see, e.g., [20], [14], [19], [15] for a modest selection), to the best of our knowledge there is no approach that consolidates these various types of models and addresses the domain's inherent heterogeneity. We proposed an approach that attempts to leverage existing models and to simplify the engineering of optimisation problems with a well-defined modelling methodology. In addition, we showed how start-up behaviour of thermal power generators presented in [16] or [19] can be extended to account for start-up times that depend on the previous down time using transition systems. We showed a MIP formulation for this adaptive start-up problem and used heterogeneous models employing different start-up behaviour as the case study for our approach. Moreover, the modelling and synthesis strategy presented allows unit operators to express individual preferences that could not be considered before. Our first experiments indicate that this may increase the willingness of single power generators to collaborate in collective schemes where autonomy is sacrificed for potential economic benefits as we could halve the number of violated soft constraints. As the process is fully automated, we plan to combine it with models of the resource-levelling problem faced in the scheduling of (short-lived) coalitions of energy consumers to achieve better prices.

***Abstract*— Smart Grid is an integrated power grid with a. reliable, communication network running in parallel towards providing two way communications in the grid. It's trivial to mention that a network like this would connect a huge number of IP-enabled devices. IPv6 that offers 18-bit address space becomes an obvious choice in this context. In a smart grid, functionalities like neighborhood discovery, autonomic address configuration of a node or its router identification may often be invoked whenever newer equipments are introduced for capacity enhancement at some level of hierarchy. In IPv6, these basic functionalities like neighborhood discovery, autonomic address configuration of networking require to use Internet Control Message Protocol version 6 (ICMPv6). Such usage may lead to security breaches in the grid as a result of possible abuses of ICMPv6 protocol. In this paper, some potential newer attacks on Smart Grid have been discussed. Subsequently, intrusion prevention mechanisms for these attacks are proposed to plug-in the threats.**

I. Introduction

A SMART grid is an intelligent energy network that integrates the actions of all users connected to it and makes use of advanced information, control, and communication technologies to save energy, reduce cost and increase reliability and transparency [1].

The backbone of the Smart Grid will be its communication network. This network is to connect the different components of the Smart Grid together, and provide two-way communication. IPv6 is a new technology which gained a massive attention, as a supporting layer in smart grid communication. The huge address space of IPv6 supports the network architecture of the smart grid communications. Besides, features like stateless address auto configuration (SLAAC) and IPSec support makes IPv6 more suitable for smart grid. IPv6 also supports prioritization of messages and different Quality of Service models, which complements several smart grid applications [8]. However, with these new advancements in technology, IPv6 is also exposed to various attacks, such as header modification attack, fragmentation attacks , etc. [5], [6]. In this paper, we focus on some of the possible ICMPv6 attacks that are particularly relevant in the context of building networking infrastructure between Smart Meters (SM), Data Collection Units (DCU) and Meter Data Management System (MDMS). We would demonstrate how these could affect the Smart Grid before proposing appropriate Intrusion Prevention Systems (IPS) to protect the grid from such attacks.

IPv4 networks often filter ICMP messages to avoid security concerns. However, for IPv6, this is not possible. ICMPv6 is used for basic functionalities and used by other IPv6 protocols like Neighbor Detection Protocol (NDP). Neighbor Discovery Protocol (NDP) is a protocol used with IPv6 to perform various tasks like router discovery, auto address configuration of a node, neighbor discovery, Duplicate Address Detection, determining the Link Layer addresses of other nodes, address prefix discovery, and maintaining routing information about the paths to other active neighbor nodes [4]. Thus, the implementation of IPv6 in Smart Grid needs some serious care to protect from the security vulnerabilities of the ICMPv6 protocol. NDP uses five ICMPv6 messages. These are:

- Router Solicitation (RS) message: Hosts send RS message to enquire about a legitimate router on the link.
- Router Advertisement (RA) message: Routers send RA message, either periodically or in response to RS message.
- Neighbor Solicitation (NS) message: Hosts send NS message to determine the link layer address of a specific node, and also to verify whether an address is already present on link or not.
- Neighbor Advertisement (NA) message: Hosts send NA message in response to the NS message.
- Router Redirect (RR) message: Routers send RR message to inform a host about a better router on its link.

With higher degree of autonomic control and decision making, a smart grid also becomes subject to several security concerns. Smart grid is generally considered as a heterogeneous, backward compatible, static, self adapting and self healing network, with a large number of devices, where two way communications is provided between Smart Meters and a Supervisory Control and Data Acquisition (SCADA) system. This requires special QoSs, like high restriction on delay, failure and voltage quality [3]. In smart

978-83-60810-58-3/$25.00

grid, availability and integrity are typically considered more important than confidentiality [9]. Also the risk factor is quite high in smart grid as compared to traditional networks. Thus, the existing solutions for cyber security often fall short of the typical requirements for a smart grid.

Some work has been done to secure smart meters and communication network of Smart Grid or SCADA systems [10]. An IPv6 based moving target defense system is provided in [11] to secure the communication between hosts. Most of the network attacks target some specific addresses, so, moving the target address will prevent hosts from being located for an attack. [12], [13], [14] explains different techniques for IPv6 address configuration schemes for smart grid. However, security solutions for specific IPv6 problems, like ICMPv6 attacks, for Smart Grid environment are still need to be addressed. In [16], a distributive, trust based approach to detect attacks in Duplicate Address Detection (DAD) phase was proposed. However, this concentrates only on one type of attack in DAD. In [17], the requirements and practical needs for monitoring and intrusion detection in AMI is discussed. In [18], a layered combined signature and anomaly-based IDS for HAN was proposed. This IDS was designed for a ZigBee based HAN which works at the physical and medium access control (MAC) layers. However, the work only considers the HAN part of AMI. In [19], a specification-based IDS for AMI is proposed. While the solution in [19] relies on protocol specifications, security requirements and security policies to detect security violations, it would be expensive to deploy such IDS since it uses a separate sensor network to monitor the AMI.

We have proposed a new Intrusion Prevention System for providing security against ICMPv6 attacks in smart grid networks. The structure of the paper is as follows. First, we discuss three important functionalities for a Smart Meter: Router Discovery, Duplicate Address Detection and Neighbor Discovery, using NDP and various ICMPv6 messages. Possible attacks and the effects of those attacks on smart grid are analyzed for each function. Finally, we propose an Intrusion Prevention System (IPS) to prevent the attacks in the Router Discovery phase and detect the attacks in the Duplicate Address Detection and Neighbor Discovery phase.

Notice that we do not claim that using NDP or ICMPv6 is the only option for realizing functionalities like router discovery or address configuration in a smart grid. As for example, instead of having an auto configurable addressing scheme, smart grids may also have independent Certifying Authority (CA) for providing addresses to newly installed SMs. However, the cost of installation and maintenance of such centrally controlled architecture may be avoided using auto configurable SMs. This paper aims to expose the security threats there and to propose suitable intrusion prevention mechanisms to safeguard smart grids from ICMPv6 misuses.

II. Smart Grid And ICMPv6 Abuses

Figure 1 shows the communication architecture of Smart Grid. Smart Energy Utility Network (SUN) hierarchically consists of three components: Home Area Network (HAN), Neighborhood Area Network (NAN), and Wide Area Network (WAN) [15]. The HAN provides the communication between the Smart Meters in a home and other appliances in that home. The NAN connects SMs to the Data Collection Units (DCUs), and WAN provides access between the DCUs and Meter Data Management System (MDMS). DCU collects data from hundreds of SMs and sends them to the MDMS. At the lowest level, the smart meters act as hosts in a network and DCUs are the routers of the network. We assume that

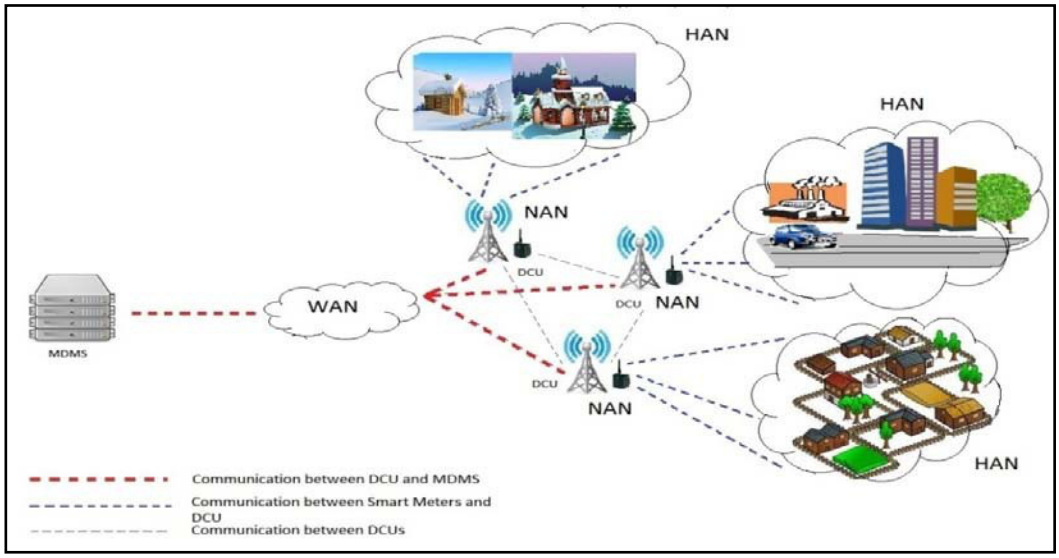

Fig. 1: Communication Architecture of Smart Grid

- Smart Meters are managed by DCUs. When a SM X is installed in a subnet, it should find a DCU, say R, to bind with. X will continue to communicate through DCU R,

until it receives any ICMPv6 Router Redirect (RR) message from R.

- Each DCU keeps a neighbor cache, storing the addresses of all DCUs in its neighborhood.
- Each subnet has a different and unique 64 bit prefix address for addressing SMs within the subnet.
- Each DCU communicates with the SMs within its subnet, and then transmits the aggregated data to DCU.
- Every SM keeps a neighbor cache to store addresses of all its one hop neighbors

A. Router Discovery

When a SM X is installed in a subnet, it should find a DCU to bind with. The Smart Meter X will continue to communicate through that DCU, until it receives any ICMPv6 Router Redirect (RR) message from the previous DCU.

Normal Procedure for Router Discovery

Normally Smart Meters discover their router or DCU through the following steps,

- First, X sends an ICMPv6 Router Solicitation (RS) message to locate a DCU in its local link.
- A legitimate DCU then responds with an ICMPv6 Router Advertisement (RA) message, with a 64 bit prefix address for its subnet.
- Then X registers that DCU as its default router in the link, and auto-configures a global unicast address based on the received prefix.

Attacks in Router Discovery phase

The most prominent attack in this phase occurs if an attacker falsely claims to be a DCU. It can spoof an RA message from a legitimate DCU and send it to the Smart Meter, with or without altering the prefix address for that subnet. In either case, the newly installed Smart Meter registers the attacker as its DCU. If the adversary alters the prefix address, then the Smart Meter will auto-configure its global address based on a wrong prefix. As a result, the Smart Meter will get blocked in the subnet and will not be able to communicate with any other Smart Meter or DCU except the attacker. The situation becomes a bit more complex when the adversary sends the RA message without changing the prefix. In this situation, the Smart Meter can communicate within its subnet. However, it becomes quite impossible for the Smart Meter to communicate beyond its subnet as the registered DCU for the Smart Meter is an attacker who is not recognized by other Smart Meters in the Neighborhood Area Network.

Once an adversary successfully convinces a newly installed Smart Meter of being its valid DCU, it can launch a myriad of conventional network attacks on the Smart Grid. It can launch a man-in-the-middle attack by intercepting packets from the Smart Meters or from the DCUs and suitable changing the Source and Destination address fields such that neither of these two entities are aware of the presence of an attacker in between. The attacker can also tweak the data contained in the intercepted packets. Another traditional network attack is the Denial-of-Service attack. The attacker can overload the network resources by generating spurious packets having the newly installed Smart Meter address as the Source Address.

B. Duplicate Address Detection

After auto configuring the address for itself, the Smart Meter X will want to know whether the address is available for use.

Normal Procedure for Duplicate Address Detection

The following steps are used for duplicated address detection.

- Smart Meter X, sends an ICMPv6 Neighbor Solicitation message for the address it wants to claim.
- If any Smart Meter on that subnet already has that address, then it sends an ICMPv6 Neighbor Advertisement message.
- If X does not receive any NA messages stating that the address has been taken, then X is able to use that address.

Attacks in Duplicate Address Detection phase

An intruder can prevent a Smart Meter from acquiring any auto-configured address, by sending an NA for the corresponding address in every NS message sent out by the Smart Meter. As a result, the Smart Meter will not be able to communicate within the network. Besides, an intruder can block a NA message from an authentic SM. This results in two or more SMs using the same address within a network. As a result of this attack, a legitimate SM can be accused of identity spoofing. Also, more than one assignment of the same address within a network can cause improper functioning during the routing phase.

In order to detect these kinds of attacks, we propose a modified version of the Duplicate Address Detection phase,

- SM X sends an ICMPv6 NS message for the address it wants to acquire.
- On receiving the NS message, every Smart Meter scans its neighbor cache information for that address. If they find the address in their cache, then they send a reply to the X.
- If any Smart Meter on that subnet already has that address, then it sends an ICMPv6 NA message.
- If the X receives neither any NA messages stating that the address has been taken nor receives any messages from its neighbors stating that the address is present in their cache, then X is able to use that address.

If X receives only the NA message from another Smart Meter but no neighborhood information about that address is received, it implies that such an address is not in existence within the subnet and some attacker is trying to prevent X from acquiring that address. If X does not receive any NA message, but its neighbors reply with their cache information stating that the address is present in their neighborhood, then the X concludes that an attacker has intercepted the NA message from the target Smart Meter and has dropped it.

Thus, X is able to use an address only when it neither receives the NA nor any neighborhood cache information from its neighbors.

If the attacker is intelligent enough, it can send both the NA message and also spoof some reply messages from other Smart Meters and change their contents. In that case, SM X will not be able to detect the attack. So, to detect this kind of attack, if a Smart Meter exists with the same address, it not only replies with an NA message but also sends its neighborhood information to X. SM X then sends unicast queries to each of the neighbors found in the reply message to verify the existence of such a Smart Meter. In this way, X can be assured whether he is being duped or whether the particular address is really being used within the subnet. However, since the reply message can also be intercepted by the attacker, it must be broadcast within the network. This will assure the delivery of the reply message to X.

C. Neighbor Discovery

Once the Smart Meter acquires a unique global address, then it can start communication through the DCU. It can also communicate with the other Smart Meters, both in its subnet and in other subnets. Smart Meters on the same subnet can communicate directly with each other without using any router or gateway when a SM has link layer addresses of other neighboring SMs. Thus it is important to store the link layer addresses of the neighboring SMs in the local cache of every SM. Neighbor Discovery facilitates the same.

Normal Procedure for Neighbor Discovery

In order to communicate with a SM B on its own subnet, a Smart Meter A has to perform the following steps,

- First, the SM A sends an ICMPv6 NS message requesting the link-layer address of B.
- If B is present in that subnet, then it replies with an ICMPv6 NA message. SM A knows the MAC address of B from this NA message.
- SM A then creates a neighbor cache entry for B that binds the MAC address of B to its IPv6 address.

Attacks in Neighbor Discovery phase

The attacks of this phase are similar to the attacks of the Duplicate Address Detection phase. Here also an intruder can try to impersonate B, and intercept all packets that are destined to B, or an intruder can block a NA reply from B so that A thinks that B is not present in the network.

III. Proposed IPS to Handle ICMPv6 Threats in Smart Grid

In section 2, we have seen three possible security breaches in Smart Grid for Router Discovery, Duplicate Address Detection and for Neighbor Discovery in sub-sections II.A, II.B and in II.C respectively. The Intrusion Prevention Systems (IPS) against each of these three attacks due to ICMPv6 vulnerabilities have been proposed in the following sub-sections.

A. Intrusion Prevention Mechanism in Router Discovery and Updation phase

In order to prevent these possible security threats, we propose a modified Router Discovery phase as follows,

- First, SM X sends an ICMPv6 RS message to locate a DCU in its local link.
- X receives an ICMPv6 RA message with a 64 bit prefix address for its subnet.
- On receiving the RA message, X extracts the DCU's address from the packet.
- X then broadcasts an ICMPv6 Echo Request message on its subnet.
- Receivers of the ICMPv6 Echo Request message will communicate with their DCU. If a new valid DCU is installed in the subnet, then the other DCUs will have information about the new DCU. If receivers of ICMPv6 Echo Request message receive Router Redirect message (RR) from their current DCU, then they reply with an ICMPv6 Echo Reply message with the address of the new DCU.
- Otherwise, Echo Reply message contains the address of the existing DCUs.
- If the DCU address in the RA message received by SM X matches with a majority of the neighbors' default routers address, then SM X concludes that the DCU is authentic. Consequently, X installs this DCU as its default router in the link, and auto-configures a global unicast address based on the received subnet prefix.
- If the received DCU's address does not match with the address of the default router of the majority of the neighbors, say C, then X concludes that it has been attacked by some adversary and C is the original DCU of that subnet.
- Subsequently, X installs C as its default router in the subnet and auto-configures a global unicast address based on the prefix of C.
- If X does not receive any Echo Reply message within a certain time, then it concludes that it has been blocked by some attacker and sends an SMS alert to the registered mobile number.

Router Updation Phase

DCUs in the Smart Grid network periodically broadcast RA messages to advertise themselves on the subnet. If a Smart Meter receives a RA from a DCU, then they change their existing DCU and register the new DCU as a router in its routing information table.

In this situation an attacker may spoof a RA message and send it to some Smart Meters. On receiving a RA message, Smart Meters then register the attacker as a router. In order to detect this kind of attacks we propose an intrusion prevention mechanism as follows,

- DCUs periodically broadcast RA message.
- On receiving a RA message with new DCU information, every Smart Meter sends a RS message to its existing DCU.

- The existing DCU, on receiving a RS message, checks whether a new DCU with higher priority is available for the subnet.
- If such a DCU exists, it sends a RR message to the SMs with the information of the new DCU. Otherwise, it advertises itself again with a RA message.
- A SM resets its DCU information if and only if it receives a RR message and the DCU information contained within the RR message matches with the previously received RA message. Otherwise, it discards the RA message.

Figure 2 shows a high level view of intrusion detection in Router Discovery and Updation phase, when an attacker spoofs a RA message from DCU and sends it to a Smart Meter X without changing the 64 bit prefix address. In the first half of the figure, an attacker spoofs a RA message and sends it to the newly installed Smart Meter X. In the second half of the figure, an attacker broadcasts a RA message to all the working Smart Meters.

The proposed IPS apparently comes with a boot-strapping limitation. It will not work properly when a new Smart Meter is installed under a new subnet. If Smart Meter X is the first meter in the subnet, then it can't consult with its neighbors to authenticate a legitimate DCU. However, in practice when a new DCU, say K, is to be introduced in a layer just on top of the SMs, some of the SMs under a neighboring DCU will be allocated under K by using RR messages from the current DCU of the respective SMs. The

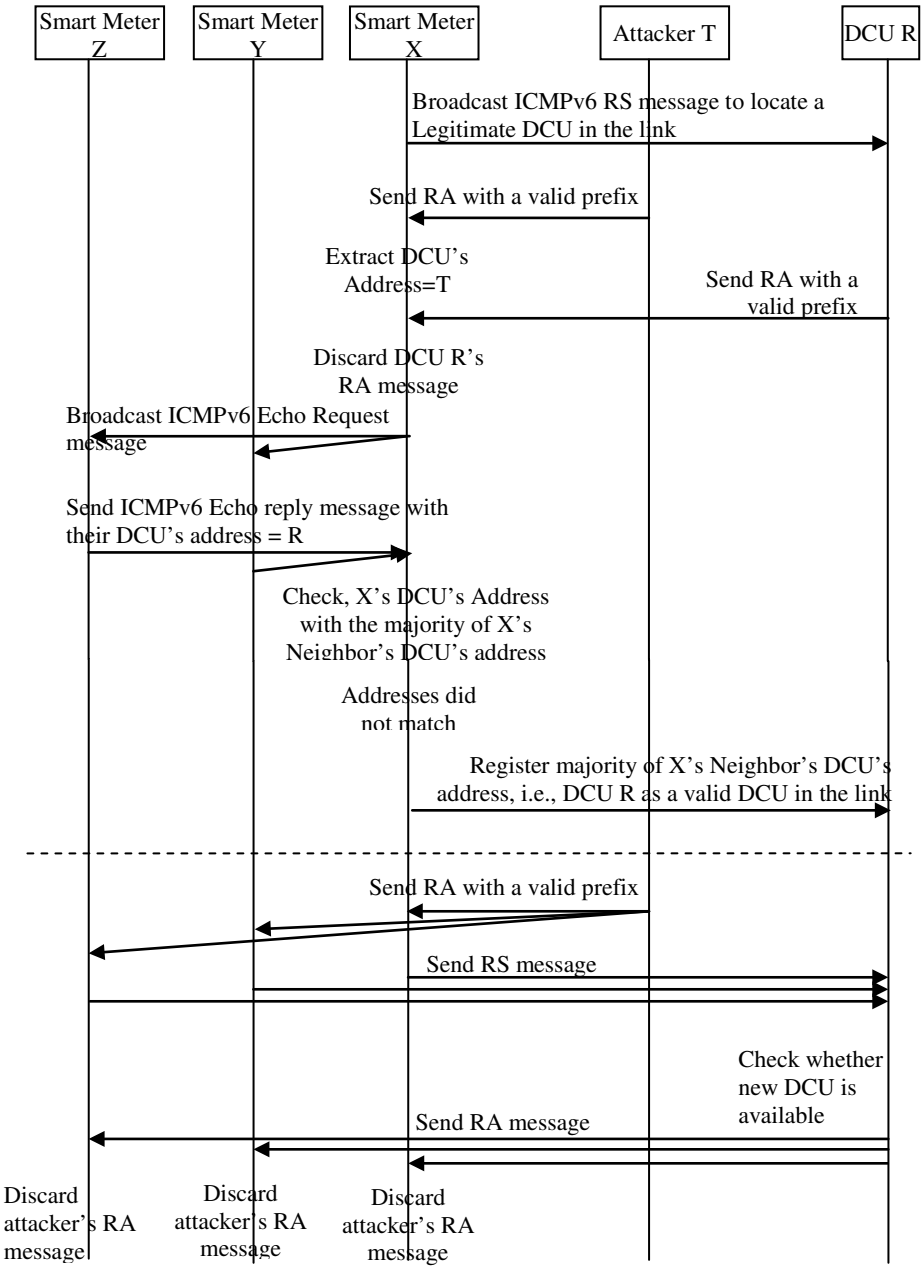

Fig. 2: High level view of Intrusion Prevention in Router Discovery and Updation phase

same is applicable for the entire Smart Grid when a new DCU is to be introduced at any higher level. Thus, the bootstrapping problem as mentioned above will not be an actual bottleneck in the context of smart grid.

B. Intrusion Prevention Mechanism in Duplicate Address Detection

In order to secure Duplicate Address Detection, the following steps are performed,

- SM X sends an ICMPv6 NS message for the address it wants to acquire, say Z.
- If Z already exists in the same subnet, then it broadcasts an ICMPv6 NA message along with the address of all neighbors in its neighbor cache.
- If Z exists, then its one-hop neighbors have Z in their neighborhood cache. These neighbors, on receiving the NS message, reply with a confirmation message.
- X builds the neighbor list of Z from the unicast confirmation messages received from Z's neighbors and verifies it with the neighborhood data sent by the node Z itself.
- If majority of the neighbors confirm the existence of Z, then X concludes that it cannot use Z. Otherwise, X sends unicast queries to those neighbors of Z from which it did not receive any confirmation message.
- Each neighbor N broadcasts Hello message to update its Neighbors. If N finds Z as a neighbor, then it sends a reply confirming existence of Z or remains silent.
- SM X continues sending these queries until either it has a majority decision or all neighbors of Z have been exhaustively queried.
- If X receives both NA message from Z and majority confirmation messages from Z's one-hop neighbors, then it repeats the process with some other auto configured address P. Otherwise, X can use the address Z.

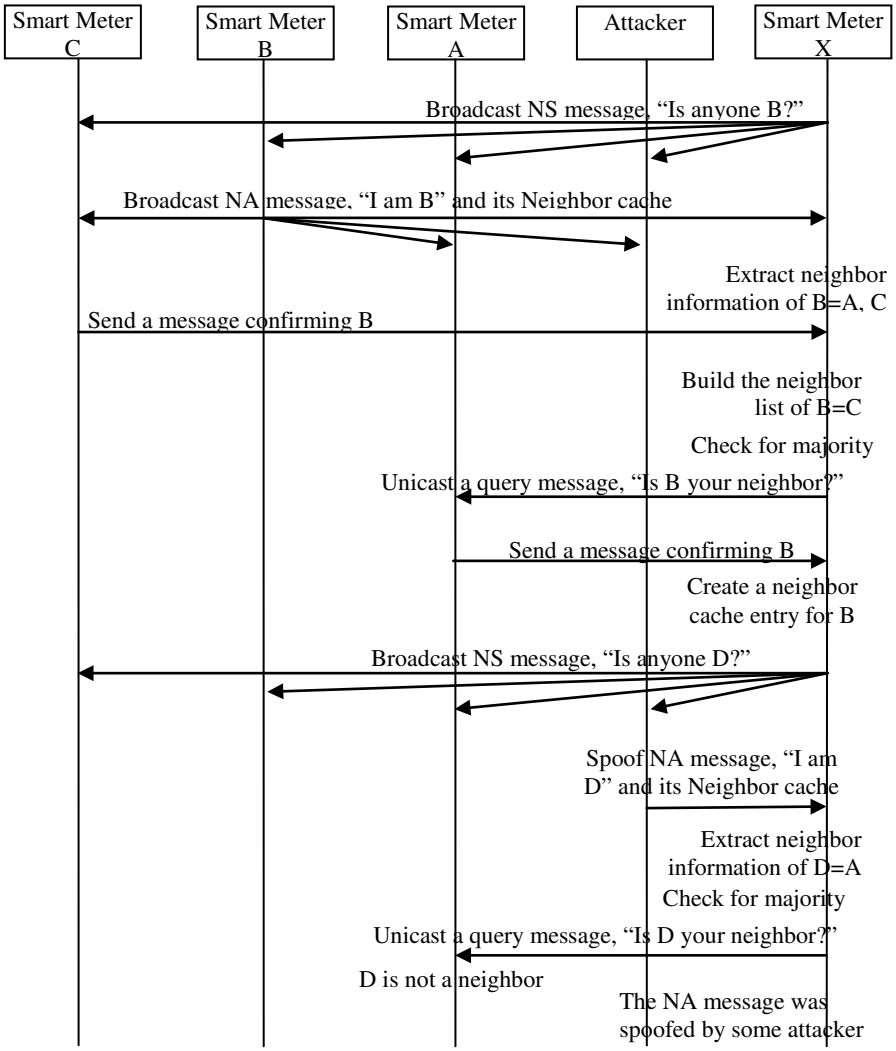

Fig. 3: High level view of Intrusion Prevention in Duplicate Address Detection phase

Figure 3 shows a high level view of intrusion detection in Duplicate Address Detection phase, when X wants to acquire address B. However, in this case, B is already present in the subnet. X verifies the presence of another SM in the subnet, with same address, i.e. B, with the help of B's neighbor list: C, A. Consequently, A wants to acquire

address D. This time an attacker falsely claims himself to be D. X successfully detects this attack.

C. Intrusion Prevention in Neighbor Discovery phase

The detection procedure is quite similar to the Duplicate Address Detection phase as discussed to section III.B. At first, SM X sends an ICMPv6 NS message requesting the link-layer address of Z. On receiving the NS message, every Smart Meter scans its neighbor cache information for that address. If they find the address of Z in their cache, then they send the address of all neighbors of its neighbor cache to X. If node Z is present in that subnet, then it replies with an ICMPv6 NA message and sends the addresses of all neighbors of its neighbor cache. From that NA message, SM X knows the MAC address of Z.

Subsequently, SM X sends unicast queries to each of the neighbors found in the reply message to verify the existence of Z. Every neighbor will broadcast their replies. If X receives a NA messages from Z and majority of reply messages from the neighbors assuring the existence of Z, then SM X creates a neighbor cache entry for Z that binds the MAC address of Z to its IPv6 address. Figure 4 shows a high level view of intrusion detection that may occur during the Neighbor Discovery phase. Here, DCU X wants to communicate with SM Z, but attacker node tries to impersonate Z.

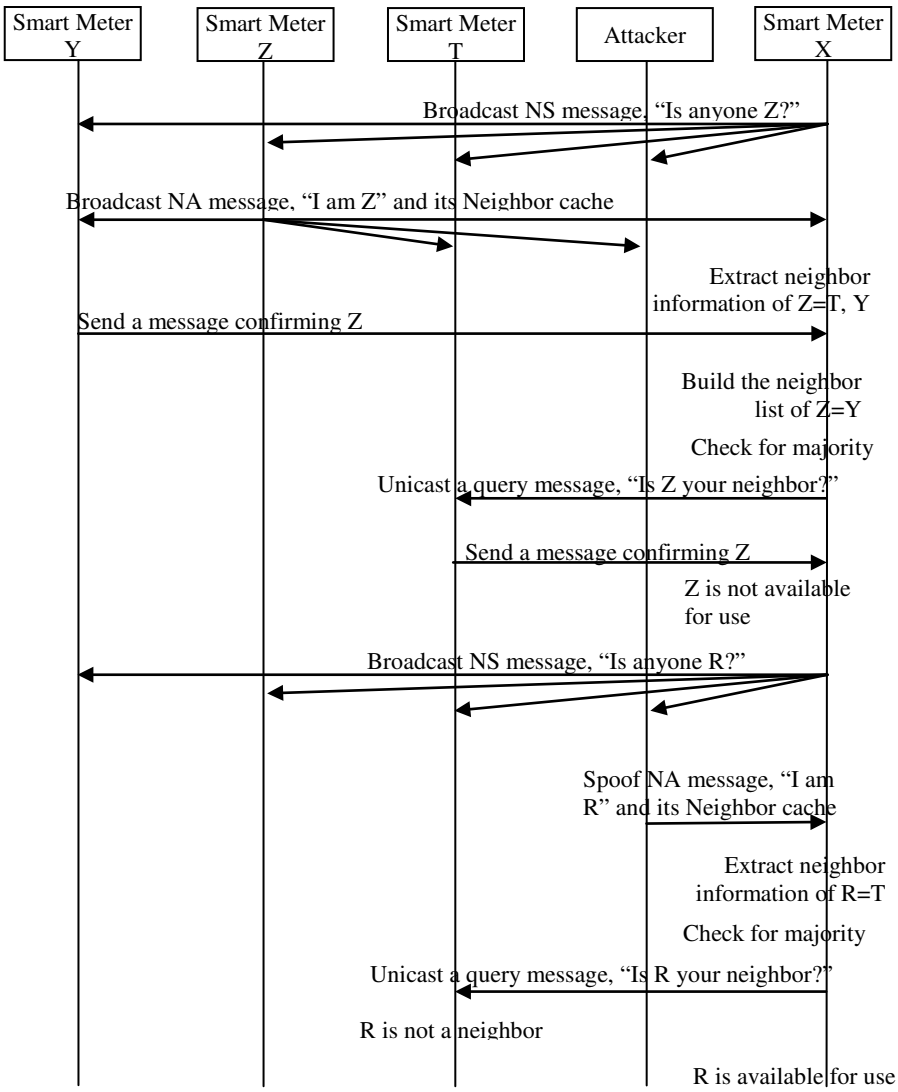

Fig. 4: High level view of Intrusion Detection in Neighbor Discovery phase

IV. Simulation Results

In order to access the performance of ICMPv6 in absence of the proposed IPS and in its presence, we have simulated an environment using Qualnet simulator software. In order to evaluate the performance of the proposed approach, two of the most important performance metrics have been considered. These are false negatives and jitter. *False negative* is measured with respect to both node density and fake router density. Jitter is compared for ICMPv6, with and without our proposed algorithm. The simulation scenario and settings are described in Table I below.

TABLE I.
SIMULATOR PARAMETER SETTINGS

Parameter	Value
Terrain area	1500X1500 m2
Simulation time	100 sec
Mac Layer protocol	DCF of IEEE 802.11b standard
Traffic Model	CBR (Constant Bit Rate)
No. of CBR applications	10 % of the number of nodes
Routing Protocol	AODV
DCU: Smart Meter	1:5

A. False Negative

False Negative occurs when a system cannot detect an attack. False negatives are often a greater threat than false positives. If there wasn't an attack and the system makes a false detection, it can affect the throughput at most. However, if there was an attack and the system is not able to detect it, then it may be disastrous. However, in our proposed IPS, there are no false positives for relatively smaller number of intruders. However, the IPS suffers from false negatives with increasing percentage of malicious nodes. Figure 5 shows that there are no false negative for 2, 4, or 6 malicious nodes out of 50 nodes. The fake router percentage represents the increasing number of fake routers or malicious nodes in a fixed number of nodes. For this experiment we take, 2, 4, 6, 8, 10, 12 fake routers in 50 nodes, with 4, 8, 12, 16, 20, 24 percentages respectively. The false negative increases with increasing number of malicious nodes. Figure 6 shows the effect on false negatives with a linear percentage of malicious nodes, i.e. a fixed percentage of fake routers or malicious nodes in an increasing number of total nodes. We carry out this experiment with 10, 20, 30, 40 and 50 nodes and 20% malicious nodes for each data set. There were no false negatives for 10, 20, 30 and 50 nodes with 20% malicious nodes. The experimental results are in line with reality where any IPS system fails when majority of nodes become compromised.

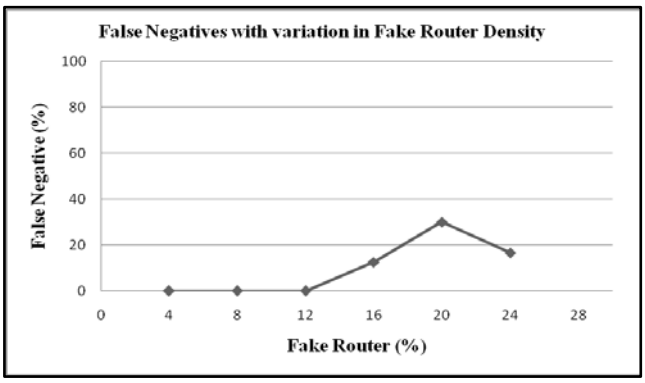

Fig. 5: False Negative vs. Number of Malicious DCUs

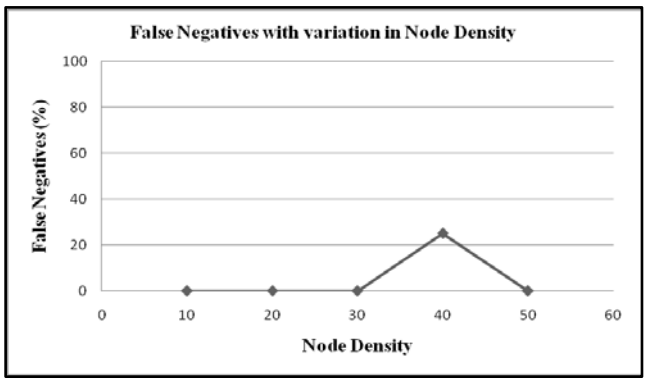

Fig. 6: False Negative vs. Node Density

B. Jitter

Jitter is expressed as an average of the deviation from the network mean latency. We measure both the Jitter for normal ICMPv6 and that with our proposed IPS for ICMPv6. Figure 7 illustrates that the proposed IPS reduces the Jitter.

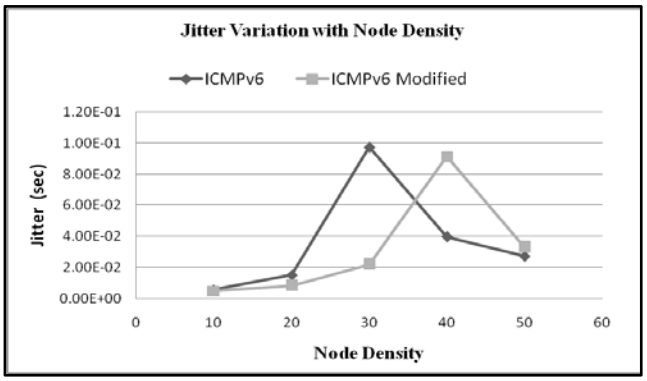

Fig 7: Jitter Vs Node Density for ICMPv6 and Modified ICMPv6

V. CONCLUSION

Integrating IPv6 with Smart Grid is quite natural, as only IPv6 could match the size of Smart Grid network. The large address space, auto configuration of addresses, QoS support technology helps Smart grid to construct a large network with a unique address specified for each and every device, efficient routing, end-to-end security. However, smart grid has very high security demand that needs to be considered before deploying IPv6 towards building Smart Grid. In this paper, the problems of using ICMPv6 in NDP and the possible effects of these problems on Smart Grid are considered. Three main functions of NDP: Router Discovery, Duplicate Address Detection and Neighbor Discovery are discussed with respect to Smart Grid environment. We first consider the normal procedure for executing each phase, and then discuss the possible attacks. Finally a prevention procedure is given to secure the system. The proposed work considers multiple security breaches on Smart Grid and provides an IPS to prevent these attacks in Router Discovery and Updation phase as well as in Neighbor Discovery and DAD phase. This, in turn, helps preventing several attacks on ICMPv6 protocol, like DoS, man-in-the-middle attack, spoofing attacks efficiently. It is also light weight and does not burden the system with unnecessary packet overhead.

A possible bootstrap problem of the proposed IPS system

has been considered and found insignificant in section III.A. The proposed methodology builds the foundation for several meaningful extensions in future. In future, we want to extend this work to detect collaborative attacks on smart grid.

ACKNOWLEDGEMENT

This work is a part of the Ph.D. work of Manali Chakraborty, a Senior Research Fellow of Council of Scientific & Industrial Research (CSIR), Government of India. We would like to acknowledge CSIR, for providing the support required for carrying out the research work. We would also like to acknowledge Jeeyan Sanyal, a student of the Masters program with Department of Computer Science and Engineering, University of Calcutta, for his contribution in the simulation process.

The work is partially supported by the PRIN "Security Horizons" project.

Software Systems Development & Applications

SSD&A is a FedCSIS conference area aiming at integrating and creating synergy between FedCSIS events that thematically subscribe to the discipline of software engineering. The SSD&A area emphasizes the issues relevant to developing and maintaining software systems that behave reliably, efficiently and effectively. This area investigates both established traditional approaches and modern emerging approaches to large software production and evolution.

Events that constitute SSD&A are:

- ATSE'14 - 5th International Workshop Automating Test Case Design, Selection and Evaluation
- MDASD'14 - 3rd Workshop on Model Driven Approaches in System Development

5th International Workshop Automating Test Case Design, Selection and Evaluation

TRENDS such as globalisation, standardisation and shorter lifecycles place great demands on the flexibility of the software industry. In order to compete and cooperate on an international scale, a constantly decreasing time to market and an increasing level of quality are essential. Software and systems testing is at the moment the most important and mostly used quality assurance technique applied in industry. However, the complexity of software systems and hence of their development is increasing. Systems get bigger, connect large amounts of components that interact in many different ways on the Future Internet, and have constantly changing and different types of requirements (functionality, dependability, real-time, etc.). Consequently, the development of cost-effective and high-quality systems opens new challenges that cannot be faced only with traditional testing approaches. New techniques for systematization and automation of testing are required.

Even though many test automation tools are currently available to aid test planning and control as well as test case execution and monitoring, all these tools share a similar passive philosophy towards test case design, selection of test data and test evaluation. They leave these crucial, time-consuming and demanding activities to the human tester. This is not without reason; test case design and test evaluation are difficult to automate with the techniques available in current industrial practice. The domain of possible inputs (potential test cases), even for a trivial program, is typically too large to be exhaustively explored. Consequently, one of the major challenges associated with test case design is the selection of test cases that are effective at finding flaws without requiring an excessive number of tests to be carried out. This is the problem which this workshop wants to attack.

This workshop will provide researchers and practitioners a forum for exchanging ideas, experiences, understanding of the problems, visions for the future, and promising solutions to the problems in automated test case generation, selection and evaluation. The workshop will also provide a platform for researchers and developers of testing tools to work together to identify the problems in the theory and practice of software test automation and to set an agenda and lay the foundation for future development.

Topics

Topics include (but are not limited to):

- techniques and tools for automating test case design:
  - model-based,
  - combinatorial.based,
  - optimization-based,
  - etc.
- Evaluation of testing techniques and tools on real systems, not only toy problems.
- Benchmarks for evaluating software testing techniques

Email: I.Bluemke@ii.pw.edu.pl.

***Abstract*— The Web Services technology has received a significant amount of attention in recent years because it allows to easily utilize and integrate existing software applications to create new business services. With the increase of interest and popularity of Web Services, web applications are developed. This way of software development causes new issues for Web Service testing to ensure the quality of service that are published. This paper describes the tool (named WSDLTest) for automatic testing of web services. The tool can be used for testing of web services for which WSDL 1.1 or WSDL 2.0 document are available. WSDLTest parses the WSDL document, and based on, it tests the web service by sending automatically generated messages. Some examples of the usage of our tool are given.**

I. Introduction

Web services are very important in providing software in the World Wide Web. They have emerged as the next generation of Web-based technology for exchanging information. They are modular, self - descriptive, self - contained applications that are based on open standard. A Web Service is a kind of Internet application based on SOAP [1] and XML [2] technology. The W3C [3] (World Wide Web Consortium) defines web service as "a software system designed to support interoperable machine-to-machine interaction over a network". Web Service relies on a family of protocols to describe, deliver, and interact with each other, such as the Web Service Description Language (WSDL) [4], the Universal Description, Discovery and Integration (UDDI) [5] protocol or the Web Service Inspection Language (WSIL) [6], and the Simple Object Access Protocol (SOAP) [1]. WSDL, UDDI, WSIL, and SOAP are all based on XML [2]. Due to the nature of standards-based architecture and XML-based messaging, Web Service is vendor-neutral, language-agnostic, and platform-independent. Therefore, developers of a Web Service are not able to assume which type of clients will use the Web Service and the developers at the client side, are not aware of which language and platform are used at the server side. A Web Service and its clients can be developed in totally different programming languages and on different platforms.

Web service can be described by a Web Service Description Language [4] document. WSDL was established as a standard by the W3C [3]. The WSDL document describes web service in terms of its interfaces with operations, types of data the web service takes or returns. Other systems interact with the Web service in a manner prescribed by its description using SOAP [1] messages.

Testing effort is often a major cost factor during software development, which sometimes consumes more than 50 % of the overall development effort [7] . Consequently, one major goal is often to reduce the testing effort e.g. by providing a tool facilitating the testing. With services the difficulty of testing increases because of the changes that this architectural style induces on both the system and the software business/organization models.

The purpose of our research was to determine the possibility and methods of testing web service based on its WSDL document. An application, named WSDLTest, has been designed and implemented at the Institute of Computer Science Warsaw University of Technology. This application can test web services for which WSDL 1.1 or WSDL 2.0 document are available. WSDLTest parses the WSDL document, and based on it, tests the web service by sending automatically generated messages.

The paper is organized as follows. Section II identifies key features of web services testing, also WSDL is briefly presented. In Section III some testing tools, using WSDL documents as a basis for testing, are discussed. Section IV focuses on the architecture of our testing tool (WSDLTest). Section V presents some results of testing a simple web service with WSDLTest. Finally, Section VI concludes the paper, highlighting some issues and future research directions.

II. Web services Testing

Testing services and service-centric systems poses new challenges to traditional testing approaches. Testing challenges derive primarily from the dynamic nature of web services and the clear separation of roles between the users, the providers, the owners, and the developers of a service. Automated service discovery and binding mean that the

This work was not supported by any organization

complete configuration of a system is known only at execution time, and this cause integration testing to be difficult. Canfora and Di Penta in [8] indicated unique features of services that add complexity to the testing.

Service testing can be performed at different levels namely:

- unit testing of atomic services and service compositions,
- integration/interoperability testing,
- regression testing,
- testing of non-functional properties.

Services testing is a recent area of investigation, numerous contributions have been presented in the literature, primarily in the areas of unit testing of services and orchestrations, integration testing, regression testing, and testing of non-functional properties. The literature also reports several investigations to improve the testability of services and service-centric systems. Canfora and Di Penta made SOA testing survey [8]. They also pointed out several problems which remain open and need additional research work e.g.: improving testability, combining testing and run-time verification, validating fully decentralized systems.

Comprehensive and excellent surveys on Web services testing can also be found in [9-12]. Several Web Services testing approaches were developed to address these new challenges, the survey can be found in [9]. Based on the surveyed Web Services testing approaches found in the literature, the existing approaches were divided by Ladam [9] into four classes:

1. WSDL-based test case generation,
2. mutation-based test case generation (e.g. [13, 14]),
3. test modeling (e.g. [15]),
4. XML-based approaches (e.g. [16]).

Hanna and Munro [17] proposed a framework that can be used to test the robustness quality attribute of a Web Service. This framework is based on analyzing the Web Service Description Language (WSDL) document of Web Services to identify what faults could affect the robustness attribute and then test cases were designed to detect those faults.

Bai and Dong [18] also are using the WSDL document to generate tests in a testing framework that includes test case generation, test controller, test agents and test evaluator.

Often the service is not able to satisfy the needs of a user but it is possible to combine existing services together in order to fulfill this need. The process of combining these services is called Web Service Composition (WSC). However much researches have been focused on the discovery, selection and composition of Web services, the testing of Web service composition is still immature [19]. Bucchiarone et al. [20] and Zakaria et al. [21] provide surveys focusing in on Web service composition. Rusli et al. provided [12] an interesting overview and evaluation of current approaches to WSC testing.

We concentrated on the WSDL-based approach to unit testing because it enables the automatic generation of tests.

A. WSDL

WSDL [4] - Web Services Description Language, is an abstract, XML-based language, which specifies location and functionalities offered by a web service. It contains specific information about the web service, for example needed parameters, returned data. XML schema is used for the presentation of WSDL description containing the messages send and received from the service. To communicate with the web service SOAP messages are exchanged and they are described by WSDL as operations. WSDL describes the format for interfaces, it can also describe interactivity of given service. WSDL description only shows the possible but not required interactions. The current, recommended by W3C [3], version of WSDL is 2.0. The older version - WSDL 1.1 is still quite common and in some software only this version is supported. Sections `<messages>` and `<portType>` were combined to create new section `<interface>` (in version 2.0)

WSDL 2.0 contains following sections:

- "*description*" - a container, inside which the remaining sections are located,
- "*types*" describes the data types send and received by a web service,
- "*interface*" describes the abstract functionality the web service provides (what messages it sends and receives, possible fault messages),
- "*binding*" provides information how to access the service,
- "*service*" provides information where to access the service.

There are also two optional sections in WSDL document:

- "*documentation*" provides textual description of a web service,
- "*import*" is used to import other XML schemas.

B. Usage of WSDL in testing

WSDL document is a description of functionalities provided by a web service. Inside this document, all "methods" and data types can be found. It is divided into several sections directly connected with each other. The section "types" contain data types, which are input and output parameters for operations. Operations are described in "interface" section. For each interface, there is a binding with the message protocol. The "binding" section of WSDL document provides knowledge about protocols bonded to given interface. "Service" sections provide information where to find endpoint for each binding. All those sections allow to determine the input and the output, as well as how and where to access the web service. Nonetheless, there is no information about what exactly the web service produces as output from input. To use effectively WSDL in testing software, following elements are needed:

- WSDL parser tool, which reads the WSDL document and extracts information.
- Oracle mechanism determining if the results of the test are correct.
- SOAP messages generator.

The process of testing based on WSDL document includes several steps. Firstly the WSDL document is parsed into

addressable memory objects. Information from parsing can be used to generate SOAP requests. Such message may contain either randomly generated parameters based on data type taken from WSDL document, or can be filled by a tester. Such approach to web service testing is applicable only when communication is bidirectional – request and response from the web service. When SOAP request is send, after a while the web service should send back response with results of its operation. These results may be later compared with oracle to determine if the web service is working properly.

III. TESTING TOOLS

There are several testing tools available on the market, which can be used for testing web services. The most recognizable tools are:

1. HP QuickTest Professional,
2. Parasoft SOAtest,
3. SOAPSonar,
4. SoapUI.

Some of these tools offer the validation of WSDL document provided by WS-I [22].

HP QuickTest Professional [23] is an automatic testing suite. It accepts both 1.1 and 2.0 versions of WSDL. The application performs automated tests on a variety of software and in many environments. It has graphical user interface, which allows performing regression and functional testing. The main testing algorithm identifies objects to be tested and performs testing of interface operations. Important function of HP QuickTest Professional is the ability to perform the validation of WSDL using the WS-I [22] tool. In this application the modification, insertion, and removal of test parts are easy. HP QuickTest Professional has a Web Service Testing Wizard Click that can be used for the definition of different options e.g. a checkpoint can be created or some actions may be selected. Everything defined in the wizard is later converted and inserted into the test. This tool has functions allowing the customization of reports with user-defined images and screenshots. Client performance-related errors (e.g. memory leakage) can be included in the standard reports with a direct link from the report to the test script. HP QuickTest Professional automates the design of tests and test cases.

Parasoft SOAtest [24] is used for testing applications build in Service-oriented Architecture. It can automate application testing, message/protocol testing, cloud testing and security testing. Its graphical user interface is Eclipse based (uses the same GUI library). It allows creating tests, defining the behavior of the tests and configuring specific tests (e.g. queue managers or database connections). SOAtest primary function is to test Web services. It automatically generates tests from key market platforms such as WSDL [4], UDDI [6], WSIL [7], XML [2], BPEL [25], HTTP traffic and other. SOAtest can validate WSDL documents and emulate the client or the server. Tests can be grouped to be executed in a sequence. Failed tests are highlighted. Parameters for requests can be entered by the user or can be read from a file. SOAtest can trace and visualize how messages and events flow through ESBs (Enterprise service bus) [26], message brokers, applications and databases, while tests are executed. Such tracing allows the interpretation of problems.

SOAPSonar [27] is testing and analysis tool specifically designed for Web Services. It can perform functional regression tests, performance tests; generate compliance reports, vulnerability checks and identity tests. It has clear graphical user interface. Tests are created via drag and drop selection. Application has also WSDL Region WS-I validation [22]. It accepts WSDL 1.1 and WSDL 2.0 documents. The professional edition of SOAPSonar has test flow management options and can create WSDL requests - response chain or data driven test for the exchange of messages. Functional tests use load testing for the performance monitoring. Security penetration tests are performed at the message layer. All versions of SOAPSonar use as test inputs and response analysis data from e.g. database tables or Microsoft®Excel files. Application can automatically change variables in message headers, message body, tasks and can change variables. SOAPSonar has also vulnerability mode, which allows associating each test request with a set of attack. It can parse the WSDL documents and generate a list of the operations available on interface described by it. It can be used to send SOAP request messages to the target Web service and capture the response.

SoapUI [28] is an open source web service testing application for service-oriented architectures. SoapUI has clear and easy to use graphical user interface, which allows for quick creation of any test scenarios. It requires WSDL files to generate tests, messages, validations and MockServices. SoapUI supports only 1.1 version of WSDL and it can easily create functional, regression, compliance, and load tests. SoapUI provides code free test environment, all tests are created by drag and drop actions. SoapUI Pro Test Debugging is an option, which allows following the flow of test, variables, properties requests and context. Data for data-driven tests can be provided from external editors such as Microsoft ® Excel. SoapUI MockServices is a feature, which allows mimicking Web Services before they are implemented. SoapUI uses WS-I profile [22] for 1.1 version of WSDL.

IV. WSDLTEST

WSDLTest is a simple application supporting unit testing of web services which are described in WSDL. In the Fig. 1 the high-level structure of WSDLTest is presented. External connections and internal interfaces are also shown. The frame at the top of figure, which consists of WSDL document and web service itself, represents remote location

that is accessed in different manner by WSDLTest application.

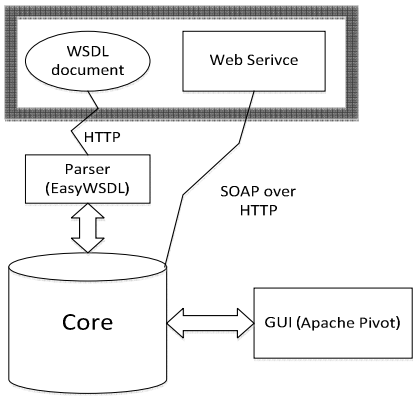

Fig. 1 Structure of WSDLTest

WSDL document is accessed via parser using HTTP connection, whereas web service is communicated thru SOAP messages transported over the HTTP connection. Core module consists of classes that support main functionality of application. WSDLTest is divided logically into Core, Parser and GUI. As a parser we used EasyWSDL Toolbox [29]. It can be used to parse WSDL 1.1 and WSDL 2.0 descriptions and transforms them in a unified object model (based on the WSDL 2.0 entities). Library is written in Java language and therefore can be used within java compatible application only. Moreover, WSDL parser can additionally export information from application object to an editable WSDL document. Other implementation details can be found in [30].

In the Fig. 2 main functions of core module are presented. Based on information from the parsed WSDL document interface bonded to SOAP [1] connection is found. From this interface all operations are extracted to determine what kind of parameters operations require and how many of them. GUI creates panel for input values of parameters or input of regular expression. WSDLTest generates all required parameters and performs tests.

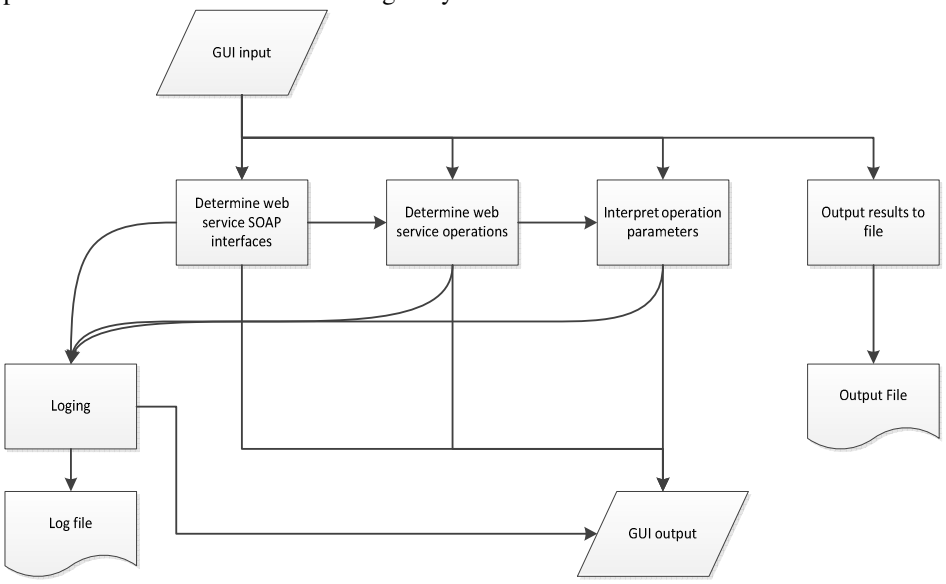

Fig. 2 Activities in Core module of WSDLTest

```
<s:element name="ValidateCardNumber">
        <s:complexType>
               <s:sequence>
                      <s:element minOccurs="0" maxOccurs="1"
                             name="cardType"
                             type="s:string"/>
                      <s:element minOccurs="0" maxOccurs="1"
                             name="cardNumber"
                             type="s:string"/>
               </s:sequence>
        </s:complexType>
</s:element>
<s:element name="ValidateCardNumberResponse">
        <s:complexType>
               <s:sequence>
```

```
14                          <s:element minOccurs="0" maxOccurs="1"
15                                 name="ValidateCardNumberResult"
16                                 type="s:string"/>
17                    </s:sequence>
18             </s:complexType>
19    </s:element>
20    ...
21    <wsdl:portType name="CCCheckerSoap">
22             <wsdl:operation name="ValidateCardNumber">
23                    <wsdl:documentation xmlns:wsdl=
24                           "http://schemas.xmlsoap.org/wsdl/">
25                           Please enter card type as VISA or
26                                 MASTERCARD or DINERS or AMEX
27                    </wsdl:documentation>
28                    <wsdl:input message=
29                           "tns:ValidateCardNumberSoapIn"/>
30             </wsdl:operation>
31    </wsdl:portType>
```

Fig. 4 WSDL document for web service ValidateCardNumbert

A. Testing modes

WSDLTest has three testing modes available for the user (shown in Fig. 3):

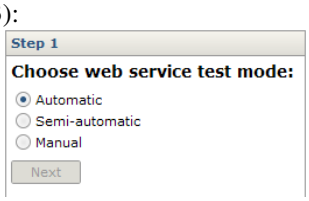

Fig. 3 Modes of operation of WSDLTest

1- *Automatic* – all tests are performed automatically. User only specifies the number of tests to be performed. All possible operations (functions of web service) defined in WSDL document are tested. For each operation random parameters are generated based on theirs defined in XML types.

2- *Semi-automatic* – parameters of operations are provided as regular expressions. For these expressions values of parameters, used in tests, are generated. User can specify number of tests and operations to be tested.

3- *Manual* – the simplest of modes, parameters of operations are given explicitly by the user.

In semi-automatic and automatic mode the oracle, containing expected test results, can be defined.

V. Example

Web service Validate Card Number [31] is a simple web service with only one method named `ValidateCardNumber`, used for credit card number validation. In Fig 4 the definition of operation `ValidateCardNumber` [lines 22-30] is given, input parameter of operation `ValidateCardNumber` [lines 1-10] and output of operation parameter `ValidateCardNumberResponse` [lines 11-19].

This service was tested using semiautomatic mode. In first test the parameter `cardNumber` was inputted as regular expression which matches any random sequence of digits of the length equal 16 (typical length of credit card number). Input window is presented in Fig.5.

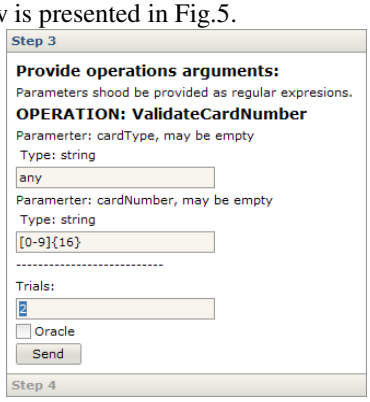

Fig. 5 Input window of WSDLTest – setting parameter values

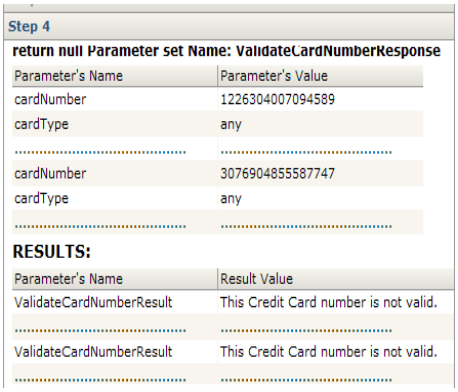

Fig. 6 Result of tests for parameters given as digits

Results, presented in Fig. 6, indicate whether the card number generated by WSDLTest is valid or not. The parameter `cardNumber` is defined as string (line 7 in Fig. 4.), so random string consisting of letters was used in next test. Credit card number can consist only of numbers, so error should be reported. WSDLTest was able to find the errort inside returned SOAP message. Results are shown in Fig.7.

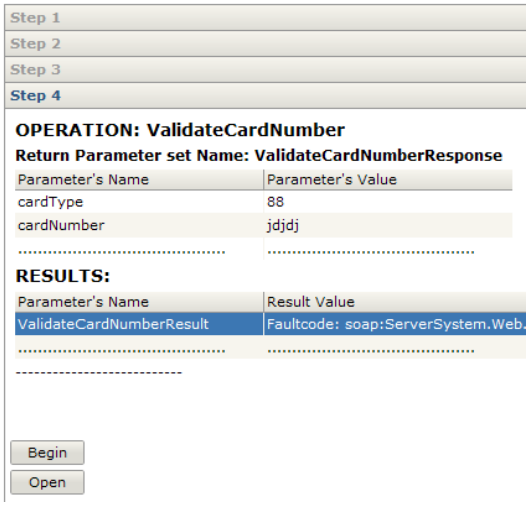

Fig. 7 Result of tests for parameters given as random string

VI. Conclusion

Web service can be specified in a WSDL [4] document. This document may be used as a basis in the automatic testing of the web service. We developed the application, called WSDLTest, which uses the WSDL document to prepare unit tests of web service. WSDLTest allows user, with basic technical knowledge, to test a web service. Testing can be performed in fully automatic mode for theoretically infinite number of trials with different parameters. The automated process of testing includes the generation of parameter values, the comparison of results with oracle and a basic validity check of the WSDL document. Tester can also provide parameter values and oracle in form of regular expression. Such form is more general than the explicit one. Regular expressions used in oracle are used to generate expected values of results, which are compared with actual results of tests.

WSDLTest can test a variety of web services described by WSDL. In this paper we presented simple example (section V). Even on this simple example it can be easily noticed that WSDLTest can be very useful in testing web services. Our tool does not have all functionalities available in other tools presented in section III, e.g. is not able to do load testing. In current version, WSDLTest is not able to read parameters from external files or mimicking web service, such functions are usually available in commercial tools. It might have some problems in testing web services with very complex data. These drawbacks can be eliminated in future versions.

WSDLTest has also an advantage over other similar tools. It can generate values of parameters from regular expressions; such functionality is not common in other tools.

***Abstract*—This paper addresses the issue of verifying transport protocol's parallel routing functionality on a vehicle gateway system. The focus of the paper is to construct a conflict-free input parameter model for testing this functionality. The input parameter model shall support the reduction of combinations to be tested and serves as a basis for automatic test case generation from a large space of input parameters. In the proposed approach, defined similarity criteria are used to cluster system input parameters represented as transport protocol routing instances into groups which stimulate similar behavior in the gateway when transport protocol routing is established. Subsequently, the two conflict-handling methods *sub-models* and *avoid* are utilized to prohibit invalid combinations of transport protocol routing instances. The proposed approach is applied on a complex example of real gateway with five buses, 390 transport protocol routing instances and diverse conflicts to illustrate its applicability.**

***Index Terms*—Transport Protocol's Parallel Routing, Input Parameter Model (IPM), Conflict Handling**

I. Introduction

TODAY'S vehicles Electric/Electronic (E/E) systems are designed as distributed systems in order to overcome the increasing complexity and to meet the diversity of requirements such as performance, comfort, safety and costs. In a vehicle distributed system, gateways are indispensable. They enable Electric Control Units (ECUs) within connected networks to interchange information necessary for accomplishing specified functionalities. During information interchange, the gateway routes data between its connected networks although they work on different communication protocols.

In a vehicle gateway system, routing data packets which are larger than a single frame of the corresponding network communication protocol is carried out with the help of transport protocol implementations and such type of routing is called TP routing. Since TP data packets are mostly large in size (flash data for example) and routing of such large data packets requires longer duration, modern gateways support TP parallel routing where multiple TP routing instances are established in parallel over the gateway in order to save time and resources, e.g., flashing multiple ECUs in parallel.

Verifying TP parallel routing of a gateway system is not a trivial problem, since a large number of possible combinations of communicating ECUs can be built for test case selection (the combinatorial explosion problem). Furthermore, in case of established TP parallel routing, different types of conflicts between ECUs need to be handled.

Combination strategies [1] are test case selection methods that focus on solving the combinatorial explosion problem raised while testing the interactions between system input parameter values by defining coverage criteria to satisfy. However, the problem in the case of verifying TP parallel routing on a vehicle gateway system is different than described problem of combination test strategies (see II-B). Hence, new techniques need to be defined.

In combination strategies, Input Parameter Models (IPMs) [2] [3] [4] [5] are essential. They represent the System Under Test (SUT) on an abstract level. Mostly, IPMs contain conflicts which must be resolved. A conflict in an IPM is due to an invalid combination of input parameter values and hence this combination must be omitted or avoided while generating test cases. Diverse conflict handling strategies such as *sub-models* and *avoid* have been suggested in literature [6] to overcome conflicts in IPMs.

This paper suggests an approach to build a conflict-free IPM used to test TP parallel routing on a vehicle gateway system. The IPM is utilized in a recursive way for test case selection, generation and execution in order to overcome the combinatorial explosion problem.

The remainder of this paper is organized as follows. Section II gives background information on terminology and the combinatorial explosion problem of testing TP parallel routing. An IPM along with conflict handling mechanisms are presented in details in section III. In section IV, the suggested IPM along with described conflict handling mechanisms are utilized in a method to reduce test suite size. The complete methodology is applied on a complex example of real gateway in section V. Section VI discusses the approach and section VII concludes the paper.

II. Background

A. Vehicle Bus Communication Systems

Generally, different bus communication systems are utilized in E/E system. In this subsection, two common types of automotive buses are briefly explained.

This work was supported by MBtech Group GmbH & Co. KGaA

978-83-60810-58-3/$25.00

1) CAN Communication Bus: Controller Area Network (CAN) bus system was originally invented to reduce the wiring harness in automotive E/E systems by developing a serial communication protocol. CAN has the capability to connect multiple ECUs directly to one medium, which leads to better management of the system complexity and the reduction of manufacturing costs. CAN protocol is an asynchronous serial protocol that enables real time communication. In CAN, the medium access is based on the concept of Carrier Sense Multiple Access/Collision Detection (CSMA/CD).

2) FlexRay Communication Bus: FlexRay was developed to deliver deterministic, fault-tolerant and high-speed communication bus required for x-by-wire applications such as steer-by-wire and break-by-wire. These applications demand more safety, performance and reliability than provided by CAN. FlexRay unifies time- and dynamic event-triggering mechanisms in one protocol. The communication in FlexRay is based on the Time Devision Multiple Access (TDMA) and Flexible Time Division Multiple Access (FTDMA) schemes of networking.

B. Terminology

The vehicle gateway is part of a distributed network system. It is a special ECU that has multiple communication channels used to communicate with other ECUs in the network in order to route data between them. Communication channels of the gateway are mostly heterogeneous in respect of characteristics and behavior. Generally, a number of ECUs (u) can exchange data over the gateway in predefined fashions. Each fashion is characterized through a set of gateway configuration parameters. These are required by the gateway to establish routing between communicating ECUs connected to different communication channels. For TP routing over the gateway, following definitions are considered:

A *TP_Routing_Fashion* describes a possible routing behavior of TP data and is characterized through a particular set of gateway configuration parameters. An example of a $TP\_Routing\_Fashion_F$ with P parameters shall be described (1) (see [7] for configuration parameters of CAN TP).

$$TP\_Routing\_Fashion_F = \{P_{F_1}, P_{F_2}, ..., P_{F_P}\} \quad (1)$$

A *TP_Connection_Channel* is an instance of a *TP_Routing_Fashion*. It has the same set of gateway configuration parameters and is utilized to route TP data between respective ECUs. A $TP\_Connection\_Channel_x$ in the $TP\_Routing\_Fashion_F$ shall be described (2).

$$TP\_Connection\_Channel_x = \{P_{F_1x}, P_{F_2x}, ..., P_{F_Px}\} \quad (2)$$

The gateway has a number of configured *TP_Connection_Channel*s for connected ECUs utilized to establish TP routing in different scenarios. Examples of TP scenarios are flashing and Onboard Diagnostic (OBD). *TP_Routing_Scenario*s shall be described as a group of s scenarios (3).

$$TP\_Routing\_Scenarios = \{S_1, S_2, ..., S_s\} \quad (3)$$

A *TP_Routing_Instance* is a relationship between a specific *TP_Connection_Channel* and a possible *TP_Routing_Scenario*. An example of a $TP\_Routing\_Instance_x$ shall be described (4).

$$TP\_Routing\_Instance_x = \{P_{F_{1x}}, P_{F_{2x}}, ..., P_{F_{Px}}, S_x\} \quad (4)$$

The gateway can be configured to serve y *TP_Routing_Instance*s in parallel. The number of parallel *TP_Routing_Instance*s *"y"* is a configuration parameter which needs to be verified. In the case of errors, the next determined *"y"* should be verified.

C. The Combinatorial Explosion Problem of Testing TP Parallel Routing

The combinatorial explosion problem mentioned in literature [8] [9] [10] shall be explained as in the following example:

Assume a distributed system consisting of a central unit interacting over communication channels with u units of the network U_1, U_2, ..., U_u. Each unit U_i uses a defined parameter p_i for communication. The parameter p_i shall have v_i possible configuration values. By assuming that configuration values of parameters are independent from each other, the number of possibilities in which the system can be configured would be $v_1 * v_2 * ... * v_u$. If each possible configuration requires c test cases to verify it, the number of test cases for exhaustive test would be $c * v_1 * v_2 * ... * v_u$. In a nontrivial software system, the values of u and v_i are large which leads to a huge number of possible combinations of parameter values.

Related to testing TP parallel routing, the goal of test is to measure the performance of the gateway to handle parallel *TP_Routing_Instance*s. The problem is more complex because:

- System input parameters are *TP_Routing_Instance*s where each consists of a set of configuration parameters.
- The number of system input parameters is not fixed. It can be different for every new release of the system.
- System input parameters include also timing parameters where the interactions are difficult to resolve.
- The number of parallel *TP_Routing_Instance*s *"y"*, which is also a configuration parameter, is used to build possible combinations to be tested. Combinations are any y elements from the system input parameter set. In case of errors, one of the goals is to determine the next *"y"* and verify it (performance measurement).
- In TP parallel routing, each additional instance will consume resources of the system and may lead to errors. Hence, it is not only a specific combination of *TP_Routing_Instance*s which can affect the behavior and may reveal errors, but also the number of included *TP_Routing_Instance*s and their values.

To verify *"y"* parallel routing of *TP_Routing_Instance*s and determine the next *"y"* in case of errors, all possible combinations from 1 to y of *TP_Routing_Instance*s should be included at least once in test cases. This results in a number

of combinations to be tested which can be calculated using equation(5).

$$X = \frac{u!}{y!(u-y)!}.y^s + \frac{u!}{(y-1)!(u-(y-1))!}.(y-1)^s + ... + \frac{u!}{1!(u-1)!}.1 \quad (5)$$

The equation (5) calculates the sum of all possible combinations for a number of ECUs (u) communicating in *TP_Routing_Scenario*s (s), where the selected number of ECUs in each term varies from y to 1.

Even for a simple system, the duration of testing for all these combinations is too high and therefore not acceptable.

III. Input Parameter Model and Conflict Handling

A combination test strategy consists generally of two steps:

1) Building a suitable IPM
2) Selecting combinations of parameter values from IPM to satisfy defined coverage criteria.

In this paper, the proposed IPM shall be used to test TP parallel routing in a recursive approach, i.e., one combination is constructed at a time. Subsequently, a test case is generated for that combination and executed. This procedure is then repeated until satisfying the defined coverage criterion. The decision on using a recursive selection and execution approach has two reasons:

1) Information from executed test cases is collected and can be used to reduce the number of combinations for the successive test cases.
2) Gained information from executed test cases is utilized to determine the worst case combinations.

In order to build a suitable conflict-free IPM, conflicts need to be defined. In a TP parallel routing, three types of conflicts are stated:

1) **Type$_A$-Conflicts**: Conflicts between *TP_Routing_Scenario*s. These are constraints describing *TP_Routing_Scenario*s not practiced in parallel.
2) **Type$_B$-Conflicts**: Conflicts between *TP_Connection_Channel*s. These are constraints describing *TP_Connection_Channel*s not allowed to be combined in parallel.
3) **Type$_C$-Conflicts**: Conflicts because of configuration parameters. These are constraints describing known or desired capabilities of the SUT.

The following example explains raised conflicts in testing TP parallel routing on a vehicle gateway system:

Assume a gateway having six *TP_Routing_Instance*s in *TP_Routing_Fashion*s (F_x and F_y) used to route TP data between connected ECUs as following:

$$TP\_Routing\_Instance_1 = (P_{F_{x11}}, P_{F_{x21}}, P_{F_{x31}}, P_{F_{x41}}, S_1)$$
$$TP\_Routing\_Instance_2 = (P_{F_{x12}}, P_{F_{x22}}, P_{F_{x32}}, P_{F_{x42}}, S_2)$$
$$TP\_Routing\_Instance_3 = (P_{F_{x13}}, P_{F_{x23}}, P_{F_{x33}}, P_{F_{x43}}, S_1)$$
$$TP\_Routing\_Instance_4 = (P_{F_{x14}}, P_{F_{x24}}, P_{F_{x34}}, P_{F_{x44}}, S_2)$$
$$TP\_Routing\_Instance_5 = (P_{F_{y15}}, P_{F_{y25}}, P_{F_{y35}}, S_1)$$
$$TP\_Routing\_Instance_6 = (P_{F_{y16}}, P_{F_{y26}}, P_{F_{y36}}, S_2)$$

Assume also that the gateway supports two *TP_Routing_Instance*s in parallel. Then, following examples explain the three types of conflicts:

- **Type$_A$-Conflicts**: *TP_Routing_Scenario* S_1 and *TP_Routing_Scenario* S_2 are non-combinable. That is, a combination of *TP_Routing_Instance*$_1$ and *TP_Routing_Instance*$_2$ is for example an invalid combination.
- **Type$_B$-Conflicts**: *TP_Connection_Channel*$_2$ and *TP_Connection_Channel*$_4$ are non-combinable, i.e., a combination of *TP_Routing_Instance*$_2$ and *TP_Routing_Instance*$_4$ is an invalid combination.
- **Type$_C$-Conflicts**: Maximum of two *TP_Routing_Instance*s are combinable, i.e., all combinations of more than two *TP_Routing_Instance*s are invalid.

As discussed in the previous section, a *TP_Routing_Instance* of gateway is a relationship between *TP_Connection_Channel* and possible *TP_Routing_Scenario*. *TP_Routing_Instance*s are input parameter values required to build a conflict-free IPM for testing. To achieve building a conflict-free IPM which supports the reduction of combinations in a recursive approach, following steps are required:

1) Collecting and extending *TP_Routing_Instance*s based on similarity criteria.
2) Handling conflicts.

A. Collecting and Extending TP_Routing_Instances based on Similarity Criteria

In collecting *TP_Routing_Instance*s, instances that stimulate similar behavior in the gateway are clustered into groups. Two *TP_Routing_Instance*s are said to be similar if and only if they have the same values for all related parameters such as routing parameters, network relationship parameters and mapped *TP_Routing_Instance*. Creating groups of similar *TP_Routing_Instance*s helps in reducing the number of combinations required for testing. The resulting combination from formulating groups are defined as *"reduced combinations"*.

Following example explains reduction achieved after groups are constructed.

Assume that the SUT has 4 *TP_Routing_Instance*s A, B, C and D (see Fig. 1) and it is configured to support 2 *TP_Routing_Instance*s in parallel. The number of possible combinations of 2 instances out of 4 would be 6 (the order has no effect). If *TP_Routing_Instance*s A,B and C,D are similar to each other, then groups can be constructed based on similarity criteria such that *Group*$_1$ consists of instances A and B, whereas *Group*$_2$ consists of instances C and D. After grouping, the number of combinations could be rather reduced from 6 to 3, because all other possible combinations would resemble a similar behavior, i.e., combinations of instances

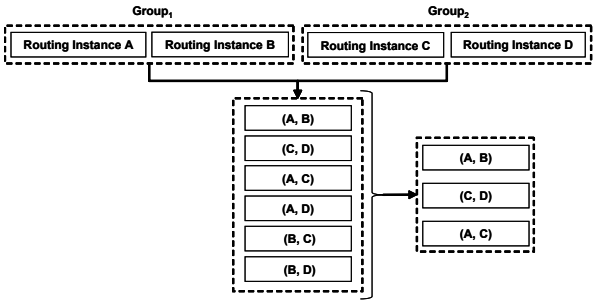

Fig. 1. Advantages of Building Similar Groups

(A, C), (A, D), (B, C) and (B, D) are all similar and can be replaced by only one substitute (A, C). Therefore (A,B), (C,D) and (A,C) are the *"reduced combinations"*.

In extending *TP_Routing_Instance*s, *Similarity Number*s and *Stress Factor*s are assigned to constructed groups. The same *Similarity Number* will be assigned to groups with *TP_Routing_Instance*s having the same routing parameters, the same *TP_Routing_Scenario* and the same characteristics for network relationship. Concerned network characteristics are the protocol type and channel bandwidth. The *Stress Factor* is calculated based on aspects such as processing time, memory usage, channel bandwidth and other channel specific aspects. *Stress Factor*s shall be assigned during test case execution. *Similarity Number*s and *Stress Factor*s are required for reducing combinations during testing. This will be discussed later in details. The basic idea to resolve the combinatorial explosion problem is by using *"reduced combinations"* formulated from constructed groups based on similarity criteria.

B. Conflict Handling

In [2], four different methods for handling conflicts in IPMs were investigated. The result of the study was that the *avoid* method is best suited with respect to size of test suite if it can be utilized. To handle conflicts with the *avoid* method; a procedure is integrated in the test case selection algorithm to prohibit choosing of conflicting combinations. Another method mentioned in the study is the *sub-models* method, in which conflicts are removed by splitting the IPM into multiple smaller conflict-free IPMs used separately to generate test cases. In this paper, a combination of these two conflict handling methods is utilized to handle the defined conflicts for testing TP parallel routing.

1) Type$_A$-Conflict Handling: Since constructed groups possess *TP_Routing_Instance*s similar to each other in all assigned parameters, *TP_Routing_Instance*s of each group will have the same attached *TP_Routing_Scenario*. To handle conflicts existing between *TP_Routing_Scenario*s, the *sub-models* method is utilized. The *TP_Routing_Scenario* is used to split IPM into sub-IPMs which are Type$_A$-Conflict-free. The resulted sub-IPMs shall have no combinable *TP_Routing_Instance*s among each other. This step can be completely achieved before executing any test case, i.e., it is not part of the recursive mechanism. Subsequently, resulted sub-IPMs are processed successively in a recursive methodology.

2) Type$_B$-Conflict Handling: As described before, a *TP_Routing_Instance* is a relationship between a *TP_Connection_Channel* and a *TP_Routing_Scenario*. In order to handle conflicts between *TP_Connection_Channel*s, the *avoid* method is utilized. To implement the *avoid* method, two reserved parameters, i.e., *"Token"* and *"Include Times"*, are attached to individual *TP_Routing_Instance*s. The value of the first parameter *"Token"* is used to decide whether a *TP_Routing_Instance* is allowed to be included in the next combination or not. The *Token* parameter can have one of the following values:

- **0:** Related *TP_Routing_Instance* having no Type$_B$-conflicts and is allowed to be included in a combination.
- **1:** Related *TP_Routing_Instance* having Type$_B$-conflicts and is allowed to be included in the next combination.
- **2:** Related *TP_Routing_Instance* having Type$_B$-conflicts and is not allowed to be included in the next combination.

The second parameter *"Include Times"* is used to hold the number of times a *TP_Routing_Instance* is included in constructed combinations. It is utilized to choose *TP_Routing_Instance*s from the same group that have not yet been included or less included than other instances. Every *TP_Routing_Instance* having Type$_B$-conflict is assigned an *"Include Times"* value "0" that gets incremeted whenever that particular *TP_Routing_Instance* becomes part of a generated combination.

In order to avoid combinations having Type$_B$-conflict, the *Rotate ()* function is called. Each time the function is called, it assigns a suitable value for parameter *Token* based on Type$_B$-conflicts and the value of parameter *Include Times*. After calling the *Rotate ()* function, Type$_B$-conflicting *TP_Routing_Instance*s with the minimum value of parameter *Include Times* will be assigned the value 1 for *Token* and all other Type$_B$-conflicting *TP_Routing_Instance*s will get the value 2. Type$_B$-conflict-free *TP_Routing_Instance*s will be assigned the value 0. The algorithm for generating the final reduced combinations will avoid *TP_Routing_Instance*s with the value 2 for *Token* parameter.

3) Type$_C$-Conflict Handling: Conflicts based on configuration parameters are constraints considered in the test case selection and generation procedure. These constraints shall be corrected if error arises, e.g., correcting the maximum number of parallel routing instances of CAN transport protocol.

IV. Reduction of Test Suite

In order to reduce the size of test suite, a new recursive test mechanism consisting of the following two test phases is proposed:

1) Testing TP parallel routing of Single Network Relationships (SNRs). An individual SNR comprises groups of *TP_Routing_Instance*s responsible for routing TP data between two specific networks of the gateway.

2) Testing TP parallel routing of Mixed Network Relationships (MNRs). An individual MNR comprises groups of *TP_Routing_Instance*s from all SNRs belonging to the same sub-IPM.

In the first test phase, testing of TP parallel routing for individual pairs of connected networks is carried out by means of groups belonging to individual SNRs. The goal of this test is to cover simple interactions (routing) between network pairs. After completing the first test phase, the second test phase is conducted. The goal of the second test phase is to cover complex interactions between multiple interacting networks by means of groups belonging to individual MNRs. Testing SNRs and MNRs separately is very useful for managing the test complexity and reducing the number of combinations. Furthermore, it provides information about possible reason for the occurrence of errors and their relationship with certain pairs of networks or parameter.

A. Coverage Criterion

Coverage criterion is an essential element of combination test strategies. It affects the complexity and the thoroughness of the test. In the proposed approach for testing TP parallel routing, coverage criteria is determined with respect to combinations of *TP_Routing_Instance*s from constructed groups. For example, *1-wise* coverage requires that at least one possible combination with maximum allowed *TP_Routing_Instance*s from every input group is included at least once in a test case. Since all *TP_Routing_Instance*s of a group stimulate a similar behavior in the gateway, any one of such a combination from each group is sufficient enough to satisfy *1-wise* coverage criterion. *N-wise* coverage criterion (exhaustive testing) requires that all possible combinations of *TP_Routing_Instance*s from *N* input groups are included in some test cases, where *N* is the number of input groups.

For an arbitrary number of input groups, the algorithm generates all possible combinations satisfying the *N-wise* interactions between the groups. The maximum number of resulting combinations is calculated as in (6):

$$X = \frac{(n+y-1)!}{y!(n-1)!} \tag{6}$$

Where *n* is the number of groups and *y* is the maximum number of allowed parallel *TP_Routing_Instance*s. Table I explains the algorithm for generating combinations with the help of an example of 4 input groups (G_1,G_2,G_3,G_4) and a maximum of 3 allowed parallel *TP_Routing_Instance*s. Resulting rows in Table. I represent the combinations and the numbers in columns represent the number of *TP_Routing_Instance*s selected from each corresponding group for test case generation. The maximum number of resulting combinations (rows) in this example can be calculated according to (6) and is equal to 20.

While generating test cases, following aspects are considered:

- To guarantee that each *TP_Routing_Instance* is included at least once in some combinations, the *Rotate ()* function is used. Upon calling this function, it generates new *Token* values for *TP_Routing_Instance*s based on the last values of *Include Times* variables and $Type_B$-Conflicts.
- The sum of column elements must be greater than or equal to the number of elements in the corresponding group in order to guarantee that each *TP_Routing_Instance* has been included at least once. If this is not the case, the remaining *TP_Routing_Instance*s from that group shall be tested individually.
- The number in each column must be lesser than or equal to the total number of *TP_Routing_Instance*s in the corresponding group. Otherwise, the combination in the related row is invalid and must be omitted.

TABLE I
COMBINATIONS FROM 4 GROUPS WITH MAXIMUM OF 3 *TP_Routing_Instance*S

G_1	G_2	G_3	G_4
3	0	0	0
2	1	0	0
2	0	1	0
2	0	0	1
1	2	0	0
1	1	1	0
1	1	0	1
1	0	2	0
1	0	1	1
1	0	0	2
0	3	0	0
0	2	1	0

0	1	2	0
0	1	1	1
0	1	0	2
0	0	3	0
0	0	2	1
0	0	1	2
0	0	0	3

B. TP Parallel Routing of SNRs

The procedure for testing TP parallel routing of SNRs is depicted in Fig. 2. The procedure accepts constructed $Type_A$-Conflict-free sub-IPMs as input and processes them successively. For each $Type_A$-Conflict-free sub-IPM, the *Selector ()* function extracts groups for the first SNR. In the next step, a combination is built for the current processed SNR with the help of the mechanism explained previously satisfying *N-wise* coverage criterion. After that, a test case will be generated and executed for the build combination. During test case generation, $Type_B$- and $Type_C$-conflicts are handled as explained previously. Result of the test case is analyzed in the following step in which *Stress Factor* is determined and configuration parameters are corrected if a variance has been observed. This procedure is repeated for all combinations until the *N-wise* coverage criteria is satisfied for each SNR. This

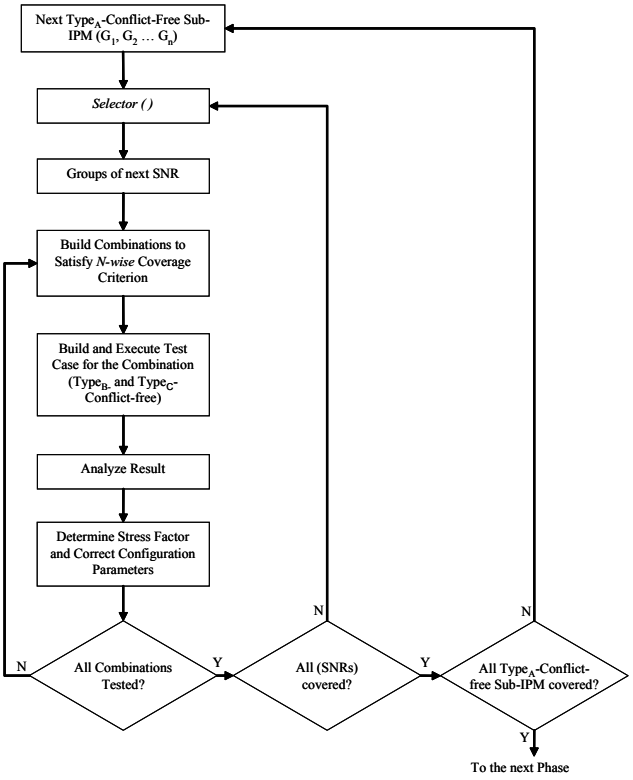

Fig. 2. TP Parallel Routing for SNRs

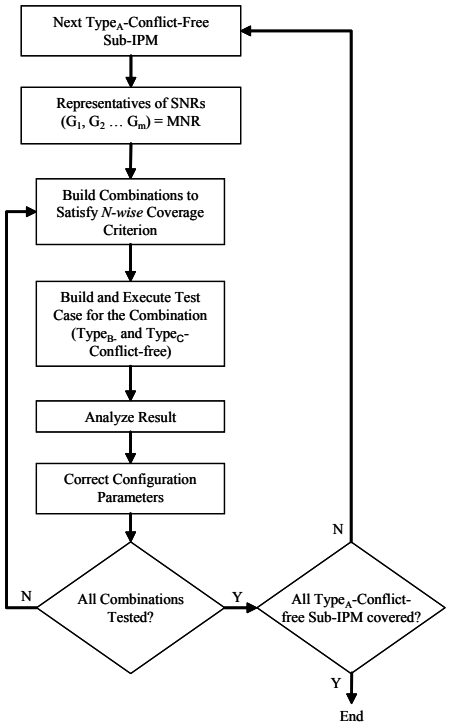

Fig. 3. TP Parallel Routing for MNRs

process is then repeated until all Type$_A$-conflict-free sub-IPM are covered. Processing combinations successively has the advantage to reduce further invalid combinations depending on the corrected configuration parameters. After finishing this phase, each group will be assigned a calculated *Stress Factor*, which will be used by the next phase.

C. TP Parallel Routing of MNRs

The procedure for testing TP parallel routing of MNRs is depicted in Fig. 3. In this procedure, Type$_A$-Conflict-free sub-IPMs are processed successively. Each Type$_A$-conflict-free sub-IPM consists of an arbitrary number of SNRs. A representative group with the best calculated *Stress Factor* for each of these SNR is selected. These representative groups are called MNR and they are the base for testing in this phase. That is, for each processed Type$_A$-Conflict-free sub-IPM, a MNR with selected groups is constructed. After selecting groups of a MNR, groups having the same *Similarity Number*s will be omitted in oder to reduce repititions in combinations. Then, the same procedure as that in previous phase is utilized to build combinations and execute test cases until *N-wise* coverage criterion is satisfied. The procedure will stop once all Type$_A$-Conflict-free sub-IPMs are processed. During recursive testing, constraints are corrected if an error is observed. This helps in further reduction of remaining combinations required to satisfy defined coverage criteria.

V. EXPERIMENT

The central gateway used in this experiment is a special electronic control unit which connects five different networks representing five functional domains of a modern vehicle. Bus systems of the five networks are listed as follows:

- A CAN network for diagnostic functional domain with 500 kilo baud, denoted as bus 1.
- A CAN network for periphery and power train functional domain with 500 kilo baud, denoted as bus 2.
- A CAN network for body functional domain with 250 kilo baud, denoted as bus 3.
- A CAN network for telematics functional domain with 500 kilo baud, denoted as bus 4.
- A FlexRay network for chassis functional domain with 10 MB, denoted as bus 5.

The gateway has 390 *TP_Connection_Channel*s which are separated in:

- 190 *TP_Connection_Channel*s used to transfer data from external device to available ECUs over the gateway.
- 190 *TP_Connection_Channel*s used to transfer data from available ECUs to external device over the gateway.
- 4 *TP_Connection_Channel*s used to transfer data between 4 couples of ECUs in the one direction.
- 4 *TP_Connection_Channel*s used to transfer data between 4 couples of ECUs in the another direction.
- 2 functional *TP_Connection_Channel*s.

Similarity criteria used to form groups are:

- Network relationship of *TP_Connection_Channel*s (source and destination networks).
- Addressing format (normal or mixed).
- Block Size (BS) and separation minimum time (STmin) if they are available.
- Cycle Repetition if it is available.
- ID Type (normal or extended).
- Address Type (physical or functional or extended).
- *TP_Routing_Scenario*

*TP_Routing_Scenario*s determined are:

- Flashing (S_1).
- Uploading (S_2).
- OBD in the one direction (S_3).
- OBD in the other direction (S_4).
- Functional routing (S_5).

Table II, table III, table IV and table V represent the resulting sub-IPMs with their corresponding groups.

Determined conflicts are listed below:

- $Type_A$-Conflicts
  - Flashing and Upload are non-combinable
  - Flashing and OBD in both directions are non-combinable
  - Upload and OBD in both directions are non-combinable
  - OBD in both directions are non-combinable
- $Type_B$-Conflicts
  - *TP_Connection_Channel*s with the same ID but different value for Node Address for Diagnose (NAD) are non-combinable
  - *TP_Connection_Channel*s with the same Slot-ID, Base-Cycle and Cycle-Repetition but different source address are non-combinable
- $Type_C$-Conflicts
  - The maximum configured parallel routing instances for CAN-CAN routing <= 30
  - The maximum configured parallel routing instances for CAN-FlexRay routing <= 8

Transport protocols implemented are based on the ISO standards, ISO 10681 for FlexRay TP [11], and ISO 15765 for CAN TP [7]. Handling $Type_B$- and $Type_C$-Conflicts during test lead to following maximum number of combinations in the first test phase:

- First sub-IPM
  - First SNR: 10 combinations
  - Second SNR: 152 combinations
  - Third SNR: 1 combination
  - Fourth SNR: 31 combinations
- Second sub-IPM
  - First SNR: 10 combinations
  - Second SNR: 78 combinations
  - Third SNR: 1 combination
  - Fourth SNR: 31 combinations
- Third sub-IPM
  - First SNR: 1 combination
  - Second SNR: 1 combination
  - Third SNR: 1 combination
  - Fourth SNR: 1 combination
- Fourth sub-IPM
  - First SNR: 1 combination
  - Second SNR: 1 combination
  - Third SNR: 1 combination
  - Fourth SNR: 1 combination

Table VI represents an example of a resulting combination from the first SNR of the first Sub-IPM. The first SNR of the first Sub-IPM consists of the groups G_1, G_2, G_3, G_4, G_{18} and G_{19} from table II. Following numbers of *TP_Routing_Instance*s have been selected to generate the first combination:

- 5 *TP_Routing_Instance*s from group G_1
- 8 *TP_Routing_Instance*s from group G_2
- 14 *TP_Routing_Instance*s from group G_3
- 3 *TP_Routing_Instance*s from group G_4

VI. Discussion

Depending on the grade of diversity in parameters for *TP_Connection_Channel*s and in connected networks; the number of formulated groups can increase. The idea is to cover the interactions between formulated groups instead of interactions between *TP_Routing_Instance*s. This helps in avoiding similar combinations and contribute to reduce the size of the test suit. If the number *N* of groups is high, either a *2-Wise* or *3-wise* coverage criteria can be used. A drawback of proposed approach is the need of system functionality expertise to define similarity criterion and calculate the Stress Factors of the groups. However this needs to be performed only once. Later on, for each new release of the system, combinations can be generated automatically.

VII. Conclusion and Future Work

In this paper, an approach for building a conflict-free IPM to test TP parallel routing on a vehicle gateway system has been proposed. Firstly, the approach utilizes defined similarity criteria to cluster system input parameters represented as *TP_Routing_Instance*s into groups stimulating similar behavior. Secondly, the two conflict handling methods *sub-models* and *avoid* are used to prohibit invalid combinations of *TP_Routing_Instance*s. In order to reduce the size of the test suite, two phases of testing have been suggested, testing TP parallel routing for SNRs in order to cover simple interactions between network pairs, and testing TP parallel routing for MNRs to cover complex interactions between multiple interacting networks. The proposed approach has been applied on a complex example of a gateway with five buses, 390 *TP_Routing_Instance*s and diverse conflicts. Generating test cases for resulting combinations from the first test phase and conducting the second test phase will be achieved in the future. Furthermore, a restbus simulation is under development to execute the generated test cases for build combinations.

TABLE II
FIRST SUB-IPM'S GROUPS

Groups	Network Relationship	Addressing Format	BS and STmin	Cycle Repetition	ID Type	Address Type	TP Routing Scenario
G_1 (19 elements)	1,2	Mixed	(32,0) (32,0)	-	Normal	Physical	S_1
G_2 (8 elements)	1,2	Normal	(32,0) (8,10)	-	Norma	Physicall	S_1

Automating Acceptance Testing with tool support

Tomasz Straszak, Michał Śmiałek

Email: {straszat, smialek}@iem.pw.edu.pl

***Abstract*—During acceptance testing different areas of delivered software system are reviewed. Usually these are functionality, business domain logic, non-functional characteristics, user interface. Although they are related to the same particular functional area, they are verified separately. This paper presents the concept and the Requirements Driven Software Testing (ReDSeT) tool, which allows for automatic integrated test generation based on different types of requirements. Tests are expressed in newly introduced Test Specification Language (TSL). The basis for functional test generation are detailed use case models. Furthermore, by combining different types of requirements, relations between tests are created. The constructed tool acknowledges validity of the presented concept.**

I. Introduction

SOFTWARE testing is one of the main steps of each development process. In this step the compliance of delivered software with the requirements is being verified. Verification procedures of comparing the system under development to its requirements and needs of its users are encapsulated in the form of acceptance tests [1]. These requirements should be understandable for the stakeholders and at the same time precise enough for the developers to produce efficient software.

To describe the expected functionality of the software system, use cases are commonly used [2]. Use cases describe interactions between external actors and the system, which lead to specific goals according to the given scenarios. Such requirements can be claimed as satisfactory to define the tests, that will be performed during acceptance testing.

A number of automatic test generation mechanisms based on use cases were proposed. Examples of such approaches can be found in work by El-Attar and Miller [3], Gutiérrez et al. [4], and Nebut et al. [5]. Beside use cases, requirement specifications contain other types of requirements, that describe different aspects of the desired software. These requirements should also be verified by executing corresponding tests. Some work has been done on the generation of tests based on business rules (see Junior et al. [6]), GUI requirements (see Bertolini and Mota [7]), and even on non-functional requirements (see Dyrkom and Wathne [8]).

All these mechanisms use model transformation, forming the area of Model-based testing (MBT), which is an evolving technique for generating suites of test cases from requirements [9]. Although different types of tests are generated from requirements models describing the same software system, usually they are not related, because they verify different aspects of the system.

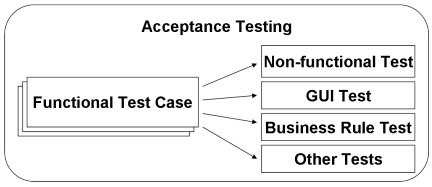

Fig. 1. Acceptance test suite based on functional test cases

This article extends the basic description of the idea presented in our previous work [10]. It focuses on automatic generation of different types of tests, integrated in functional test cases with test scenarios executed during acceptance testing. These tests are generated on the basis of interrelated requirements describing many aspects of the developed software system, making this idea MBT-compliant. The element that joins the different types of testing is the functional test case related to the use case scenario as shown in Figure 1.

This concept is based on the test metamodel defined as the Test Specification Language (TSL) and implemented within the ReDSeT tool (Requirements Driven Software Testing). The tests are generated automatically based on the requirement specification created with the Requirements Specification Language (RSL) [11]. As RSL provides notation for precise use case scenarios, generation of test cases verifying the system behaviour is significantly facilitated. Additional information contained in scenario sentences (notions from the domain vocabulary) and other related requirements allow for generating tests of different types. All the tests generated on the basis of RSL-based requirements form a complete test suite for acceptance testing.

II. Detailed requirements expressed in RSL

As in other test generation solutions, the basis for automatic generation of tests is the precise specification of requirements. As mentioned above, the described solution is based on requirements specifications created with RSL. The main features of this language are: clear separation of descriptions of the system's behaviour and descriptions of the system's domain. Functional requirements can be presented in three equivalent forms: structured text with hyperlinks to domain elements, an activity diagram or a sequence diagram. The elements describing the system's domain are depicted as notions on so-called notion diagrams. Each notion has operations that can be performed in regard to the particular notion. RSL allows for precise specification of requirements, which is understandable even for ordinary people who do not have technical expertise.

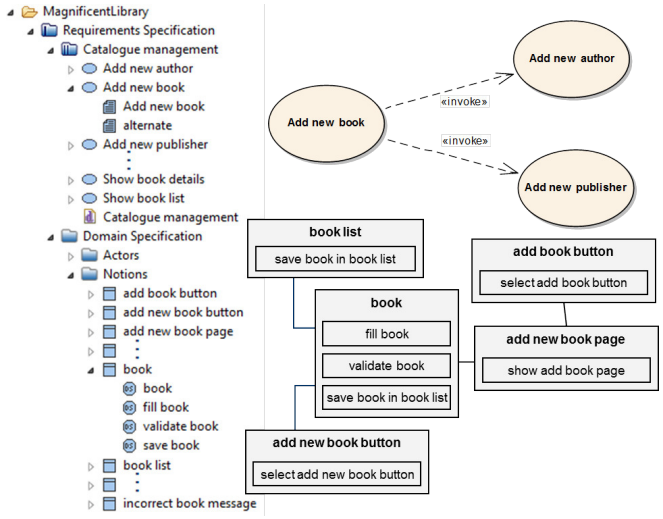

Fig. 2. Example of requirement specification structure, use cases and notion diagrams expressed with RSL

Main Scenario

precondition: book list is ready to add new book
1. User *selects* add new book button
2. System *shows* add new book page
=>invoke/INSERT Add new author
=>invoke/INSERT Add new publisher
3. User *fills* book
4. User *selects* add book button
5. System *validates* book
=>cond: book valid
6. System *saves* book in book list
final: success
postcondition: new book is added to book list

Alternate scenario

precondition: book list is ready to add new book
1. User *selects* add new book button
2. System *shows* add new book page
=>invoke/INSERT
=>invoke/INSERT
3. User *fills* book
4. User *selects* add book button
5. System *validates* book
=>cond: book invalid
5.1.1 System *shows* incorrect book me
final: failure
postcondition: book list has not changed

Fig. 3. Use case scenarios - textual representation

The language has a precise specification of its syntax and semantics [11] with methods of its use explained e.g. by Nowakowski et al. [12]. Figures 2, 3 and 4 shows an example requirements specification, created in RSL.

All the elements of a requirement specification are grouped in packages in a tree structure. Simple requirements described with free text can be used to define business rules or non-functional aspects of the system. Use cases defining the functionality of the system are described with structured scenarios (see Figure 3). Scenarios consist of numbered sentences in a simple grammar called SVO-O (Subject Verb Object - indirect Object). These sentences are constructed with notions stored in the domain vocabulary. This is illustrated with two scenarios (main and alternative) of the *Add new book* use case. The same information is presented in Figure 4 in the form of an activity diagram that is generated automatically from the scenarios.

The notions are referred-to in scenario sentences through hyperlinks (*book*, *book list*, *edit book button*, *edit book page*) and are presented on a notion diagram, that is similar to a class diagram. The relationships between notions, and notion operations are defined automatically according to the scenario sentences where these notions appear or are defined manually by the requirements engineer. The notions and their operations used in use case scenarios, describe the business logic and the user interface elements.

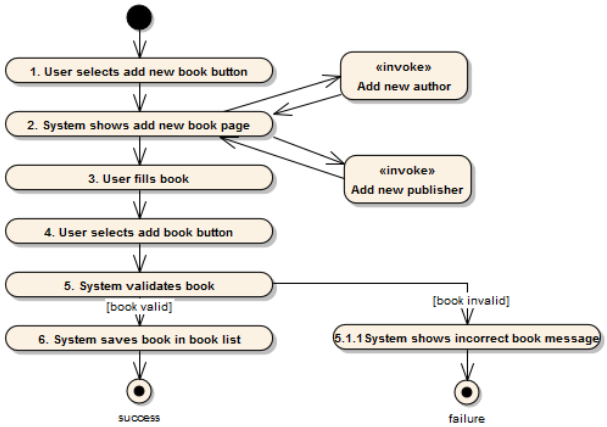

Fig. 4. Use case scenarios - activity representation

All the requirements can be related. To depict relations between use cases, a special invoke relationship is used (see Figures 2 and 4). It allows to determine under what conditions and in which step of a use case scenario another use case is to be called (see Nowakowski et al. [12] for more details). What is important, RSL is based on a formal metamodel. This allows for automatic processing of information contained in the requirement specification. This characteristics of RSL will be used for generating test cases.

III. Automating Test Generation

To define acceptance test suite and to ensure accurate and automatic transition from RSL-based requirements to tests, Test Specification Language (TSL) was developed. This language is based on a metamodel defined in the Eclipse Modeling Framework (EMF) [13] and is out of scope of this paper.

The main idea of TSL is to provide notation for reusable tests, that are understandable for non technical people and precise enough for detailed verification of the software system. All tests are grouped in a tree structure, called the Test Specification (see Figure 5), that groups tests assigned to a specific release of software. Each test contained in a test specification represents a procedure for verifying software in the context of a single requirement. Such a verification is made by examining all the check points defined inside the test.

The basic structure of a TSL test specification consists of two packages: Abstract Tests and Concrete Tests. The first of these includes tests generated directly from the requirement specification: mostly use case tests, notions, as well as tests of other types. A use case test corresponds to a use case, and includes test scenarios, as shown in Figure 5. Tests of other types, in addition to use case tests (verifying the behaviour of the system), can verify the business logic, user interface, non-functional aspects (performance, usability, etc.) or any other aspect of the system that is described through requirements.

A use case test scenario includes the initial condition (a precondition sentence) that must be met before the execution

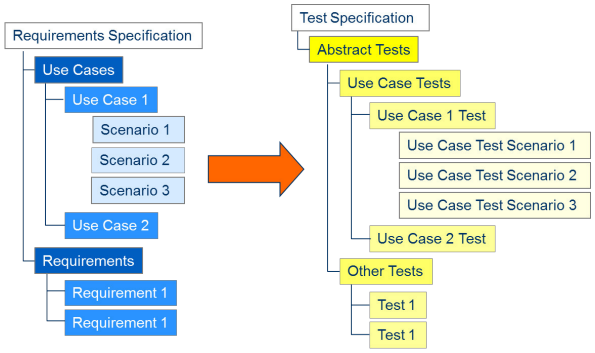

Fig. 5. Test generation based on the requirement specification

of actions described in this scenario and the final condition (a postcondition sentence) that describes the desired state of the system after the scenario is executed.

Every use case test scenario, generated from an RSL use case scenario, is a sequence of actions forming a dialogue between the primary actor and the system. Every such action is expressed by a single sentence in the SVO grammar (see Graham [14] for an original idea). These sentences describing single actions can have check points assigned. In addition to action sentences, two additional sentence types were introduced: condition and control sentences. They are used in a scenario to express the flow of control between alternative scenarios of the same use case as well as between scenarios of different use cases (see work by Śmiałek et al. [15]).

An important feature of requirement specified with RSL, is the possibility to create relationships. Due to generation of test specifications on the basis of these requirements, also relationships between tests can be created. The invocation relations between use cases are translated to become relations between use case tests. This provides information on the steps of the use case test scenario and on the conditions under which scenarios of other use case tests should be called. Relationships to other requirements are translated to relationships from use case tests to tests of other types.

Having two languages (RSL and TSL), which have definitions that are based on metamodels, automatic transformation from requirements to tests becomes possible also allowing for further acceptance test composition. There is a couple of common rules applied in the transformation:

- The structure of the packages containing use cases and notions is reflected in the structure of the packages in the Test Specification.
- Each element of a Test Specification that reflects an element of a requirement specification holds the identifier and the tree path of that element.

The transformation is performed in several steps according to the transformation procedure, that is presented in Figure 6. At the beginning of the transformation a new Test Specification structure is created (step 1). The basic Test Specification structure consists of a root node named using the pattern of "Software Case Name - date" and two child Test Packages named "Abstract Tests" and "Concrete Tests".

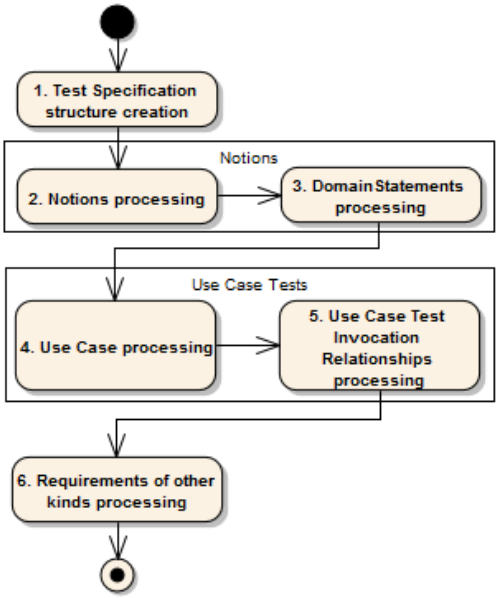

Fig. 6. RSL to TSL transformation procedure

All SVO sentences within the use case test scenarios are built of the notion's domain statements. For this reason, RSL notions should be transformed first (step 2). For each RSL notion, a TSL notion is created. The name, description and attached notion attributes are transferred.

For all TSL notions, domain statements contained in corresponding RSL notions are created (step 3). For each RSL notion, its domain statements are transferred into a TSL domain statement. The phrases contained in the RSL domain statement notions, used as direct and indirect objects, are pointed to by the *directNotion* and the *indirectNotion* attributes.

Having the notions with the domain statements transferred, the use case tests can be processed (step 4). For each RSL use case, a use case test is created and placed in a proper test package within the use case test structure. The name and the description are transferred directly. All the scenarios contained by the RSL use case are transferred into a use case test scenario. On the basis of the RSL scenario pre- and postcondition, adequate pre- and postonditions are created and attached to the use case test scenario. The sentences of the RSL scenarios are transferred into the correct specialisation of the use case test scenario sentence. The ordering number and the sentence text are set. For every SVO sentence, a proper domain statement is found and a relation to the corresponding domain statement is created. For every control sentence, a test invocation relationship is created with an empty use case test as its target.

The target use case tests of the test invocations are set after all the use cases are transferred into the use case tests (step 5). For each test invocation relationship contained in the control sentences, a correct use case test is found and set.

At the end of the transformation (step 6), tests of other kinds are created. Each RSL requirement that is not a use

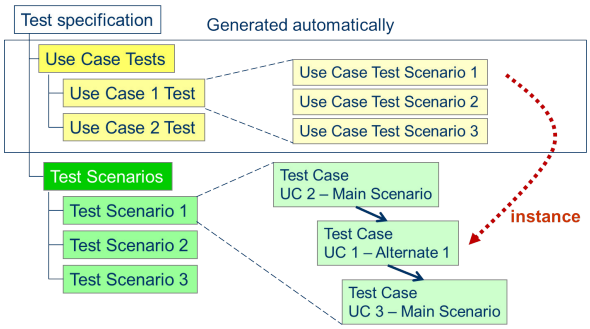

Fig. 7. Test scenarios composed of test cases

case and is classified as a requirement of specific type (e.g. business logic requirement, user interface requirement, non-functional requirement) is the basis for generating a test, which supplements use case tests, scenarios, sentences or notions. RSL requirements relations between use cases, notions and requirements of specific types are transformed into test relationships. As RSL currently does not support basic requirements of specific types, only non-functional requirements are automatically transformed into non-functional tests.

IV. Instantiating Tests

A scenario of a use case test determines the conditions, steps and check points that will be subject to verification for the use case implementation. These elements will be used in acceptance testing after placing them in test scenarios and assigning specific test data values. Test scenarios are grouped within second-level packages in the basic structure of a test specification named Concrete Tests, as shown in Figure 7. They are defined by a test engineer as a set of ordered instances of use case test scenarios, that we call test cases. A test case describes a procedure for verification of a system's functionality and is composed of ordered steps in the form of SVO sentences. Each step can contain check points with assigned test data values and can be related with instances of other type tests. These other test instances are automatically created during instantiation. They are related to a test case, just as abstract tests of other types are related to use case test scenarios and particular scenario sentences.

A test scenario constructed with test cases also builds the context for the test data. The initial test data values are set by the test engineer as the precondition values of the test scenario. Test data values describe basic business objects as well as GUI elements. The test data in the scope of one test scenario is passed between test cases as their pre- and postcondition values. The test data values are changing according to the functionality and the business logic that is under tests. It can be noted that although the test cases cannot be formally related to each other, within the manually created test scenarios, they indirectly refer to business processes that are implemented within the system being tested.

The instantiation procedure of a use case test scenario is performed in at least as much steps as the test scenario is supposed to have. Figure 8 presents the procedure for

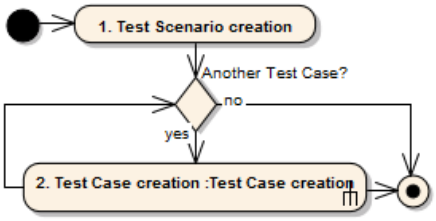

Fig. 8. Test Scenario creation procedure

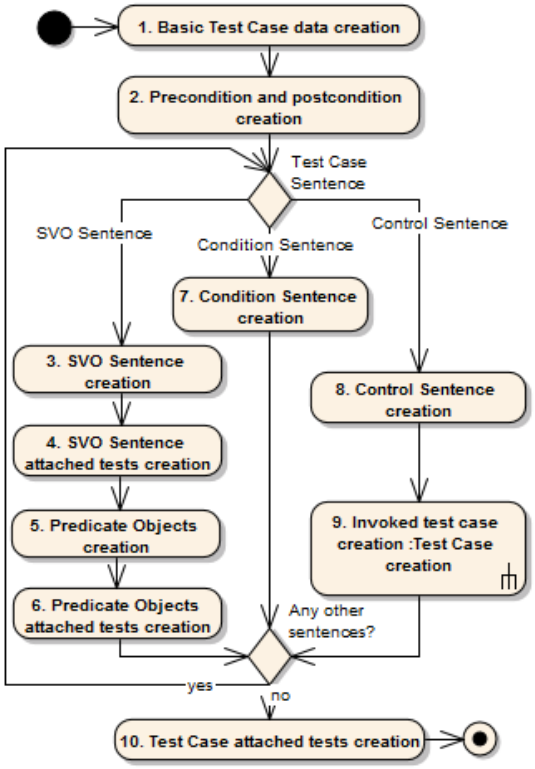

Fig. 9. Test Case instantiation procedure

test scenario creation. The test scenarios are inserted in the instance tests package. During creation, the name and the description of the test scenario should be given. All the steps of a test scenario are created as test cases. The number of test cases depends on the test engineer, who defines the steps of the test scenario. Each time a new test case is created, the instantiation procedure is performed. The procedure is presented in Figure 9.

At the beginning of the procedure, the test case order number is set. For each nested test case, the order number is segmented, e.g.: *2.3.1*. The name of the chosen use case test scenario and the description of the corresponding use case test are transferred into the test case (step 1), the same as for the use case test scenario pre- and postcondition (step 2).

Having the test case created, SVO, condition and invoke sentences are being created. SVO sentences (step 3) are transferred with their sentence order number and sentence text. Direct and indirect objects of the sentence predicates are

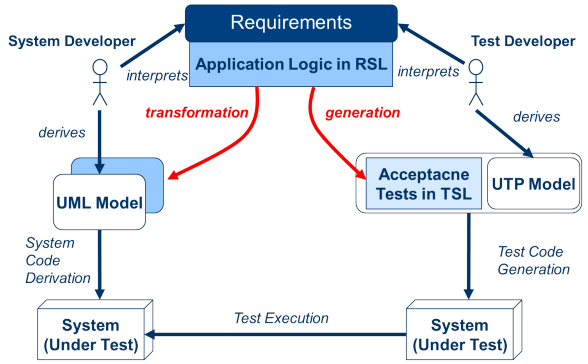

Fig. 10. TSL as UML Testing Profile complement

created on the basis of the direct and the indirect notions of the domain statement (step 5). All abstract tests of other types, related to the domain statement pointed to by the predicate relation and by the domain statements' direct notion and indirect notion relations, are transferred into adequate instance test specialisations (step 4 and 6). These instance tests of other types are contained in the SVO sentences of the test case and in the direct or the indirect object. The condition sentences are transferred with the sentence order number and the sentence text (step 7).

Depending on the test engineer's decision, the nested test case depicted by the control sentence can be created on the basis of a use case test related through a test invocation relationship to the currently processed use case test (step 8 and 9). If the use case test invocation is used, one of the invoked use case test scenarios in instantiated recursively. At the end all other abstract tests related to a use case test scenario are transferred into adequate instance test specialisations (step 10). These tests are contained within the test case.

V. TSL as an Extension of the UML Testing Profile

TSL can be seen as a stand-alone language but it can be easily interfaced with other languages for model-based testing. Prominently, it can be used in conjunction with the UML Testing Profile [16].

Figure 10 presents an appropriate usage scenario. Starting from requirements, a system developer delivers UML models, which are the basis for developing the system. The same requirements are used for manual creation of UTP models. On the basis of these test models, detailed unit and integration tests can be executed. However, this does not include high-level acceptance tests. Here, TSL offers an extension allowing to derive such tests directly and automatically from functional requirements.

The usage of RSL for defining application logic allows for automatic transformation of requirements into code and into acceptance tests in TSL. During these transformations, requirements-to-UML models and requirements-to-TSL-test traces are being created. These traces facilitate linking of UTP models with corresponding acceptance tests in TSL through UML models.

VI. Tool Support

The tool supporting the described idea of automatic test generation based on requirements is called ReDSeT (Requirements Driven Software Testing). It is based on the Eclipse Rich Client Platform. This enables integration with the ReDSeeDS tool (www.redseeds.eu, [17]) which provides advanced editors for requirements (for use cases, notions and other requirements) described with RSL. The generated test specification can be included in the same Eclipse project as the requirements specification and code. This allows for integration of activities at different stages of the software development project. As the repository of the test specification is based on the EMF technology [13], the TSL meta-model can be easily extended in order to handle other types of tests that are adapted to different types of requirements associated with use cases.

To start working with the ReDSeT tool, the requirement specification should be transformed into the test specification. When the automatic transformation is complete, the test engineer is able to manage the test specification organised in a tree structure using the Test Specification Browser and other dedicated editors enclosed in the ReDSeT perspective. Use case tests and use case test scenarios, along with test scenarios and test cases are presented in the Test Editor area. The Detailed Test View is dedicated for viewing check points and editing test values contained in all the types of tests. To create test scenarios and to instantiate use case test scenarios as test cases, dedicated wizards are available.

In order to perform acceptance tests according to test scenarios defined in the ReDSeT tool, the test execution scripts need to be generated. The test scripts, that are composed of test cases, contain detailed steps for the testers in the form of structured text. Each line represents one test with its name, description, input data values and expected state of the system for the specified elements.

The example of test execution script in the form of a CSV text file is presented in figure 11. The rows describing steps of a test scenario have solid background and are shown as numbered test cases. Each sentence of the test case is numbered with the test case number and the SVO sentence number. For each direct and indirect object of the SVO sentence, an additional row for data input or output appears. For example, in the step *2.1 SVO 3*, there are presented the input test data and the values for the author attribute (row number *2.1.SVO 3 DirObj*). Additional tests of other types, related to a sentence or to a direct or indirect object appear as separate rows. For example, a GUI test is presented in the step *2 SVO 2 DirObjGui Test*. This test is attached to the direct object of the step *2 SVO 2*.

On the basis of such a test execution script, the testers can verify the delivered software system. The results of each test step can be noted in an additional column. In case the test fails, the corresponding requirement can be found by tracing to the appropriate requirements element. The implementation units can be precisely located by examining traces to code, as described by Śmiałek et al. [18].

Test Type	Step	Test Name	Description	Test Data	Input Value	Characteristic to test	Expected result
Test Case	1	Show book list	---	---	---	---	---
SVO Sentence	1 SVO 1	User selects show book list button	---	---	---	---	---
Domain Object	1 SVO 1 DirObj	show book list button	---	---	---	---	---
SVO Sentence	1 SVO 2	System fetches book list	---	---	---	---	---
Domain Object	1 SVO 2 DirObj	book list	---	---	---	---	---
SVO Sentence	1 SVO 3	System shows book list page	---	---	---	---	---
Domain Object	1 SVO 3 DirObj	book list page	---	---	---	---	---
Test Case	2	Add new book	---	---	---	---	---
SVO Sentence	2 SVO 1	User selects add new book button	---	---	---	---	---
Domain Object	2 SVO 1 DirObj	add new book button	---	---	---	---	---
SVO Sentence	2 SVO 2	System shows add new book page	---	---	---	---	---
Domain Object	2 SVO 2 DirObj	add new book page	---	---	---	---	---
GUI Test	2 SVO 2 DirObjGUI Test	Asterisk marking mandatory fields	Empty mandatory fields should be marked with asterisk	---	---	Asterisk marking mandatory fields, when they are set	Empt mandatory fields marked with asterisk
Control Sentence	2 Control	INSERT Add new author	---	---	---	---	---
Test Case	2.1	Add new author	---	---	---	---	---
SVO Sentence	2.1 SVO 1	User selects add new author button	---	---	---	---	---
Domain Object	2.1 SVO 1 DirObj	add new author button	---	---	---	---	---
SVO Sentence	2.1 SVO 2	System shows add new author page	---	---	---	---	---

VII. Conclusion

The proposed idea and the ReDSeT tool bring a complete solution for creating acceptance tests for the systems that are focused on user-system interaction. The preparation of test specifications can begin during the requirements formulation stage. Consecutive generation of tests allows to reach test complexity that corresponds to the level of detail of the final requirements. The basis for creation of a set of test scenarios are detailed use cases. Requirements defined in RSL significantly facilitate automatic test generation, and TSL allows for expressing interrelated tests in a way that is comprehensible to the audience responsible for acceptance testing. It can be noted that the proposed method is based on black box testing and is independent of the implementation technology of the system under test. On the other hand, since RSL and TSL are based on metamodels, the whole idea is close to Model Based Testing which goes into the details of system design.

In terms of future work, traces from requirements to test cases are planned to be used for generating requirements with test coverage reports. These traces will be subject to further research on regression test selection. Another area that is planned to be a subject of further research is using RSL, TSL and model transformations [19] as implementation of Test Driven Development (TDD) [20] and Behaviour Driven Development (BDD) [21]. These ideas assume that test effort is already incorporated at an earlier point of software development process. The proposed solution seems to have potential for automating the process of generating unit and acceptance tests and executing them on the basis of RSL requirements. It is also planned to develop the mechanism for extracting of test scripts as input for tools that automate test execution (e.g. IBM Rational Functional Tester, Selenium). It would bring a complete solution for detailed use case based testing.

Abstractions on Test Design Techniques

Marc-Florian Wendland
Systems Quality Center
Fraunhofer Institute FOKUS
Berlin, Germany
marc-florian.wendland@fokus.fraunhofer.de

***Abstract*—Automated test design is an approach to test design in which automata are utilized for generating test artifacts such as test cases and test data from a formal test basis, most often called test model. A test generator operates on such a test model to meet a certain test coverage goal. In the plethora of the approaches, tools and standards for model-based test design, the test design techniques to be applied and test coverage goals to be met are not part of the test model, which may easily lead to difficulties regarding comprehensibility and repeatability of the test design process. This paper analyzes current approaches to and languages for automated model-based test design and shows that they are lacking important information about the applied test design techniques. Based on this analysis, we propose to introduce another layer of abstraction for expressing test design techniques in a tool-independent, yet generic way.**

Keywords- Model-based testing (MBT), test generation, automated test design, test design techniques, UML Testing Profile (UTP)

I. INTRODUCTION

THE degree of automation in industrial software testing was consequently raised within the last two decades. In the 1990s, efforts had been undertaken to increase the degree of automation for test execution, resulting in today's accepted technologies like keyword-driven testing [3]. Standards have been built upon this principle like TTCN-3[1] or the newly developed ISO 29119 [9] standards family. With the wide-spread acceptance of UML in the late 1990s and the advent of UML 2 early 2000s, the idea to automate also parts of the test design activities was pursued in research and industry. The outcome of these efforts is what is known today as model-based testing (MBT) and test generation. Both, automation of test execution and automation of test design rely on abstraction of irrelevant details. Of course, when it comes down to actually test execution, the abstracted details need to be provided, but this is commonly accepted to be pertinent and indispensable. In keyword-driven testing approaches, the so called adaptation layer is in charge of making logical test cases executable [21].

[1] http://www.ttcn-3.org

The UML Testing Profile (UTP) [12] is a modeling language for MBT approaches based on the UML. It is the first industry-driven, standardized modeling language for MBT. It was adopted by the Object Management Group (OMG) as far back as 2003 and is currently under major revision. In addition, the European Telecommunications Standardizations Institute (ETSI) has funded efforts to develop its own modeling language for MBT, called Test Description Language (TDL). Thus, two important technical standardization bodies offer languages to build MBT methodologies upon.

Interestingly, none of the above mentioned standards provides concepts to specify the test design techniques that shall be applied for test generation. This seems inconsistent, since one of the most communicated benefits of MBT is automated generation of test artifacts and the increased systematics, comprehensibility and repeatability of the test design process [20]. Until today, there is no generally accepted approach found in the literature how test design techniques for model-based test generation shall be specified the best. In fact, almost every test generator provides its own proprietary configuration for specifying the test coverage goal. This lead to several issues regarding comprehensibility and repeatability the automated test design activities. Moreover, the exchangeability of test generators on models, even of the same modeling language, becomes risky since it bears a great potential for loss of relevant knowledge.

This paper addresses the abstraction from technical, tool-dependent representations of test design techniques by providing an extensible language framework for specifying tool-independent test design techniques that can be shared across multiple test generators. This step is a consequent evolution of the automation through abstraction principle already applied in keyword-driven testing or test generation. The contributions of the work are:

- A thorough analysis of current approaches to model-based test generation.
- The development of a conceptual model of test design based on the ISO 29110 standard. The conceptual model builds the foundation on which the abstractions of test design techniques rely on.

978-83-60810-58-3/$25.00

- The refinement of the conceptual model with an approach to test generation that is motivated by means of directives and strategies.
- Provision of an extensible, yet flexible UML profile-based implementation of the refined conceptual model as an extension to the UTP

The remainder of this paper is structured as follows:

Section 2 describes the problems of today's approaches to automated test design from the viewpoint of comprehensibility and repeatability. Section 3 elaborates the conceptual model of test design and the refinement towards test design directives and test design strategies. Section 4 discusses the extension of the UTP with test design directives and test design strategies. Section 5 demonstrates the feasibility of our approach by applying it to two non-commercial test generators, i.e., the Spec Explorer and Graphwalker. Section 6 presents the work related to ours. Finally, section 7 concludes our work and highlights future work in that context.

II. Problem Statement

Most of the today's model-based test generators are able to work on UML or derivatives. In this paper, we employ the SpecExplorer[2] and the Graphwalker[3] generation engine that do not operate directly on UML, but on closely related concepts. The SpecExplorer input is actually based on a textual representation of an Abstract State Machine (ASM) [7] which is called Spec#. On contrast, the input for Graphwalker is GraphML, a XML format for describing graph structures. Both test generators can operate on graph structures, although the input format is different. These input formats can be derived from UML behaviors, though. In the last years, we have in particular integrated these two test generators with UTP, which allows us to generate the required input format from the very same UTP model for both generators ([23], [22]). Our overall vision is to integrate a wide variety of test generators with UTP to counteract the broadening of proprietary, yet technically incompatible modeling languages.

Hence, the following problem statement was identified in the context of MBT with UTP, so is the technical solution presented in this paper. The conceptual solution, however, is not bound to any particular modeling language.

A. Test Design Techniques in MBT

If we consider the commonly understood advantages of MBT – such as efficient solutions for test design, increasing the degree of automation, prevention of loss of knowledge by using (semi-)formal models, more systematic and, even most important, repeatability of test case derivation and self-explanatory of test specifications ([20],[6]) – MBT comes along with an indispensable change of paradigms for testing activities. The most central artifact in an MBT approach should be the model itself, so test processes have to move from a document-centric to a model-centric paradigm. A model that describes test-relevant information from a tester's point of view is called *test model*. A test model is a "… model that specifies various testing aspects, such as test objectives, test plans, test architecture, test cases, test data etc." [12]. The UTP, in combination with UML, provides a test engineer with numerous possibilities for building test models, since it offers the expressiveness of UML and amends it with test-specific artifacts. Thus, UTP is deemed suitable to support the change to the model-centric paradigm where test models are single source of truth. Even though not as a dedicated concept, UTP allows for modeling the inputs for test generation just by relying on the underlying UML concepts. Inputs to test generation are referred to as test model in the ISO 29119 terminology as well. To avoid confusion with the much broader understanding of a test model given by the UTP specification, we henceforth refer to inputs to test generation as test design models. ISO 29119 defines test design as all activities in a test process that actually derive test cases, test data and test configuration from test conditions. This derivation may be carried out automatically or manually. The term automated test design is commonly known as test generation.

Even though UTP is an expressive language, it does not offer concepts to specify the test design techniques that shall be applied for deriving test artifact. If we consider the before mentioned benefits of MBT, first and foremost test generation, it is most surprising that one of the most important information for automating the test design activities is missing in the test model: The information about which test design techniques shall be carried out on the test design model by the test generator. In other words, the information why a certain test artifact has been generated is not part of the test model. As a matter of fact, today's test generators define their own proprietary presentation of test design techniques that resides within the tool. It complicates, however, the application of an entire model-centric approach to testing, for it does not allow integrating all the required information into the test model. This can have severe implications, since it may easily happen that the applied test generator shall be replaced, for whatever reason, while the defined test design techniques shall be retained. If this happened and access to the previous test generator is not given any longer, the information where a certain test artifact originated from in the first place is lost.

Figure 1 (a) illustrates this problem in a three-layered-approach. The domain layer encodes the test model (more specific, the test design model), which it is completely decoupled from a certain test generator and simply focus on the specification of a system under test. The engine layer, in

[2] http://research.microsoft.com/en-us/projects/specexplorer/
[3] http://www.graphwalker.org

TABLE I.
INVESTIGATION OF TEST GENERATORS

Generator	Input	Output	Configuration	Paradigm	License
Spec Explorer	Spec# (C#)	NUnit Test Cases	Coord Language	1-way (not centric)	Free
MBTsuite	UML Activity / StateMachines	Proprietary	Settings in the tool	1-way (not centric)	Commercial
Conformiq	UML-approximated StateMachine	Proprietary	Settings in the tool	1-way (not centric)	Commercial
Graphwalker	GraphML	Sequence of Strings	Command line parameter	1-way (not centric)	Open Source
Tedeso	UML approximated-Activity	Proprietary	Settings in the tool	1-way (not centric)	Commercial
CertifyIT	UML and OCL	Proprietary	Settings in the tool	1-way (not centric)	Commercial

contrast, is the most fundamental component of a test generator. It is, conversely, completely decoupled from the domain layer and simply operates on its inputs, without taking into account where that input comes from. Both capabilities, complexity and underlying principle of the engine layer vary among test generators from powerful symbolic execution (like the SpecExplorer) to a simple traversal engine that simply operates on already explored graph structures such as finite state machines (like the Graphwalker). Regardless how powerful or sophisticated the generation engine actually is, it is necessary to transform the information encoded in the domain layer into a format understood by the generation layer. A mediator, an adaptation layer, is required. An adaptation layer is a tool-specific component that serves two purposes. First, it transforms (***γ(i)***) the input ***i*** (i.e., a test design model contained in the test model) into a format understood by the test generation engine. Secondly, it offers some kind of interface to the test analyst in order to configure the generation engine. We call this the configuration (***c***) of a test generator. The configuration contains the information of which test design technique shall be applied to the input i. For example, the SpecExplorer is configured with a proprietary language called coord. If the user wants to ensure a certain traversal order of events, he/she has to specify a regular expression over events. This is called a scenario in coord terminology. The semantics of the coord scenario matches with the standardized specification-based test design technique scenario testing in ISO 29119. This information ought to be part of the test model for it contains important test-relevant information to comprehend the automated test design activities. This holds true for other test design techniques and further test generators as well. TABLE I lists a few of the commercially relevant or prominent open source test generators that fit into our view of MBT. Interestingly, all of the investigated generators do offer proprietary means to configure the generation engine. Furthermore, none of these generators really follow the model-centric paradigm, since they simply employ the test design models for the purpose of test generation. There is commonly no feedback of the generated test cases into the test model in order to abide by the single source of truth principle as proposed and described by Wendland ([23], [24]). This is a situation we strive to improve with our work with our work.

B. *Abstractions of Test Design Techniques*

We propose to abstract from a tool-specific representation to tool-independent representation of test design techniques. Fig. 1 b) illustrates this abstraction. The configuration (shaded grey) are extracted from the tool-specific layer and abstracted (***α(i)***) to test design techniques that are part of the test model itself. The adaptation layer is still required to transform the input ***i*** (i.e., the test design model plus tool-independent test design techniques) into the input format ***γ(i)*** for the generation engine. As such, it is possible to share test design techniques across multiple test generators that provide an adapter for the utilized test design technique. With test design techniques removed from the realm of a specific test case generator and becoming part of the test model a more holistic approach to test design is being provided and the process gains transparency, repeatability and comprehensibility. Such an approach is in-line with the idea of abstraction for test generation as it is done for MBT [18], but for the specification of test design techniques instead of the test design model. This abstraction of test design techniques has not yet been discussed in the literature.

III. A CONCEPTUAL MODEL OF TEST DESIGN

The conceptual field of test design techniques is actually well known. Several academic and industrial literature deals with the application and formalization of test design techniques for different test design models. A good overview is given by Utting [21] and ISO 29119-4 [9]. Based on the concepts and terminology provided in ISO 29119, a conceptual model of test design can be deduced (see Fig. 2) which will be explained in great detail in the subsequent sections.

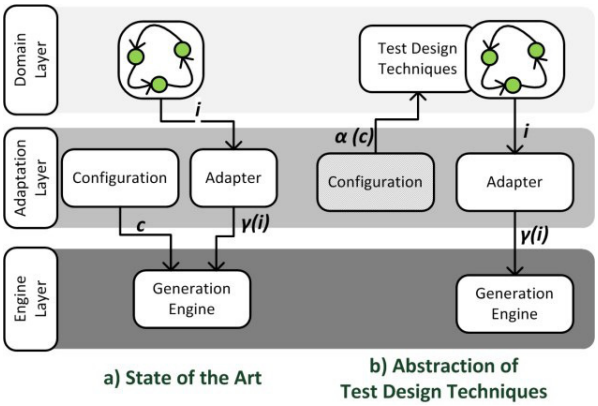

Fig. 1 Abstraction of test design techniques

A. The Principles of Test Design

The derivation of test artifacts is usually done by applying a test design technique, or ad-hoc if no systematic approach is applied. A test design technique is a method or a process, often supported by dedicated tooling that derives a set of test coverage items from an appropriate test design model. The test design model is obtained from the identified test conditions. According to ISO 29119, a test condition is a "testable aspect of a component or system, such as a function, transaction, feature, quality attribute, or structural element identified as a basis for testing." A test analyst utilizes the information accompanied with the test conditions to construct the test design model in whatever representation. This gave rise to Robert Binder's famous quote that testing is always model-based [1]. A test design model refers to a specification of the expected behavior of the system under test that is represented either as mental model, informal model, semi-formal model, or formal model.

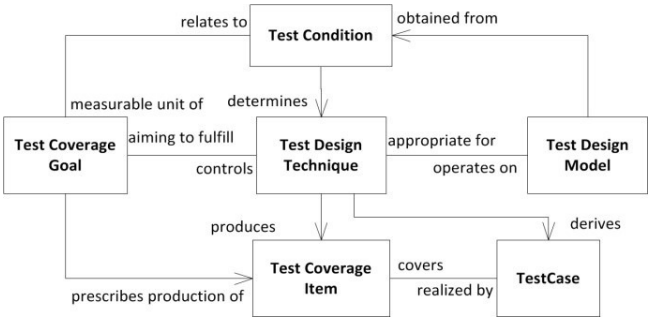

Fig. 2 A conceptual model of test design

As always with models [19] the test design model must be appropriate for the test design technique to be applied. An inappropriate model might not be able to produce an optimal result. The details of a test design model can usually be derived from the test conditions of the test basis.

There is a correlation between the test design technique and the test design model, however, since both are determined or influenced by the test conditions. For example, if the test condition indicates that the system under test might assume different states while operating, the test design model may result in a finite state machine (FSM) or similar. Consequently, a test design technique (like state-based test design) is most likely to be applied on this test design model.

A test design technique tries to fulfill a certain test coverage goal (the term used by ISO 29119 is *Suspension Criteria*, which is actually not that commonly understood). A test coverage goal determines the number and kind of test coverage items that have to be derived from a test design model and represented as test cases. The actual derivation activity might be carried out manually or in an automated manner.

A test coverage item is an "attribute or combination of attributes to be exercised by a test case that is derived from one or more test conditions by using a test design technique" [9]. The term test coverage item has been newly introduced by ISO 29119, thus, it is expected not to be fully understood at first sight. A test coverage item is usually been obtained from the test condition, and made been explicit (in a sense of that it can be used for coverage analysis etc.) through a test design technique. The following example discusses the subtle differences between test condition, test design model and test coverage item:

Let us assume there is a functional requirement that says the following: "If the On-Button is pushed and the **system** is *off*, the **system** shall be *energized*."

The bold words indicate the system under test, the italic words potential states the system under test shall assume und the underlined word an action that triggers a state change. According to ISO 29119, all the identifiable states (and the transitions and the events) encoded in the functional requirement represent the test conditions for that system under test. A state machine according to the test conditions would represent the test design model. As test design technique could be decided to be structural coverage criterion like transition coverage or similar. The test coverage goal would represent a measurable statement about what shall be covered after the test design technique has operated on the test design model. This might be one of Chow's N-Switch-Coverage 0 like full 1-Switch-Coverage (or transition-pair coverage). The test coverage items would eventually be represented by all transition pairs that have been derived by the test generator, and which are finally covered by test cases.

However, there are certain inaccuracies in the ISO 29119's test design concepts which are subsequently classified into three issues.

1) Test Coverage Calculation

At first, the term *test coverage*, defined by ISO 29119 as the "degree, expressed as a percentage, to which specified coverage items have been exercised by a test case or test cases", does not take the actual number of potentially

available test coverage items into account. According to the given definition of test coverage, the coverage would always be 100% since it is calculated on the actual derived test coverage items. What is missing is a calculation of all test coverage items that actually should be derived. Otherwise, it would be possible to state that 100% test coverage has been achieved, even though just 10% of all to be covered test conditions were actually covered. This is in particular relevant for model-based approaches to test design, for the test coverage items are usually not explicitly stored for further test case derivation, but rather automatically transformed into test cases by the test generator on the fly. This means that in today's model-based test generators the test cases always cover 100% of the derived test coverage items. This is just consequent, since the test coverage items were derived according to a specific test coverage goal, thus, the test design technique only selected those test coverage items (out of all potentially reachable test coverage items) that are required to fulfill the test coverage goal. Ending up in a situation where the eventually derived test cases would not cover 100% of the produced test coverage items would violate the whole idea of specifying test coverage goals.

2) Output of Test Design Techniques

Test design techniques do not only derive test cases, but also test data or test configurations. The test design process deals with the derivation of all aspects that are relevant for finally executing test cases. The test configuration or test interface (i.e., the identification of the system under tests, its interfaces and the communication channels among the test environment and the system under test) is a crucial part of each test case, when it comes down to execution. Same, of course, holds true for test data. In this paper we deal not with the generation of test configuration, however, test data generation is covered.

3) Test Design Techniques Are Not Monolithic

The concept of a test design technique, as defined and described by ISO 29119, needs to be further differentiated. In relevant, yet established standards for industrial software testing (such as ISO 29119, IEEE:829 and ISTQB) a test design technique is described as a monolithic concept. This is not the case, because the actual test derivation process consists of a number of techniques that represent distinguished course of actions to achieve test coverage. These courses of actions operate in combination with each other to derive the desired test coverage items. Those techniques contribute their semantics to the overall test design activity for a given test design model. Examples for well-known strategies are structural coverage criteria or equivalence partitioning, but also less obvious and rather implicit strategies like the naming of test cases or the physical structure or representation format of test cases. For example, the so called State-Transition test design technique might be based on an extended Finite State Machine (EFSM). Hence, the sole application of structural coverage criteria (like all-transition-coverage etc.) might not suffice to produce executable test cases, for EFSM may also deal with data inputs, guard conditions etc. By adding also data-related techniques (such as equivalence partitioning) to structural coverage criteria, it is possible to explore and unfold the EFSM into an FSM that ultimately represents the available test coverage items for finally deriving test cases. So, the discussion gives rise to the fact that the conceptual model of ISO 29119 regarding test design techniques shall be further differentiated to allow combining several test design techniques with each other in a systematic manner.

B. Towards Strategies and Directives

When further differentiating the concept of test design technique, a wider search beyond the field of testing of software systems seems to be appropriate. Based on what was discussed earlier, test design techniques are required to be grouped by different test design process, thus, they are reusable. Test design techniques are consequently decomposed into a thing that groups different techniques and the techniques themselves. This conceptual structure is similar to the Business Motivation Model (BMM) [14] concepts for directives and strategies (see Fig. 3). We adapt the terms directives and strategies for the scope test design.

The BMM provides a fine-grained conceptual model to analyze the visions, reasons and influencers of a business (or endeavor) in order to deduce its overall motivation. The BMM is enunciated in the Semantics of Business Vocabulary and Business Rules (SBVR) [15], a standard which is by the OMG, a standard which is adopted by the OMG to formalize a vocabulary for semantically documentation of an organization's business facts, plans and rules.

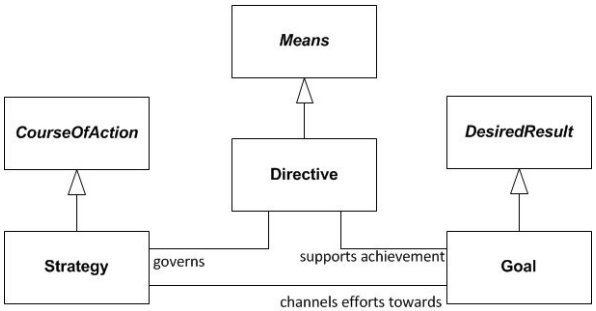

Fig. 3 Relations of Strategy, Directive and Goal

Notwithstanding the motivation for BMM to apply directives is outside of MBT in the first place, the BMM contains concepts and notations that can be beneficial to the realization of test design directives and test design strategies. According to BMM a *directive* is a means to achieve a certain goal. A *goal* is a statement about a state or condition of the endeavor to be brought about or sustained through appropriate *means*. Therefore, a directive (as specialized

means) utilizes (a set of) strategies that are governed by the directive to achieve the goal. A *strategy* channels efforts towards the achievement of that goal. This means that the same strategy can be utilized by different directives in order to achieve different goals, hence, strategies are reusable across directives. The notions of strategy, directive and goal can be mapped to the *business* test design. The BMM goal would map almost inherently to the ISO 29119 concept test coverage goal. As with a goal, a test coverage goal imposes a condition on the test design activity that need to be achieved in order to deem the test design activity completed. Since BMM strategies are the actual actions that need to be carried out in a controlled manner, the notation of BMM strategy stands for a single test design technique, such as equivalence partitioning, all-transition-coverage or similar. The directive, however, does not have a direct counterpart in the ISO 29119 conceptual model on test design. From a logical point of view, it is part of the test design technique concept even though not explicitly enunciated. We are going to leverage the notion of strategies and directives for the area of model-based test generation in order to refine the ISO 29119 conceptual model with test design strategies and directives that replaces the monolithic test design technique.

C. Refined Conceptual Model of Test Design

This section mitigates the conceptual imprecisions of the ISO 29119 conceptual model of test design by further differentiating the test design technique into test design directives and test design strategies. These notions are adopted from the BMM. Fig. 4 shows the redefined test design conceptual model in which the monolithic test design technique is split up into test design strategy and test design directive.

A *test design strategy* describes a single, yet combinable (thus, not isolated) technique to derive test coverage items from a certain test design model either in an automated manner (i.e., by using a test generator) or manually (i.e., performed by a test analyst). A test design strategy represents the logic of a certain test design technique (such as structural coverage criteria or equivalence partitioning) in a tool- and methodology-independent way and is understood as logical instructions for the entity that finally carries out the test derivation activity. Test design strategies are decoupled from the test design model, since the semantics of a test design strategy can be applied to various test design models. This gives rise to the fact that test design strategies can be reused across different test design models. This fits with the more general notation of a strategy that can be utilized by several means. The intrinsic semantics of a test design strategy, however, needs always be interpreted and applied within the context of a test design model. According to and slightly adapted from the BMM, this context is identified by a test design directive.

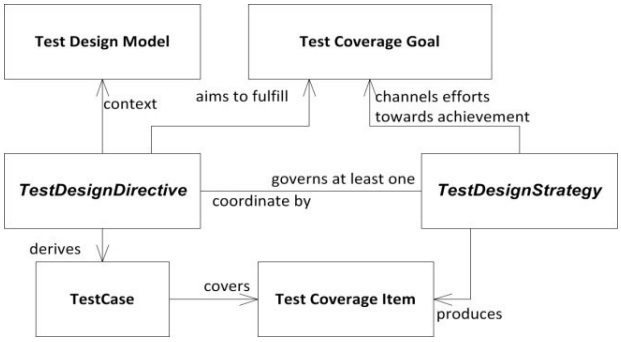

Fig. 4 Redefined conceptual model on test design

A *test design directive* governs an arbitrary number of test design strategies that a certain test derivation entity has to obey to within the context of a test design model. A test design directive is in charge of achieving the test coverage goal. Therefore, it assembles appropriately deemed test design strategies to eventual fulfill the test coverage goal. The assembled test design strategies, however, channel the efforts of their intrinsic semantics towards the achievement of the test coverage goal. The test coverage items that are produced by test design strategies are always fully covered, thus, they are reduced to a pure transient concept. According to Fig. 1 b), the test design directive will be passed to the tool-specific adaptation layer, since it is the test design directive that has access to all required information. At first, it specifies the test design models out of which test artifacts shall be generated. Next, it governs the test design strategies that shall operate on the test design models. In the next sections, we show an implementation of the conceptual model as UML profile.

IV. A Language Framework for Test Design

The implementation of the refined ISO 29119 conceptual model on test design was from the very first idea incepted as an extension of the UTP. This mitigates one of the most obvious deficiencies of the UTP and allows the creation of fully comprehensible test models. The extension is kept most flexible, so that new test design directives and test design strategies can be easily incorporated.

A. Realization as UML Profile

Since the test design framework has to be kept minimalistic and left open for multiple modeling and testing methodologies, it is important to find a means to not being too intrusive while defining the framework. Fortunately, a UML profile grants all capabilities of MOF-based metamodels, so it is possible to utilize the concepts of derived unions and subsetting properties. Fig. 5 shows the elements of the language framework.

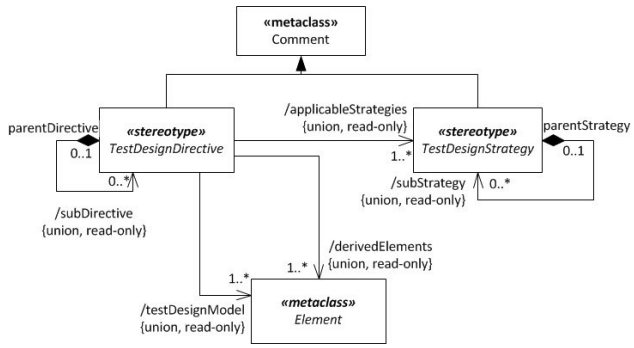

Fig. 5 A UML profile of test design

Both stereotypes test design strategy and test design directive extend the UML metaclass *Comment.* Comment is a semantic-free element of UML, usually used to add notes or documentations to other elements. Applying a test design strategy stereotype onto a Comment turns the Comment into a test design strategy. Same, of course, holds true for test design directive. According to the BMM and the refined ISO 29119 conceptual model of test design, a test design directives establishes associations to one or multiple test design strategies. This means that a test design directive might be composed of several test design strategies. Both test design strategy and test design directive are abstract concepts which means they need to be further specialized in order to be applicable. This is, of course, on purpose, since it is infeasible to foresee each and every test design directive or test design strategy of every existing or new methodology in the future. Thus, the language framework must under all circumstances not restrict a test analyst if he/she wants to define new test design strategies or directives.

A test design directive establishes two further associations to the most fundamental metaclass in the UML metamodel, i.e., *Element*. One association captures the semantics of identifying the allowed test design models for a specialized test design directive, the other represents a trace link to the actually derived elements. The language is again left open as much as possible, because there is no reason why a certain elements of UML should be spared out as test design model or generated element. As with the associations to test design strategies, the specializations of test design directives are responsible to fill these derived unions with reasonable information.

The main benefit and most powerful characteristics of the language framework is the fact that an appropriate tooling can access all available information of any existing specialized test design strategy or test design directive by using the MOF reflection capability at runtime (i.e., modeling time). This enables tool vendors to build a complete and sophisticated tooling on basis of this minimalistic framework without taking care of future extensions. As soon as new specializations of test design strategies and directives are made accessible to the modeling tool, they can be utilized at once.

B. Libraries of Test Design Strategies

As already stated in section *Towards Strategies and Directives*, test design strategies bear the potential to be leveraged by different test design directives. It is not possible to navigate from a test design strategy to a test design library explicitly (it has to be said that the MOF capabilities allows the navigation of so called non-navigable association ends – this is an essential precondition for the language frameworks adaptability). A test design strategy actually does not have to be aware with which test design directives it is associated with, since the evaluation and realization of the semantics of a test design strategy in the context of a test design model is done by the adaptation layer of a test generator. On domain level, it is sufficient to limit the combination of test design strategies in the context of test design directives. Since test design strategies are more or less autarkic concepts, it is possible to develop libraries of well-known and accepted test design strategies and to make them accessible to the developer of a new test design directive.

Predefined libraries for test design strategies make in particular sense when it is prescribed (by a standard or company-wide test strategy or policy) which test design strategies are permitted within the test process. By building libraries (and appropriate tool support), test managers or test analyst are able to define a canonical list of test design strategies that shall be exclusively used. This counteracts, for example, violations of such test strategies and fosters, at the same time, consistency among different test design activities of the same test process.

C. Integration of Test Generator Capabilities

In order to integrate on the language framework, it is required that each integrated test generator need to propagate its meta-information into the language framework. The most important meta-information [5], of course, is the information about which test design strategies the test generator can realize via its adaptation layer. The language framework provides all required information to enunciate these meta-information. Fig. 6 illustrates the integration of the SpecExplorer and Graphwalker with the language framework.

D. Provision of Test Generation Services

As a proof-of-concept, we have combined the language framework with the existing UTP and integrated it into our academic test modeling environment Fokus!MBT [24]. As test generators we employed the previously mentioned Graphwalker and SpecExplorer. As part of the tool integration, we created two test design directives (one for each test generator) with appropriate test design strategies. The result can be seen in Fig. 6.

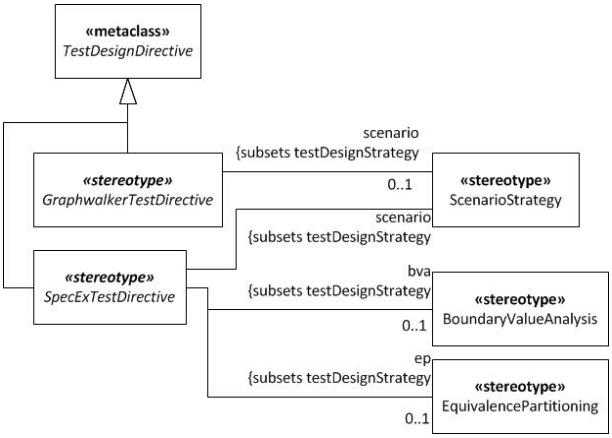

Fig. 6 Definition of test design directives

In Fokus!MBT, a test design directive is considered to identify an accessible test generation service. A test generation service is in its simplest essence a single test generator that is integrated with the language framework. However, a test generation service might also consist of a set of test generators realizing the associated test design strategies. The term test generation service abstracts from the physical representation of the test generation approach.

A test design directive is tightly bound to a test generation service, which in turn comes along with an appropriate adaptation layer. Since Fokus!MBT is based on Eclipse, we utilize the extension point mechanism of Eclipse to identify a test generation service by means of the test design directive. The input validation process is crucial, since only test design models the adapter can map into the input format of its respective engine are allowed to be passed to the engine. In Fokus!MBT, a specialized test design directive can be associated with a set of validation constraints. What is not shown in this picture is the case, if the input validation detects constraint violations. If this happens, the tester is notified about the details of the input validation process.

V. EVALUATION

Let us assume we have an EFSM as test design model that consists of five states and five transitions and a global state variable *x* of type Integer. The according state machine is defined by the following state-transition-table (TABLE II):

TABLE II.
EXAMPLE EFSM

Source	Input (i)	Action	Output (o)	Target
initial	-	x := 0	-	*s1*
s1	i ≥ 0 and i ≤ 5	x:= x+i	x	*s2*
s1	i = 1000	x:= x+i	x	*s3*
s2	i = 3	x:= x-i	x	*accepting*
s3	-	x:= x-5	x	*accepting*

This implies that there are two paths available, which are *sc1* = {*initial→s1, s1→s2, s2→accepting*} and *sc2* = {*initial→s1, s1→s3, s3→accepting*}, where → denote the transition. There are no further guard conditions defined on the transitions for the sake of simplicity. Let us further assume that we want to apply the scenario test design strategy with both the Graphwalker and SpecExplorer engine, where the desired scenario is *sc1*. In addition, we want to apply boundary value analysis, if data generation is possible. So, we define the following two test design directives:

```
SpecExTestDirective 'specex' :=
      testDesignModel = EFSM
      testDesignStrategies :={
       scenario {events = sc1} and
       boundary value analysis {values = 1}
      }

GraphwalkerTestDirective 'gw' :=
      testDesignModel := EFSM
      testDesignStrategies :={
       scenario{events=sc1}
      }
```

The SpecExplorer is capable of generating inputs based on given constraints. The transition *S1→S2* has a constraint defined that the input value must be in a range [0..5]. In Fokus!MBT, range constraints are modeled as UML::Interval. As said before, the configuration of the SpecExplorer engine I s done via *coord*. The respective adaptation layer transforms the test design directive and the referenced test design model into the coord representation. The scenario test design directive is transformed into a SpecExplorer scenario, which is then further used for the exploration. The transformation of the EFSM into the ASM is not part of the paper. Please refer to the DOME case study of the REMICS case study.

In contrast, the *GraphwalkerTestDirective* does not have a test design strategy for boundary value analysis defined, since the generation engine is not capable of generating input values.

After executing bot test generation services, the following test coverage items have been derived:

- SpecExplorer – 2 Test Cases

  #1: *initial→s1(-/-),s1→s2(0/0), s2→s3(3/-2)*
  #2: *initial→s1(-/-),s1→s2(5/5), s2→s3(3/2)*
- Graphwalker – 1 Test Case

  #1:initial→s1,s1→s2, s2→s3

This result is not surprising since the Graphwalker is not able to generate any data at all. Depending on the applied methodology to test generation, this might be not a problem. As a matter of fact, the resulting test cases are mostly of abstract nature, i.e., they are lacking concrete data. These

data information need to be applied later on in order to make the test cases executable.

VI. Related Work

The term *test directive* was firstly introduced and defined by [2] in her PhD as "… a collection of test-specific information which, when combined with the system model, derives a test model." The PhD of Dai, however, dealt solely with the derivation of test configurations from existing system models. Therefore, she treated test directives as specifications of single model-to-model transformation rules in a platform-independent manner. The set of combined test directives yielded a complete transformation which generated a test configuration. Our approach, in contrast, deals with the generation of test cases and test data in addition to test configuration.

Friske [5] presented an early idea to specify test coverage goals in generator-independent manner. He leveraged OCL in the context of UML State Machines to define structural coverage criteria like transition coverage or 1-Switch coverage 0. They specified two requirements for the integration of arbitrary test generators into their OCL framework. Firstly, the test generator to be integrated had to follow a two-step generation process. The first step has to generate the test goals (or test coverage items as defined by ISO 29119, the second step to derive test cases from these test goals. The second requirement requests that each generator publishes its metadata regarding its generation capabilities. The idea is quite similar to what we proposed in our work, however, there is no proof-of-concept described that actually realizes the pure theoretically OCL-based approach. Furthermore, it is not clear how strategies for automated test design can be integrated that are not pertinent to the generation of test coverage items (or test goals) but to the derivation of test cases from these test coverage items. For example, the strategies how generated test cases shall be named or finally realized in a compositional sense (decompose test case behavior into several separated pieces of behavior or build monolithic test case behaviors) are essential decision in each test design activity. In our approach, such adjacent strategies can be integrated in the same way as any other strategy. Finally, our experiences with the application of model-based testing techniques in the industry have shown that most testers are not familiar with formal languages like OCL.

Fourneret et al. [4] have presented an approach to model-based security verification and testing of smart-cards based on a dedicated language for security properties. The language is integrated with the UMLsec approach [10] and allows test engineers specifying what a security test generation shall generate. Thus, it enables domain experts to express the strategies for the test generation approach in a non-technical way. A proof-of-concept was done with the commercial CertifyIt [4] test generation tool. The specific test design strategies of that language could be integrated with the test design directives framework in order to make them applicable outside of UMLsec.

Wendland has used of test directives in the context of MBT based on a proprietary metamodel for testing purposes [22]. This work can be seen as the very first approach for an abstracted view on test design techniques based on test directives. Back in those days, the notion of test strategies was not used, though. In contrast, to the work presented in this paper, the former approach tried to develop a modeling framework that was intended to condense the indivisible parts of test design techniques in order to construct a concrete test design technique dynamically. This was much too complex, and yet not applicable.

VII. Conclusion and Future Work

In this paper we had dealt with abstractions of test design techniques in the realm of automated test design based in the context of MBT. We had clearly identified the problem statement that today's approaches to MBT are not that comprehensible, repeatable and flexible as the existing academic and industrial literature in the last decade promised to be. In fact, a full understanding of the automated test design activities within an MBT approach requires access to the applied test generator(s), since they keep the knowledge of the applied test design techniques. This is the main challenge we addressed in this paper. The overall aim is to finally capture all test-relevant information independent of any implementation within the test model itself. This is the only way to ensure a seamless change of paradigms from document-centric to model-centric testing activities. Therefore, we analyzed the conceptual domain of test design compliant with the ISO 29119 standard. We described three issues of the ISO 29119 conceptual model on test design and mitigated them by introducing the notions of test design strategies and test design directives. These pure conceptual notions were subsequently mapped onto a concrete language framework realized as a UML profile. This profile is a most minimalistic realization of the conceptual model and integrates well with the UTP. The reason to go for a UML profile was a natural decision in our work in order to fill the conceptual gap of UTP regarding the specification of test design techniques. Finally, as a proof-of-concept we have described and illustrated how the language framework can be integrated into modeling environments. We therefore used our academic test modeling environment Fokus!MBT[5]. The illustrated proof-of-concept was kept minimal since it was not the scope of the paper to describe a full case study.

The experiences we made and results we obtained from the integration of SpecExplorer and Graphwalker on UTP

[4] http://www.smartesting.com
[5] http://www.fokusmbt.com

and the suggested language framework gave confidence that every of the listed test generators in this paper can be integrated with this approach. Another side-effect of the language framework is that the concatenation of different test generations engines can be achieved rather easily [11].

Future work in the realm of standardization will in particular be channeled towards the new major revision of the UML Testing Profile, which is currently undergoing. As said before, the absence of a facility to specify test design techniques on model level was already complained about. The requirements document of the new UTP version [16] requests precisely such a facility. Our contribution in this area will be minimal language framework presented in section *A Language Framework for Test Design*.

While writing this paper, we are already working on the integration of a usage-based test generator [8] and behavioral and data fuzzing generator [18] with the proposed language framework in the context of the EU project MIDAS[6] w

To conclude the achievements of our work, we have shown that different test generators are able to be integrated on an abstracted representation of commonly accepted (or proprietary) test design techniques. In addition, we think this language framework is flexible to allow for a fine-grained adjustment of applied test design techniques. Our work fills the conceptual gap of MBT approaches in this regards and, thus, allows for a more holistic and comprehensible approach for automated test design based on (semi-)formal models.

ACKNOWLEDGMENT

Most parts of the work presented in this paper were funded by the EU projects REMICS (no. 257793) and MIDAS (no. 318786).

***Abstract*—This paper describes how the proven test design technique of the classification tree method is extended within the classification tree editor in order to contribute to current test design matters. The classification tree editor not only provides the tooling to use the method but also to apply new and helpful features in the test design process. This includes the automatic generation of test cases and test sequences according to desired test depth and focus, automated boundary value analysis, various tool couplings to integrate in each individual test process and supporting features like test evaluation or test coverage analysis amongst others.**

***Keywords*-classification tree method; classification tree editor; combinatorial interaction testing;**

I. Introduction

THE classification tree method [1] as well as the editor [2] have been developed at Daimler's research department for software technology in the 90ties. In the last 20 years both, method and tool became proven in practice around the world.

The classification tree method as a black box test design technique was introduced by Matthias Grochtmann and Klaus Grimm in 1993 [1]. The basic idea of the classification tree method is to separate the input data characteristics of the system under test into different classes that directly reflect the relevant test scenarios. The descriptive method covers the categories of test case design needed in industry, such as *equivalence class tests*, *boundary value analysis* [3], *interface testing*, as well as *combinatorial* [4] and *statistical testing* [5].

In the last 6 years where Berner and Mattner took over the further development of the classification tree method and the editor, it got extended by academic research results and industrial input. This includes additional statistical testing methods [5], a professional requirements tracing [6], a synchronization to test management, test evaluation, coverage analysis or support for website testing [7]. The classification tree editor supports thus the tester in the test design phase. It offers multiple functions to structure the test problem, to systematically generate test scenarios and to do all this within the scope of the testers environment.

The outline of this paper is as follows: Section II introduces the classification tree method, while Section III shows how it will prove to serve testers needs for a more automated way in designing test cases within the classification tree editor. Section IV the integration into the test process with requirements and test management tools are introduced. Section V details Excel import and combinatorial test coverage analysis, test evaluation is given in Section VI. Related work can be found in Section VII, while conclusion is drawn in Section VIII.

II. Test Case Design using the Classification Tree Method

A. How to create a classification tree

The basic idea of the classification tree method is to separate the input data characteristics of the system under test into different classes that directly reflect the relevant test scenarios (*classifications*) [1]. The main source of information is the specification of the system under test or a functional understanding of the system should no specification exist. Two significant steps must be performed to create a classification tree:

- The identification of relevant factors involves the determination and structuring of the relevant test scenarios and their interrelations to other parts of the system under test.
- The test specifications combine the relevant factors needed in order to achieve the desired test coverage.

The first phase begins with the identification of the classifications that are relevant for testing based on a functional description and understanding of the system under test. For each classification, there may be several input data that are all to be considered during testing, the *classes* of a classification.

Each classification should have a limited number of clearly defined input scenarios for the system under test. The input data characteristics are used to define the input ranges required for the relevant test scenarios. This is a classification in the mathematical sense: The set of all possible inputs is disjointly and completely classified into subsets - the classes. The separation based on the input data characteristics is done independently for each test scenario, and can therefore be done easily.

This approach applies the concept of equivalence class testing [3]: Testing with a data item that is representative of an equivalence class makes tests with all other elements of the same class redundant and therefore unnecessary because

978-83-60810-58-3/$25.00

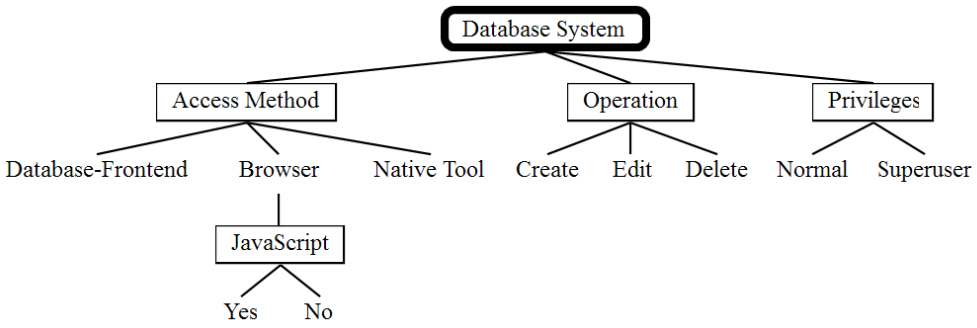

Fig. 1. Test Object *Database Management System*

there should be no difference in how they are handled during execution of the system under test.

Example. Figure 1 shows a classification tree for a database management system. Three aspects of interest (*Access Method*, *Operation* and *Privileges*) have been identified for the system under test. The classifications are partitioned into classes which represent the partitioning of the concrete input values. In our example the refinement aspect *JavaScript* is identified for the class *Browser* and it is divided further into two classes *Yes* and *No*.

B. Dependency Rules

Often, there are dependencies or constraints [8] between some classes of the classification tree. To overcome this design gap, the CTE offers to describe the relationships between the elements of the classification tree by defining dependency rules. The classification tree editor provides two mechanisms for defining dependency rules:

1) Logical dependency rules between the classes of a classification tree using propositional logic. The result is that test cases that would not fulfill the previously defined rules are not generated and vice versa [9].
2) Numerical dependencies between the classifications using logical and numerical operators. They serve to express mathematical dependencies between the elements of the classification tree [10].

C. Boundary Value Analysis

The boundary value analysis [3] is a helpful tool to run an analysis automatically with user specified input. There are two ways of applying the boundary value analysis within the CTE. The first is for an initial analysis, the second is to analyze and expand a classification tree with more possible parameters and intervals see Fig. 2.

For the initial analysis, the CTE supports to create parameters and intervals. For each interval it is possible to set the boundary borders so that CTE will create the corresponding boundary values. The classification tree is created from the specified values.

For the analysis or expansion of the tree, the CTE loads the existing data into its own data model. Then it is possible to add new parameters and intervals. The CTE then generates the boundary values and adds additional elements to the tree.

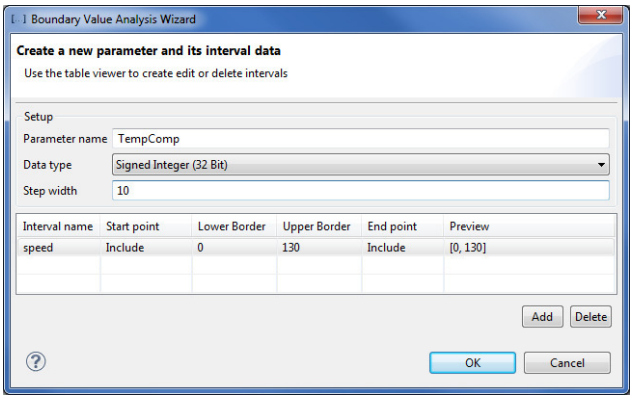

Fig. 2. Parameter and interval settings in CTE

III. Test Case Generation Facilities within the CTE

In practice, not every test generation mechanism is applicable to every test problem. Thus, there are numerous facilities available within the classification tree editor (CTE) in order to serve testers in many ways. The following test case generation mechanisms are implemented in the CTE.

- combinatorial test case generation
- prioritized test case generation
- test sequence generation

A. Combinatorial Test Case Generation

For combinatorial testing, the question is on how to achieve adequate test coverage without having to test too much. Complex software testing problems easily reach a maximum number of test cases of several billions. This is not feasible to handle. So a wise, structured and reproducible selection of test cases according to the current test problem saves effort, time and helps to actually better understand the testing focus. For this, combinatorial testing with all of its aspects is ideal. It brings variation to a test suite with a clear definition of the test intensity.

The CTE offers combinatorial test case generation facilities that support the structured variation [5], [9]. This includes pairwise combination, threewise combination, minimal test coverage and individual combinatorial rules.

The minimal combination $A + B$ ensures that each class of classification A and each class of classification B is considered in at least one test case.

The pairwise combination $(A_1, \ldots, A_n)$ ensures that each class of the classifications A_1 to A_n is combined pairwise with every other class in at least one test case.

The threewise combination $(A_1, \ldots, A_n)$ ensures that every possible combination of three classes of the different classifications A_1 to A_n is generated in at least one test case.

Higher strength interaction coverage can be achieved by practical testing approaches [11]. The key to unlocking better performance for higher strengths of interaction, seems to rely upon the use of constraints, which reduce the number of possibilities to be considered. In CTE, constraints are defined in terms of dependency rules.

Individual combination rules may be designed upon the needs of each test problem. All standard operators are available for that.

Logical expressions are used to formulate dependency rules. The CTE XL allows to specify any kind of logical dependency rules, containing {*AND*, *OR*, *NOT*, $\Rightarrow$, $\Leftrightarrow$, *XOR*, *NOR*, *NAND* }. Parentheses are used to formulate more complex expressions [9].

B. Prioritized Test Case Generation

In addition to the above mentioned classical combinatorial test case generation, the CTE offers the possibility to add weights to classes for a prioritized test case generation [5].

Weights on classes can be used to create test cases in an order corresponding to their relevance. For example, those tests that have revealed most of the failures in previous runs can be executed more frequently.

Within CTE, weights are distributed to classes in order to generate prioritized test cases according to occurrence, error or risk probability. The result is a test suite of tests covering the pairwise combination criterion and being sorted according to their relevance most relevant test cases at the top of the test suite, least relevant at the bottom [12]. By using the optimize menu, the tester can adjust the test suite individually by selecting the weighted coverage see Fig. 3.

C. Test Sequence Generation

Many software-based systems are state-based. Thus, test data used in test steps of one test sequence must provide a logical sequence to run the desired state transitions. The manual modeling of test sequences important for testing is a challenging task for the tester. Within the CTE this can be done automatically [13].

The tester defines simple state machines [14], modeling the behavior of the system see Fig. 4. Test cases are then derived from that.

A possible application for Hardware-in-the-loop testing has been discussed recently [15].

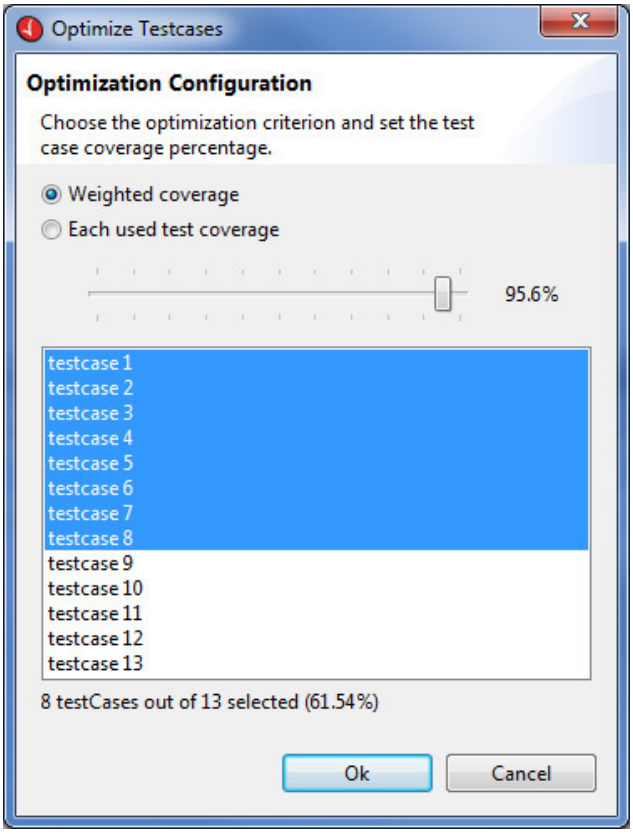

Fig. 3. Optimizing test suites according to weighted coverage in CTE

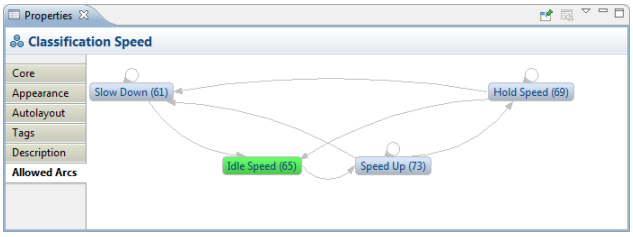

Fig. 4. Allowed arcs for the example classification speed in CTE

IV. Requirements Tracing and Test Management

A. Requirements Tracing within CTE

In the development process, test design is not the first action to take. Before even thinking about testing, the function must be specified. For this, there are several requirements management tools on the market which serve to define and monitor specifications.

For test design, a connection to those requirements might be a huge advantage with regard to traceability. Also, when linking requirements to test cases, gaps can be detected.

The CTE offers the tester to link tree elements and test cases to requirements from MS Access or IBM Rational DOORS [6]. The result is a requirements matrix that directly shows where there is still work to do (Fig. 5). Linked and not yet used requirements can be visualized.

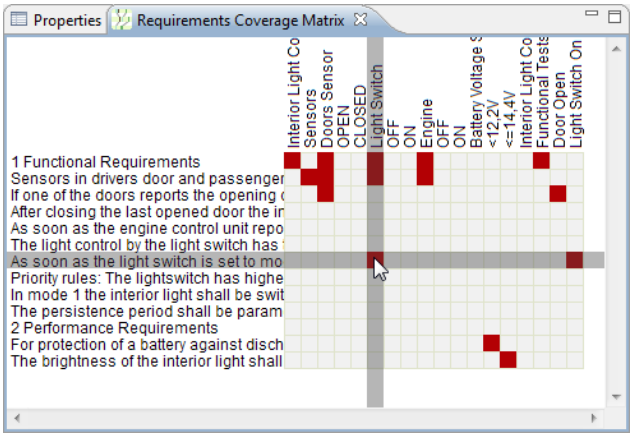

Fig. 5. Requirements matrix view in CTE showing linked CTE objects

Often, requirements change in the process. For this, synchronizing the changed database shows the tester in CTE where to modify the classification tree in order to be conform to the specification [6].

This connection is currently one way to get information from DOORS to use in CTE. In several practical projects, a bidirectional connection has been established, where the results from CTE were exported to the corresponding DOORS module.

B. Test Management in CTE

Parallel to all activities in the test process, test management is essential. For this, CTE synchronizes with HP ALM to commit or submit test cases from and to the test management tool. All information relevant to the tester will be downloaded from the server and also uploaded with updated data. This is supported by a comprehensive mapping mechanism in CTE (Fig. 6). The classification tree will be saved to the central folder on the server in order to make it available for other users for systematic testing.

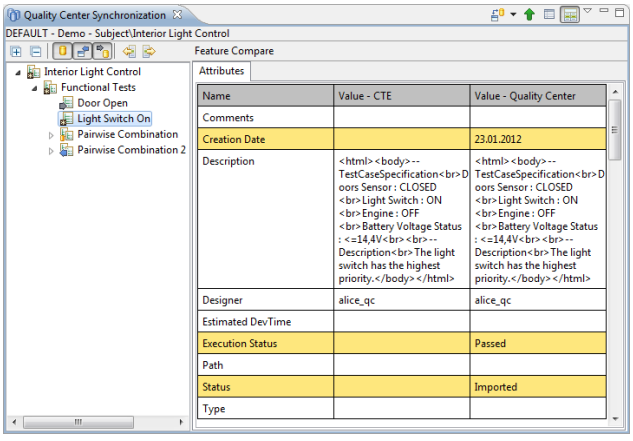

Fig. 6. CTE view of the HP ALM synchronization status after adding new values

Currently, the synchronization is made with the test plan module. For future work, it is planned to extend that connection to the requirements information in order to have a consistent and traceable process, and to extend it to read the information from the test lab which shows information to evaluate the performed tests.

V. Excel Import and Coverage Analysis

A. Excel Import

The most common tool for test design is Excel. There are many different ways in practice to use it within the testing process. With this background, an Excel import to continue with a systematic testing approach in essential.

All Excel sheets no matter if the column or the rows represent the test cases are imported into CTE, as well as the already defined test cases. So the classification tree is built, the test cases are imported and further combinatorial testing can be performed.

B. Coverage Analysis

In practice, the need to give a value for coverage increases. The tester needs to know how *good* the defined test cases are. Within the CTE, the coverage analysis gives a basic overview of the covered tuples see Fig. 7.

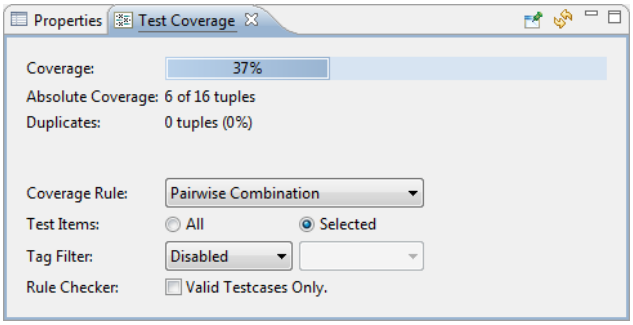

Fig. 7. Test coverage of a set of existing test cases to the coverage rule pairwise combination

If we refer to the Excel import above, it is hard to tell how good or bad the manually defined test cases that have been imported are. With the coverage analysis function, these imported test cases can be compared to specific generation criteria like the pairwise rule, or the minimal coverage rule. According to the result, test suites can then be complemented in order to reach the desired coverage criteria.

VI. Test Evaluation

Throughout the test process, test evaluation is the final step to determine the relevance of the test results. Within CTE, test results for test cases can be either imported or added and then evaluated. The CTE can track test results in terms of *Passed*, *Failed*, *Error*, *Not Executed*. By means of a root cause analysis, the error rate of single classes can be detected and thus gives important information on possible defects of the system under test.

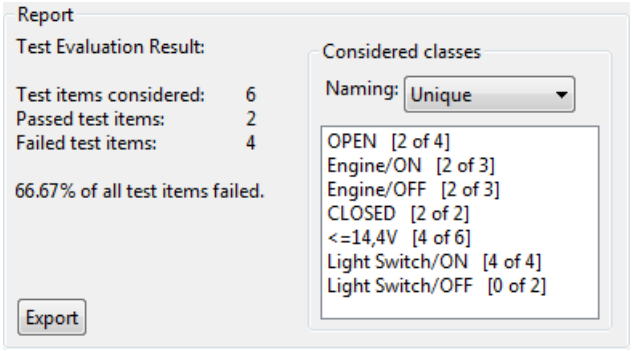

Fig. 8. Test evaluation report in CTE showing the considered test items and their failure rate

In the example given in Fig. 8, six test cases were considered for evaluation: Two passed while four failed. For all failed test cases, detailed results are given in the right part of the Figure, e.g. whenever *OPEN* was used in a test case, it failed two of four times. The last two entries *Light Switch/ON* and *Light Switch/OFF* are most interesting here: Whenever *Light Switch* was *ON*, the test case failed while with *Light Switch ON* there were no problems at all.

VII. Related Work

There is a broad body of work on combinatorial (interaction) testing [4], [16]–[25].

Elbaum et al. provide good overviews of existing prioritization approaches [26]. There has been some work on test case prioritization that considered limited resources [27], [28]. There are some known algorithm supporting prioritized test case generation. The first is an algorithm published in [29], which is an extension to [30]. For efficiency reasons, this algorithm does not consider constraints. The other approach supports constraints and is based on Binary Decision Diagram (BDD) [31]. CTE XL Professional also uses the latter [5], [12]. Search based solutions for test case generations have been presented for both, conventional [8], [32] and prioritized [33] test case generation.

A body of work on the application of the classification tree method and CTE can be found in recent work [34]–[37].

An introduction to root cause analysis can be found in [38], while there are several case studies available, e.g. [39]. The idea of combining the field of (combinatorial) testing with (root) cause analysis is not new, e.g. Cleve and Zeller try to find failure causes through automated testing [40]. The reduction of test suites down to failure-causing combinations is the background of [41], [42], so this approach might not fit too well for regression testing, where new errors can occur. The adaptation of combinatorial testing has also been discussed more recently in [43]. Beside widely positive works, Ramler et al. see limitations with the integration of cause analysis to combinatorial testing, although there is customer demand [44].

VIII. Conclusion

Regardless of the system under test, level of integration, test phase and domain, the classification tree editor is universally applicable [34]–[37]. This method has found a worldwide acceptance over the last two decades and has been used by commercial data processing, aviation and aerospace industries, and many others, for example, for examining the Hubble Space Telescope [45].

The systematic approach, starting from functional requirements, with understandable, reliable (intermediate) results, supported by an efficient, automatic test case generation, ensures that there are no gaps in the testing process and the resulting specifications.

Future work is twofold, first to ease the creation of classification trees, e.g. by importing logs [46] and second the transformation of test specification from the CTE to executable test cases.

***Abstract*—Model-based testing is a technique for generating test cases from a test model. Various notations and techniques have been used to express the test model and generate test cases from those models. Many use customized modelling languages and in-depth white-box static analysis for test generation. This allows for optimizing generated tests to specific paths in the model. Others use general-purpose programming languages and light-weight black-box dynamic analysis. While this light-weight approach allows for quick prototyping and easier integration with existing tools and user skills, optimizing the resulting test suite becomes more challenging since less information about the possible paths is available. In this paper, we present and compare three approaches to such black-box optimization.**

Keywords—model based testing; test automation; evaluation; test generation; optimization

I. Introduction

MODEL-BASED testing (MBT) [1] is a technique for generating test cases from a test model. As opposed to manual test design, where a test expert designs test cases one by one, in MBT the test expert designs a test model to represent the system behavior and uses an MBT generator tool to generate a set of test cases from it.

As the generator can potentially create a very large number of test cases for any non-trivial model, optimization approaches are often applied to choose which tests to include in the generated set. Many optimization solutions [2, 3, 4, 1, 5] use a custom notation combined with a specialized runtime environment to represent the test model, allowing for performing an in-depth white-box static analysis, e.g., symbolic execution, of the model. Tools such as constraint solvers can then be applied on this information to find test cases that yield short paths to reach given coverage targets [3, 6, 5]. Some use manually crafted scenarios to guide the generator towards specific paths [2].

In our work, we have aimed to provide light-weight solutions suitable for easy industry adoption and to support a fast iterative testing process through rapid prototyping of test models, test generation, and test execution, while still providing good test coverage and useful test results. We use a general-purpose programming language (Java) to represent our test models, allowing use of all language features, tools, libraries, and the standard (Java) virtual machine (JVM) runtime. This enables using existing development skills and toolsets such as test libraries and environments, integrated development environments, and continuous integration systems, along with any features they provide. Our open-source test generator called OSMO Tester [7] has been successfully applied, together with industry partners, to test large scale real industry systems.

Our test model is as an executable program, executed in different ways by the generator to produce test cases. We allow use of different, evolving versions of the language platform (virtual machine) and features to create the model and run the generator on it. As the model can make use of third-party libraries and networked services, we assume no access to source code or even all binaries for analysis. Such limitations are common in practical settings (e.g. [8]). In this context, we cannot apply approaches based on white-box static analysis but rather rely on dynamic analysis and information available at runtime. We call this type of test generation *model-based black-box test generation*. While there has been extensive research into optimizing test generation using static analysis based approaches, little work exists in optimizing model-based black-box test generation.

In this paper, we describe three algorithms for optimizing test generation in this type of an environment. All of them are based on generating a large set of potential tests in parallel and picking the most optimal ones based on given coverage criteria. One is targeted at *online testing* where test generation and execution are interleaved. Two others are targeted at *offline testing* where the test set is first generated and later executed in a separate phase. We compare the strengths and weaknesses of the three algorithms and make usage recommendations.

The rest of the paper is structured as follows. Section II presents background on our modelling notation and test generator. It also defines how we assess achieved test coverage over the test model. Section III presents our optimization algorithms. In Section IV, we evaluate each algorithm individually in terms of achieved coverage, generation time and test length. In Section V, we compare the different approaches to each other. In Section VI, we compare our results with related work. We conclude in Section VII with a summary of the paper and discussion of future research directions.

II. Background

To provide background for the following sections, we first briefly outline our modelling notation and model structure and describe our notion of test coverage, including how model elements are used to calculate coverage.

978-83-60810-58-3/$25.00

A. Modelling Notation

OSMO Tester uses a generic programming language (Java) as the modelling language. The models are executable and capture a set of possible test steps and how they can be combined to produce valid test cases. To generate test cases, the test generator executes different paths through the model which is often referred as a *model program* [9, 10]. In Figure 1, we illustrate our notation using a simple test model for a counter which can perform two functions: *increase* (the value of the counter by one) and *decrease* (the value of the counter by one). For illustration purposes, we will later use '+' to represent the increase step and '-' the decrease step.

In this model, the *system under test* (SUT) is represented by the *sut* variable. This example illustrates an *online* testing approach where the test steps are concretely executed against the SUT as they are generated. In an *offline* approach, the test steps yield a script which also includes the input for the SUT and the checks to perform against its states and output.

```
1: public class CounterModel {
2:  @Variable  //annotation to identify interesting model state to generator
3:  private int value = 0;
4:  private Counter sut = new Counter();
5:  private Requirements req = new Requirements();
6:  @BeforeTest
7:  public void start() {
8:    value = 0;
9:    sut.reset();
10: }
11:  @Guard("decrease")
12:  public boolean allowDecrease() {
13:    return value > 1; //when true, "decrease" is enabled
14:  }
15:  @TestStep("decrease") //enabled when above guard true
16:  public void decreaseCounter() {
17:    value--; //updates our model state
18:    sut.decrease(); //execute test step on SUT
19:    assertEquals(value, sut.value); //test oracle, check model vs SUT
20:    req.covered("decrease"); //user defined coverage requirement
21:  }
22:  @TestStep("increase") //has no guards, so is always enabled
23:  public void increaseCounter() {
24:    value++; //updates our model state
25:    sut.increase(); //execute test step on SUT
26:    assertEquals(value, sut.value); //test oracle, check model vs SUT
27:    req.covered("increase"); //user defined coverage requirement
28:  }
29:  @CoverageValue( public String zero() {
30:    return "" + (value == 0);
31:  }
```

Figure 1. Example counter model program.

The two basic model elements here are the methods annotated with *@TestStep* and *@Guard*. The *@TestStep* methods represent test steps that are executed by the test generator at different times to produce a test case. In MBT, these are also referred to as *actions* [11] and *action methods* [5]. Each test step invokes a function on the SUT, updates the model state, or checks the SUT state and output against the expected values (the test oracle). A sequence of these steps forms a *path* through the model, producing a test case.

To define the potential paths, i.e., the steps the generator can take in a specific model state, the test generator executes all *@Guard*-annotated methods (line 11 in Figure 1). These define rules for enabling test steps. When the guards for a step become true, the step is enabled, and the generator can choose to take any of the enabled steps. The guards are matched to steps based on the names given as annotation parameters. For example, in the beginning *value* is 0 and thus the guard for *decrease* is false, meaning the test can only start with the *increase* step.

B. Specifying Coverage Values

In our example, the current value of the counter is stored in the model as the *value* variable. The annotation *@Variable* identifies this variable to be of relevant for the generator to track for coverage. To provide a test oracle, the *value* variable is constantly updated to match the expected value as result of actions executed against the SUT (lines 17 and 24). These actions are the test steps invoking the *increase* and *decrease* functionality of the actual SUT (lines 18 and 25). The test oracle compares the actual value in the SUT with the expected value in the model (lines 19 and 26).

We also define a set of additional terms for elements of the model when calculating our test coverage. We use the term *step-pair* to refer to two steps following one another in a test case. For example, a path of '++-++' would have three unique step-pairs: '++', '+-', and '-+'.

Coverage *requirements* (lines 20 and 27) can be used to tag specific paths of interest through the model. Methods annotated with *@CoverageValue* annotation (line 29) can be defined to produce values to record as covered for specific paths. Typically, these record specific instances or combinations of interest for model state. In our example, it records whether the value `zero' is covered by a path. As such functions are typically related to model state, we refer to them as *user defined state* coverage. When two different values are observed in a sequence inside a test path, the term *state-pair* coverage is used. State-pairs are recorded similarly to step-pairs but with the user defined state values.

The annotations, variable names and values, and method information are accessed at runtime using the standard JVM reflection support, maintaining the black-box quality of our approach.

C. Coverage Calculation

In order to evaluate model coverage achieved by the generated test cases, our generator keeps track of any coverage values it has observed during test paths. Users can give weights to the different model elements to focus coverage where interesting. For example, one can set some weights to zero to ignore them, or tune state weight lower to avoid large state-spaces taking over all others.

The model elements used for coverage calculation and their default weights used by our tool are given in Table 1. The default weights are based on our experience with various test models and related test generation.

Using E to represent a model element and W its weight, the formula to calculate the coverage score is:

$$\sum_{N=1}^{7} (E_N * W_N)$$

N	Model Element	Default Weight
1	Variables	10
2	Variable values	1
3	Test steps	20
4	Step pairs	30
5	Requirements	50
6	User defined states	50
7	State-pairs	40

Table 1. Coverage elements.

That is, the number of unique values observed for each model element is multiplied by the weight for that element, and the sum of these forms the coverage score for a test case. For example, a test case TC1 with a path of '++-++' would cover 1 variable (*value*), 3 variable values (1,2,3 for *value*), 2 steps ('+','-'), 3 step-pairs ('++', '+-', '-+'), 2 requirements ('increase', 'decrease'), 1 user defined state ('false'), and a single state pair ('false-false'). The score of this path is thus 10*1+1*3+ 20*2+30*3+50*2+50*1+40*1 = 333.

The coverage score for a test suite (all test cases together) is calculated by adding up all items in all test cases and then applying the formula. For example, suppose a test suite consists of TC1 defined above and a test case TC2 covering the path `++--+'. If TC2 was the only test case, its value would be 10*1+1*2+20*2+30*4+50*2+50*2+40*3 = 492.

However, since TC1 is already in the suite, only the new elements added by TC2 are considered. These are a new step-pair '--', a new user-defined state 'true' and two new state-pairs 'false-true' and 'true-false'. Thus the suite score rises by 30*1 (step-pair) + 1*50 (state) + 2*40 (state-pairs) = 160. The final coverage score for this test suite is then 333+160 = 493. In general, our scoring function guarantees that the score of a test suite is independent on the order of adding test cases.

A common goal for testing is covering variance over important properties of the SUT [12]. The goal of our coverage algorithm is to provide a measure of overall model variance coverage for the optimization algorithms, which we expect to be designed to represent important aspects to test in the SUT.

III. Optimization Algorithms

In this section, we describe our optimization algorithms. First we describe the online optimization algorithm (Section 3-A), followed by the two offline algorithms (Sect. 3-B and 3-C).

A. Online Algorithm

Online testing interleaves test generation with test execution. Once the generator chooses a test step, it immediately executes it against the SUT; once the step has finished executing, it chooses the next step, etc. For us, online testing provides immediate test results and gives fast feedback to the test generation, modelling and evaluation process, and thus we want online test generation to be as fast as possible.

This type of real-time online test generation prevents us from doing optimization beforehand as we need to support cases where changes are made to the model, the generator is immediately invoked, and tests are generated and executed. To support this scenario, our online optimization algorithm explores sets of potential future steps while the previously chosen step is still executing.

The high-level algorithm is described in Figure 2. When the generator has chosen a step to execute (using the algorithm in Figure 2) but before it has executed it, it starts the exploration of the next step in parallel threads (or concurrently on a networked larger machine as discussed in [13]). It takes the sequence of steps so far executed (LS) for the current test case and the exploration depth (D) given by the user as input. The exploration depth defines how many steps the algorithm tries to look into the future in parallel to current step execution.

```
Input: current model instance and state CM used for concrete test generation,
       list of steps LS currently taken in test case, the exploration depth D.
Output: The next step to take.
1. execute all model guards on CM to construct the set of enabled steps ES
   Set the set of potential future paths PP to empty set ∅.
2. for each step S in ES
3.   create a new instance M of the model program
4.   set M in exploration mode
5.   execute all steps in LS on M to reach current test state for M
6.   execute S on M to reach a new state NS
7.   decrease D by 1
8.     if D > 1, repeat from 2
9.     else add this path for M to PP
10. set value for best path score B to 0, create new empty set of best paths SB
11. for each potential path P in PP
12.   calculate coverage score CS for P
13.   if CS > B, clear SB and set B as CS
14.   if CS == B, add P to SB
15. return a random choice from SB as the next step to take
```

Figure 2. Algorithm for online optimization.

The starting point is the current concrete model instance CM (and its state) used to generate test cases. To explore the potential future paths, the algorithm starts with the set of enabled steps ES, that is the set of steps in CM where no guard returns false, as explained in Section II-A. For each step S in ES, a new instance M of the model program is created. This is set to exploration mode by invoking *@ExplorationEnabler* annotated methods on the model. This should, for example, replace a reference to a real SUT with a mock version that invokes no real functionality and thus has no visible side-effects when steps in M are invoked. The current set of steps LS is executed on this M to achieve the current generation state for M. This is repeated for each S, so that each S has its own instance of M that is in the same generation state.

For each of these instances of M, the associated S is invoked. If the exploration has at this point reached depth D, the coverage score for each M is calculated and that is the score that is given to this path. If D is not yet reached, all these executed paths for the different instances of M are taken as the new sets of steps LS and the algorithm starts from beginning for all these, with the value of D reduced by one.

In the end, all the final paths are taken and the highest scoring ones are collected. If there are several, the one that has the highest score fastest (in fewer steps) is taken. If several are still equal, one is chosen at random. The next unexecuted step on this path is given as a choice for the generator. In some cases, the algorithm still has to wait some time for the parallel exploration to finish. This can be mitigated by forming an "exploration buffer". That is, exploring several future steps at a time when there is a chance and using that as a buffer.

B. *Offline Algorithms*

Our offline optimization algorithm has two different variations. One aims to optimize for a large test set covering a high variation of the test model elements, using the coverage formula presented in Section II.B. The other one aims to optimize for minimal test lengths to cover specific targets in the test model.

Greedy Variation Optimizer. The version targeting high variation is a form of greedy algorithm. It is described in Figure 3. The main arguments it takes from the user are the population size (PS) and the timeout value (TO). The number of parallel generators (P) to run can also be configured but defaults to the number of processing units for the system.

The greedy algorithm runs P versions of generators G in parallel. In Figure 3 This is represented as $G_{1\text{-}P}$ meaning there are P different instances of test generators. The different ones are referred to as G_x, where x stands for one value from 1-P, or one instance of the generator. Each G_x is configured with the test generator configuration (GC) provided by the user and automatically populated with a unique randomization seed (to produce different test cases). Each G_x generates a given number of new test cases (PS). The new generated set of tests GS for G_x is merged with the existing test suite TS (which starts empty). Every T in TS is then iterated and highest scoring tests are added to the existing test suite TS for each G_x. First, the test T that has the highest coverage score in GS is added to TS and removed from GS. This process repeats until GS is empty or no T gets a positive score. Same procedure is done for each G_x generating a new GS and merging with TS.

Finally, once the overall generation timeout TO is reached or TS has not changed throughout the entire iteration, the process is stopped for that G_x. Once all G_x are finished, the TS for all G_x are combined to form the final optimized test set OS which is returned. This is done similar to creating the set for a single generator, starting with the highest scoring test in the overall set, followed by the test that adds most to this test (suite), and so on.

Input: generator configuration GC, population size PS, timeout TO, degree of parallelism P.
Output: Generated test suite OS
1. create P instances of test generator as $G_{1\text{-}P}$, configured with GC
2. for each G_x, in $G_{1\text{-}P}$ run the following in parallel
3. create empty test suite TS (∅)
4. create unique randomization seed for G_x
5. use G_x to generate PS new test cases as the test set GS
6. add tests in TS to GS
7. clear TS, setting TS to empty set ∅
8. for each test T in GS
9. calculate added score AS for T when added to TS
10. add highest scoring T to TS and remove it from GS
11. if any T remains in GS with AS > 0, iterate from step 8
12. if timeout TO has been reached, stop generation with G_x
13. else if TS scores higher or is shorter than previous TS
14 continue from line 5
15. else stop generation with G_x
16. wait for all G_x to finish
17. merge results for all G_x using lines 8-11 as output set OS
18. return OS

Figure 3. Greedy algorithm for offline optimization.

Single Target Optimizer. The *single target* offline optimization approach, described in Figure 4, aims to generate a set of test cases where each coverage requirement is covered by a single test case of the shortest possible length. This can be useful if specific tests are needed but we want to have them generated from the model as opposed to manual scripting.

This algorithm starts by generating test cases as random walks through the model, using a set of P test generators $G_{1\text{-}P}$ running in parallel. Each G_x is used to generate a given number PS of test cases. When a G_x finds a new test case T that covers a previously uncovered requirement R, it changes the global generator state to target finding R and to only allow the steps in T. T now becomes the *reference test,* called BT, for covering R. Upon finishing their iteration of generating PS tests, each G_x reconfigures itself with the new global generator state. This means that the goal of every G is to find a shorter path to cover R. The set of R to find can be given to the algorithm or it can pick them up from the model as it generates tests from it.

To further help the generators find potentially shorter paths, the global state is modified after each iteration to look for only those tests which are shorter than BT. Each G_x is configured to allow each available step one time less than in BT. If any G_x finds a new test T with a shorter path to R, this T becomes the new BT for R and all G_x reconfigure to target shortening this new BT. After test timeout TO is reached or the path cannot be shortened any more (it only has instances of one step), the final BT for R is added to the final output set OS.

Finally, the search is restarted with the goal of finding a new test for an uncovered R. The previously covered requirements are ignored at this point. The process is repeated until all requirements have been covered or suite timeout SO is reached.

Input: generator configuration GC, population size PS, suite timeout SO, test timeout TO, degree of parallelism P.
Output: Generated test suite OS with one test case for reaching each requirement R
1. create P instances of test generator as $G_{1\text{-}P}$, configured with GC
2. create unique randomization seed for each G_x in $G_{1\text{-}P}$
3. while SO has not been reached
4. run each G_x in parallel to generate PS test cases as test suite TS
5. if any test T in any TS for any G_x reached a new uncovered R
6. set R as target to cover for each G_x
7. set best test BT for R to T
8. for each step S in BT
9. reconfigure all G_x to only allow the steps in (BT – S)
10. use G_x to generate PS new test cases TS2
11. if any test T2 in TS2 is shorter than BT, set BT to T2
12. iterate from line 8 until minimal BT achieved or TO is reached
13. add BT to final output test suite OS
14. iterate from line 1 until SO is reached or all requirements are covered
15. return OS

Figure 4. Single target algorithm for offline optimization.

IV. EVALUATION

In this section, we describe the evaluation of the algorithms. Due to space reasons, we cannot include all the details of all the test runs here. The detailed results are available in [14].

While we have experience with several industry models, we cannot describe these due to confidentiality reasons. Thus our evaluations use three publically available models. Two of these, a test model for a movie reservation system (ECinema), and for a GSM SIM card [1], are ported from the ModelJUnit MBT tool [15]. The third model was previously developed by us for a web application called iTrust, which is a role-based healthcare application [16]. While these are not actual industry models, in our experience the relevant complexity is similar in terms of relevant structural coverage elements of the model such as states, and test steps. The models are available as part of our tool website and repository [7]. Table 2 summarizes the sizes of these models in terms of their model elements (used in coverage calculations).

Model	Steps	Step-Pairs	States	State-Pairs	Reqs
ECinema	19	177	9	40	17
SIM	15	240	2.6k+	22k+	32
iTrust	40	800	47	1124	11

Table 2. Model sizes.

We used the default coverage weights described in Table 1 with one exception. For the SIM model we set the state weight to 5 and state-pair weight to 1 in order to avoid the huge state space taking over all other coverage criteria. This is a typical example of tuning the coverage weights per domain as discussed in Section II-B.

A. *Online Algorithm*

For this algorithm, we are interested in the improvements of coverage when compared to the baseline approach of random step selection and any delay it adds. That is, we are interested in the cost and benefit of exploring the next step(s) while the previous are executing.

To set our evaluation parameters, we did an initial scalability study in which we found that test length of 100 steps and a depth of 2 were the most suitable parameters. Thus we used these in the online algorithm evaluation.

Coverage. To evaluate the algorithm in terms of coverage, we ran the test generator against each of the three test models. We did this with the random algorithm, and with the exploration algorithm using depths of 1 and 2. We repeated each of these experiments 100 times and collected the minimum, maximum and average achieved coverage for each algorithm in each configuration for each model. The results indicate that exploration algorithm generally outperforms the random selection for all our coverage criteria.

Timing. To evaluate the timing aspect of the algorithm, we used the iTrust system as a test subject as it was tested through the web-based graphical-user interface (GUI), which in our experience is a good candidate platform for parallel optimization due to test execution delays. The experiment was run on our laptop system, also running the SUT, including the database server, and the webserver. Test execution used the Selenium WebDriver (Chrome) component, allowing control of an actual browser to simulate a test user using the application. Thus, the flow is the same as with an actual user, with all the requests going through the whole SUT from the browser to the backend database and back.

As random selection is practically instant, it was used as a baseline for comparison. To briefly summarize the interesting parts, exploration at depth of 1 (Expl-D1) is in all cases faster than the execution of the concurrent test step (Random). Exploration at depth of 2 (Expl-D2) is in most cases much slower than the step execution time. This means that, for our setup, the depth of 1 is very reasonable, while depth of 2 is slower, although it does also achieve a much higher exploration score that depth 1.

Our goal in this study was also to evaluate the general feasibility of the approach to achieve near real-time test generation and execution. Here, this is true for depth 1. With optimizations and faster computing resources (e.g., [13]) we believe this is within reach for depth 2. Of course, this also largely depends on concrete test execution speed, which may give us more or less time for exploration. In our experience, long delays are common in many cases, specifically, with GUI-based testing.

B. *Greedy algorithm*

For this algorithm, we were interested in evaluating how well it covers variation over the test model structure. We were also interested in the time it takes to achieve the coverage and length of the resulting test cases.

Coverage. To evaluate the algorithm in terms of coverage, we again used all three of our test models. Comparing the results against the baseline random selection algorithm and the online optimization algorithm, Greedy generally outperforms the other two over long term. However, while Greedy performs much better than exploration in the long run, it may sometimes perform slightly worse for some properties.

Figure 5 shows the overall coverage score evolution for one run of each algorithm as new tests are added to the test suite. The coverage score shown is the overall score of the test suite as shown in Section II-II.C. The obvious observation is how random selection yields much lower coverage score than the other algorithms. What is not so clearly visible is how the exploration algorithms score slightly higher than greedy in the beginning, with greedy surpassing depth 1 at test 30 and depth 2 at test 100.

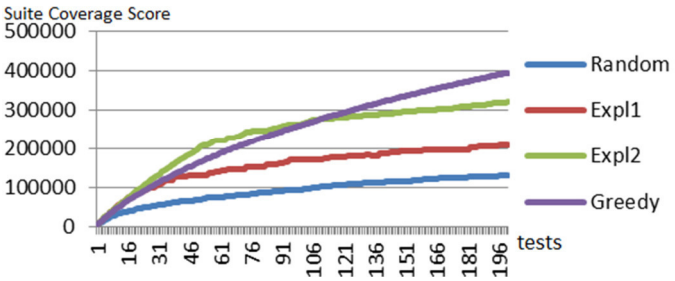

Figure 5. Coverage score evolution over 200 tests.

Timing. Unlike the online exploration algorithm, the greedy algorithm takes time to start and build the test suite for later execution. In this case running the greedy algorithm with our desktop configuration takes about 165 minutes. This is the delay one would have to wait before starting to execute the tests. Compared to the online exploration algorithm, the online version has no delay in the start and the overall generation time for the exploration at depth of 1 is about 20 minutes and for depth 2 about 105 minutes.

C. Single Target Algorithm

To evaluate the single target algorithm, we started by investigating the limits of the algorithm. To do this, we a model with 10 test steps, each always enabled. Thus the probability of taking any one of them with random choice is 10%. It has one requirement to cover, and the length of the path that needs to be taken to cover this requirement can be configured by the *target* parameter. Different values for this parameter were then applied with tests of different length.

The results indicated that the algorithm could always reduce the path to the shortest in all these configurations. Additionally, we used binomial distribution to verify these results. These calculations matched our experiments and thus confirmed the algorithm is useful for such model requirement coverage optimization. This also shows how this type of probability analysis can be used to tune the search parameters when we have an idea of the complexity of paths we need.

To further evaluate the performance, we used the SIM model as a test subject. It had a set of 35 coverage requirements defined by its original authors, and our target was to cover these with one test each. The results indicated that three requirements were not covered at all. In order to find out the reason, we manually analyzed the test model for the paths to reach these requirements. We found that due to complex ways the different test steps and model variables interact, it was not possible to reach those requirements in any way. While we are not the authors of the model, we assume that this is the result of model evolution where the requirements have not been rechecked, perhaps due to the complexity of this process. In any case, such knowledge in itself is valuable to better understand the test model and the generated test cases.

As for the 32 covered requirements, we found that the algorithm did find the minimal path to reach each of these requirements in the model. The results are good but we also realize that there can be more complex cases where the paths are more difficult to minimize due to dependencies between model steps and state variables. We leave further exploration of such models for future work. Again, we remind that the detailed results are available in [14].

V. Discussion

Out of the three algorithms that we have presented, the online optimizer and the greedy offline optimizer target similar goals. Both try to optimize coverage for a variation of chosen parts of the model for each test case and the overall test suite. The single target offline optimizer is different in trying to generate a set of test cases where each one reaches a specific path requirement. It is not looking for the overall variation using our coverage score but rather for a specific set of test cases, each with a minimal set of steps for reaching a given requirement.

As shown in Figure 5, the online exploration approach gains coverage faster in the beginning but loses to greedy over the long term. This is due to the online algorithm finding many uncovered steps, states and their combinations in the beginning but lacking vision in later test cases for how to achieve a state from which it can again gain more coverage score. It is also due to the states being distributed more after the initial set has been covered. The greedy version, on the other hand, selects from a large set of random tests, where the initial tests may not be as good as those in the online exploration version but where over time it finds more uncovered coverage elements in the larger set of random tests. For generating an overall regression test suite, a combination of these could be useful.

Overall, we prefer to use the online exploration algorithm when working on models for systems where test execution takes non-trivial time. One example is when we are evolving the models and trying to determine the impact of the modification on test results. In these cases, the algorithm quickly produces a variation over different parts of the model. If we want to focus this variation on specific parts of the model, we use scenarios to guide the generator to only consider these parts and the algorithm to produce a variation over these chosen parts. Scenarios are a way to tell the generator to ignore some steps completely, use a specific sequence to start every test, and to limit the number of times a test can contain some steps.

If we need the ability to execute large test suites, we have found the greedy or even the random approach to work better. When the tests execute fast (e.g., testing middleware or application logic), it is possible to run a large test set fast even on a single multi-core machine. In such a case, in the time it takes for the optimization approaches to produce the test set, the random selection and its online execution have very likely already achieved a high coverage score and also covered additional combinations. For slower to execute cases such as GUI-based testing, some of these benefits may also be achievable with large-scale testing tools such as Selenium Grid (e.g., overnight or over the weekend using a large set of machines) when we want to perform very extensive test runs.

One of the main considerations for us is the fast evolution of the test models. Modern software development is fast paced and changes are frequent, especially with agile software development practices. In such environments, we prefer the online approach. This allows us to version control only the test model (as opposed to thousands of tests), generate and execute the tests, modify the model and repeat. However, we also find it useful to generate an offline test suite for cases where we want a specific set covered every time, e.g., one larger set executed to provide a high overall model coverage once the external test interfaces have sufficiently stabilized.

This also brings us to the single target optimization algorithm. While the larger test suites generated by the greedy and online optimization algorithms generally also cover the requirements defined in those models, and in many cases a single test case covers many requirements, there can still be value in specific test cases. For example, they are useful to show management and domain experts how specific test requirements are covered by a concise set of test cases, or how specific paths through the model are formed by the generator. They can also be used as a smaller set of offline test cases to support a larger online test generation and execution process.

Our results indicate that using the single target algorithm, coverage requirements can often be more easily found by generating much longer test cases that the expected required length to cover the requirements, and then having the tool minimize them. As noted, the probability calculation presented in Section IV-C can be a useful tool to set these parameters.

One advantage of online testing compared to its offline counterpart is the ability of the former to adapt to responses and state changes of the SUT on the fly [1], e.g., when testing a non-deterministic system. While the algorithms we have presented mostly assume a deterministic test response, the online version can also adapt to non-determinism, with the exploration becoming the estimation of future paths, and each estimate is re-calculated for each new step.

As shown in Figure 5, the optimizations help achieve a more diverse coverage according to the defined score weights when compared to the random choice. We also found it useful, in practice, to add random variation to the generated test cases, to avoid expert bias, i.e., cases not considered by the human expert but exercised in practice. We find that the generation and optimization approaches based on our diverse coverage score (greedy and online look-ahead) work well to achieve such goals. Practically, they focus on achieving the given model coverage criteria and interleave these with elements of randomness in different parts. That is, the result may not be fully optimized to produce the smallest possible test sets, but generally, we prefer this over too aggressive optimization. This provides a good tradeoff between generating huge random test sets and only generating manually defined specific test sets, which do not make use of the large scale capacity of test generators and are subject to expert bias in what is tested.

VI. Related Work

Test optimization in MBT has been a popular research topic with various tools and approaches being implemented. Tools such as Conformiq [3], Uppaal [4], and Spec Explorer [5] use customized modelling languages, and static analysis-based approach with symbolic execution and constraint solving to optimize test sets. Mostly these approaches target offline test generation, while some work [6, 4] has also made use of two-phased test generation where static analysis is first performed and the resulting information is used to aid in online test generation. In contrast, our approaches are targeted to cases where such static analysis is not available due to the complexity of the modeling language and environment.

Various approaches using general-purpose programming languages for modelling have also been presented. Model programs similar to ours are used in MBT tools such as Spec Explorer [5], PyModel, NModel [10], and ModelJUnit [1]. All of these tools use variations of random search for test selection. Spec Explorer, PyModel and NModel support guiding test selection through user defined scenarios which slice the model to focus test generation around the specific parts of the model. Similar scenarios are also supported in our generator, and these can be used together with the optimization approaches we presented to focus testing on specific model parts.

A black-box optimization approach for test generation from models expressed using general purpose modelling languages is also available with ModelJUnit [15]. It supports executing the test model in a simulation mode as a pre-analysis phase before starting the actual test generation. Possible sequences of steps observed in these runs are collected and used to guide the actual online test generation in the following phase. However, this approach does not consider the state of the model, which defines what paths are available, and thus the set of paths assumed by the optimization analysis are different from the actual ones available during generation. The difference to our approaches is that we do not use a separate pre-analysis phase and produce accurate results where the exact paths and impacts on coverage are known.

Regression test selection, minimization and prioritization are topics related to optimizing test suites [17]. These typically consider the optimization in terms of different ways to cover the SUT implementation [17]. In this paper we have discussed optimization of test model coverage using a more varied set of coverage criteria at a higher abstraction level. However, investigating ways to use works such as described in [17] together with our approach is an interesting topic for future work.

The techniques presented in this paper can also be viewed as a multi-objective test optimization problem. We aim to cover the items defined for the scoring function in Section II, which can be seen as a fitness function in the terms of search-based testing (see e.g., [18]). The algorithms we apply for coverage score optimization can be seen as a dynamic multi-object optimization algorithm for the test suite. Various approaches in search-based optimization have been applied before [18] but none in our knowledge to model-based test generation with black-box constrains. In fact, we are not aware of previous work in MBT for optimizing a set of coverage criteria as diverse as the one we optimize in this paper.

A multi-objective approach to test suite optimization for product lines is presented in [19], targeting objectives such as cost of test case, cost of test requirement and product variants. Test coverage is considered as single coverage requirements on the test model as opposed to our extensive model variation coverage support. An interesting aspect to integrate with our work could be the association of cost to certain test targets as part of the coverage score function.

In software testing and verification, various combinations of static analysis and (random) test data generation have been used. For example, directed automated random testing (DART) [20] combines static analysis and observations about the running system with random inputs to guide it towards new paths. Java PathFinder (JPF) [21] enables generating test paths based on a combination of symbolic and concrete executions. While these are different testing approaches than MBT, combining the information from these types of different sources with test generation (similar to [6]) and the approaches presented in this paper could be an interesting future research topic. While it may be prohibitive in terms of wait time to perform such extensive pre-analysis, a possible approach could be to perform this as a background process during modelling similar to what is described for executing unit tests in [22].

In general, a lot of work in automated test generation targets the traditional code coverage as a test target. When additional test coverage targets are considered, these are typically specific coverage requirements such as labels on the test models [23]. In addition to the optimization algorithms we presented in this paper, the coverage scoring method itself extends these with wider generic model coverage criteria (the model structure elements), supported by domain-specific criteria (user defined state and variables).

Random testing has been shown to work well in various situations [24, 25], and some criticism has been voiced on the effectiveness of guided random testing approaches when the same coverage can be achieved by simply executing a large set of random test cases in the same time [25]. We share this view in noting that executing a very large set of random tests should yield the same or even higher coverage over time as our optimization approaches do. The aim of our approaches is to practically choose a reasonable subset of such a larger set under different use cases.

VII. CONCLUSIONS

In this paper, we presented three different approaches to test optimization in black-box model-based testing. We then evaluated their performance and provided comparisons on the strengths and weaknesses of each. Our evaluation highlights the benefits of these different approaches over the traditional random choice and their usefulness in different contexts. The online version works well to provide added coverage when prototyping slow to execute test cases. The greedy offline optimizer gives a test suite for higher overall model coverage. The requirements targeting optimizer can help provide specific test cases where useful. Combining potential benefits of these approaches with static analysis where possible would be an interesting future research topic. Domain-specific applications of these approaches, including customizations of algorithms and modelling languages, are also interesting future topics.

3rd Workshop on Model Driven Approaches in System Development

FOR many years, various approaches in system design and implementation differentiate between the specification of the system and its implementation on a particular platform. People in software industry have been using models for a precise description of systems at the appropriate abstraction level without unnecessary details. Model-Driven (MD) approaches to the system development increase the importance and power of models by shifting the focus from programming to modeling activities. Models may be used as primary artifacts in constructing software, which means that software components are generated from models. Software development tools need to automate as many as possible tasks of model construction and transformation requiring the smallest amount of human interaction.

A goal of the proposed workshop is to bring together people working on MD languages, techniques and tools, as well as Domain Specific Languages (DSL) and applying them in information system and application development, databases, and related areas, so that they can exchange their experience, create new ideas, evaluate and improve MD approaches and spread its use. The intention is to target an interdisciplinary nature of MD approaches in software engineering, as well as research topics expressed by but not limited to acronyms such as Model Driven Software Engineering (MDSE), Model Driven Software Development (MDSD), and OMG's Model Driven Architecture (MDA).

1st Workshop on MDASD was organized in the scope of ADBIS 2010 Conference, held in Novi Sad, Serbia. From this year, MDASD becomes a regular bi-annual FedCSIS event.

Topics

Submissions are expected from, but not limited to the following topics:

- MD Approaches in System Design and Implementation – Problems and Issues
- MD Approaches in Software Process Models
- MD Approaches in Databases and Information Systems
- MD Approaches in Software Quality and Standards
- Metamodeling, Modeling and Specification Languages
- Model Transformation Languages
- Model-to-Model, Model-to-Text, and Model-to-Code Transformations in Software Process
- Transformation Techniques and Tools
- Domain Specific Languages (DSL) and Domain Specific Modeling (DSM) in System Specification and Development
- Design of Metamodeling and Modeling Languages and Tools
- MD Approaches in Requirements Engineering and Business Process Modeling
- MD Approaches in System Reengineering and Reverse Engineering
- MD Approaches in HCI development
- MD Approaches in GIS development
- MD Approaches in Document Engineering
- Model Based Software Verification
- Theoretical and Mathematical Foundations of MD Approaches
- Organizational and Human Factors, Skills, and Qualifications for MD Approaches
- Teaching MD Approaches in Academic and Industrial Environments
- MD Applications and Industry Experience

***Abstract*—Model transformation is a key concept in model-driven software engineering. The definition of model transformations is usually based on meta-models describing the abstract syntax of languages. While meta-models are thereby able to abstract from superfluous details of concrete syntax, they often loose *structural* information inherent in languages, like information on model elements always occurring together in particular shapes. As a consequence, model transformations cannot naturally re-use language structures, thus leading to unnecessary complexity in their development as well as analysis.**

In this paper, we propose a new approach to model transformation development which allows to simplify and improve the quality of the developed transformations via the exploitation of the languages' structures. The approach is based on context-free *grammars* and transformations defined by *pairing* productions of source and target grammars. We show that such transformations exhibit three important characteristics: they are *sound*, *complete* and *deterministic*.

I. Introduction

MODEL transformations are key to model driven engineering (MDE). Surveys on model transformations [1], [2] show their expanding application areas: model translation, model composition, refinement, and other.

In an MDE setting, the syntax of models is given in terms of *meta-models* which themselves conform to their own meta-models (e.g., MOF [3]). Meta-models define the *abstract syntax* of languages, abstracting away from the details of concrete syntax like keywords and ordering of elements. Model transformations thus operate on abstract syntax. While meta-models describe model elements and their direct relations, they fall short of describing more complex interrelations like sets of model elements always occurring together in particular shapes. In some cases, meta-models are enriched with OCL [4] constraints to enforce such shapes in models.

In contrast to MDE, traditional approaches to language definition (and translation) define languages by *grammars*, often given in an Extended Backus-Naur Form (EBNF) [5]. These translation techniques operate on concrete syntax. While the details of concrete syntax are in general unimportant (and thus make translation definition unnecessarily confusing), the *structural* information contained in the grammars is highly useful for defining translations. The productions of the grammars define the structures available in the languages, and by relating productions of grammars (as done in syntax-directed translation [6]) we can easily specify how language structures are mapped onto each other.

This work was partially supported by the German Research Foundation (DFG) within the Collaborative Research Centre "On-The-Fly Computing" (SFB 901).

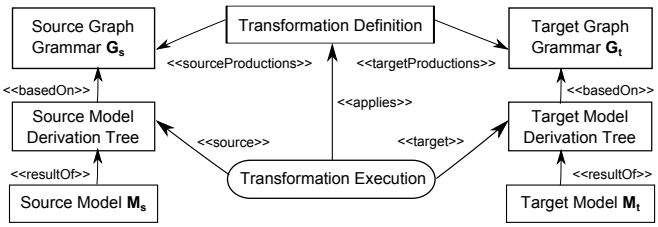

Fig. 1: Overview of our approach

An ideal approach for model transformation should thus combine these two approaches, taking the best of both: have language definitions with the abstract syntax of meta-models and the structures of grammars, and build model transformations on these definitions. An early approach following this idea, although not in the area of model transformations and not with meta-models but with graphs, is the one of Pratt [7]. Pratt defines *pair grammars* as a way of relating the grammars of two languages, thus obtaining a natural way of relating languages and building translations from one to the other.

The objective of this paper is to bring the idea of pair grammar based translation to the world of MDE and model transformations, lifting it to the level of abstract syntax while preserving its advantages. We also extend it in order to cover a broader variety of model transformations.

Fig. 1 gives an overview of our approach. The transformations we focus on are model-to-model transformations. Our models are given in abstract syntax and are generated by grammars. For this generation purpose we use a type of context-free graph grammars – *hyperedge replacement graph grammars* [8] – typed and constrained by meta-models. Transformation rules – like pair grammars – relate productions of the source with those of the target grammar. Model transformations are executed on the *derivation trees*: given a source model $\mathtt{M_s}$, its derivation tree in the source grammar is obtained by parsing, and used by the model transformation to produce a derivation tree in the target grammar, and thereby the corresponding target model $\mathtt{M_t}$.

We exemplify our approach on a transformation from activity diagrams to the process algebra CSP [9]. We also prove

important qualities of the transformations developed with our approach – *termination*, *soundness*, *completeness*, and *determinism*. Showing these quality properties for a transformation described using current state-of-the-art techniques is usually hard, if not impossible [10].

First, in Sec. II we give background on grammar-based language definition and show our source and target grammars. Then, we introduce our approach in Sec. III and in Sec. IV show the quality characteristics of the developed transformations. In Sec. V we demonstrate extensions of our approach, and in Sec. VI we evaluate it in comparison with the most closely related approaches in MDE. Finally, we survey related work in Sec. VII and conclude in Sec. VIII.

II. Background

There are two fundamentally different ways of specifying the syntax of a given language: with (context-free) grammars or with meta-models. Our approach is built on grammars generating instances of meta-models, i.e., graphs. In the following, we introduce the main concepts of the grammar-based language definition and show how they can be lifted to graph-based languages, enabling grammar-based definition of modelling languages and model transformations utilizing these definitions. We show how our example modelling languages for activity diagram and CSP can be described using such grammars. Finally, we introduce the transformation example used later to demonstrate our approach.

A. Grammar-Based Syntax Definition

In their original usage, grammars define languages of strings via a set of generative rules. We briefly review some general definitions of grammars for string languages [6] because our graph grammars is a natural extension of string grammars.

Definition 1 (Grammar)**.** *A* grammar $G = (N, \Sigma, P, S)$ *consists of a set of* non-terminal symbols N*, a set of* terminal symbols Σ*, a set of* productions P *and a designated* start symbol $S \in N$*. Each production* $p \in P$ *is of the form* $p = (l, r)$*, with* $l \in (\Sigma \cup N)^* N (\Sigma \cup N)^*$*, i.e., a string of symbols with at least one non-terminal, and* $r \in (\Sigma \cup N)^*$*.*

A grammar $G = (N, \Sigma, P, S)$ *is called* context-free *iff every production* $p \in P$ *has the form* $p = (n, r)$ *with* $n \in N$*.*

Applications of productions derive new strings from given ones by a process called *rewriting*. A string $s \in (N \cup \Sigma)^*$ is rewritten into a new string by a context-free production $(n, r) \in P$ by finding n in s and replacing it with r. In this way, a grammar defines the set of strings that can be *derived* from its start symbol S. This set is called the *language* of the grammar G.

Definition 2 (Language)**.** *Let* $G = (N, \Sigma, P, S)$ *be a grammar. A* sentence *of* G *is a string* $s \in \Sigma^*$ *of* terminal *symbols that can be derived from* S *using a finite sequence of applications of productions in* P*. The language* $\mathcal{L}(G)$ *of* G *is defined as* $\mathcal{L}(G) = \{s \in \Sigma^* | s \text{ is sentence of } G\}$

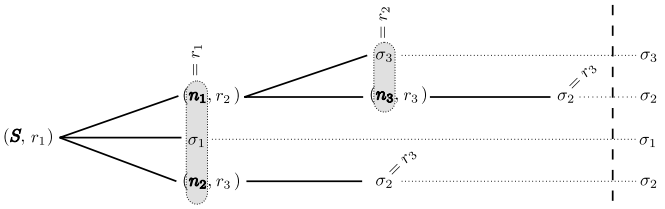

Fig. 2: A derivation tree deriving $\sigma_2\sigma_1\sigma_2\sigma_3$ from S

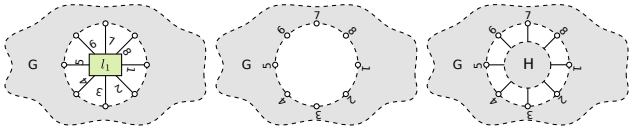
The advantage of context-free grammars is that parsing can be done efficiently [6]. Parsing a sentence in a language using a context-free grammar gives us a *derivation tree*, i.e., a structure showing the application of productions from the start symbol leading to the derived sentence. A derivation tree for a sentence defines its *structure* and confirms its language membership in $L(G)$ (i.e., syntactical correctness). The inner nodes of such a tree are labelled with productions. The root is labelled with a production that consumes the start symbol of the grammar. Every leaf of the tree is labelled with a terminal symbol. Fig. 2 shows an example derivation tree for the sentence $\sigma_2\sigma_1\sigma_2\sigma_3$.

In general, there can be multiple derivation trees for a sentence in one grammar that are not equivalent in their structure, making the grammar ambiguous. In our approach, we only consider *unambiguous* grammars for defining source and target languages, to ensure deterministic behaviour of the developed transformations (see Sec. IV for details).

Definition 3 (Unambiguous Grammar)**.** *A grammar* $G = (N, \Sigma, P, S)$ *is called* unambiguous *iff for every sentence* $s \in \mathcal{L}(G)$ *its derivation from* S *is unique if performed "leftmost derivation first".*

Because most models in MDE contexts are graph-based (since meta-models are graphs), we need context-free grammars producing graphs as sentences instead of strings. We use *hyperedge replacement graph grammars* (HR grammars) [8] which fulfil these requirements. HR grammars operate on *hypergraphs*, a generalization of graphs where edges, called *hyperedges*, can have more than two end points. These end points are called *attachment points* and their number is the arity of a hyperedge. Hyperedges take the role of non-terminal and terminal symbols. For replacing hyperedges in graphs by sub-graphs during rewriting, we need to specify how these sub-graphs are to be embedded. To this end, the replacing sub-graphs are equipped with *external nodes*, and rewriting proceeds by replacing the hyperedge with the sub-graph gluing together each external node with the attachment node of its corresponding attachment point.

More precisely, a *hyperedge replacement rule* $l_1 := H$ has three parts: a single n-ary non-terminal hyperedge l_1, a hypergraph H with $k \geq n$ external nodes replacing the hyperedge, and an (injective) *mapping* g of the k external nodes of H onto the n attachment points of l_1. Unlike string productions, graph replacement rules need to explicitly define how the new graph is attached to the remaining context. In HR grammars this is done via the mapping g. Fig. 3 shows a sketch of the replacement process (for $k = n$). First, the



(a) Matching (b) Removal (c) Gluing

Fig. 3: Rule application in hyperedge replacement grammars

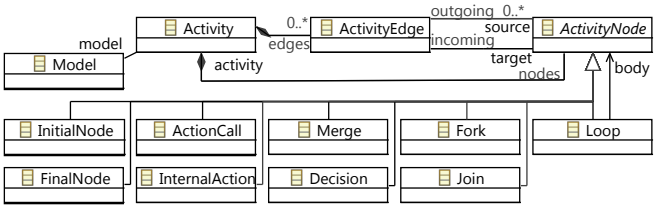


Fig. 4: Source meta-model: Activity diagrams

hyperedge l_1 is found by matching (a) and removed (b), then the graph H is inserted (c) by gluing all its external nodes with the attachment nodes of l_1 according to the mapping g. Due to lack of space, we refrain from giving a more formal definition here. All definitions of string grammars carry over to HR grammars: an HR grammar has the same parts as a string grammar (non-terminals, terminals, productions and a start symbol) and its language is a set of hypergraphs. The membership problem for HR grammars is decidable [8] which guarantees the existence of the derivation trees we are going to use.

Now, we can define both the source and target language we use to demonstrate our grammar-based model transformation approach in terms of hyperedge replacement grammars. We exemplify our approach on a transformation from activity diagrams to the process algebra CSP [9]. The HR grammars for these two languages are compliant with the respective meta-models, i.e., the graphs which our grammars generate are all instances of the meta-models. For this, we use (a simplified version of) the meta-model of UML activity diagrams [11] (see Fig. 4) and the CSP meta-model from [12].

The meta-model of activity diagrams only contains basic diagram elements, their hierarchy, and associations with multiplicities. It does not describe higher-level *syntactic structures of the language*. For example, in a well-formed activity diagram each *decision node* should be eventually followed by the corresponding *merge node* for the branches of that decision. Although these kinds of inductive language structures are intuitive to the transformation developer, they are usually not described in the meta-model.

Fig. 5 shows six out of eleven productions of our source HR grammar. Productions are given in abstract (plus some in concrete) syntax, in the form $l := H$, using bars to distinguish different right-hand sides of productions. Non-terminal hyperedges are depicted by dashed lines. Types and the number of attachment points of a non-terminal hyperedge are determined by the associations of the meta-model elements which it groups. The mapping between attachment points and external nodes is depicted by using the same numbers, one

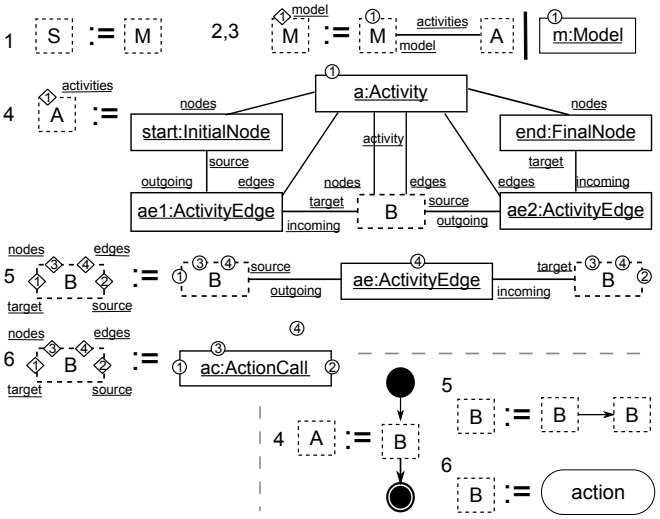

Fig. 5: HR productions subset for activity diagrams (abstract, concrete syntax)

given in a diamond and the other in a circle. Multiple external nodes can be mapped to one attachment point. Not all external nodes have to be connected in the graph (see production 6).

This grammar describes well-formed activity diagrams containing zero or more activities (productions 1 – 3) with exactly one *initial* and *final* node, and at most one recursively-defined high-level *syntactic structure block* called *B* connected to exactly one initial and final node (production 4). The non-terminal edge *B* can be replaced by one of the following structures: a *block sequence* (production 5), a *fork/join block*, a *decision/merge block*, a *loop*, an *internal action* or an *action call* (production 6). Note that our decision/merge constraint is now represented by the corresponding production which only allows to generate these elements together connected in a shape. Other language structures are also produced in this systematic way.

Fig. 6 shows the relevant subset of our meta-model compliant HR grammar for CSP. A *model* described by this grammar can contain a set of *processes* (productions 1 – 3) generated from non-terminal edges labelled *P*. A *process description* represented by non-terminal *PE* (production 4) can contain various expressions: a *sequential* or *parallel* process composition (productions 7 – 8), an *if-then-else* expression (production 9), an *event* followed by another process expression (production 10), *another process* (production 6), or an empty process *SKIP* (production 5).

B. Transformation Example

Both grammars we have defined will be used to describe our example transformation. We describe a transformation from activity diagrams to CSP, frequently employed for analysis purposes [13]. Alternatively, we could, for instance, use the activity diagrams to first-order logic transformation example from [14].

Fig. 7 shows our sample activity diagram of an enrolment and the corresponding CSP process. Here, we see the concrete

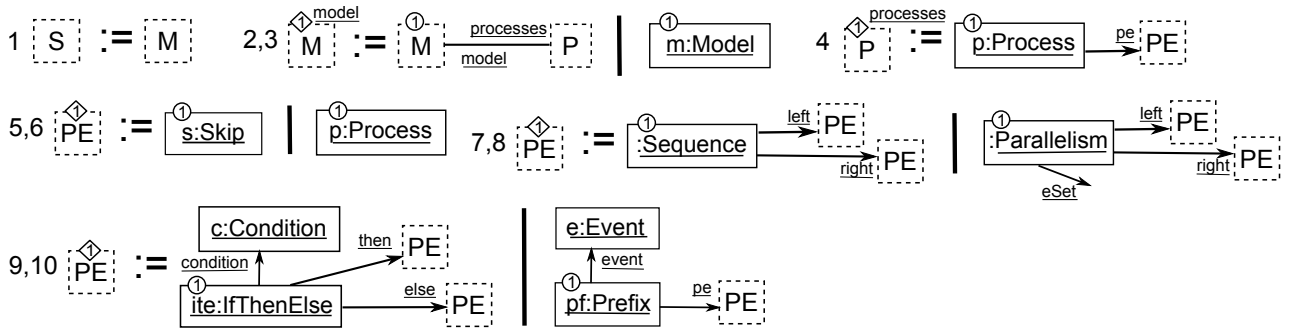

Fig. 6: HR productions subset for CSP (abstract syntax)

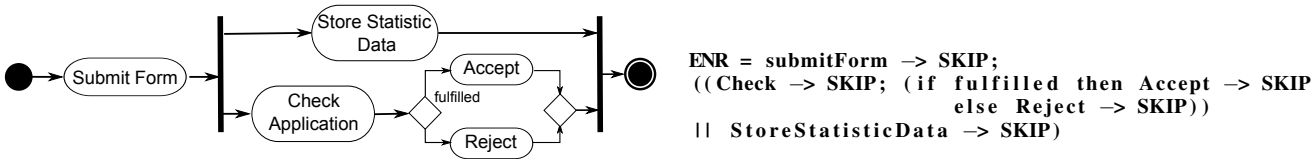

Fig. 7: Enrolment activity diagram (left) and its CSP process (`Check` abbreviates `CheckApplication` event) (right)

syntax of CSP: `->` is an event prefix, `;` a sequential composition, `SKIP` an empty process, `||` a parallel composition and `if-then-else` a conditional choice. We require every activity to be transformed into a process and every block sequence and fork/join block into a sequential and parallel process composition, respectively. A decision/merge block is to be transformed into an if-then-else expression and an action call into an event followed by a SKIP. Loops, although absent in this example, are transformed into recursive processes with conditions. Next, we show how this transformation logic can be structurally described using our approach.

III. Transformation Development

Our main goal is to allow an intuitive model transformation definition by mapping high-level syntactic structures in source and target languages onto each other. In terms of grammars, this means relating (or *pairing*) source and target productions creating corresponding structures. During execution of the model transformation these relations will be used to identify which target production is triggered for which source production.

Our model transformations operate on derivation trees of source and target models. Given a derivation tree for a source model, we incrementally construct a derivation tree for the target model by applying corresponding productions. Thereby, 1-to-1 correspondences between non-terminal edges in the source and target derivation trees help to keep track of related model structures.

Fig. 8 shows a sample transformation rule relating the source production for a sequence of activity blocks to the target production for a sequence of process expressions[1]. It states that when a block sequence is replacing a non-terminal hyperedge

[1]To simplify, we show transformation rules without HR grammar details.

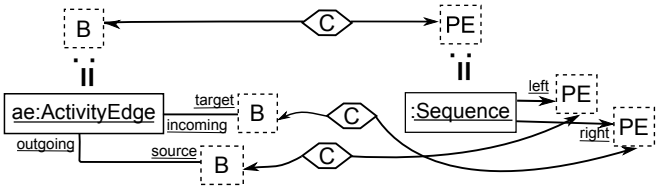

Fig. 8: Transformation rule: Block sequence to process sequence

of type *B* (block) in a source derivation tree, a sequence of process expressions should replace the corresponding hyperedge of type *PE* (process expression) in the related target derivation tree. In addition to relating productions, the transformation rule links source non-terminal edges of type *B* and target non-terminal edges of type *PE* via a 1-to-1 correspondence of type *C*. These correspondences determine which target edge will be replaced by the target production, when the linked source edge is replaced by the related source production. The notion of correspondence is inspired by triple graph grammars (TGGs) [15].

Fig. 9 shows further rules of the transformation definition for our example. It relates productions in the following way:

- Rules 1, 2: Productions for non-terminal (1) and terminal (2) edges representing *models* in the source and target grammars are related. Non-terminal edges in rule 1 are linked via a correspondence later required by rules 2 – 3.
- Rule 3: Production of a non-terminal edge of type *A* representing an *activity* is related to the production of a non-terminal edge of type *P* representing a *process*. The correspondence between model non-terminal edges is kept and other produced edges are linked for later application of rule 4.
- Rule 4: The production of an activity containing a *block* represented by a non-terminal edge of type *B* connected

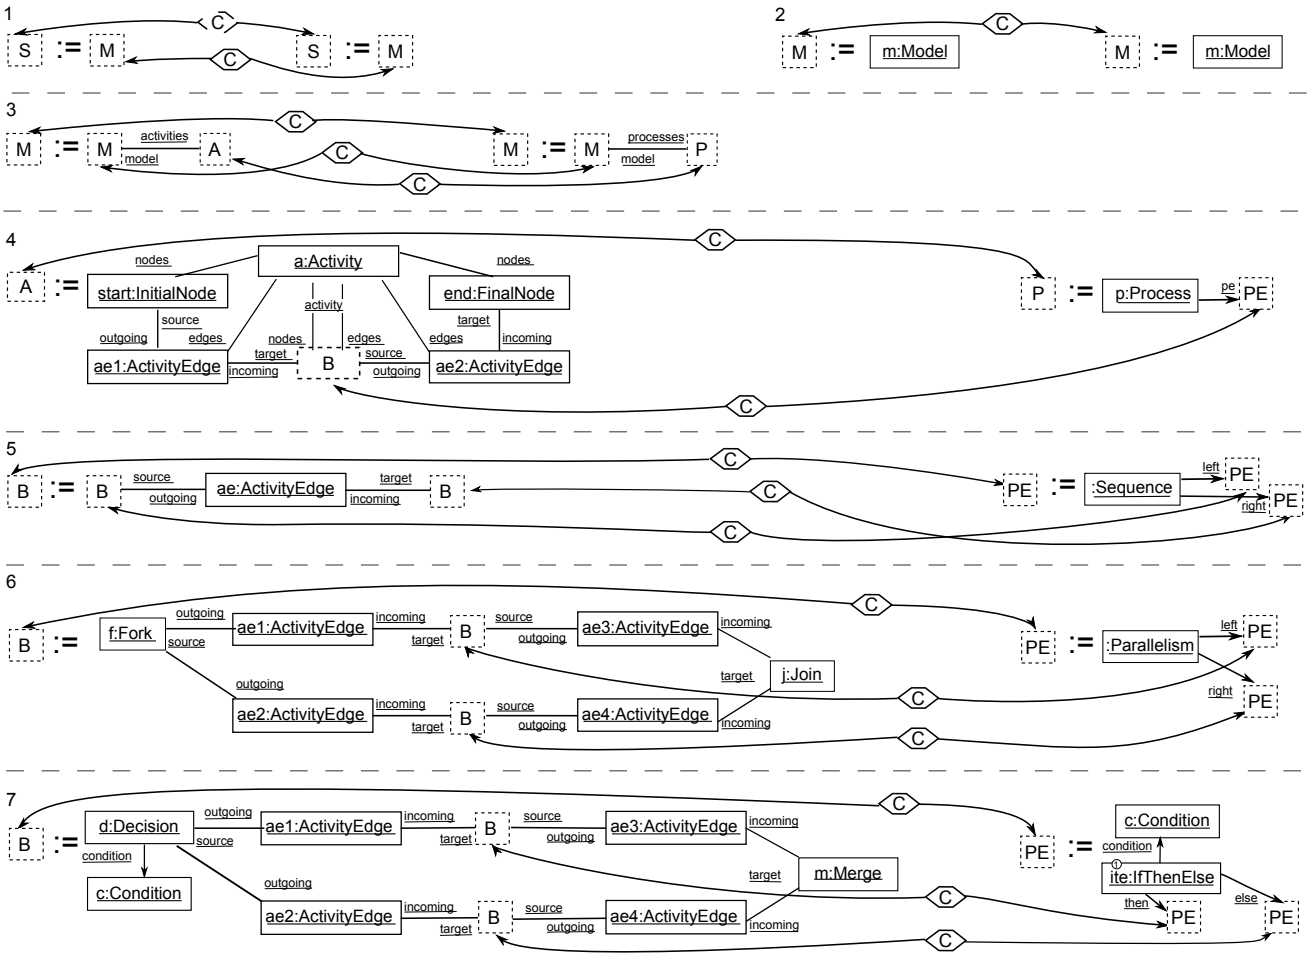

Fig. 9: Transformation definition (fragment): Activity diagram to CSP

to the initial and final nodes is related to the production of a process with a *process expression* represented by the non-terminal edge of type *PE*. The produced non-terminal edges are linked via correspondences which are required later for applying rules 5 – 7.

- Rules 5 – 7 relate different types of activity blocks to different process expressions: A *sequence of blocks* is related to a *sequence of process expressions* (5), a *fork/join* block to a *parallel composition* of process expressions (6), a *decision/merge* block to an *if-then-else* expression (7). Correspondences are created on the same principle as before.

In general, if the transformation definition between two HR grammars G_s and G_t has the following form (extended in Sec. V):

1) In each rule:
   a) a source production $p_s = (n_s, r_s)$ is related to a target production $p_t = (n_t, r_t)$;
   b) left-hand side non-terminals n_s and n_t are linked via a correspondence (start non-terminals S_s, S_t are always linked);
   c) each non-terminal edge in r_t has exactly one corresponding non-terminal edge in r_s,
2) For each source production $p_s = (n_a, r_a)$ in P_s and each correspondence between the edges of type n_a and n_b in some rule (or initial S_s to S_t correspondence), there is exactly one rule relating p_s to a target production p_t, where $p_t = (n_b, r_t)$, to cover all combinations of types of corresponding pairs (n_a, n_b),

and G_s is unambiguous, then the resulting transformation has some important characteristics which we show in Sec. IV. Now, we discuss how the transformation rules we have just defined are executed.

The transformation is executed on a source model in two steps: first, the source model is parsed to get its *leftmost derivation tree*[2] and then the transformation rules are applied to construct the target derivation tree (and the target model).

In the first step, a source model is parsed with respect to the source HR grammar. As HR grammar based parsing is decidable [8], for each source model we either get its leftmost derivation tree or a message that it is not parsable. If a model can not be parsed, it is not in the source language, and hence will be rejected by our transformation returning *not applicable*.

[2]Derivation tree representing leftmost derivation. Leftmost derivation in HR grammars is analogous to the one for string grammars (see [7]).

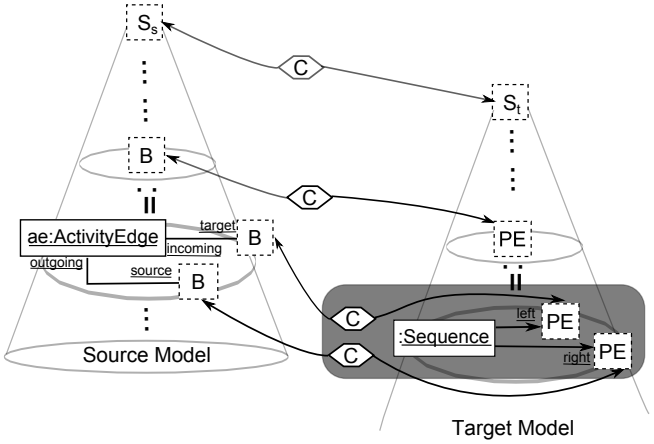

Fig. 10: Transformation execution sketch

In the second step, we build the target derivation tree by first initializing it by the edge of type S_t which has correspondence to the edge of type S_s in the source tree. Next, we iteratively construct the target tree in the following way: we traverse the source tree to find the next non-terminal edge e_s and the source production p_s that has rewritten it. Then, we consider each correspondence c of the edge e_s and find the transformation rule that pairs some p_t with the source production p_s, and where the left-hand side non-terminals are equal to the types of the edges linked by c. Finally, we apply the target production p_t to the target non-terminal edge linked to e_s through c, and create additional correspondences according to the transformation rule. The transformation terminates once the complete source derivation tree has been traversed and all correspondences have been considered. Due to the context-freeness of HR grammars [8], we can use any traversal method.

Fig. 10 sketches the transformation execution, highlighting a single production in the source derivation tree for our example applied to an edge of type *B* with the corresponding edge *PE* in the already created target tree fragment. The dark grey rectangle frames the result of applying the suitable transformation rule 5 (Fig. 9) to the corresponding edge *PE*.

IV. Transformation Properties

Besides allowing for a natural way of transformation definition by mapping logically equivalent concepts onto each other, our method for building model transformations exhibits some important properties. A transformation defined using our approach and fulfilling the criteria mentioned above is, by construction:

a) *terminating* – for any input model, the transformation terminates and returns either a resulting model or *not applicable*,
b) *complete* – all valid, i.e., parsable, models are transformable,
c) *sound* – a valid and transformable model is always transformed into a valid model (parsable in the target grammar),
d) *deterministic* – the output model and its derivation are fully determined by the input model.

For the last property, we require the source grammar to be unambiguous (see Def. 3). Due to the page limit, we only give proof sketches for each of the properties here. In the sketches, we emphasize the conditions on the transformation definition that are sufficient to guarantee these properties. In the following we refer to the source and target HR grammars as G_s and G_t, to the input (source) model as M_s, to the output (target) model as M_t, and to the transformation as τ.

*a) **Termination**:* As described in the last section, τ first parses the input model M_s, yielding a source model leftmost derivation tree T_s (or *not applicable*). Since our approach is based on *context-free* grammars, this is guaranteed to terminate. Then, a *single* G_t production applications is performed by τ for every G_s production application and correspondence c of the edge rewritten by it in T_s. Since these productions' applications are guaranteed to terminate, and the set of correspondences, and T_s *are finite*, the whole process is also guaranteed to terminate.

*b) **Completeness**:* For completeness, we have to show that if $M_s \in \mathcal{L}(G_s)$, $\tau(M_s)$ will not fail. If $M_s \in \mathcal{L}(G_s)$, the first step (parsing) will always succeed, and return T_s. In Sec. III, we have demanded that τ contains a transformation rule for *every production* in G_s and *every correspondence type* an edge rewritten by it might have. Hence, we can transform every production application in T_s into an application in T_t.

Next, we look at the derivation of the output target model M_t via T_t. For completeness, we need to show that this derivation does not fail, i.e., that all target productions are applicable at the place where the transformation wants to apply them. Both G_s and G_t are *context-free*, so the existence of the non-terminal edges ensured by the correspondences is all that is needed to ensure applicability of the target productions. When considering the next source production application, we apply the related target production to the non-terminal edge corresponding to the edge rewritten by the source production. Therefore, since the source production is applicable and τ contains rules for every type of correspondence that non-terminal edge rewritten by it might have, the target production is applicable too. Thus, τ always returns a model for a valid M_s and thus, τ is complete.

*c) **Soundness**:* It remains to be shown that $M_t \in \mathcal{L}(G_t)$. This can be reduced to the question whether the target tree T_t is complete, meaning that no non-rewritten non-terminal edges are left after the application of the transformation.

From requirements in Sec. III, every non-terminal edge produced by a target production is *linked by a correspondence* to a non-terminal edge in T_s. And since $M_s \in \mathcal{L}(G_s)$, all source non-terminal edges produced are eventually rewritten. This implies that all target non-terminal edges produced are also eventually rewritten by the related target productions, i.e., T_t is complete. Thus, we have $M_t \in \mathcal{L}(G_t)$.

*d) **Determinism**:* Since G_s *is unambiguous*, the production of T_s is deterministic. The tree T_s fully determines which rules are applied to construct the target tree, and where. This is because each production on the target side is uniquely determined by the source production and the correspondence

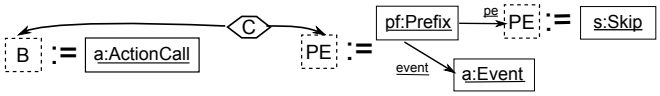

Fig. 11: Transformation rule: Action to an event followed by SKIP process

of the source non-terminal edge it rewrites. The target side of this correspondence also uniquely determines where the target production is applied. We thus, obtain exactly one target derivation tree, and consequently exactly one target model. Therefore, no two different target models can be the transformation result for a single M_s.

V. Extensions

As you might have noticed, we still have to describe a couple of rules to complete the definition of our sample transformation. The remaining rules need to transform: an action call (1) or an internal action (2) into an event followed by a SKIP process, and a loop (3) into an equivalent recursive process, since CSP does not natively support loops. In these two cases we need to relate *two or more* target productions that form a derivation sub-tree to a single source production. To allow this, we extend our approach by relating *derivation sub-trees* instead of relating *single productions* in transformation rules.

Fig. 11 shows such an extended rule for case 1 (2 is analogous): it relates the production for an action call to a sub-tree combining two target productions to create an event followed by a SKIP process. Since all non-terminal edges created by these target productions (one *PE*) have been consumed in the sub-tree, we only require a correspondence for left-hand side non-terminals of the first productions.

Fig. 12 shows the rule for case 3 and, thereby, the second extension of our approach – so called *non-local rules*. This type of rule allows the use of an *additional correspondence* between non-terminals, and uses its target non-terminal as a root of an *additional derivation sub-tree* containing one or more productions. During the transformation execution, when a correspondence of the defined additional type is found and the rule can be applied, the defined additional sub-tree is assigned to its target of this correspondence, replacing it.

Both extensions can be combined within one rule as seen in Fig. 12: it relates the production for a loop to the production for a process reference *L(c)* and uses a correspondence between two model non-terminals (*M*) to create the referenced process *L(x)*. This process consists of an *if-then-else* expression with the first non-terminal edge *PE* in the *then* branch linked to the body of the activity loop represented by the edge *B*, followed by the recursive call to itself, which terminates when the condition *x* fails. The new process is placed directly under the output model edge *M* which makes the result of this rule *non-local* and different from previous examples.

As for the conditions we imposed on our transformation for it to have the desired properties (see Sec. IV), they now need to be adjusted. A full explanation is out of the scope of this paper, thus, we only provide an idea of required adjustments.

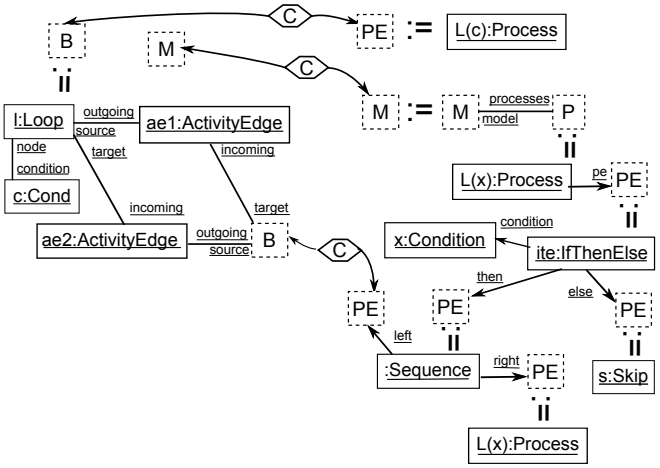

Fig. 12: Transformation rule: Loop to an equivalent recursive process

First, for multiple properties, when a rule relates derivation sub-trees, all non-terminal leaves of the target sub-tree have to have corresponding non-terminal leaves in the source sub-tree. Next, for determinism, the absence of two simultaneously applicable transformation rules need to be guaranteed: either by disallowing rules with the same correspondence and one source sub-tree being a sub-tree of the other, or by introducing rule priorities. Furthermore, for completeness, the presence of rules covering all possible source model derivation steps must be guaranteed: either via coverage analysis or forbidding to use source sub-trees with more than one production. In the case of non-local rules, to guarantee determinism, exactly one correspondence of the specified additional type must exist when the rest of the rule is applicable. Plus, the same correspondence condition as for the main target sub-tree must hold for non-terminal leaves of the additional target sub-tree.

VI. Tool Support & Evaluation

To support the approach we have designed a tool chain involving existing state-of-the-art tools: a graph grammar parser of the AGG [16] framework and the EMorF [17] transformation engine. The chain requires source and target grammars modelled as instances of our HR grammar meta-model extended with grammar-specific non-terminal and terminal type classes. All meta-models are specified in the *ECore* meta-modelling language of the *Eclipse Modelling Framework* [18]. The specified source and target grammars are used as input of our *Eclipse* based *Grammar-Based Model Transformation Framework* that allows the definition of transformation rules and validate their compliance with the conditions from Sec. III. The framework makes use of existing transformation languages and engines like TGGs [15] and EMorF engine by translating the created transformation into its declarative, language (and engine) specific implementation operating on trees. Other combinations of languages and engines like ATL [19] with its engine can also be used.

Fig. 13 shows the described tool chain with the used artefacts for the case when TGGs and the TGG engine (here

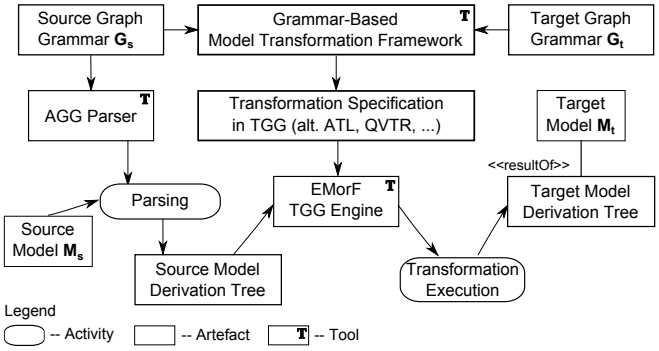

Fig. 13: Tool support for grammar-based transformations with TGGs and EMorF as implementation platform

EMorF) were chosen as the target execution platform for the developed transformation.

To evaluate our approach, we compare it on our running example with the most common transformation development practices in MDE, where meta-models are used in combination with declarative, imperative, and hybrid transformation languages. Meta-models may contain additional classes (e.g., *StructuralActivityNode* in UML [11]) to group (other) classes.

When a source meta-model does not include such structural classes, then the transformations that require this structural information defined on it have to use *imperative constructs*. Often they are also combined with recursion. In our example, such constructs are required to locate the related decision and merge activity nodes to build the corresponding sequence of processes in CSP.

```
rule Decision2IfThenElse extends DefaultNode2Skip {
from d  : AD!Decision
to   ps : ProcessExpression!Sequence (
   left  <- pe,
   right <- d.findMrg(d.outgoing.first().target,0)
 ),

 pe : ProcessExpression!IfThenElse (
   then <- d.outgoing->select(...).first().target,
   else <- ..., condition <- ...
)}

helper def:findMrg(n:AD!ActivityNode,i:Integer)
: AD!Merge =
if n.oclIsTypeOf(AD!Merge) then
 if i > 0 then
  thisModule.findMrg(n.outgoing.first().target,i-1)
 else
  n
 endif
else
 if n.oclIsTypeOf(AD!Decision) then
  thisModule.findMrg(n.outgoing.first().target,i+1)
 else
  thisModule.findMrg(n.outgoing.first().target,i)
 endif
endif;
```

Listing 1: ATL code fragment: Decision / merge block to if-then-else process sequence

Listing 1 shows implementation of this transformation step in a widely used general-purpose hybrid model transformation language ATL [19], which relies on meta-model based language definition. We use the meta-models from Sec. II-A to define the source and target languages of the ATL transformation. We use an ATL matching rule to transform a decision node d to an if-then-else process expression pe (rule *Decision2IfThenElse*). But to link the target expression pe to the next process expression, which should be the result of transforming the merge node corresponding to the decision node d, we have to use recursion to find that merge node. For this purpose, we implement a recursive search helper *findMrg* that follows the path starting in d and skips intermediate decision/merge pairs until it finds the right merge node.

To use this recursive search in ATL, we have to assume well-formedness of activity diagrams, ensured by extra OCL constraints. Such OCL constraints are not always defined and, if they are, they contain recursion and considerably complicate the complete meta-model based language definition. Furthermore, the need for imperative constructs forbids the use of declarative languages and significantly complicates readability and analysis of the transformations. In fact, most techniques aiming to guarantee transformation quality [20], [21] only consider declarative rules and are not applicable here.

Another solution to build structure-based transformations is to use transformation rules to create the required structures in a suitably defined (by meta-model containing structural classes) correspondence model as done in [22] using TGGs. As the previous imperative solution, the correspondence-based solution does not guarantee quality of the developed transformations, and it complicates their understandability and analysis.

If meta-models include structural classes, it is possible to define declarative structure-based rules in TGG-like format with better readability than in the previous solutions, and with more analysis possibilities. Still, as far as we know, there are no approaches showing completeness and determinism even for such declarative transformations. Unlike these common practices, our approach natively supports structure-based transformations keeping their rules graphical and concise (see Fig. 9, rule 7), and guarantees their quality.

Discussion: Transformation rules defined using our approach stay declarative (see Fig. 9) which brings multiple advantages: simpler and more intuitive transformation rules that are easier to understand and maintain especially when grammar productions are represented in concrete syntax; and guaranteed transformation quality properties discussed in Section IV. The only part that stays imperative is the source model parsing. Parsing causes most of the complexity in our method, but its mathematical foundations for HR grammars [8] guarantee termination and predictable worst-case run-time.

The conditions we currently put on transformations defined by our approach to guarantee their quality (Sec. III) might be too restrictive even with the use of extensions (Sec. V) for some purposes. In such cases, a developer can still define structure-based declarative transformations using our approach and employ existing testing and verification techniques to check their quality.

The choice of HR grammars for language definition currently limits our approach to the transformations between

context-free graph-based languages. We plan to address this limitation and take context-sensitive languages into consideration using grammars proposed in [23].

HR graph grammars, which we use to define source and target languages, in general, are more restrictive and complex than pure meta-models (with structural classes). However, when compared to meta-models with OCL constraints enforcing (when possible) the same structural well-formedness constraints on e.g., activity diagrams, HR grammars typed over meta-models present a more concise, intuitive, and powerful way to describe such constraints.

An a meta-model, an HR grammar only needs to be created once per language and, can then be used by any developer for any grammar-based transformation involving this language. The complexity of an HR grammar can affect the complexity of the grammar-based transformation using it, but this is also the case with meta-models.

VII. Related Work

For years, compiler construction benefits from syntax-directed translation [6]. This technique relates single string grammar productions via 1-to-1 relations and requires both grammars to have the same non-terminals, building a very basic version of our approach. Pratt [7] was first to propose to apply this technique to graphs and show that the resulting transformations are deterministic and reversible (under conditions). Our approach extends [7] to n-to-m relations between productions, n-to-m correspondences between non-terminals, and shows additional properties for the developed transformations. Thus, we consider a much larger scope of transformations than the approach from [7].

TGGs proposed in [15] were also inspired by Pratt [7] and were first to contain explicit correspondence nodes. However, the focus of TGGs was on relating context-sensitive productions to support data integration without the consideration of transformation quality properties. In MDE today, TGGs are defined on meta-models and relate model patterns gradually matched during the execution instead of grammar productions. The only approach we are aware of, that uses TGGs with meta-models to define structure based transformation in [22], has already been compared to in out evaluation in Sec. VI.

Halfway between grammars, as in our approach, and meta-models is the transformation development and validation approach proposed in [24]: it relates source model patterns with target productions and states extensive criteria for the transformation quality assurance. Target language in this approach is defined through graph grammar productions. However, it is unclear how the target grammars used there are defined and whether the related target productions can always be applied when the source pattern is found during the transformation execution. In [24] transformation execution strategy is defined manually whereas, in our approach it is automatically obtained during the source model parsing making it less error prone. Like us, authors of [24], consider transformation characteristics: termination, and confluence; however, they do not consider soundness and completeness.

Other approaches like [25], [26], [27] advocate transformation development by-example and by-demonstration, and do not directly focus on structure based transformations. Like us, these approaches recognize the problem of over abstraction of language definition through meta-models, but deal with it using examples to describe corresponding structures of the source and target languages, whereas we use graph grammar productions. By such example-based approaches it is not always clear whether the examples or the transformation should be adapted when the result is not yet satisfactory, how many examples are needed. Whether the developed transformation has desired properties is, as far as we know, not addressed by any of these approaches.

Several other approaches [28], [29] directly apply classic techniques to model transformations. Unfortunately, non of them considers properties of the developed transformations.

In [28] the authors attempt to use TXL [30] – a generic source transformation framework – to develop model transformations. They consider meta-model based languages, and transform them into TXL string grammars. TXL string grammars do not have the expressiveness and visualization advantages of graph grammars we use leading to very limited applicability of the TXL-based approach. Transformations described in TXL are fine-grained with explicit execution policy, which makes them flexible, but also complex and difficult to understand and maintain. This method can be placed halfway between the syntax-directed translation and our approach.

In [29] the authors attempt to simplify transformation development by eliminating the need to learn specialized languages. They regard models and meta-models as abstract data types – abstract structures with operations. On top of the types they define a minimal imperative model transformation language with formal semantics. This approach brings models and transformations into the world of programming, whereas our approach lifts translation techniques to graphs. Both last approaches use meta-models and none of them directly considers high-level structures in languages and transformations based on these structures, as we do. Transformation quality is not take under consideration either.

We consider our approach as the next step towards efficient and quality-aware transformation development that can be realized based on existing state-of-the-art including some approaches described above and the commonly used technologies like ATL [19] and TGG [15].

In general, use of alternative notations for modelling language definition – meta-model vs. graph grammar – raises the issue of integration and interoperability of approaches and tools respectively. Various methods address this issue by defining transformations between the alternatives [31], [32], [33], applying inference to obtain graph grammars [34], or combining them as different views for multi-level modelling [35]. The later option is the one we use.

Finally, we want to point out that the simplest version of our method has been recently successfully used in [36] for semantic-based machine translation in the field of computational linguistics.

VIII. Conclusion

In this paper, we have presented a grammar-based model transformation development approach that allows to naturally consider structures of involved language. We have employed HR grammars to specify source and target languages, and defined transformation rules by relating their productions and adding correspondences between non-terminals. We have shown that model transformations defined using our approach terminate and are sound, complete, and deterministic. We have also presented some extensions of the approach.

Future Work: Currently, we are working on the extension of initial case studies to evaluate our approach and continue improving the tool support. In the future, we look to support computation of attributes, while still keeping the desired transformation properties. When expressiveness of HR grammars is not sufficient, we plan to explore the decidable contextual graph grammars proposed by Drewes in [23].

***Abstract*—In this paper we present a Multi-Paradigm Information System Modeling Tool (MIST) that supports Extended Entity-Relationship (EER) approach to database design. MIST components currently provide a formal specification of EER database schema specification and its transformation into the relational data model, or the class model. Also, MIST allows generation of Structured Query Language (SQL) code for database creation and procedural code for implementing database constraints. In addition, Java code that stores and processes data from the database, may be generated from the class model.**

I. Introduction

IN THE last few decades, a number of information system (IS) development approaches have emerged. Some of methods that are still in use include: Entity-Relationship (ER) data model proposed by Chen [8] with its further extensions, relational data model [9], form type (FT) model [15], and object-oriented model [22].

Throughout our previous research [2], [15], [16], [17], we have developed a tool named IIS*Studio, to allow a usage of FT concepts in the IS design process. IIS*Studio provides an approach to an evolutive and incremental IS development. The approach is purely platform independent and it strictly differentiates between the specification of a system and its implementation on a particular platform. IIS*Studio currently provides the following functionalities: (i) conceptual modeling of database schemas, transaction programs, and business applications of an IS; (ii) automated design of relational database subschemas in the 3rd normal form (3NF); (iii) automated integration of subschemas into a unified database schema in the 3NF; (iv) automated generation of SQL/DDL code for various DBMSs [2]; (v) conceptual design of common GUI models; (vi) automated generation of executable prototypes of business applications; (vii) modeling check constraints and untypical functionalities of business applications [16]; and (viii) reverse engineering of relational databases to FT models [1].

With the emergence of Model Driven Software Development (MDSD) paradigm and Eclipse Modeling Project (EMP) [10] with an appropriate tooling, we decided to implement some of the existing IIS*Studio functionalities using these technologies. The motivation came from our intention to provide designers of ISs a possibility to use Eclipse environment and thus reduce steep learning curve for new users of IIS*Studio. Therefore, we have developed a domain specific language (DSL) allowing a specification of IS form type models. A detailed specification of this language is presented in [7].

One of the main goals of IIS*Studio is to provide a designer conceptual modeling by creating platform independent models. As designers mainly use other approaches than FT for this purpose, we have decided to support not only FT concepts, but also Extended Entity-Relationship (EER) data model, as a commonly used, traditional approach. Therefore, we have developed a DSL for the specification of EER database schema specifications, named EERDSL. Together, FT and EER are the approaches of our new Eclipse-based tool both providing conceptual database schema modeling. The tool is named Multi-paradigm Information System modeling Tool (MIST). In MIST, both approaches may be used simultaneously. For both FT and EER models, we provide in MIST a transformation into a relational data model. In our previous research on database reengineering approaches [1], we have developed a transformation from a relational data model to a FT model, named relational to form type transformation (R2FT). R2FT is used to transform an EER model into an FT model via relational data model.

As EER approach is present in almost every book on databases, we believe that MIST may also be used for educational purposes, such as learning about: (i) EER concepts and developing a database specification at the conceptual level; (ii) transformations of EER to relational database schema specifications; (iii) transformations of EER to class models; and (iv) MDSD approach by means of the EER approach the students are familiar with, since it is extensively taught in the previous database courses.

In this paper we present the architecture of MIST. It comprises several components that support not only conceptual modeling with FT and EER approaches, but also code generation. The main focus in the paper is on tool components supporting EER approach and transformations from EER to relational and class models. A detailed presentation of the code generators is out of the scope of this paper. Let us just notify here that we have developed both SQL and Java code generators. The SQL Generator provides SQL statements for creating database tables and all basic types of constraints according to SQL ANSI standard. Besides, the code of inverse referential constrains, as they are defined in [3], is generated. As it has to be implemented in a procedural way, different

Research presented in this paper was supported by Ministry of Education, Science and Technological Development of Republic of Serbia, Grant III-44010.

generators are needed for each target database management system (DBMS). Our tool currently supports generation of PL/SQL statements for Oracle DBMS. Our Java code generator provides a generation of Java classes from a class model. Generated Java classes are used in Java programs for storing loaded data from a database.

Apart from Introduction and Conclusion, the paper is organized in four sections. In Section 2 we present the architecture of MIST, while in Section 3 we present EER, Relational and Class meta-models. The aforementioned meta-models are used in the following transformation specifications: (i) the EER data model to relational data model transformation, named EER2Relational and (ii) the EER data model to class model transformation, named EER2Class. These transformations are presented in Section 4. In the same section we present results of applying the aforementioned transformations in our example and the excerpts from generated SQL and Java code. In Section 5, we present related work.

II. The Architecture of MIST

In this section we present the architecture of MIST. Its global picture is depicted in Fig. 1. MIST comprises the following components: FTDSL, Synthesis, Business Application Generator, EERDSL, EER2Rel, EER2Class, SQL Generator, Java Generator, and R2FT. In the following text, we explain each of the components from Fig. 1.

FTDSL component allows designers to specify a platform independent model (PIM) of an IS. FTDSL comprises Ecore meta-model specification of FT PIM concepts and a textual DSL based on these concepts. With the DSL a designer may specify a database schema of an IS, business applications and their graphical user interfaces (GUIs). After an IS is specified at the PIM level, the Synthesis component is used to generate a model of a relational database schema. The Synthesis component implements an improved synthesis algorithm, as it is presented in [14]. First, the component takes a form type specification and transforms it to a Universal Relation Schema (URS) specification. URS and all its benefits are presented in [14]. The synthesis algorithm takes the URS specification and produces a relational database schema as an output. As the FT component may be used to specify business applications of an IS, the MIST architecture includes a Business Application Generator component. This component takes a FT model as an input and generates Java code of a modeled business application. As the specification is enriched with GUI details, the generated application prototype may be executed and used to perform basic CRUD operations over the database.

EERDSL component provides a conceptual specification of an IS database model. Unlike FTDSL, EERDSL is used to specify IS database models only, without specification of business applications and their GUIs. We have created both textual and graphical notations for EERDSL. The textual notation was developed using the Xtext tool, while the Eugenia tool was used to develop the graphical notation. One of the benefits of having a textual notation is that textual editors may be used as an alternative option for more experienced users, or when the Eclipse environment is unavailable. The textual notation also allows a usage of commonly used textual version control systems to provide a better collaboration inside the developer team. Most database designers, however, are using some EER graphical notation. Several different graphical notations for the EER approach exist. Here we have implemented the notation presented by Thalheim in [21]. Both graphical and textual notations may be used by a designer simultaneously, while specifying an EER model. By this, two different viewpoints over the same model are provided in MIST.

EER2Rel component of MIST provides a transformation of EER model to a relational data model. Models being transformed conform to the EER meta-model and relational meta-model, respectively. The meta-models are presented in the following section. The relational data model may be further used in the process of SQL code generation. For this purpose,

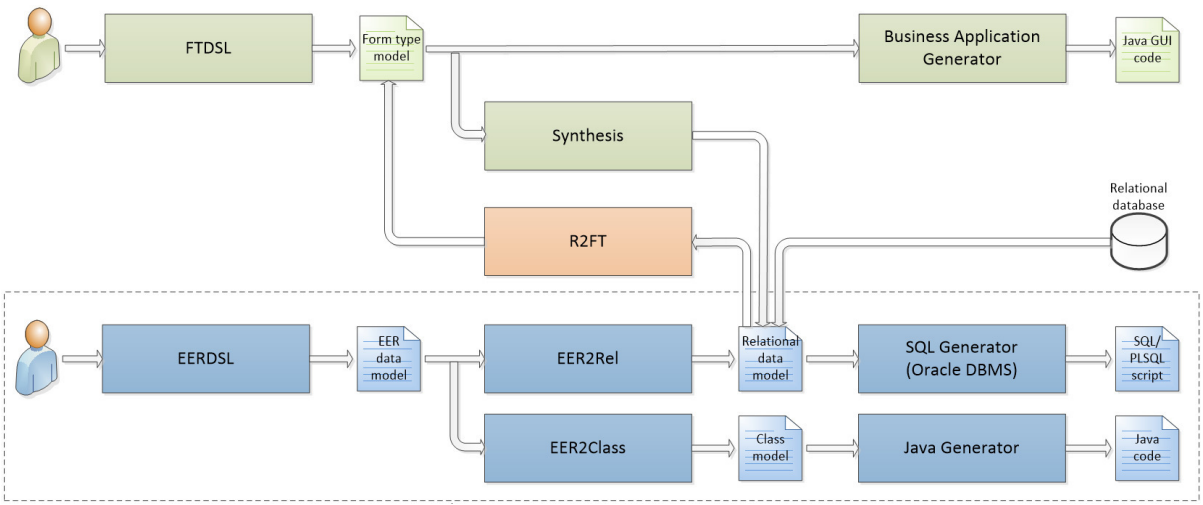

Fig. 1. The architecture of MIST

the SQL Generator component is developed. Currently, it provides generating SQL code for Oracle DBMS.

EER2Class component of MIST provides a transformation of an EER model to a class model. The class model conforms to the class meta-model presented in the Section 3. The class model may be used to generate code in some of the object-oriented programming languages. Our Java Generator component is used to generate Java code from the provided class model.

In order to provide reverse engineering of the relational database model to the FT model, R2FT component has been developed. The component comprises a transformation specification from the relational data model to the FT model. Also, this component may be used to transform an EER data model to the FT model through the relational data model.

III. EER, Relational, and Class Meta-Models

In this section we present in more detail meta-models used in EER approach. In Subsection A, we present our EER meta-model and introduce an example used throughout the paper. Our goal is to test the approach on this example. Further evaluations of the approach are also possible, such as comparing its quality and efficiency with the FT approach. However, this comparison is not presented in this paper due to the space limitations. In Subsection B, we present the relational meta-model, while in Subsection C we present the class meta-model.

A. EER meta-model and an example

In this subsection we present the EER meta-model depicted in Fig. 2. In the rest of this section we present the names of meta-model and model concepts in italic. This meta-model represents the abstract syntax of EERDSL used for specifying data models at the conceptual level. The root concept in our meta-model presented in Fig. 2 is *EERModel*. Each EER model comprises one or more *Entities* and zero or more *Relationships*, *Gerunds*, and *Domains*.

Entity concept is used to specify a class of observed real world entities in the IS being designed. In some approaches, the *Entity* concept is named as *Entity Type* concept. According to [21], we adopt the name *Entity*.

Each entity has zero or more attributes that are modeled by *Attribute* class. Attributes represent properties of real world entities that are of importance for the specified IS. For each attribute, a domain is specified. A domain represents a specification of possible values that can be assigned to an attribute and it is modeled using *Domain*. A domain must be based upon a primitive domain, such as integer, string, real, boolean, date, and time. The primitive domain is modeled by an enumeration *PrimitiveDomain*. An assignment of a domain to an attribute is modeled by *AttributeDomain*. For each attribute, length and default value may be specified. This way of restricting domains allows their reusability. Therefore, domains may be specified once at the level of EER model, and reused and further restricted at the level of attributes. An entity may have one or more keys modeled by *Key*. Each key comprises one or more attributes of the entity. Only one key may be declared as the primary key. This is modeled by *primaryKey* association.

In the meta-model from Fig. 2, different types of relationships between entities are modeled by: *Relationship*, *ISA*, *Categorisation*, and *IdentificationDependency*. An n-ary relationship between entities is modeled by *Relationship*. For each entity its role, minimum, and maximum cardinalities must be specified for each relationship. Minimum cardinality may be provided with the values of zero or one, while a maximum cardinality may be provided with the values of one or more. Entity role and cardinalities are modeled by *RegularEntity*. Each relationship may have zero or more attributes. IS-A

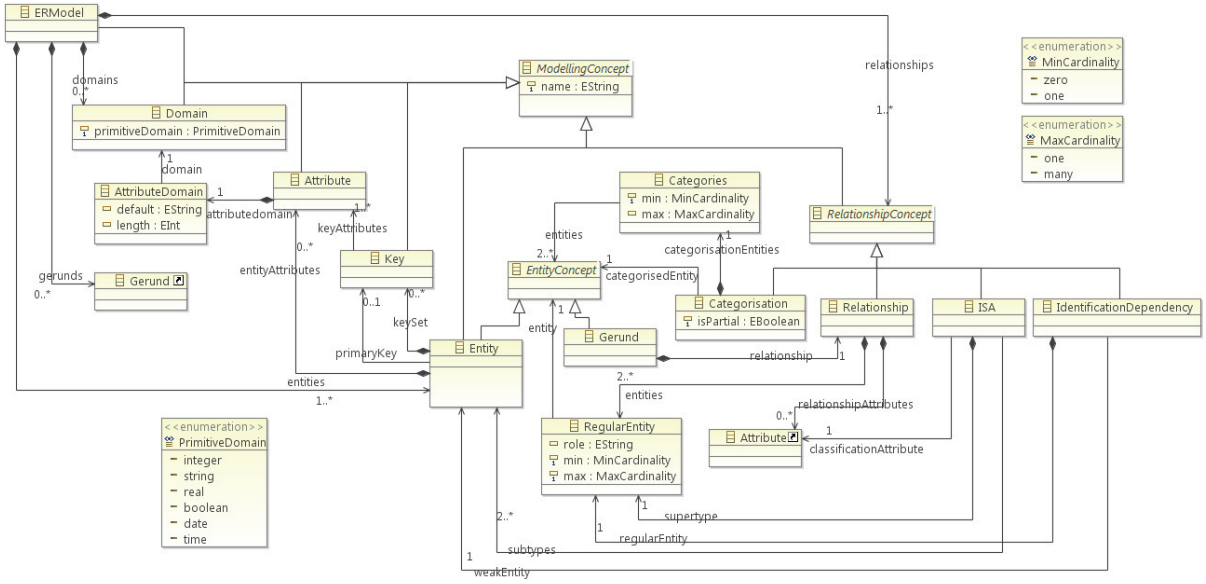

Fig. 2. EER meta-model

relationship, modeled by *ISA*, represents a specialization of entities. For each IS-A relationship a single supertype entity should be provided. This is modeled by *supertype* association. Also, for each IS-A relationship, subtype entities should be provided. This is modeled by *subtype* association. Categorization relationship represents a classification, i.e. typization relationship between entities. It comprises two or more category entities, modeled by *Categories*, and a single categorized entity. Identification dependency relationship concept is modeled by *IdentificationDependency*. A weak entity is modeled by *weakEntity* association, while regular entity is modeled by *regularEntity* association.

An n-ary relationship may participate as an entity in another relationship. Such relationship is called gerund and modeled by *Gerund*. A gerund may take a role of a regular entity in an n-ary or identification dependency relationship. Also, it may take a role of a specialized entity in a specialization, and category entity in a classification.

In Fig. 3, we present our example specified using a textual notation of EERDSL. The textual notation is chosen as it is rarely encountered while specifying EER models. However, due to the limited space, we omit repetitive constructs from the textual specification. We model a part of a Faculty IS, named *FacultySystem*, responsible for storing data about students and their grades.

Students are modeled with an entity named *Student*. Each student has four attributes: *studentID*, *studentsYear*, *studentName*, and *studentSurname*. Primary key named *keyStudent* comprises *studentID* attribute. Subjects are modeled with *Subject* entity having two attributes: *subjectID* and *subjectName*. Primary key named *keySubject* comprises *subjectID* attribute. Teachers of a faculty are modeled as *Teacher* entity and are described by *teacherTitle*, *teacherID*, *teacherName*, and *teacherSurname* attributes. *TeacherID* is the only attribute in *keyTeacher* primary key. Relationship between teachers and subjects they teach is modeled by *TeachesClasses*. Each teacher may teach one or more subjects, while a subject may be taught by one or more teachers. The relation between students and subjects is modeled as *Takes* relationship. Each student may enroll one or more subjects, while a subject may be enrolled by zero or more students. Relationship *Grades* models students' grades given by teachers. As only a teacher that teaches a subject may grade students enrolled on that subject, relationship *Grades* must relate relationships *Takes* and *TeachesClasses*. Therefore, relationships *Takes* and *TeachesClasses* must be represented as gerunds. Each student that takes a subject may be graded by exactly one teacher teaching the subject. A teacher teaching a subject may grade zero or many students of the subject. For each grading *examDate* and *grade* attributes are specified.

```
EERModel FacultySystem {
 domains {
  Domain int primitiveDomain integer,
  ... // omitted domains: varchar, Date, and Time
 }
 entities {
  Entity Student {
   attributeSet {
    Attribute studentName domain varchar(20),
    Attribute studentSurname domain varchar(20),
    Attribute studentID domain int,
    Attribute studentYear domain int
   }
   keySet {
    keyStudent (studentID)
   }
   primaryKey  keyStudent
  },
  ... // omitted entities: Subject and Teacher
 gerunds {
  Gerund Relationship Takes {
   entitiesInRelationship {
    Student (one,many),
    Subject (zero,many)
   }
  },
  ... // omitted gerund for relationship TeachesClasses
 relationships {
  Relationship Grades {
   entitiesInRelationship {
    Takes (one, one),
    TeachesClasses (zero,many)
   }
   attributeSet{
    Attribute grade domain int,
    Attribute examDate domain Date
   }
  }
 }
}
```

Fig. 3. Example of Faculty IS specification in EERDSL

B. Relational meta-model

In this subsection we present our relational meta-model. The root concept of the relational meta-model presented in Fig. 4 is *Database*. Each database schema comprises *Tables*. *SystemDataTypes* represent predefined data types built into each DBMS, while *UserDefinedDataTypes* represent user defined restrictions on existing data types. Each table comprises one or more columns, modeled with *Column*, and constraints inheriting the abstract concept *Constraints*. At the level of a relational database specification, for each table following constraints may be specified: (i) primary key constraint modeled by *PrimaryKeyCon*, comprising an array of columns; (ii) unique constraint modeled by *UniqueCon*, comprising an array of columns having a unique combination of values; (iii) foreign key constraint modeled by *ForeignKey*, comprising: an array of columns, referenced table, and primary key constraint or unique constraint of referenced table; and (iv) check constraint modeled by *CheckCon*, comprising a logical expression.

C. Class meta-model

In this subsection we present our class meta-model. We have modeled only the most basic concepts to specify elements for a representation of data in object oriented programs. The root concept of the class meta-model depicted in Fig. 5 is *ClassModel*. All concepts are grouped into packages modeled by *Package*. A package comprises zero or more *Classes* and

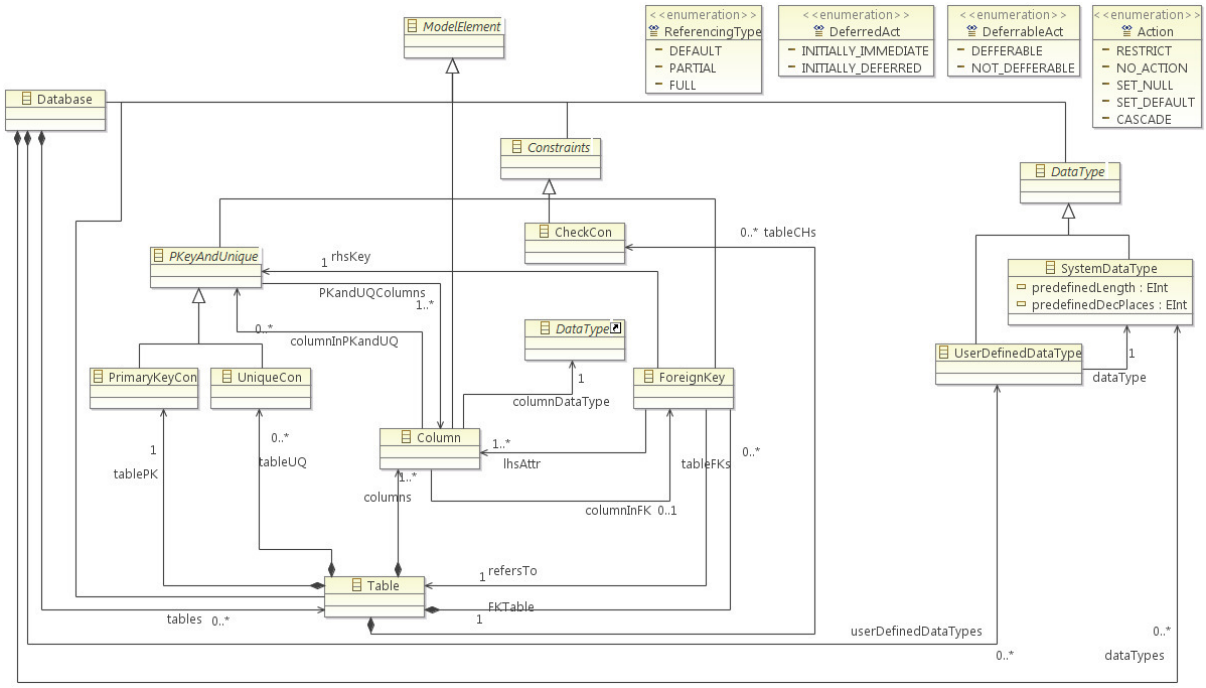

Fig. 4. Relational meta-model

other *Packages*. Each class comprises zero or more fields, modeled by *Attribute* concept, and methods modeled with *Function* concept. Data types are modeled by *Type*. Classes and types inherit the abstract *Classifier*. This concept is specified in order to allow attributes and functions to have both primitive and class types as their type, and the return type respectively. Finally, for each attribute, class, and function an access modifier should be provided. Possible access modifier values are modeled as an enumeration, which comprises following values: private, protected, default, and public.

IV. From EER Data Model to Generated Code

In this section we present two transformations: EER2Rel for transforming an EER model into a relational data model and EER2Class for transforming and EER model into a class model. Transformations are specified in ATL transformation language (ATL) [13]. We present ATL code for the most representative transformation rules. In this section we present the results of applying transformations on the example. Finally, generated code fragments of our example are presented at the end of this section.

Once an EER database model is specified using EERDSL, it may be transformed to the corresponding relational model. In Table I, the first two columns represent all of the corresponding concepts between the EER and relational meta-models. Based on these correspondences, concrete ATL transformation rules are specified.

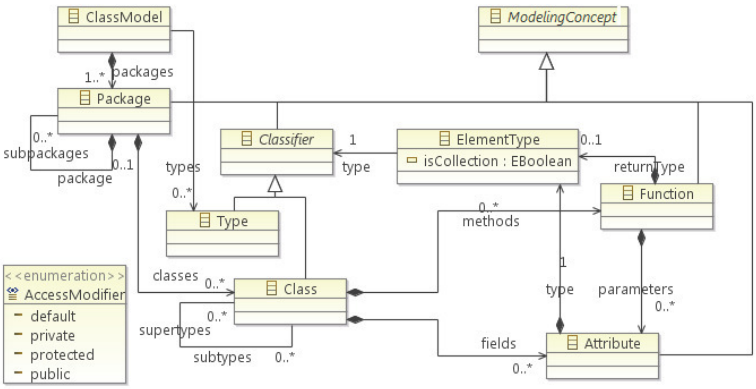

Fig. 5. Class meta-model

TABLE I
TRANSFORMATION ELEMENTS FROM AN EER MODEL TO RELATIONAL AND CLASS MODELS

EER model	Relational model	Class model
EERModel	**Database**	**ClassModel, Package**
Domain	**UserSystemType**, **SystemDataType**	**Type**
Entity	**Table**	**Class**, **Function** (Constructor)
Attribute	**Column**	**Attribute**, **Function** (Get/Set)
Key	**PrimaryKeyCon** (if the key is entity's primary key)	-
Relationship	**Table** (if all maximum cardinalities are *many*)	**Class** (if all maximum cardinalities are *many*), **Function**
Gerund	**Table**	**Class**, **Function**
Identification dependency	**Columns** of the propagated primary key are included into the primary key of the table created from a weak entity. **Foreign key** is created to reference the table created from regular entity.	For a class created from a weak entity, an **object-member** is created referencing a class created from a regular entity.
ISA	**Columns** of the propagated primary key are included into the primary key of the table created from a subtype entity. **Foreign key** is created to reference the table created from supertype entity.	A class created from a subtype entity **inherits** a class created from a supertype entity.
Categorisation	**Foreign key** is created to reference the table created from category entity.	For a class created from a categorized entity, **object-member** is created referencing a class created from a category.

Each EER database concept may be transformed directly to a relational database concept. A system data type is created from EER primitive domains and for each restricted domain, specific user system type is created. Tables are created from three different concepts in EER model: *Entity*, *Gerund*, and *Relationship*. All entities and gerunds are transformed directly into tables, while only the relationships that have maximum cardinality of *many* on both sides, are directly transformed into tables.

In Fig. 6 we present a transformation rule for transforming entities into tables. When transforming an entity to a table, the table name is the same as the name of the entity. For each entity, the following types of columns may be created: (i) columns created from attributes of the entity being transformed; (ii) columns created from attributes of a relationship having a maximum cardinality *one* on the transformed entity side; (iii) columns created from primary key attributes of related entities, where the entity being transformed is on *one* side of a relationship; (iv) columns created from primary key attributes of related categories in categorization relationships; (v) columns created from primary key attributes of related regular entities in identification dependency relationships where transformed entity plays a role of weak entity; and (vi) columns created from primary key attributes of related supertypes in ISA relationships. In this transformation rule, the aforementioned columns are created in both declarative and imperative way. The declarative part of the ATL rule may be used to create the first two types of columns. The creation of these columns does not require the creation of foreign keys and assigning the columns to a foreign key. Therefore, such columns do not require additional references to be set and as such they may be created in a fully declarative way. The imperative section of the ATL rule must be used for the next four types of columns. These columns represent copies of already created primary key columns in other tables. As such, foreign keys must also be created and *lhsAttr* and *columnInFK* references must be assigned to the created foreign keys and columns respectively. A foreign key must also reference a table containing original primary key columns with *refersTo*

```
rule Entity2Table {
  from e : ER!Entity
  using {--omitted variables used in do section }
  to t : RDBMS!Table (
    name <- e.name,
    columns <- e.entityAttributes -> union(
      e.getConnectedRelationshipsForEntity() ->
      collect(e1|e1.relationshipAttributes) ->
      flatten()),
    tablePK <- e.primaryKey
  )
  do {
    --FKs, columns from entities related with Mto1
    --This entity is on one side
    for(r in e.getConnectedRelationshipsForEntity())
    {
      t.tableFKs <- thisModule.CreateForeignKeys(
        r.getConnectedRegularEntity().entity, t,
        r.getConnectedRegularEntity().entity.
          getPrimaryKeyAttributes(),
        r.getConnectedRegularEntity().min=#one,
          r.name);
    }
    --FKs and columns from regular entites in ID rel
    ids <- e.getRegularEntitiesForWeak();
    thisModule.cols <- Sequence{};

    thisModule.cols <- Sequence{};
    for (sup in isaIds) {
      t.tableFKs<-thisModule.CreateForeignKeys(sup,
        t, sup.getPrimaryKeyAttributes(), false,
        'ISA');
    }
    pkcolumns <- pkcolumns->append(thisModule.cols)
      -> flatten();
    --create PK from appropriate columns
    if (t.tablePK.oclIsUndefined()) {
      t.tablePK<-thisModule.Key2PKMtoN(pkcolumns,
        t.name);
    } else {
      t.tablePK.PKandUQColumns <- pkcolumns;
      for (pkc in pkcolumns) {
        pkc.columnInPKandUQ <- t.tablePK;
      }
    }
  }
}
```

Fig. 6. Entity to table transformation

reference. As the created foreign key is a part of the newly created table, the foreign key must be assigned to *FKTable* reference. The creation of these columns and foreign keys is provided in a form of the ATL called rule. We have specified a *CreateForeignKey* called rule which creates columns from primary key columns of a related table and a foreign key referencing that table. This rule adds both created columns and the foreign key to the newly created table and populates all of the aforementioned relationships between foreign key, tables and columns. Due to the space limitations, we have not presented *CreateForeignKey* rule in this paper, but its explicit invocation is presented in Fig. 6 Arguments that are provided are as follows: (i) entity transformed to a table being referenced with a foreign key; (ii) table containing the foreign key, i.e. referencing table; (iii) primary key containing attributes that are transformed to referenced columns; (iv) a boolean value specifying whether an inverse referential integrity should exist; and (v) a string value to be appended to the names of newly created columns in order to avoid name conflicts with previously created columns.

Besides being foreign key columns, columns created from a supertype and a regular entity in ID relationship must be a part of a primary key. In presented ATL rule, as to collect all primary key columns we use a global attribute helper named *cols* and a local variable named *pkcolumns*. *CreateForeignKeys* uses *cols* to return created columns as the return value is used to return a created foreign key. Returned columns are then appended to the other columns contained in *pkcolumns* variable which is local variable declared in the ”using” section of an ATL rule. At the end of an imperative section of *Entity2Table* rule, primary key of a table is set. If a primary key has already been created in the declarative part of the rule, *pkcolumns* are simply appended to *PKandUQColumns* of the existing primary key. The *columnInPKandUQ* relationship is set for each column referencing a primary key the column is a part of. However, a primary key may not be created in the declarative part of the rule. That may be the case if the entity from EER diagram does not have a specified primary key, e.g. a subtype in ISA relationship. For those entities a called rule *Key2PKMtoN* is invoked which creates a primary key and sets all of the appropriate references between columns and the primary key.

Unlike entities, which are all transformed into tables, only relationships that are not contained in gerunds and that have all maximum cardinalities of *many* are transformed into tables. ATL rule that transform such relationships into tables is presented in Fig. 7 Attributes belonging to the relationship are transformed into the table columns. However, when a relationship between two or more entities is transformed from EER to a relational specification it must reference all primary key columns from all related entities. Similarly to the aforementioned *Entity2Table* rule, former columns are created in a declarative way while latter ones are created in an imperative way.

Finally, tables are also created from gerunds. Each gerund encapsulates a single relationship and it may be a part of another relationship. As such, a gerund has all traits of relationships and entities. Therefore, *Gerund2Table* transformation rule is a combination of both *Entity2Table* and *Relationship2Table* rules. It should be noted that a gerund may not be a subtype of inheritance relationship, a weak entity of an identification dependency relationship, or a categorized entity in a categorization relationship. Therefore, the imperative code from *Entity2Table* creating foreign keys and columns from these kinds of relationships is not a part of *Gerund2Table* rule. The code of *Gerund2Table* is not presented in this paper due to the space limitations.

```
rule Relationship2Table {
  from
    --M:N relationship not contained in a gerund
    r : ER!Relationship (not r.isGerund() and
        r.areMaxCardinalitiesMany())
  using {--omitted variables used in do section }
  to
    t : RDBMS!Table (
      name <- r.name,
      columns <- r.relationshipAttributes
    )
  do {
    keys <- r.getConectedKeyAttributesSequence();
    thisModule.cols <- Sequence{};
    for (k in keys) {
      pks <- pks.append(k -> first() ->
        getPKForAttribute());
      t.tableFKs <- thisModule.CreateForeignKeys(
        k -> first() -> getParentConcept(),t,k,
          r.relationship.isIrc(k -> first() ->
            getParentConcept().name)
        k -> first() -> getParentConcept().name);
    }
    t.tablePK <- thisModule.Key2PKMtoN(
      thisModule.cols, t.name);
  }
}
```

Fig. 7. Relationship to table transformation

The transformation of an EER model to a class model is very similar to the *EER2Relational* transformation. In Table I, the first and the third column represent all of the corresponding concepts between the EER and class meta-models. Instead of tables, classes are created and instead of columns each class has attributes. One notable difference is the lack of constraint concepts. In the class model, primary keys are not created which eases the transformation specification. Instead of creation of foreign keys, an attribute of referenced class type is created. If a relationship has a maximum cardinality of *many* then the attribute is a collection of referenced classes. The second difference is the existence of functions. For each class a parametrized constructor is created and for each class attribute, get and set methods are created.

In Fig. 8 we present results of the transformation of our example. In the leftmost part of the figure, we present the same example as in Fig. 3 opened in the Eclipse “Sample Reflective Ecore Model Editor”. This model has served as the input model for both EER2Rel and EER2Class transformations.

Output of EER2Rel is presented in central part of Fig. 8. Each of three EER entities, *Student*, *Teacher*, and *Subject*, has been transformed into a table with the same name.

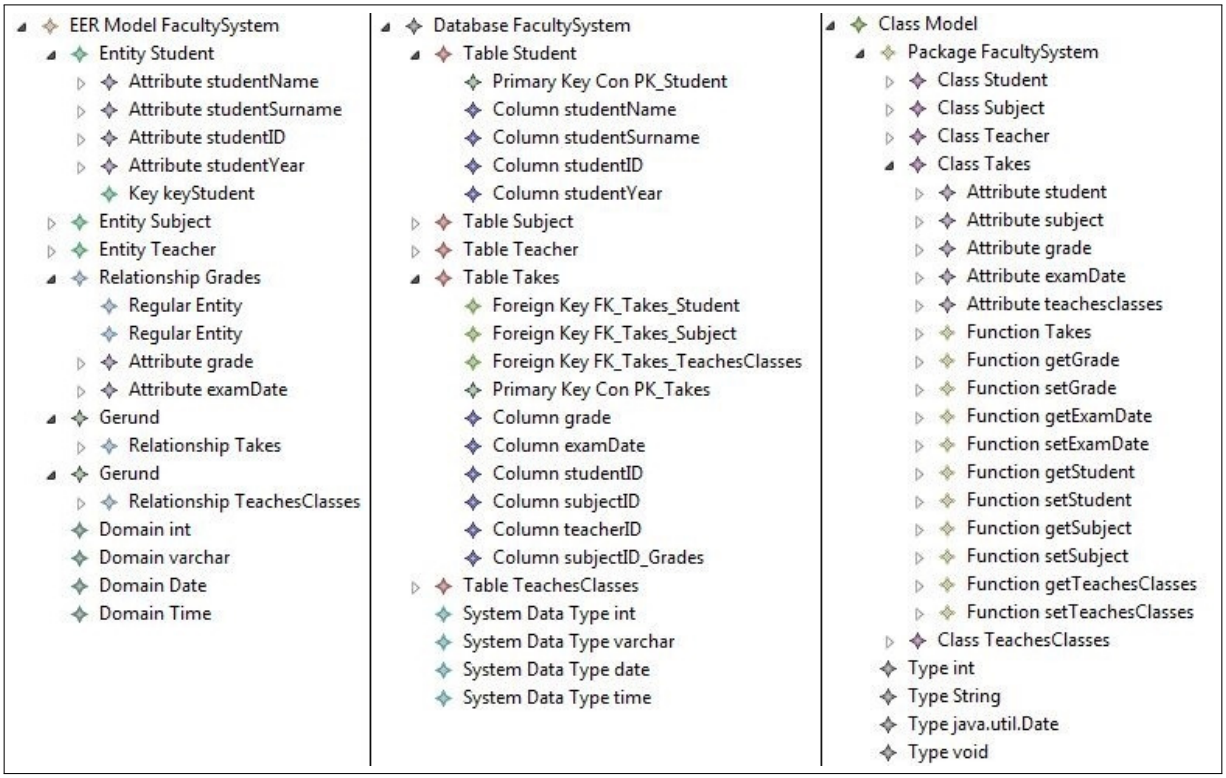

Fig. 8. Faculty IS example: the EER model, the relational database model, and the class model

Here, we present table *Student* in more details. The table contains columns created from *studentName*, *studentSurname*, *studentYear*, and *studentID* attributes of *Student* entity in EER model. From *keyStudent* in *Student* entity, *PK_Student* primary key is created. All the references between the key and attributes are preserved in a form of references between primary key and appropriate columns. Due to a lack of space, these references are not shown in Fig. 8. The gerund *TeachesClasses* is transformed into a table with the same name. Its columns are created from primary key columns of related *Teacher* and *Subject* tables. Appropriate foreign keys are also created for these columns. A primary key of *TeachesClasses* table represents a union of all primary key columns from *Teacher* and *Subject* tables. However, more interesting case of gerund to table transformations is the case of *Takes* gerund. Its relationship relates entities *Student* and *Subject*. Just like in the case of *TeachesClasses* gerund, the resulting table, named *Takes*, will have columns and appropriate foreign keys that reference primary key columns from both *Student* and *Subject* tables. These columns are *studentID* and *subjectID* with their foreign keys *FK_Takes_Student* and *FK_Takes_Subject*, respectively. Gerund *Takes* is related with the gerund *TeachesClasses* with the relationship *Grades*. This relationship is not to be transformed into a separate table as it has a maximum cardinality of *one* on the gerund *Takes* side. Instead, all of the relationship attributes from the *Grades* relationship will be created in *Grades* table as its own columns. Primary key attributes of *TeachesClasses* are to be referenced form appropriate columns in *Takes* table. Therefore, *Takes* table has *grade* and *examnDate* created from the attributes of *Grades* relationship. Columns *teacherID* and *subjectID_grades* with foreign key *FK_Takes_TeachesClasses* reference primary key attributes from *TeachesClasses* table. Let us note that *subjectID* from *TeachesClasses* table had to be renamed in *Takes* table as there was already a column with that name. We chose to append the name of a relationship through which the column was created in the table at the end of a column's name. As names of relationships are unique in the EER model, renamed attributes will all have unique names in their tables.

Output of EER2Class is presented in the rightmost part of Fig. 8. Only a detailed overview of a *Takes* class is given. Similarly to the relational model, a class model has five classes: *Student*, *Subject*, *Teacher*, *Takes*, and *TeachesClasses*. First three classes are created in a straightforward manner from the entities with the same name. *TeachesClasses* is created from *TeachesClasses* relationship. As relationship *Takes* relates *Student* and *Subject* entities, table *Takes* has two object-members: *student* and *subject*. For the same reasons as in the relational model, class *Takes* has two attributes from *Grades* relationship and an object-member representing *Teaches Classes*. These two attributes are grade and *examnDate* and an object-member is named *teachesclasses*. For object-members that represent a collection, a Boolean value of *isCollection* attribute should be set to *true*. For example, object member *teachesclasses* is of

the collection type, as it is created from *Grades* relationship that has a maximum cardinality of *many* on the side of *TeachesClasses*. In addition to attributes, a parametrized constructor and get and set methods are created. For each method a body is automatically generated in a form of a string.

In Fig. 9 we present excerpts from the generated SQL and Java code. In the left part of the figure we present a statement for creating *Takes* table as well as statements that add constraints to this table. In the same figure we present a part of the procedural code that handles inserting new tuples into tables on top of which an inverse referential constraint is enforced. In our example these two tables are *Subject* and *TeachesClasses*. In order to allow simultaneous insert in both tables, a view *View_Subject_TeachesClasses* is created that will allow such insert. An algorithm that handles such insert is a part of a generated trigger named *TRG_IRI_Subject_TeachesClasses_View*. Finally, in the right part of Fig. 9 we present generated Java code for the *Takes* class. We have omitted repetitive code of get and set methods.

V. Related Work

Since Chen proposed ER data model in [8], many papers have been published discussing ER data model, its features, extensions, and practical application. We found only one paper presenting EER data model implementation in the Eclipse environment using MDSD principles. In [12], the authors present EER meta-model and the EERCASE tool based upon it. The tool provides all of the EER concepts represented with Elmasri-Navathe's graphical notation [11].

Our tool is also integrated with the Eclipse environment, so as to provide beginners with an easy of use tool as they are already familiar with the environment. EERDSL component of our tool provides all concepts from the EER approach. All concepts are represented with widely used graphical notation presented also by Thalheim in [21]. Apart from graphical notation, provided by all of the aforementioned tools, our tool also provides EER modeling with a textual notation. Similarly to the aforementioned tools, our tool also supports generation of SQL and Java code from an EER model. Additionally, our tool allows generation of the procedural code for implementation of the inverse referential constraints. Currently, only a generation of PL/SQL code is provided.

There are numerous Computer Aided Software Engineering (CASE) tools to support EER approach, such as PowerDesigner [20], ERWin [5], SmartDraw [19], Oracle Designer [18], or Cameo Data Modeler [6] for MagicDraw. These are mainly commercial and widely used CASE tools and as such they provide proprietary graphical notation for EER usually supporting only selected concepts. In contrast to aforementioned CASE tools, EERDSL provides all of the theoretical EER data modeling concepts. Our tool also supports data modeling using the textual notation. EERDSL is the component of the MIST tool that also provides modeling using the FT concepts. MIST is the only tool that supports the usage of the FT concepts.

VI. Conclusion

During our previous research we developed FT components for our Multi-Paradigm Information System Modeling Tool (MIST). These components provide specification of an IS database schema, business applications and their graphical user

```
...
CREATE TABLE Takes (

    private int grade;
    private java.util.Date examDate;
    protected java.util.ArrayList<TeachesClasses> teachesclasses;

    public Takes(Student student, Subject subject,
            int grade, java.util.Date examDate,
            java.util.ArrayList<TeachesClasses> teachesclasses) {
        this.student = student;
        this.subject = subject;
        this.grade = grade;
        this.examDate = examDate;
        this.teachesclasses = teachesclasses;
    };

    public int getGrade() {
        return this.grade;
    };

    public void setGrade(int grade) {
        this.grade = grade;
    };

    //omitted rest of the get/set methods
}
```

Fig. 9. Generated SQL and Java code

interface elements. However, designers widely use EER approach for database schema modeling. Therefore, we provided MIST components supporting EER approach, to offer designers a choice of two alternative conceptual level approaches to create IS specifications at the platform independent level. As both approaches allow a generation of relational database model from a conceptual specification, it is also possible to provide transformations between the two specifications via relational data model. Currently, we have developed a transformation from a relational to the FT model. It allows a designer to create a model using the EER approach, and then use the FT approach to enrich the specification with details of business applications and their GUI elements.

The MIST tool prototype is ready to be used in database and MDSD courses at our faculty. This should provide us with the practical experience and user feedback, allowing further improvement of the tool and new lessons to be learned.

In addition to the conceptual level meta-model and the transformation to the relational data model presented in the paper, we have developed several other model-to-model transformations and code generators. Our SQL Generator component provides generating SQL scripts and procedural code for inverse referential integrity constraints, from a relational model. Also, starting from an EER model, a class model of a database may be created and Java classes are generated. In this paper, our intention was not to give all the details about developed meta-models and transformations. Instead, we tried to focus just on those meta-model details that are necessary to recognize a general picture of the components supporting EER approach.

As components that support EER approach are public to a user and well documented, they may also be used in the educational purposes. It may be used in database courses to assist students in better understanding basic concepts of EER and the rules of EER to relational model transformations. A possible usage is in courses on domain specific languages and model driven software development, as students may familiarize themselves with new concepts using well-known EER concepts.

Several future research directions are possible, including a specification of MIST meta-models semantics and new features of the MIST tool. In order to formally specify semantics of our meta-models, one of the approaches presented in [4] should be used. This could allow us to fully automate the construction of tools supporting our language. Next, in order to fully support simultaneous conceptual specifications with EER and FT approaches, several further research directions are possible. One of them may include an implementation of EER2FT and FT2EER transformations that would allow transformations from one to another conceptual level specification. Also, another research direction would be to extend EERDSL with new concepts allowing more detailed specifications of data models. These new concepts should provide new constraint specifications at the conceptual level. For example, formal specification of database check constraints at the level of EER model is in many approaches poorly supported, or not supported, at all. As we already provide a conceptual specification of the check constraint at the level of FT models, we plan to create the appropriate formalisms for its specification at the level of EER model, too.

***Abstract*—Large-scale distributed data processing has gained significant momentum in research in the past decade. With the introduction of MapReduce, many frameworks have been developed that either implement MapReduce or provide additional functionalities useful in a larger domain. While the framework introduced in the MapReduce paper performs batch-processing of data, Apache Storm performs real-time computation on data. Storm does this with the help of Topologies, and the constituents of the Topology are developed using General-purpose Programming Languages (GPL). A Domain-specific Language (DSL) can provide a higher level of abstraction over GPLs and model the specialized features of a particular domain in a better way. In this paper, we propose the development of Storm Topology generator (Stormgen), a DSL for Storm Topology development, and show how the specifications of this DSL can be utilized during the code generation of exact Storm Topology components in Java. The parser and code generator for Stormgen's syntax are developed using the Eclipse Modelling Framework. The practical use of Stormgen is illustrated with a case study which considers the modelling of a Topology for the Word Count application.**

***Index Terms*—Domain-specific modelling, Languages, Eclipse Modelling Framework, Apache Storm, Code generation**

I. Introduction

THE ADVENT of big data analysis created a need for making systems that handled such data in a fault tolerant and distributed manner. Google's paper [1], which introduced the MapReduce programming model, and Yahoo! [2], with its Hadoop framework, succeeded in meeting this need. Several additions and improvements to Hadoop and other such frameworks have been made, owing to the diversity in the meaning and purpose of the data being analysed. In the case of real time, event-based and unbounded data, such a task must be approached in a manner different from that advocated by the frameworks named above. Apache S4 and Apache Storm, apart from a few other frameworks, have made this possible.

MapReduce eases the development of parallel batch-processing programs that conform to the map-reduce programming paradigm. Storm [3] can be used for real-time processing of data for a wide set of data processing use cases, some of which are listed below:

1) Stream processing, which includes processing of messages, updating of databases, etc.
2) Continuous computation, where data streams can be queried continuously and results can be streamed into clients.
3) Distributed Remote Procedure Calls (RPC), where the processing of a complicated query can be distributed and parallelized.

All these features can be easily implemented using the simple, yet, powerful primitives provided by Storm.

Storm involves the creation of a Topology [4] of computation, i.e. a graph with nodes and directed edges. The directed edges between nodes provide the paths that can be used by the event stream between the said nodes. Each node performs a stream transformation, i.e. accepts an input stream and emits a modified stream. There are also a special set of nodes that are dedicated to fetching the input data stream from an external source, if not creating the streams by themselves.

Hence, the developer has to write the code for each node in the Topology, and assemble the nodes with their connecting edges to finally obtain the graph. All this needs to be done using the Storm Application Programming Interface (API) [5], which is supported by multiple programming languages (Java Virtual Machine (JVM) based and non-JVM based) such as Java, Ruby, Scala, Python, etc. Commonly, various data mining and machine learning tools are deployed on Storm nodes, which generally fit the use cases mentioned above.

The Storm framework is developed under the Eclipse Public License, and is available to open use by companies and other organizations. Git and Altassian JIRA are used for version control and issue tracking, respectively, under the Apache incubator program. Some organizations that have employed Storm are Twitter, Groupon, Alibaba, The Weather Channel and FullContact.

DSLs [6] are small, simple and highly-focused specification languages developed for a clear and small problem domain. They are tailored to a specific application domain. They offer substantial gains in expressiveness and ease of use compared to the use of GPLs in the same domain. By employing well-known concepts, abstractions and notations derived from the problem domain, they are easy to learn, understand and use, both by developers and domain experts.

Further, DSLs facilitate the use and reuse of domain knowledge. They are not constrained to be like programming languages. One of the main advantages is that they transcend the boundaries of programming. They tend to be more descriptive and verbose than GPLs. Hence, using DSLs, domain experts can directly contribute to the development effort by validating, modifying and even independently developing DSL programs.

978-83-60810-58-3/$25.00

Every time a Storm Topology needs to be created, hundreds of lines of Java code will have to be written by the developer. Anyone who needs to deploy their application on Storm would first have to learn how to develop Storm Topologies using general purpose languages. This could waste a lot development effort and time, that could instead be used for improving the application at hand.

For these reasons, any DSL for the Storm domain should create a simple, quick and reliable means for assembling a Storm Topology and deploying the intended application. Of course, the domain knowledge of Storm and its concepts is still necessary, and the application should be deployable within the scope of the DSL. Further, the creation of the Storm Topology in an ad-hoc manner using the DSL can be used for testing the application on this framework.

XText [7] is an open-source framework for developing programming languages and domain-specific languages. It provides a parser, abstract syntax tree generator and a Java code generator. It is a part of the Eclipse modelling project. We used XText to create Stormgen.

The rest of the paper is organized as follows: the related work in this area is given in Section 2. A domain specific meta-model for Topology development in Storm, which is used for developing the abstract syntax of Stormgen, is discussed in Section 3. Based on this meta-model, the textual concrete syntax of Stormgen is presented in Section 4. The transformations from the specifications required for Code generation are elaborated in Section 5. A case study is presented in Section 6, where Stormgen is used to develop a Storm Topology for the popular "Word Count" problem. Finally the conclusions and possible future improvements are discussed in Section 7.

II. Related Work

XText, as a tool to develop DSLs, is gaining large popularity in the research community, due to its simplicity, stability and facilities. In [8], XText was used to create a DSL called SEA_L which is used in Semantic Web enabled Multi-agent Systems. This paper follows a similar analysis performed in [8] to present the DSL developed.

Other instances where DSLs have been created using XText includes [9]. In this work, the XText framework was used to describe the implementation of an assembler editor for the development of assembly code. The editor supports specific assembler instructions. The other features provided by this editor are content monitoring, detection of repeated instructions, and prediction to assist user input. Our DSL also comes with such an editor. XText comes with a customizable user-interface component, which can be used to create an Eclipse-like IDE for the DSL being created. This way, all the useful Eclipse development features can be provided to our DSL.

In yet another research work [10] selected dependability of multi-agent system (MAS) as the domain. The key requirement in this domain is an efficient verification of a Topology model of a power system. As a result, they developed a DSL as a reliability evaluation solution offering a significant rise in the level of abstraction towards MAS utilized by the system. They made use of Eclipse Ecore, as it becomes a common denominator, in which both meta-models and abstract syntax trees are defined. Eclipse Ecore is a meta-modelling framework, part of the Eclipse Modelling Project, and we have made use of this to prepare our meta-models.

Where distributed fault-tolerant systems are concerned, as discussed in [11], Pig Latin is a DSL that is used to create and execute MapReduce jobs on Hadoop. The Pig Latin syntax has the declarative style of SQL and the low-level, procedural style of MapReduce. This language is especially useful for an expert in RDBMS systems and SQL to perform MapReduce jobs without requiring knowledge of the MapReduce programming paradigm and Hadoop. Hence, it lies at a very high level of abstraction. However, our DSL does not provide that level of abstraction, as a user cannot fully exploit the various features of Storm, if restricted only to an SQL-like interface. Instead, a user with knowledge of the features of Storm can develop a Topology that can best fit the problem at hand. Esper is the Pig Latin equivalent in Storm, i.e. it provides streaming of SQL queries on top of Storm.

Other DSLs for Storm [4] include Redstorm [12], Scala DSL, Clojure DSL, etc. Each of these DSLs require knowledge of programming languages like Scala, Ruby and Clojure. Our DSL aims to alleviate the use of GPLs and provides simple constructs close to plain English to develop the Topology. We have evaluated Stormgen against Redstorm at the end of this paper.

III. Abstract Syntax

The abstract syntax of a DSL describes the domain concepts and their relations without any consideration of their meaning. In terms of Model-driven development, a domain model or data model represents the data we want to work with. The data model is generally independent of application logic. The meta-model is used to describe the structure of the domain model. The abstract syntax is described by a meta-model. This constitutes the analysis phase of the development of the DSL.

As mentioned earlier, a Storm Topology consists of a collection of nodes that do some processing and transformation on the incoming data stream. Broadly, there are 2 types of nodes that can exist in a Storm Topology:

1) **Spouts**
   These are nodes that create an input stream of data for the Topology either by generating it randomly on the fly, or by connecting to a third party source of events through a streaming API (for example, the Twitter streaming API [13]). The Spout collects the events from the source and emits them to the rest of the Topology. It can never have a stream input to it from any other node. In essence, it is the source vertex of the Topology. A directed graph, however, can have multiple source vertices. Similarly, a Topology can have multiple Spouts of different types.
2) **Bolts**
   These are nodes in the Topology that do some computation or processing on the incoming data stream(s) and emit the data to the downstream operators. Bolts at

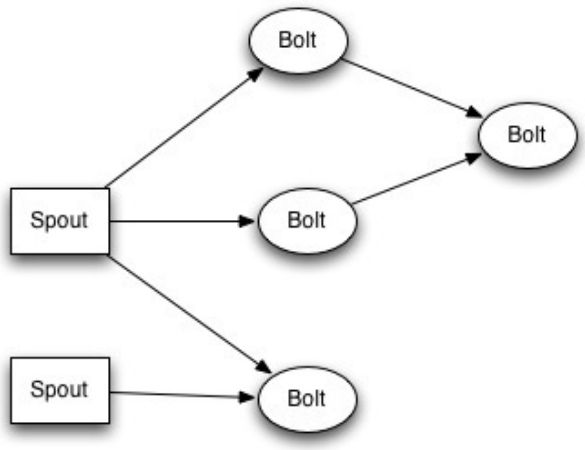

Fig. 1. Spouts and Bolts in a Storm Topology, as given in [4]

the end of the Topology do not emit data downstream. Bolts can do anything from filtering of data, execution of functions, communication with databases, database operations such as aggregations, joins, etc. They can perform either simple or complex stream processing.

A Topology can finally be assembled by adding Spouts and Bolts and the necessary edges between nodes. Fig. 1. shows a sample Topology.

Eclipse Modelling Framework (EMF) comes with two meta-models; Ecore [14] and Genmodel. The Ecore meta-model is used to store the information of the defined classes, whereas the Genmodel is used to store all the information required for code generation. EMF was chosen as the modelling platform mainly because it makes the domain model explicit, providing clear visibility. Moreover, EMF takes care of interface generation and the factory for object creation.

Ecore specifies a set of elements that could be used in the development of the meta-model. These elements are similar to some of the elements in the UML Class diagram:

1) EClass: This represents a class element. It can have zero or more attributes and references.
2) EAttribute: This represents an attribute, consisting of a name and type.
3) EReference: This represents an end-point of association between 2 EClasses.
4) EDataType: This represents the data type of an attribute. For example, *java.util.ArrayList*.

Our abstract syntax provides EClasses called Bolt, Spout and Topology. Fig. 2. shows the Ecore meta-model [14] for our model. The Storm API [5] provides interfaces to create Spouts and Bolts. For every Spout and Bolt a class has to be created and must override all the interface methods.

The aim of the final DSL is to provide very simple implementations of all the well-known characteristics of Spouts and Bolts. All the well-known features are captured in the *API* EAttribute. The Property EAttribute allows the user to define any data member (variable) and the Operation EAttribute lets the user define any function (method).

Some of the important features of the Bolt API are listed below

1) Prepare, which is used for the pre-deployment configuration of the Bolt.
2) Execute, which receives a tuple from the input stream, does some processing on the stream, and emits the result to the output collector.
3) Output Field Declarer (OPFields), which declares what logical type or key the fields in the emitted tuples assume.

Similarly, some of the important features of the Spout API are listed below

1) Open, which is used for the pre-deployment configuration of the Spout.
2) NextTuple, which connects to the source of the data stream, parses the stream into tuples, and emits them to the rest of the Topology.
3) Output Field Declarer (OPFields), which declares what logical type or key the fields in the emitted tuples assume.

Finally, the Topology assembly is done with the help of a TopologyBuilder class of the Storm API. The builder can either add Spouts or Bolts. As Bolts will have incoming edges, the adjacent upstream node needs to be specified as well. While adding a Spout to the Topology, the logical name and the instance of the class containing the source code should be provided. As any given node can be replicated multiple times during deployment, this number is provided as well while adding the Spout. While adding the Bolt, the same parameters as in the case of the Spout need to be provided. The logical name of the upstream operator needs to be defined using the "grouping" EAttribute.

IV. Textual Concrete Syntax

The textual concrete syntax of Stormgen is provided with XText [15]. XText is a language development framework to provide textual modelling languages. It can be used for creating a sophisticated Eclipse-based development environment. XText is based on Extended Backus Naur Form (EBNF) [16] rules. Hence, the design phase in the development of Stormgen constitutes the description of the EBNF rules.

As explained in the Related work section, we make use of the XText features in order to create an Eclipe-IDE user interface for Stormgen. This way, auto completion, syntax colouring, rename refactoring, bracket matching, auto edit,etc are provided for the syntax. By defining EBNF rules, the constraints discussed in the Abstract Syntax section of Stormgen's meta-model are realized. With these capabilities, the new DSL possesses both the structure and the static semantics of the Storm domain. The structure is defined by the method signatures and the semantics by the constraint code.

The rest of this section discusses the structure of the grammar used to specify Stormgen.

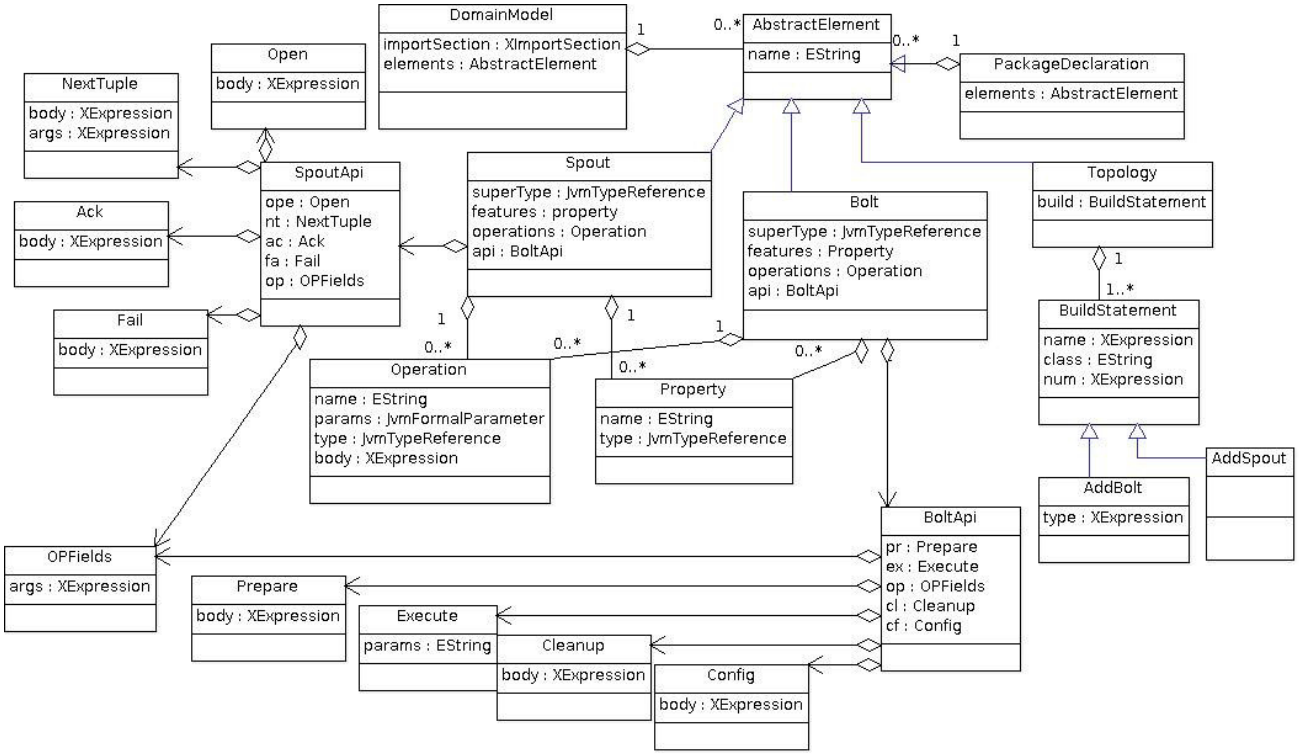

Fig. 2. Meta-model for Stormgen

Every Stormgen file should include the specifications of all the 3 major entities in the DSL, i.e. Spout, Bolt and Topology or they can contain a subset of the entire specification (For 1 or more entities).

In the beginning of the domain model all the non-Storm library related imports need to be specified. Due to the use of various JVM Elements here such as the Identifiers, Function parameters, and blocks of Java code, we made use of Xbase [17] to specify all the terminals in our grammar.

Once the imports have been specified, the rest of the file should model either a Spout, Bolt or Topology. Example 4.1 shows the implementation of this feature.

Example 4.1 (Imports and file header):

```
Domainmodel:
    importSection=XImportSection?
    elements+=AbstractElement*;
AbstractElement:
    PackageDeclaration | Bolt | Spout
    | Topology;
```

In the case of a Bolt, the meta-model constraints have to be followed. Every Bolt needs to have a well-defined name, followed by the type of Bolt primitive it is trying to implement. For example, it could implement the BaseRichBolt or IRichBolt types provided by the Storm Bolt API. The user can then optionally include basic members and methods following Java-like syntax. The rest of the code should include all of the abstract methods of the API. Example 4.2 demonstrates the Bolt syntax.

Example 4.2 (Bolt syntax):

```
Bolt:
'Bolt{'
  'Name:' name=ValidID,
  ('Type:' superType=JvmTypeReference)?,
  ('Members:' (features+=Property)+)?,
  ('Methods:' (operations+=Operation)+)?,
  ('Prepare:' pr=Prepare)?,
  'Execute:' ex=Execute,
  ('Cleanup:' cl=Cleanup)?,
  ('OutputFields:' op=OPFields)?,
  ('Config:' cf=Config)?
'}'
```

Within the Bolt API, while the implementation of the Execute feature is mandatory, the rest of the features are not. Within the Execute attribute, the emit function (outputting a tuple downstream) is called by defining the 'emit' keyword, followed by the sequence of parameters to emit.

Example 4.3 (Bolt API emit statement):

```
Execute:
'execute {'
```

```
    ('emit ('(params+=ValidID
       (',' params+=ValidID)*)')')
    '}';
```

The Spout syntax has a similar structure to the Bolt syntax, as shown in Example 4.4

Example 4.4 (Spout syntax):

```
Spout:
  'Spout{'
    'SpoutName:' name=ValidID,
    ('Type:' superType=JvmTypeReference)?,
    ('Members:' (features+=Property)+)?,
    ('Methods:' (operations+=Operation)+)?,
    ('Open:' ope=Open)?,
    'NextTuple:' nt=NextTuple,
    ('Ack:' ac=Ack)?,
    ('OutputFields:' op=OPFields)?,
    ('Fail:' fa=Fail)?,
  '}'
```

Like the Bolt, the Spout needs to be provided by name and type. The Spout could implement IRichSpout or BaseRichSpout types. The Spout can also have optional Properties and Features. Within the Spout API, the NextTuple feature needs to be included, but the rest are optional. The emit property is defined in the NextTuple function.

Finally, the grammar for building the Topology is given in Example 4.5.

Example 4.5 (Topology Syntax):

```
Topology :
    'Topology' name=ValidID '{'
     build+= BuildStatement*
    '}'
    ;
BuildStatement:
    AddSpout | AddBolt;

AddSpout:
   'addSpout{
    'SpoutName:name=XStringLiteral',
    'SpoutInstance:clas=QualifiedName',
    'Parallelism:num=XNumberLiteral
    '}';

AddBolt:
    'addBolt{
      'BoltName:name=XStringLiteral',
     'BoltInstance:clas=QualifiedName',
     'Parallelism:num=XNumberLiteral
     'Upstream:(Name:up=XStringLiteral,
      Type:(type = 'shuffle'|
      type= 'fields')+
     '}'
Config : ('default'|'custom')
```

The Topology grammar lets the user add any number of Bolts and Spouts to the Topology. Apart from specifying the primitive arguments of both Bolt and Spout, the logical name of the adjacent upstream node to every Bolt is provided. Additional configuration information needs to be applied to the Topology, such as the number of Worker processes per node, code concerning the submission of the Topology to the Storm daemon processes, etc. Using the default option with the 'Config' field (as shown in Example 4.5), the default configuration is generated for ad-hoc Topologies.

XText can generate EBNF rules from a given meta-model but we prefer to define EBNF rules manually to supply some preferred syntactical restrictions and constraints such as defining relations in a specific order (XText cannot extract the order from the meta-model because the meta-model does not have such an attribute by itself), defining at least one or more than one relation, etc.

V. Code Generation

It is not sufficient to complete the DSL definition only by specifying the notations and their representations. The complete definition requires that the semantics of the DSL's concepts are mapped to Java constructs. The mapping is provided through model to code transformations where the final executable software code for exact Storm Topology creation is obtained. Code generation for the instance models are provided by the Xtext Framework [15].

Many of the existing model driven engineering approaches accomplish code generation by writing strings to text files. XTend is a flexible and expressive dialect of Java, which compiles into readable Java compatible source code. XTend prepares a compiled output of Java source code that is similar to the equivalent hand-written code, both in structure and performance. Unlike other JVM languages XTend has no interoperability issues with Java.

Like XPand [19], XTend [18] is a template engine, which allows creating textual output using EMF models. XTend requires an EMF meta-model and one or more templates to translate the model into text. Once the requirements are provided and an EMF model [20] is defined, the code generator can be deployed. XTend traverses the abstract tree created by XText and generates the code along the way.

However, compared to XPand, XTend has the following additional benefits as explained in [21]

1) XTend is fast because XTend code is translated to Java code without adding overheads or dependencies at runtime.
2) XTend is debuggable as XTend code is translated to Java code. Hence, advanced Java debugging tools can be used. Additionally the Eclipse debugger provides the option to debug either the XTend source code or the generated Java code.
3) Better Integrated Development Environment (IDE) support.
4) As templates in XTend are expressions which yield some value, multiple templates can be composed and

the results can be passed around and processed.
5) Better extendibility.

Hence, the code generation for Stormgen is done using XTend.

Every EClass in the meta-model has a corresponding definition in the grammar. The grammar rules have to then be mapped during code generation into various components of the target generated program. As mentioned in the previous section, the 3 main components that have to be included in the Domain model are Spout, Bolt and Topology. The code generator has an "inferrer" defined for each of these 3 components.

The IRichBolt interface is used to implement the Bolt in the model. So during generation, the corresponding statement needs to be included, along with the required import. This is followed by the generation of the constructors.

Example 5.1 (Generating constructors):

```
members += element.toConstructor[
 for (feature : element.features)
 {
   parameters += toParameter
   (feature.name, feature.type)
 }
 body = [
   for(feature:element.features)
   {
     append ("this."+feature.name+
     "="+feature.name+";")
   }
  ]
]
```

Properties have to be translated into corresponding Java class member variables and Operations have to be translated to corresponding Java class functions

Finally the Bolt API attributes are translated into Java functions, which override the functions in the IRichBolt interface. All the attributes have to be appended with correct function call and arguments, having imported the corresponding arguments from the Storm library.

The Spout code is generated in a similar manner to that of the Bolt. The IRichSpout interface is implemented to provide all the necessary functions to override. The constructor of the Spout class is generated. All the instances of the Property EClass are translated into Java class members and all the instances of the Operation EClass are translated into Java class functions. Finally all the overridden methods are defined with the required prototype and the fully qualified arguments.

Topology has different grammar constructs from Bolt and Spout. Hence the code generation is slightly different. In order to build a Topology, a TopologyBuilder instance from the Storm API needs to be created. The Topology Builder instance can then be used to add Spouts and Bolts, constituting the assembly process. The adjacent upstream nodes for the Bolts are also specified. This builder instance is implicitly created, and the DSL provides EClasses like AddSpout and AddBolt to add the Spouts and Bolts to this implicit instance.

Over and above this, there is a lot of code that is used to configure the Topology for a local mode execution. All this is hard-coded into the generator, and generated for every possible Topology created using this DSL.

VI. Case Study: Word count

Word count [22] is a very popular problem that is especially used to understand the functioning of various distributed, fault-tolerant data processing systems, including Storm.

In word count, a very large document is provided as input to the framework and the expected output is a report of the frequency of every single word in the document. This is a fairly simple application to develop, and we will be using this example to underline the simplicity and power of Stormgen.

First we need to analyse the problem and understand how it can be modelled into the Storm domain. In essence, the Storm domain involves the creation of Topologies using Spouts and Bolts. So we now need to understand what components are required to develop a solution to this problem.

We need a real time data stream for processing. So we decided to simulate the same by constructing a RandomSentenceGenerator Spout which has a list of sentences, and randomly emits a sentence every time the 'NextTuple' routine is called by the framework.

Now that our data stream consists of Tuples, each being a randomly selected sentence, these sentences need to be split (removal of whitespaces) into words. To carry out this operation we construct a SplitSentence Bolt which accepts an input tuple containing a sentence, splits the sentence into words and emits each word downstream. This operation of splitting the sentence is written directly in Java.

The SplitSentence Bolt subscribes directly to the RandomSentenceGenerator Spout. As the process of splitting sentences doesn't need to be done at any specific instance of the SplitSentence Bolt, normal shuffle grouping is used to group the tuples to the instances of this Bolt.

Now that the SplitSentenceBolt generates a stream of words, these words need to be counted. For this, we construct the WordCounter Bolt, which accepts a word and increments the word's count, which is stored in a local Hash Map. This Bolt is the final Bolt in the Topology and does not emit any data subsequently. This Bolt subscribes to the SplitSentence Bolt. However, there should be a constraint enforced here. If different instances of the *same* word go to different instances of the WordCounter Bolt, then obviously the total count reported by each Bolt will be wrong. So it is important to ensure that *all* instances of the same word should go to the same instance of the Bolt to ensure a correct count. This can be achieved by using the Field stream grouping in Storm.

For convenience, in the DSL for our domain model, we have created 4 files:

1) RandomSentenceSpout.strgen
2) SplitSentenceBolt.strgen
3) WordCounterBolt.strgen

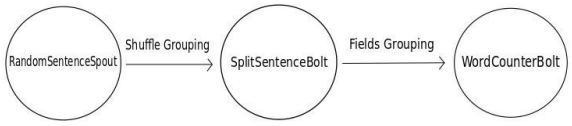

Fig. 3. The word count Topology

4) WordCountTopology.strgen

Note that all the entities could also be defined in a single Stromgen file.

Fig. 3. shows how the Topology looks like. In the WordCountTopology.strgen, we construct the Topology with the given Spouts and Bolts. The contents of the WordCountTopology.strgen file are shown in Example 6.1. The generated Java code for the Topology is given in Example 6.2. The examples of the other 3 code files are not included due to space constraints. Only if *all 4* of the source files are specified correctly will the correct Java application code will be generated.

Example 6.1 (Word count Topology Stormgen model):

```
package org.Topologies {
  Topology WordCountTopology {
    addSpout{
      SpoutName:"Spout",
      SpoutInstance:
        Spouts.RandomSentenceSpout,
      Parallelism:10
    }

    addBolt{
      BoltName: "split",
      BoltInstance:
        Bolts.SplitSentenceBolt,
      Parallelism: 5,
      Upstream: ("Spout",shuffle)
    }

    addBolt{
      BoltName: "count",
      BoltInstance:
        Bolts.WordCounterBolt,
      Parallelism: 5,
      Upstream: ("split",fields)
    }

    Config: default
}
```

Example 6.2 (Word count Topology generated java code):

```
package org.Topologies;

@SuppressWarnings("all")
public class WordCountTopology {
 public static void main(String[] args){
  backtype.Storm.Topology.TopologyBuilder
   builder = new backtype.Storm.Topology.
       TopologyBuilder();

  Config conf = new Config();
  conf.setDebug(true);
  builder.setSpout("Spout",
       new Spouts.RandomSentenceSpout(),
       10);
  builder.setBolt("split",
       new Bolts.SplitSentenceBolt(),
       5).
       shuffleGrouping("Spout");
  builder.setBolt("count",
       new Bolts.WordCounterBolt(),
       5).
       fieldsGrouping("split");

  if (args != null && args.length > 0){
    conf.setNumWorkers(3);
    StormSubmitter.submitTopology(args[0],
      conf, builder.createTopology());
  }
  else {
    conf.setMaxTaskParallelism(3);
    LocalCluster cluster =
       new LocalCluster();
    cluster.submitTopology("word-count",
       conf, builder.createTopology());
    Thread.sleep(10000);
    cluster.shutdown();
  }
 }
}
```

As it is evident from this case study, Stormgen greatly simplifies the assembly of a Topology. With the simple, verbose syntax of Stormgen we could generate the equivalent Java code for the whole Topology. Further, Stormgen is abstracted to capture just the domain concepts. Hence, only the Storm-API related specifications need to be specified using the DSL. The rest of the Java code can be generated once this specification is provided.

VII. Evaluation

As mentioned in the Related Work, there are several DSLs available for Storm, such as Redstorm, Scala DSL, Clojure DSL, etc. They provide a similar level of abstraction as Stormgen. However, the user is expected to know Scala, Ruby or Clojure, which are GPLs, but provide a simpler syntax than Java. Stormgen provides a simple, intuitive syntax for the development of the core components of the Topology. This syntax is not based on any GPL. Additionally, Stormgen permits the programmer to introduce Java code into the DSL whenever any specific functionality has to be incorporated.

The primary use case that Stormgen is developed for, is the deployment of third-party applications on Storm. As men-

tioned earlier, Storm is normally used for larger data mining or machine learning applications that need real-time, fault-tolerant and distributed data processing. Further, additional development effort has to be expended on understanding how to develop Storm topologies using Java. Instead, once the user has learnt the domain concepts, Stormgen can be directly used to create the necessary components of the topology and payload the various units of the third-party application on these components.

Redstorm [12] is a DSL for Storm developed using JRuby. All the components have to be written in Ruby. While JRuby does permit the direct use of Java code, it requires special configuration when access to non-bundled Java libraries is required. Non-bundled Java libraries will be required when a third-party application is being deployed on Storm. Stormgen solves this problem by permitting ordinary Java imports to be mentioned in the DSL file, which is added in verbatim to the generated code. This alleviates the need for any special configuration and the user can directly focus on the Topology development.

VIII. Conclusion and Future Work

In this paper we have presented our DSL, Stormgen, describing the motivation behind developing it, and further explaining in detail what went on in the whole software development process. In the analysis phase, the Abstract syntax was specified with the help of domain-specific meta-models. These meta-model concepts were then mapped to the concrete textual Syntax during the design phase. The next phase involved mapping the textual syntax to code by the construction of the code generator. Finally, we tested Stormgen with the popular WordCount application. All this was done entirely using tools such as Ecore, XText and Xtend, provided by EMF.

As explained throughout the paper, Stormgen allows the user to develop Topologies for Storm by simply applying domain knowledge and concepts to the domain model. Stormgen also allows the user to import external Java code, so that any other Java applications can be deployed seamlessly into Storm.

In future, Stormgen can be upgraded to incorporate support for additional Bolt/Spout interfaces apart from the BaseRich and IRich Bolt/Spout. While the existing implementation is sufficient to cover most use cases, providing the support for the other interfaces would cover each and every feature provided by Storm. Finally, using the Eclipse Graphical Modelling Framework (GMF) [23], a graphical DSL can be developed to supplement the textual DSL. The graphical DSL would provide a simple graphical user interface (GUI) to draw the graph of the Topology and a convenient technique to configure each node and stream (edge). This would provide a more intuitive visualization to the Storm Topology development.

Study of Interoperability between Meta-Modeling Tools

Heiko Kern
University of Leipzig
Augustusplatz 10
04109 Leipzig, Germany
Email: kern@informatik.uni-leipzig.de

***Abstract*—Modeling is a fundamental concept in software engineering and other system development disciplines. Nowadays the modeling process is supported by powerful modeling tools. Generally speaking, tools which support the definition and usage of self-defined languages are called meta-modeling tools. An important requirement for meta-modeling tools is the interoperability among each other. For instance, interoperability helps to build complex tool chains covering the whole development process. Furthermore, interoperability can also avoid the vendor lock-in effect. Thus, interoperability facilitates the replacement of a tool by a new tool better fitting the customer needs. The objective of this paper is to investigate the current status of interoperability between meta-modeling tools. In more detail, we study the degree of model exchange between meta-modeling tools and look for typical exchange approaches. The study focuses on meta-modeling tools and approaches which are being used in practice or the real world, respectively.**

I. Introduction

MODELING is a fundamental concept in software engineering and other disciplines. A model represents a system in an abstract way. The abstraction helps to improve the understanding of a system and can facilitate the communication between different stakeholders. Beyond that, in modern development approaches (e.g. Model-Driven Software Development (MDSD) [22] or Domain-Specific Modeling [11]) models are increasingly used for automating development tasks such as code generation, model transformation or model-based testing.

Beside a theoretical foundation of modeling, a suitable tool infrastructure is necessary to enable the practical usage of MDSD approaches. Current modeling tools offer a variety of features which support the user during the modeling process. Modeling tools supporting the definition as well as the usage of self-defined languages are called meta-modeling tools. The modeling languages in these tools are generally defined by meta-models. Examples of such meta-modeling tools are MetaEdit+ [11], Generic Modeling Environment [15] or Microsoft Visio [4].

An important requirement for meta-modeling tools is the interoperability among each other. Interoperability is the ability of two or more tools to work together. For instance, often a tool is dedicated to a specific task. Tools have to work together or inter-operate to build complex tool chains covering the whole development process. Another issue is the evolution of a tool landscape. Interoperability can avoid the vendor lock-in effect. Thus, interoperability facilitates the replacement of a tool by a new tool better fitting the customer needs.

The objective of this paper is to investigate the current status of interoperability between meta-modeling tools. Although there are a variety of approaches, the current state of practice in the area of modeling is unclear. In more detail, we want to study the degree of model exchange between meta-modeling tools and look for typical exchange approaches. The study focus on meta-modeling tools and approaches which are used in practice or the real world, respectively. We mainly consider the import and export features of meta-modeling tools in order to exchange models and meta-models. The objective can be founded with the following two research questions:

– *Question 1: What is the degree of interoperability?* The first research question investigates the degree of interoperability. We want to analyze between how many of the involved tools an exchange of models is possible? Based on our experience, we assume that the model exchange between different meta-modeling tools is insufficient. This study will prove this assumption.

– *Question 2: What are the approaches to realize interoperability?* In order to give a satisfying answer to this question, research of approaches is necessary. There are already a variety of approaches in theory and literature. However, in this study we want to identify approaches used in practice.

The paper is structured as follows. In the subsequent section, we give a foundation of the interoperability concept. In section III we present a set of aspects which helps to scope the investigation. Afterward in section IV, we describe the methodology for the tool selection and analysis of these tools. In section V we present the results of the study and discuss the validity of these results. Finally, we conclude in section VI.

II. Interoperability

Interoperability is in research and in practice a subject of discussion since there are software systems. The word consists of two parts: “inter-operate” and “ability”. Inter-operate means that two systems can work together [6] and the suffix ability expresses “the ability of a system [...] to work with or use the parts or equipment of another system” [1]. A basis for interoperability is the capability to exchange information between two or more systems and to use the information that has been exchanged [2]. Furthermore, interoperability is

978-83-60810-58-3/$25.00

the basis to integrate systems. Integration is also an widely-used term in software and system development and can be defined as the combination and coordination of separate things, elements or units into a whole, so that they work together effectively [1], [3]. Regarding the concept of interoperability, integrated systems must be interoperable in any form, but interoperable systems do not need to be integrated. Interoperability extends the borders of already existing systems and enables the connection to other systems. Here, interoperability is often associated with loosely-coupled systems, where systems keep their autonomy [17]. In contrast to this, integration is characterized by a closely-coupled systems, where system are interdependent and difficult to separate from each other.

Another term in this context is migration. Generally, migration denotes processes of spatial movement. In information technology there are different application areas for migration, such as software systems, databases, application systems or hardware. A migration in the area of software systems is, for instance, updating from one major software release to the next highest version of the same software vendor. Already existing data, settings or specific extensions have to be transferred to the new software system.

The focus of this article is the interoperability of different meta-modeling tools. In this context, interoperability deals with the exchange of models and meta-models between meta-modeling tools. The exchange is realized as a migration of models and meta-models from one tool to another. The migration from one to another tool should be an isomorphic relation in order to preserve the structure and semantics of models. The terms integration, interoperability and migration can be used as synonyms in this paper.

III. Scope of Study

There are a variety of problems and solutions concerning the interoperability issue. This shows, for instance, the annotated bibliography from Wicks [26] which contains a huge amount of papers about the interoperability issue. In this section, we define a set of aspects or dimensions which helps to scope the research (questions) of this study. The finding and selection of these aspects are based on a theoretical study of different approaches and problems through literature analysis and the authors's knowledge. The dimensions and their properties are not eligible for completeness but fit the objective of this paper.

A. Unification Mechanism

One of the main reason for missing interoperability is heterogeneity between artifacts that have to be exchanged (e.g. models and meta-models). This heterogeneity between the models can be, for instance, of syntactic or semantic nature. To achieve interoperability between the participating models it is necessary to overcome this heterogeneity and to find a unification between different structures. We can distinguish between the following two fundamental unification mechanisms.

1) Common Structure: A mechanism to realize interoperability is to avoid heterogeneity a prior by defining a common structure. The definition can be regarded as a development process for a standard. Such a standard defines, for instance, a common structure of models and meta-models, their semantics and a specification for the exchange of models. If all systems conform to a selected standard, interoperability is guaranteed by this standard. Standards can address different aspects of the exchange of models and languages. In the domain of modeling, there are standards which define a whole language (syntax, semantic and pragmatics). One example is the Unified Modeling Language (UML) [7]. Additional to this, there are standards which define a whole meta-modeling environment (e.g. Meta Object Facility (MOF) [20] or Eclipse Modeling Framework (EMF) [23]) and a corresponding exchange format (e.g. XML Metadata Interchange (XMI) [21]). Meta-modeling and modeling tools which are implementing MOF, UML and XMI as serialization syntax can exchange models and meta-models without problems (theoretically).

2) Transformation: Another mechanism is the transformation of different models and meta-models. A transformation defines a mapping between different structures in order to overcome heterogeneity. Similar to standards, transformation can address semantic or syntactic issues. If there is no standard in order to exchange data between tools, transformations are a powerful approach to exchange models or meta-models. The mechanism of a common structure and transformations are not mutually exclusive. A proprietary meta-modeling environment can implement a standard by using transformations in order to create a model and meta-models conforming to this standard. But this is only possible up to a certain degree.

B. Modeling Level

A meta-modeling tool consists of a modeling and a language level. On the language level (also called as meta-modeling level) a language engineer can define different modeling languages by the creation of meta-models. These modeling languages can be used by a modeler at the modeling level to create models. Based on these two levels, we differentiate between the following two cases of model exchange.

1) Model Level: The exchange on the model level includes only the models themselves. The exchange of languages is excluded on this level.

2) Language Level: Additionally to the exchange on the model level, it is possible and necessary to exchange languages between meta-modeling tools. The exchange of artifacts on language level includes generally the exchange on model level. A sub-aspect on this level is the language preservation. Generally the source and target models and language should be isomorphic. Language preservation can relate to the meta-model and the concrete syntax of language.

C. Topology

Meta-modeling tools exchange their data by using different topologies. The concept of topology originally stems from the field of computer networks and is also used in software

and system integration (e.g. Enterprise Application Integration [16]). The topology concept can be transferred to the area of meta-modeling tool integration. We can distinguish the following topologies.

1) Point-to-Point: A simple topology is a point-to-point connection which connects two tools directly to each other. In this case a tool exports their models and meta-models via a file. The target tool imports this file and reads the models and meta-models. If an external transformation is part of this point-to-point connection, than we have an indirect point-to-point connection. Otherwise, we talk about a direct point-to-point connection.

2) Complex Topologies: If there are more than two meta-modeling tools involved in the integration, a point-to-point integration can be insufficient. For that reason, there are more complex integration topologies such as star or bus. A star topology is characterized by the fact that there is one common exchange format or interface to exchange models and meta-models between all participating tools. The realization of a star solution often requires an additional integration component, which is in the center of the integration architecture. This component controls the integration process and serves as a common structure for models and meta-models. Realizations of more complex structure are, for instance, Model Bus [9] or BPM-X-Converter [1].

D. Integration Layer

The integration of software requires access to artifacts that should be exchanged between the software systems. Generally there are different layers to access these artifacts. Integration layers describe on which layer the exchange of artifacts is realized. Based on the integration of software development tools [25], we can differentiate between the following typical integration layers.

1) Data: Models and meta-models can be represented as data in files or databases. Hence, the integration can be realized on the data layer. Many tools enable the export and import of models and/or meta-models as files. In this case, no complex infrastructure is necessary for building an integration solution. The disadvantage of this approach is that the serialization of models and meta-models as data are often complex. The processing of these complex data structures implies a complex solution (transformations and/or exchange formats).

2) Function: Above the data layer, many tools provide an API with different functions. The usage of functions are easier than operating directly on the data layer because complex operation are encapsulated. Typical functions are the selection and creation of model elements. There are integration approaches which uses the function layer instead of the data layer.

3) Presentation: The third layer is the presentation layer. The exchange on presentation layer often only considers the graphical representation of models. For instance, the export as image considers only the graphical representation. In doing so, the import is unsatisfying because the access of single model elements is impossible. A further example of exchange at presentation layer is the approach of Object Linking and Embedding (OLE).

Topology	Point-to-Point		Complex Topology
Integration Layer	Data	Function	Presentation

E. Research Scope

Based on the dimensions described in this section, we setup the scope of the study as follows. Table I shows an overview of the selected investigation dimensions.

- *Unification Mechanism*: The study includes the investigation of common structures (standards) and transformation approaches.
- *Modeling Level*: We investigate approaches on model and language level but the focus lies on approaches on the languages level while preserving the language structure.
- *Topology*: We study interoperability approaches that realize a direct point-to-point connection between tools.
- *Integration Layer*: The study considers all layers but we focus on data layer.

IV. Selection and Analysis of Tools

A. Tool Selection

The selection of tools is an important aspect of this study because the tools form the basis for later analysis. For the tool search we mainly use the World Wide Web. Finding meta-modeling tools is a difficult task because the term meta-modeling tool is a theoretical term that is often used in the context of the Model-Driven Engineering community. Tool vendors uses different names for their meta-modeling tools. Beside the term meta-modeling tool, we use different synonyms such *meta-case tool* [24] or *modeling tool*. Most meta-modeling tools are denoted as modeling tools with the ability to define their own language. Hence, we also include in our search the general word *modeling tool*. Based on the initial set of tools, we filter the tools by the following criteria.

- *Maturity level*: The tools must fulfill a certain maturity level. A tool must be installable and usable for later analysis. Many tool vendors provide a trial version of their tool. The most tools are available as desktop applications but there are also web-based tools.
- *Concrete syntax*: A further requirement concerns the concrete syntax of models. We only select meta-modeling tools that enable the definition of graphical modeling languages.
- *Modeling domain*: The third criterion concerns the modeling domain of tools. Generally, meta-modeling tools are tools which allow the definition of domain-specific

languages in different domains. This implies that many tools have a universal/generic character. However, many modeling tools relate to a certain modeling discipline. In this study we focus on the following domains: software development, business process modeling, and data modeling.

– *Meta-modeling capability*: The last criterion is the meta-modeling capability. We can distinguish between the heavyweight and lightweight approach [8]. The heavyweight approach enables the creation of a language through the definition of a complete new meta-model (e.g. MetaEdit+). The lightweight approach adapts an already existing meta-model (e.g. UML profile mechanism). A tool must support the heavyweight meta-modeling approach by using a three-level model hierarchy consisting of model, meta-model and meta-metamodel.

Table III in the appendix shows the modeling tools we found during our search. Each tool in this list fulfill the first three selection criteria. The third column in Table III shows the meta-modeling capability of each tool. We only include tools that support the heavyweight meta-modeling approach. The last column indicates that a tool is included in this study. Overall the study includes 20 tools which fulfill the defined criteria.

B. Tool Analysis

The analysis starts with the installation of each tool. Afterwards, we investigate the import and export functionality. Typically, there are different interface layers: user, function and data interfaces. We concentrate on the user interface and especially on the tool menus. Often tools provide a menu entry for import and export of modeling artifacts. Some tools have no extra import and export menu because they offer this functionality in the load and save menu.

In addition to the user interface analysis, available documentation is used to find out exchange possibilities. For instance, we use product information and manuals because a lot of tool vendors emphasize and describe their import and export capabilities.

Some tools provide import and export capabilities in their programming interface or provide a generator component that can be used to implement export and import scripts. These functions are excluded in the study. We only include export and import interfaces that already exist. The exchange possibilities have to be ready to use without any programming of generators or functions.

Furthermore, we restrict the analysis of the exchange possibilities of a tool. We test the exchange mechanism in order to understand the approach used, but we do not investigate the quality of the model exchange. Table IV in the appendix shows the result of this analysis. The table contains the import and export capabilities of each tool. Based on this raw data, we derive the results in the next section.

V. Results

A. Unification Mechanism

1) Common Structure: Many tools use the approach of a common structure in order to exchange their meta-models and models. But the used formats are often a proprietary definition which realize the saving and loading of models instead of the model exchange between different tools. However, some tools use the Visio format in order to exchange models and language elements. In addition to the proprietary formats, there are standards which allow only the exchange of models. These models must conform to a certain (standard) language. For instance, some tools enable the export and import of BPMN-XML [19]. But these standards do not allow the exchange of languages or meta-models. Finally, there is no common format – with the exception of the Visio format – that is used to exchange meta-models and models between different tools.

2) Transformation: The exploration of transformation approaches are difficult because most tools implement their import and export process as a black box. Hence, we can only investigate transformations which are explicit or visible during the import or export. We found some tools which support transformations during the exchange. The first approach is used in Agilian, Visual Paradigm for UML and Business Process Visual Architect. The transformation is realized by a wizard which allows to configure a mapping between Visio models and models of this tool. The mapping can only be applied to certain modeling languages. A further tool which supports a mapping during the exchange process is ARIS. This tool allows a configurable import of Visio models. The description of the configuration is realized in XML on language level. Generally the transformations are not comparable to powerful transformation approaches such as Eclipse Epsilon Transformation Language (ETL) [14] or Atlas Transformation Language (ATL) [10].

B. Modeling Level

1) Model Level: Some meta-modeling tools contain pre-defined modeling languages. Based on these pre-defined languages, some tools offer a language-specific exchange. An example is Agilian that allows the export of BPMN-XML and Business Process Visual Architect that enables the import of BPMN-XML. These specific languages are often standards in a certain domain. Regarding the unification mechanism, this approach follows the strategy of a common structure to exchange models. The limitation to a certain language is unsatisfying in the context of meta-modeling tools.

Additional to this, there is an approach allowing the generic exchange of models between tools. The approach can exchange each model as a generic graph or tree. But the interpretation of models which conform to this generic format is unclear because of the missing language definition.

For instance, the following tools support exchange on the model level:

– Agilian, Visual Paradigm for UML, Business Process Visual Architect: These tools allow the import of Visio

stencils, but the imported masters of a stencil are not part of a target language. Masters are transformed into a separated icon library. Thus, these tools allows only the import of models conforming to a certain language. Please note, a Visio stencil can be regarded as a meta-model [13].
- ARIS: This tool allows the import of Visio models. It is not possible to import stencils. ARIS offers a mapping function which enables a mapping between Visio stencil elements and certain ARIS language elements. Based on this mapping, ARIS imports Visio models.
- Edraw Max: This tool enables the import of Visio models. It is impossible to import stencil elements.
- Lucidchart: This tool allows the import and export of Visio models. The export was not testable in the free version. The import transforms only graphical elements and no stencil elements.
- *Dia:* Dia allows the import and export of Visio models without stencils.

C. Language Level

In contrast to the model level, there are tools which allow the exchange of modeling languages and models conforming to these languages. In this case, the exchange approach transforms the source language into the target language. Based on this transformation, all models conforming to the source language are transformed into models, which are conformed to the target language. Some tools provide the reverse order of these transformations, that is, the tool imports model elements and after that the tool creates the corresponding language elements. But this reverse order leads to the problem that the import only considers a certain set of language elements.

- *ConceptDraw:* ConceptDraw enables the import of Visio models. Additionally to the import of models, ConceptDraw can import language elements (Visio masters). ConceptDraw indirectly imports the master elements via the model import. ConceptDraw also allows the export of models to Visio but there is no stencil support.
- *iGrafix:* This tool allows the import of Visio models by using the clipboard and the tool also imports stencil elements which are used by the imported model elements.

D. Degree of Interoperability

Table II shows the export and import connections of the investigated tools. The vertical axis is the source tool and the horizontal axis is the target tool. The source tool exports models and the target tool imports models. For instance, there is a directed connection from Visio to Concept Draw. That is, Visio can export models and ConceptDraw can import these Visio models. We differentiate the connections depending on their modeling level. The rectangle (□) stands for an approach that supports the exchange of languages (meta-models) and models. The plus sign (+) represents an approach which supports only the exchange on model level. This includes the approach for the exchange of language specific-models and the approach for the generic exchange of models. We combine both signs (⊞), if a tool supports exchange of languages and models as well as language-specific exchange or generic exchange of models.

The diagonal in the matrix shows that each tool allows the exchange of their own languages and models because each tool can save and load their own language definitions and models. Additionally, many tools allow the exchange on the model level (language-specific or generic model exchange). There are only three connections which allow the transformation of languages and models. The matrix also shows that Visio plays a key role because a lot of tools enable the import of Visio models.

All in all, there are $20 \times 20 = 400$ directed connections in this matrix. We assume that the export and import between the same tool is a basic feature in order to save and load models and languages. For this reason, we exclude the diagonal in our calculation. Thus, we have $20 \times 20 - 20 = 380$ possible connections. Out of these connections, there are 30 connections between different tools. This leads to a ratio of 7.9%. There are 27 connections that allow the exchange on model level, a ratio of 7.1%. Regarding the exchange on the language level, there are only three connections. This is a ratio of 0.8%. Hence, the degree of interoperability can be considered low.

E. Further Observations

Generally we identified different data formats for realizing the exchange of model data. One known exchange format for models is XML Metadata Interchange (XMI) [21]. We consider XMI in our study but we are not focus on XMI because their close relationship to MOF, EMF and UML. Other meta-modeling tools do not use XMI for realizing the exchange of their models and meta-models. Another mechanism to exchange models is the usage of graph formats such as Graph Exchange Language (GXL) [27] or GraphML [5]. Graph formats are suitable for exchange models because models and meta-models can be regarded as graphs. For instance, MetaEdit+ uses an adapted version of GXL for serializing their models and meta-models, but no other tool in the study can import this graph format. yEd can import the GraphML format. A further observation is that some tools provide Excel exports. This is not for exchange reasons, but rather than a format to make reports. Beside the possibilities to exchange meta-models and models, there are a lot of language-specific formats, depending on the tool's domain. For instance, in this study many tools support typical formats from the business modeling domain such as BPMN-XML, BPEL [18] or XPDL [28].

Another observation is that there are more tools allowing import than tools allowing the export of models. This could be a strategic reason. Most tools support the import because tool vendors want to increase their usage and often it is necessary to import data in order to replace other tools. The export is undesirable because the tool vendors try to bind their customers to a certain tool.

The last observation concerns the transformation capabilities. Some tools allow the definition of mappings between

models or languages in a simple and limited way. The tools do not provide powerful transformation languages such as ATL or ETL.

F. Threats to Validity

The interoperability between meta-modeling tools is between 0.8 and 7.9%. If we take a look at our study restrictions, the interoperability could be higher than these measured values. We focus on a limited set of tools in a selected domain. Maybe other tools in other domains have a higher interoperability degree. Furthermore we only looked for interoperability mechanisms that are provided by the tool itself. Some meta-modeling tools provide a generator which allows to generate every exchange format. Furthermore, we exclude external tools, such as BPM-X-Converter, which allows the migration of models between meta-modeling tools.

In contrast to this, we can argue for a lower value of interoperability. We only investigated the opportunity to import and export models. We cannot say anything about the quality of these exchange mechanisms. Furthermore, some tools relate very close to Visio. Hence, the import and export is easy for these tools. This is maybe similar to MOF-implemented meta-modeling tool. If we would not consider the Visio imports on language level, the interoperability would go against zero.

VI. CONCLUSION

In this paper we presented a study about interoperability between meta-modeling tools. The study included 20 tools in the area of software development, business process modeling and data modeling. In the first part of this paper we defined the investigation scope. In the second part, we analyzed the tools and presented the results.

Regarding the first research question about the degree of interoperability, we can give the following answer. Depending of the approach considered, the degree of interoperability is low with values between 0.8% and 7.9%. The answer to the second question is more complicated because of the different approaches. Regarding the modeling level (section V-B), we identified the following three approaches: (1) the exchange of models which conform to a specific modeling language, (2) the generic exchange of each model without their modeling language, and (3) the exchange of models with their language. Besides the aspect of the modeling level, there are many other dimensions including many other approaches for interoperability.

In our future work we want to increase the degree of interoperability between meta-modeling tools. We assume a main reason for the missing interoperability is the heterogeneity between the different meta-modeling languages of the tools. Despite the heterogeneity, there are common concepts which can be mapped to each other. These similarities and differences are described in a comparative analysis between different meta-modeling languages [12]. Based on this, we can develop a transformation-based adapter approach in order to enhance the model and meta-model exchange.

TABLE IV
IMPORT AND EXPORT FORMAT OF META-MODELING TOOLS

Agilian	
Import	Rational Rose (mdl) files, Rational DNX files, BizAgi project file, specific XML, XMI (1.2, 2.1), Eclipse UML2 (XMI 2.1), Visual Paradigm project file, MS Excel file with spcific schema, Visio drawings, Visio ERD, Visio drawing/stencils into Agilian Stencil, NetBeans 6.x UML diagrams, Telelogic System Architect, Telelogic Rhapsody, PowerDesigner project file
Export	BPMN2.0-XML, specific XML, XMI (1.2, 2.1), Eclipse UML2 (XMI 2.1), Visual Paradigm project file, MS Excel file with specific schema, VPP (ZIP project archiv)
ARIS Business Architect	
Import	XML with specific schema, UML (XMI1.1)
Export	ADF (ARIS filter), XMI, XML, Visio (VDX), BPEL, ADB (ARIS database)
Business Process Visual Architect	
Import	BizAgi project file, XML, BPMN2.0-XML, XPDL2.1, Telelogic System Architect, Excel, Visio
Export	BPMN 2.0 XML, XML, BPMN2.0-XML, XPDL2.1, Excel
ConceptDraw	
Import	Visio (VDX), MS PowerPoint
Export	CDX file (XML), Visio (VDX), MS PowerPoint
Cubetto Toolset	
Import	–
Export	ETZ format
Dia	
Import	Visio models, Dia, Dxf (specific XML file), SVG, Xfig
Export	Visio models, Dia, Dxf (specific XML file), SVG, Xfig
Edraw Max	
Import	Visio
Export	
Enterprise Architect	
Import	Database Schema, specific Visio models (Communication, Activity, Class, Object, Compontent, Deplayment, Custom), Doors, XMI (UML 1.1, 1.3 or 2.x), ARCGIS, ODM (OWL/RDF), Rhapsody, Rational Software Architect (EMX/UML2)
Export	XMI 1.0 (UML1.3), XMI 1.1 (UML1.3), XMI 1.2 (UML1.4), XML 2.1 (UML2.0), MOF1.4 (XMI1.2), MOF1.3 (XMI1.1), specfic XML, Ecore, OWL/RDF, BPMN2-XML
iGrafix Process	
Import	Visio models and metamodels
Export	BPEL XML, XPDL, XML
Lucidchart	
Import	Visio models (vdx, vsd, vsdx)
Export	Visio models (vdx)
MetaEdit+	
Import	GXL-adapted (models and meta-models)
Export	GXL-adapted (models and meta-models)
Microsoft Visio	
Import	–
Export	–
PowerDesigner	
Import	Excel, ERwin, XMI, Rational Rose (MDL), SIMUL8 file, specfic Visio models
Export	UML2, XMI2.1 XML schema files
Visual Paradigm for UML	
Import	ERWin Data Modeler project files, BizAgi project file, System Architect business process diagram, XMI (1.2, 2.1), Excel, Visio, Visio ERD, Visio diagram to Stencil, Rational Rose (MDL) files, Rational DNX files, Rational Software Architect files, PowerDesigner project file, Telelogic Modeler
Export	BPEL, XPDL, JPDL, BPMN2.0-XML, XMI (1.2, 2.1), Excel, SCXML
yEd	
Import	Graph Markup Language (GRAPHML), yWorks Binary Graph Format, Graph Modeling Language (GML, XGML), Trivial Graph Format (TGF), Gedcom Data (GED)
Export	–

***Abstract*—Alvis is a formal modelling language. It combines graphical modelling of communication schema and a high level programming language to describe behaviour of individual system entities. An Alvis model can be verified formally by using methods based on a system state space. The paper presents the design and the command list of the Alvis Virtual Machine. The aim of the project is to provide an execution environment for Alvis language. Moreover, one of the goals is to allow different hardware units to run Alvis models. Thus, a virtual machine was chosen as a solution.**

I. Introduction

ALVIS [1], [2], [3] is a formal modelling language designed to provide a user friendly method for developing concurrent systems, especially embedded ones. *Agents* are basic entities of Alvis models. Usually they run concurrently and communicate with one another. From a user point of view a model consist of two layers. The *code layer* provides a high level programming language used to describe agents behaviour. It's syntax is similar to C, Java or Pascal and it provides high level constructions as loop or conditional statements. The *graphical layer* (called a communication diagram) is a visual hierarchical language used to define communication channels between agents [1]. The language is being developed at AGH-UST in Krakow, Department of Applied Computer Science. An on-line manual and software supporting modelling with Alvis can be found at the project web site *http://fm.kis.agh.edu.pl*.

States of a model and transitions among them are represented using a labelled transition system (LTS graph [4]). An LTS graph is used to verify the corresponding model formally with model checking techniques [5]. The Alvis Compiler allows users to write LTS graphs in different formats.

Aldebaran format is used to export LTS graph to the CADP Toolbox [6]. Thus, system behaviour requirements can be provided by using μ calculus [7], [8] or XTL [9] and the CADP Toolbox can be used to check whether the model satisfies them. All things considered, the result of developing concurrent systems with Alvis is an easy to understand model with properties verified formally. Moreover it creates an open environment that allows using other tools based on system state graph semantics. The only thing that is required is an appropriate export function in Haskell.

This paper addresses the problem of executable Alvis models by using virtual machine. The paper presents binary code organisation and the virtual machine design and operation. The presented solution allows execution of a formal Alvis models.

The paper is organised as follows. Section II provides an overview of developing formal models with Alvis and associated tools. The AVM design assumptions and operation are presented in section III. The binary code organisation is described in section IV. Section V deals with details about all the AVM instructions. The paper is summarised in the final section.

II. Alvis Environment

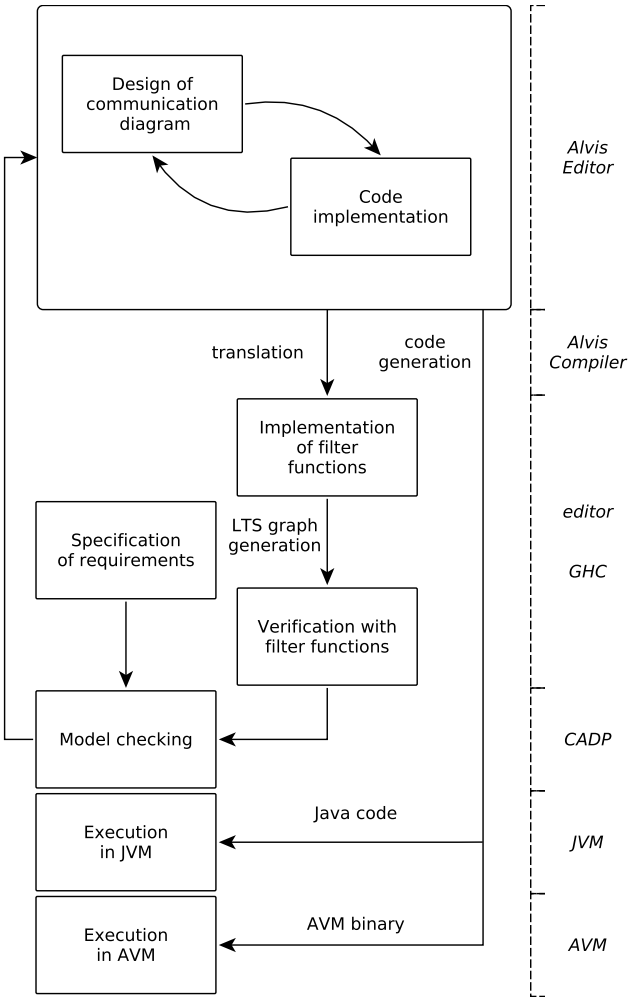

Figure 1. The modelling and the verification process with Alvis

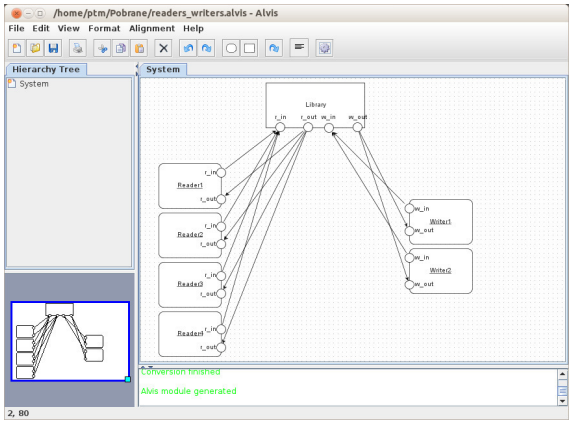

Figure 2. Alvis Editor

The scheme of the modelling, verification and execution process with Alvis is shown in Fig. 1. From a user's point of view, the process starts from designing a model using a prototype modelling environment called *Alvis Editor* (shown on Fig. 2). A system can be designed using a hierarchical representation of Alvis model. With *Alvis Editor* user can collapse and expand any valid part of a system back and forth. It is a very useful feature from the human point of view. However, before applying transformation methods, it has to be flattened. This Alvis system representation proved to be the best one for machine processing.

It is worth mentioning, that from the very beginning of Alvis all model transformations meant to be fully automatic. It was so to remove any "ideas" that user may introduce to system during human-powered translation.

A flat model is translated into Haskell [10], [4] source code and its Haskell representation is used to generate the LTS graph. A designer is able to define additional Haskell functions (called *filtering functions* [4]) that search an LTS graph for some states or parts of the graph that meet given requirements. The source code is compiled with the GHC compiler [11]. The results of the received program execution are the LTS graph for the given model and the report of the model verification with filtering functions. Further verification is performed with the CADP Toolbox [6] and the μ calculus [7], [8] or XTL [9]. Furthermore other tools that support LTS system specification might be used with little effort from the user.

For testing and educational purposes LTS graph can be exported to the DOT format and visualized. It is a useful feature during learning to model with Alvis. Unfortunately, it can be used only to fairly small systems (in terms of generated state space).

Alvis model can also be translated to an executable form. Currently Java target and a dedicated virtual machine, presented here, are supported. As it is shown on Fig. 1 it is not required for a model to be formally validated before execution. Any syntactically correct one can be translated to executable form, however it is wise to perform this step.

For more details on the Alvis syntax see [1] and the on-line manual at the project web site. The formal semantics for Alvis can be found in [2].

III. AVM DESIGN AND OPERATION

Alvis Virtual Machine was designed to run Alvis models without modifying its structure. Common problem in using formal methods in real cases is translation from a model to code. Even properly designed system can be ruined during implementation phase. Thus an *executable specification* concept was introduced and becomes more and more popular in different applications and forms f.e. [12], [13]. The whole Alvis project is a part of that conception. It brings a modelling environment and, by generating LTS of the possible system states, it provides ability to verify formally given system with tools that operate on a such representation [6].

As it will be presented in section V, AVM instruction set almost completely reflects Alvis language statements. The main goal here is to provide identical execution paths as generated in LTS graph [4]. AVM can be considered as a high level virtual machine. It has a very complex commands and is more like BEAM Erlang VM than JavaVM [14], [15]. Also the architecture of the Alvis Virtual Machine can be classified as register VM. Most of the operations are performed "in place" with variable location treated as operational registers.

Like in most virtual machines, the common operation that precedes execution, is code loading. In AVM this procedure prepares binary code for execution.

The preliminary step is checking cryptographic keys. It is based on public-private key pair. A code is signed with private key. The machine has a public key of the software supplier.

If the cryptographic signature is included in code it will be checked before execution. If it passes, the next steps for preparing code for execution will be performed, otherwise the loading will be abandoned.

There are two strategies being considered for the loader. First one, is for devices with large RAM pool. In that case, the whole binary code is loaded to RAM. It is very simple yet effective. There is no need to copy initial values for variables. All offsets are relative to the beginning of a code or the beginning of a given block.

The second code loading strategy is for devices with limited RAM capacity and FLASH memory like embedded SoC or microcontrolers. In that case a code resides in program memory alongside with AVM itself and before execution an additional step has to be performed.

Data field of the variable is moved to the RAM and an additional record is created to translate original address (in ROM/EEPROM) to the actual location. Unfortunately, this slows the execution which is the price for decreasing RAM occupancy. During execution a function which fetches variable, its pointer is modified by additional address translation step. The direct and indirect variable fetching is presented on Fig. 3.

To support online code upgrade AVM may use double code buffer. If the device is powerful enough the new code may be loaded during executing the old one.

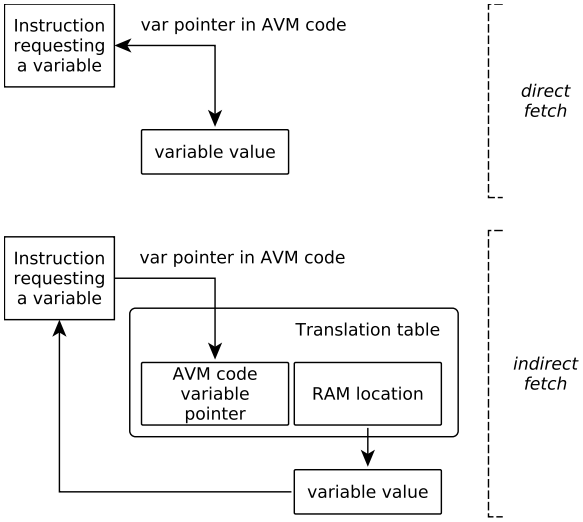

Figure 3. Direct vs indirect variable access

The machine performs all the necessary steps of preparing code for execution while executing the current one. It will be run as a background task. When new code will be ready, machine will restart and begin executing a new one.

Current AVM implementation is a bytecode interpreter. It fetches instruction from specified locations and runs them. Every AVM instruction has a function associated within virtual machine, responsible for its execution.

If a block is executed by VM, a *next instruction after block* (see block description in Section IV) is placed onto agent's *return stack*. When it reaches *block end*, this address is popped and execution continues from that location. In term of efficient virtual machine design and implementation it is suboptimal, but the main goal here is to reflect original model behaviour.

Dynamic memory management is minimized in AVM to simplify code execution and increase reliability. The only dynamic data structures required during execution are:

- stacks for agents for tracing block processing,
- data fields if code is run form ROM,
- address translation table if code is run from ROM,
- temporary storage for guard evaluation.

IV. Code format

In this section a detailed binary code organization for the Alvis Virtual Machine is presented. It is organized in top-down fashion, starting form overall description and ending with details about subsequent elements. The size information is presented as bytes.

Two byte word was chosen as a primary data size for AVM. Thus limits the maximal code size to 2^{16} bytes, including all extensions. As AVM is a high level virtual machine and its instruction are complex, it is enough for fitting quite large systems in its address space.

Table I presents general organization of the AVM code. First is the *header* block, then *functions* block. After it, agent's data are placed sequentially. The size of every block depends on the model.

Table I
General AVM binary code organization

Header	Functions	Agents	Crypto

The AVM *header* block is presented in Table II. It starts with a magic number, which is "AVM " in ASCII code. Next element is a version number. Virtual machine cannot load the code if magic word is incorrect or version number is higher than it can understand.

The function block offset represents displacement from beginning of the AVM binary code to the first function (see Sec. III). The last two elements describes agents in model. First one is an agent counter and the second is a table with offsets to a specific agent structures.

Table II
AVM Header

Name	Description	Size
MAGIC	Magic number 'AVM '	4
VERSION	Code version	4
FUN	Function block offsets table	2
ACNT	Size of the agents table	2
AGENTS	Agents block offsets table	2
SECURITY	Cryptographic extension block offset	2

The agent block is shown in Table III. It consists of: agent's name truncated to 12 characters, mainly for debug purposes, agent's code offset from beginning of AVM code, location of port and variable definitions. The overall single agent code organization is presented in Table V. The *STATE* field contains actual code pointer, execution block and agent state information (see [2]).

Table III
Active agent header

Name	Description	Size in bytes
NAME	Agent name	12
STATE	Agent state	8
CODE	Agent code block	6
PCNT	Ports count	2
PORTS	Ports table pointer	2
VCNT	Variables count	2
VARS	Variables table pointer	2

Table IV
Variable block

Name	Description	Size in bytes
NAME	Variable name	12
TYPE	Variable type	2
LOCATION	Value pointer	2

Table IV presents variable structure. The variable table consists of such elements. The whole variable block combines variable table and variable values. NAME and TYPE are left here mainly for debug reasons and their removal is considered to reduce code size.

Table V
AGENT BINARY CODE ORGANIZATION

Agent header	Ports	Variables	Code

The active port structure is presented in Table VI. This element is generated for every port's data type pair. It holds port's name type identifier for transferred data and pointer for the other side port structure.

Table VI
ACTIVE PORT BLOCK

Name	Description	Size in bytes
NAME	Port name	12
TYPE	Type of data	2
CPORT	Connected port	2

Passive agent definition is in Table VII. It is almost identical to active agent. The only difference is it holds passive ports definitions instead of active ones.

Table VII
PASSIVE AGENT BLOCK

Name	Description	Size in bytes
NAME	Agent name	12
STATE	Agent state	2
PCNT	Ports count	2
PPORTS	Ports table pointer	2
VCNT	Variables count	2
VARS	Variables table pointer	2
CODE	Code pointer	2

Table VIII
PASSIVE PORT BLOCK

Name	Description	Size in bytes
NAME	Port name	12
TYPE	Type of data	2
CODE	Port's code block	6

Table IX presents security extension block. It consists of: key type, key data length and key location as an offset from code beginning.

Key type specifies how the key data should be interpreted during code loading. Virtual machine which is not able to process a specific key type, should refuse to execute the code. Key type may by set to NULL value. In that case, no code verification is performed and key length and value pointer should also be set to NULL.

Table IX
SECURITY EXTENSION BLOCK

Name	Description	Size in bytes
TYPE	Key type	2
SIZE	Key length	2
LOCATION	Value pointer	2

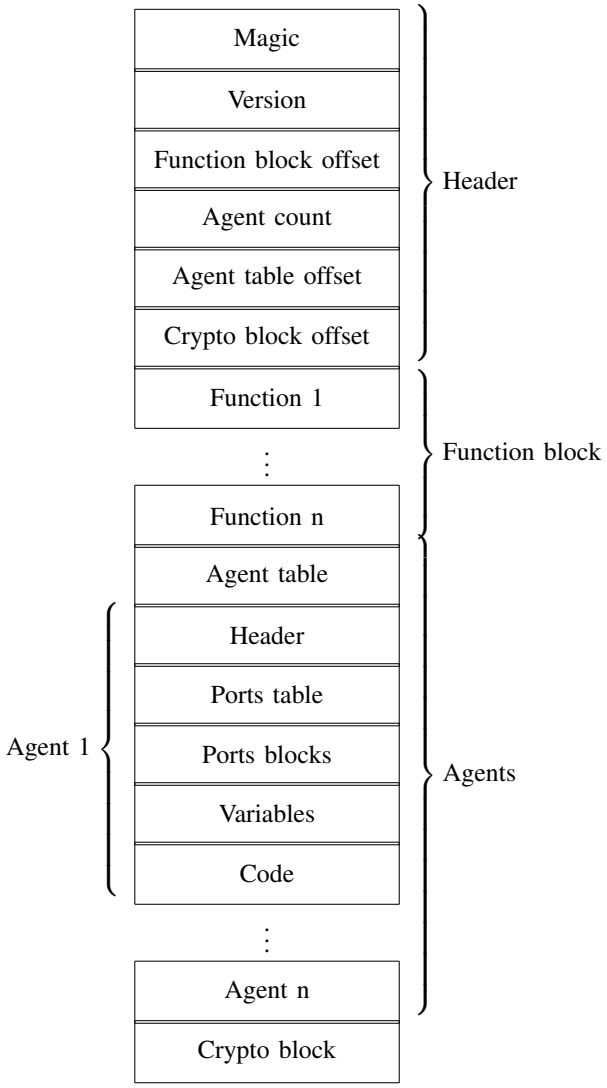

Figure 4. Example binary code map

Figure 4 shows an overview of the complete AVM binary code. The header is presented in detail. Then function block is placed. After it is an agent table. Then all the agents are located. The final block is occupied by cryptographic extension. This block location is not crucial for the AVM operation. It represents actual block placement but it can be reorganized. It is because most of the offsets are relative to the beginning of the AVM code (magic word location). This makes code generation more complicated because, in fact,

some linking operations are applied during that phase. An advantage of that approach is faster code loading and easy code execution. No linking is required during code loading. Also, multiple memory access is not required to access a specific structure nor additional memory to cache frequently used object locations.

V. INSTRUCTIONS

Below all the instructions supported by the Alvis Virtual machine are presented. All of them are shown as a small tables where there is instruction and type parameters (if any) in the first column, and short description in the second column. Binary format of the instruction is equal to the first column contents.

Instructions were divided into two blocks. The first one consists of instructions present in Alvis itself, whether the second one is composed of instructions added to allow Alvis models to be executed on small embedded systems with limited resources, in case it is impossible to fit native Haskell code.

Haskell is not a problem during generation of LTS graph because its already there. Executing even simplest functions as an arithmetic operations in Haskell is perfectly reasonable. But in embedded environment Haskell brings a huge overload to smaller systems. In such case, using it to do a few additions do not seem to be a good idea.

Moreover, during examination of already created test models during Alvis development, this subset allows for running quite large set of code without involving Haskell binaries.

The following types of arguments are used in AVM binary code:

- agP agent pointer - offset to specified agent structure;
- fP function pointer - offset to the start of specific function;
- vP variable pointer - offset to specific variable;
- pP port pointer - offset to specified port structure;
- ppP passive port pointer - offset to specified port structure;
- cP code pointer - offset to specified instruction;
- bs block specification - it consists of three code pointers (block start, block end, first instruction to execute after block);
- char 8 bit signed character;
- uint32 32 bit unsigned integer;
- int32 32 bit signed integer;
- double 64 bit double precision floating point number;
- list list of any of the simple data types (char, uint32, int32, double);

All offsets are relative to beginning of the AVM binary code. It speeds up code execution by allowing to fetch specific data without multiple memory access. Moreover, it simplifies a "virtual memory" (see Fig. 3) implementation for devices where code lays in read only area. In this case, some portions of the data have to be moved to random access memory which is required for execution. This design feature complicates a bit code generation, but it is a consequence of execution requirements for small devices.

NULL	do nothing

The *NULL* instruction does nothing. However, it increments agent's program counter and consumes some time during execution.

START	start agent
agP	agent pointer

The *START* instruction begins execution of agent pointed by the first argument. Its state is changed from *initialized* to *ready*.

EXIT	stop agent
agP	agent pointer

The *EXIT* instruction stops execution of agent pointed by the first argument. Its state is changed to *finished*.

EXEC	execute function
fp	function pointer

The *EXEC* instruction executes specified function. Function arguments are hard-coded inside so there is no need for passing them.

NEXEC	native exec
nfP	native function pointer
uint32	argument count
vP	result pointer
vP	first argument pointer
...	...
vP	n-th argument pointer

The *NEXEC* instruction is a wrapper for executing natively implemented functions. It requires pointers for all arguments and for result. Also types of AVM arguments have to match natively implemented function. Function code has to be compiled and linked with AVM.

IF	start agent
fP	guard pointer
bs	true block specification

The *IF* instruction is the simplest implementation of the *if* Alvis statement. It is the case when there is no *elseif* or *else* clause. If a guard function evaluates to *true*, it executes a code block, otherwise the next instruction specified by *bs* is selected.

IFE	if-else instruction
fP	guard pointer
bs	true block specification
bs	false block specification

The *IFE* instruction covers the case when there is an *else* statement in Alvis code. If its value is interpreted as true, its first block is executed, otherwise second block is executed.

IFEIFE	select instruction
uint32	branch count
fP	first guard pointer
...	...
fP	n-th guard pointer
bs	first branch block
...	...
bs	n-th branch block
bs	else branch block

The *IFEIFE* is the most complicated version of the *if* statement in Alvis. It is the case when there is *if-elseif-else* form of the statement. It consists of table of guards and a table of connected code blocks to execute. The last code block is an else branch one and it is executed when all guard functions evaluate to *false*. There is also the *IFEIF* virtual machine instruction. The only difference from *IFEIFE* is it has no else branch.

The *if* statement was split into several cases because during example code analysis, the most commonly used statement was *if* or *if-else* one. It was made to optimize VM instruction execution and to make implementation clearer.

LOOP	conditional loop
fP	guard pointer
bs	block specification

The *LOOP* instruction executes specified block as long as associated guard function evaluates to true. Otherwise, the next instruction denoted by *bs* is used.

LOOPE	timed loop
uint32	dalay value
bs	block specification

The *LOOPE* is a special loop instruction. It loops indefinitely, but each iteration should start every *delay value* milliseconds. To achieve the process a time stamp is taken before code block execution. After it, another time stamp is taken and the remaining time is calculated. If there is some time left, agent suspends its execution.

JUMP	unconditional jump
cP	code pointer

The *JUMP* instruction performs an unconditional jump to specified code location.

IN	input from port
vP	input variable pointer
pP	local port pointer
pP	remote point pointer

The *IN* instruction performs communication with other agent via port specified. It requires a variable structure pointer to store a new value, local port structure and remote port structure.

OUT	output to port
vP	output variable pointer
pP	local port pointer
pP	remote point pointer

The *OUT* instruction performs communication with other agent via port specified. It requires a variable structure pointer to send value, local port structure and remote port structure.

INP	input from passive port
vP	input variable pointer
pP	local port pointer
ppP	remote point pointer

The *INP* instruction performs passive agent call via specified port. The caller is an active agent. It requires a variable structure pointer to save new value, local port structure and remote passive port structure.

OUTP	output to passive port
vP	output variable pointer
pP	local port pointer
ppP	remote point pointer

The *OUTP* instruction performs passive agent call via port specified. The caller is an active agent. It requires a variable structure pointer to send value, local port structure and remote passive port structure.

INPP	input from passive port
vP	input variable pointer
ppP	local port pointer
ppP	remote point pointer

OUTpP	output to passive port
vP	output variable pointer
ppP	local port pointer
ppP	remote point pointer

The *INPP OUTPP* instructions perform passive agent call via port specified. The caller is a passive agent. They require a variable structure pointer to send or save to, local port structure and remote passive port structure.

SELECT	select instruction
uint32	branch count
fP	first guard pointer
...	...
fP	n-th guard pointer
bs	first branch pointer
...	...
bs	n-th branch pointer

The *SELECT* instruction reflects Alvis's *select* statement. It consists of a table of guard functions and a table of code blocks. Guards are evaluated sequentially. If guard evaluates to *true*, a corresponding code block is executed.

READY	check if port is ready for communication
pP	port pointer

PREADY	check if passive port is ready for communication
ppP	passive port pointer

The *READY* and *PREADY* instructions check if a specified port is ready for communication. It is required for guard functions mainly in select statement.

Table X
INTERNAL COMMANDS FOR FUNCTION EXECUTION

ADD	add operands
SUB	subtract operands
MUL	multiply operands
DIV	divide operands
HEAD	get head of a list
TAIL	get tail of a list
INS	insert element in list at the beginning
ADD	append element to list
AND	logical and
OR	logical or
NOT	logical not

Table X presents summarized list of AVM commands implemented for internal functions. Almost all of them take three arguments except for the last one which takes two. The binary layout of instructions is presented below.

{INSTR}	instruction code, see Table X
vP	result
vP	first operand
vP	second operand

All the operations are defined for appropriate datatypes. Arithmetical instructions are automatically applied to all simple types. Conversions are executed as in ISO-C standard [16].

Presented AVM instruction list should not be considered as closed. AVM is in active development phase and commands are added, removed and reorganized.

VI. Summary

The Alvis Virtual Machine was presented in the paper. The main goal of the project is to provide executable form of an Alvis models. There is an Alvis to Java conversion already done, which was a test drive for Alvis Compiler code generation facility. AVM is a second attempt for automatic Alvis code execution.

AVM was designed for executing a formally checked code in high availability environment. Thus a code signing and a double code buffer were introduced in it.

The first feature is crucial for upgrading AVM code in installations where the software provider has no full control over device and running unauthorized code is a security risk.

The second feature is required in situations when device has to work continuously while providing ability to hot code swapping.

AVM is currently under development and presented features may be a subject to a change.

***Abstract*—Model-driven software development is surrounded by numerous myths and misunderstandings that hamper its adoption. We have designed our course of model-driven development approach with the goal to introduce it from the viewpoint of a programmer as a pragmatic tool for solving concrete problems in development process. The course covers several techniques and principles of model-driven development instead of concentrating on a single tool. To explain these techniques we use a case-study that is iteratively developed by the students during the course. In the paper we explain the structure of our case study, contents of individual iterations, and our overall experience with this approach.**

I. Introduction

MODEL-DRIVEN software development approach (MDSD) promises increase of development speed and quality of resulting software by the use of formal model of the system as a basis for its implementation [1]. Understanding MDSD, however, suffers from several myths that hamper its adoption. This section discusses these myths to provide the motivational context to our work. In the rest of the paper we present our approach to MDSD teaching that is tailored to overcome these myths.

A. Myth 1: MDSD is a large-scale approach

MDSD is mostly viewed from the perspective of large-scale software architecture. A new system or a family of systems is supposed to be implemented by describing every significant part and aspect of the system using formal models (for example in [2]). In practice, however, it is not always the case. When a system development begins, it may not be known that a whole product family would be needed in the future. Therefore, it is not clear beforehand that model-driven development would be applicable and that investment in it would pay off.

Of course, in reality MDSD can be considered in a smaller scale, where only specific parts of the system are generated based on models. In this case, the knowledge of MDSD can be useful even for a single programmer (or a small team) working on a part of the system and introduction of MDSD may not require significant changes in the architecture of the system as a whole.

B. Myth 2: MDSD requires massive tool support

MDSD is often associated with integrated modelling tools or language workbenches. These tools cover development of meta-model, a domain-specific language used to express models and a generator that produces runnable code based on a model. Modelling tools may also provide environment for development of the model itself. These tools, however, are often complex and require high learning costs. What is more important, the use of such tools poses the risk of vendor lock-in.

Although integrated tools may be useful in a lot of situations, they are not necessarily required by the model-driven approach. It is possible to use a set of independent tools for separate parts of the model-driven development infrastructure (e.g., for language processing, for code generation, etc.). This approach allows looser coupling and greater flexibility in the choice of tools.

C. Myth 3: MDSD requires special software development process

It is considered that model-driven approach requires the use of a special software development process, where meta-model and modelling language must be completely specified and implemented before a model of a system can be developed. This opinion renders MDSD as very inflexible and incompatible with agile development processes that are currently favoured.

Modelling infrastructure, however, can be developed iteratively. Meta-model, language processor and generator can evolve together with the rest of the system. The use of small-scale MDSD and simpler tools as described in previous paragraphs greatly simplifies such iterative development process and allows using MDSD along with common agile methodologies.

D. Myth 4: MDSD is not widely used in practice

Without a deeper insight it seems that MDSD is not a widely used approach in practice. In reality, model-driven and generative approaches are indeed wide-spread and even considered a good practice for pragmatic programming [3]. Most of the examples, however, represent small-scale MDSD applications which include:

978-83-60810-58-3/$25.00

- Generators of database schema and object-relational mapping (ORM) code from the description of a data structure (used in various ORM tools).
- Generators of code for accessing web services based on WSDL description.
- Tools for graphical user interfaces design that generate code according to a graphical representation of the user interface.
- IDE plugins for specific technologies that are able to generate skeletons of repetitive artefacts (e.g., GWT plugin for IntelliJ Idea that can generate standard GWT RPC service artefacts).
- Spring Roo generative framework that allows to implement custom code generators for various repetitive code artefacts (currently published generators focus on web-based CRUD application domain).

Furthermore, the MDSD application is often hidden from a programmer by libraries and frameworks that allow to specify behaviour using a model without knowing details of model processing. In case of dynamic languages such as Ruby, internal domain-specific languages can be used for description of models and code generation can be replaced with run-time program modification using reflection. This approach makes the use of MDSD even less obvious.

II. Pragmatic Model-Driven Programming

We designed the MDSD course with these considerations in mind. The course is intended for graduate students that would mostly become software engineers in their future career. Because of this, we wanted to demonstrate the approach from the viewpoint of a programmer. This led us to the following goals:

1) *Keep it practical.* We wanted to maximize the possibility that our students would be able to use the learned skills and techniques in their future careers. This means that these techniques should be applicable in a wide range of situations.
2) *Teach principles using realistic examples.* Students should understand the basic principles of the topic as they have much higher level of applicability than any concrete tool. At the same time we should illustrate these principles using realistic examples, tools and approaches that can be directly used in practice.

For these reasons we need to teach MDSD in a way that challenges myths described in the previous section. First of all, we show the students that model-driven approach is not limited to large-scale solutions. Although we demonstrate development of a complete system using MDSD, parts of the system are modelled and generated separately showing different scales of modelling.

We also do not use any full-fledged MDSD tool for the whole development process. Instead, we concentrate on several development techniques and tools behind them from the perspective of the main components of the MDSD infrastructure. If we apply the language-oriented perspective, we can divide the components and techniques that we teach as follows:

1) *Abstract syntax* – meta-model that describes structure of models:
   - definition of meta-model using classes in object-oriented language,
   - composition and reuse of models.
2) *Concrete syntax* – domain-specific language used to specify a model:
   - implementation of delimiter-directed parser,
   - internal domain-specific languages,
   - the use of parser generator,
   - generic XML parser.
3) *Semantics* – generator used to produce code based on the model:
   - generation by direct transformation,
   - generation using templates, templates composition and reuse.

All of the listed technologies and approaches are used in the course. In the beginning of the course students are building simple version of MDSD tools themselves (e.g. parser, generator). Later on, when the complexity of tasks arises we are fluently switching to the well-known MDSD tools (e.g. parser generators, tempalting engines). In the end of the course, students are able to compare tools and approaches and choose the most effective one in a particular situation.

The techniques that we teach can be combined in various ways to power MDSD. At the same time, they can be used even separately for a wide range of programming tasks. From this aspect our approach is similar to the one used by Folwer in [4].

All taught techniques are demonstrated on a single case study that is developed in an iterative manner. Meta-model used in a case study is gradually extended showing evolution and composition of meta-models and languages during the system development. We also show that a meta-model can be reused even if the implementation of a language processor is replaced. Thus we demonstrate parallel evolution of different components of the MDSD infrastructure. It also shows the possibility to use usual agile development processes with connection to MDSD.

III. Case study

In this section we introduce the case study we use to teach MDSD in our course. *CrudComp* is a fictive company, which develops CRUD (create, retrieve, update delete) applications for different domains storing entities and their properties and relationships (e.g. employee, department). They have started with a single application but their success brought them new customers. *CrudComp* soon identified fundamental requirements shared across all the applications they developed for their customers. Each CRUD application has to provide means for:

- data entry,
- data validation,
- data persistence into an (external) memory, and
- data presentation in a user interface.

They also identified a few non-functional requirements for the applications concentrating on technology.

- *User interface technology* – the customers expect a migration to a new user interface type in the near future (e.g., mobile, web).
- *Storage technology* – currently the applications are supposed to work with a relational database, but some of the customers consider transition to a file system or a NoSQL database.
- *Service-oriented architecture* – *CrudComp* providentially expects that the customers will want to export the CRUD functionality as the web services for integration with other business applications.

These specifications led the *CrudComp* to design a multi-tier architecture for their CRUD applications consisting of 3 layers: user interface, service and data access. The architecture skeleton is depicted in Figure 1.

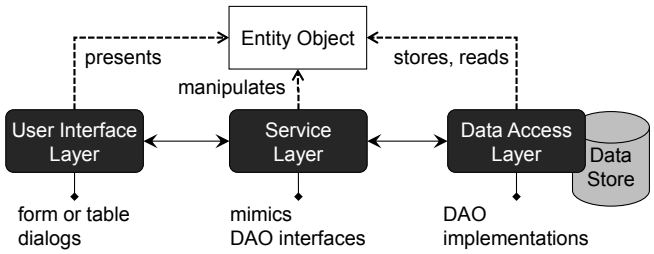

Fig. 1. Multi-tier architecture used by *CrudComp* CRUD applications

The architectural framework defined applications skeleton, but there would still be quite a lot of repetitive work. Luckily, one of the *CrudComp* employees was an enthusiast for MDSD and generative programming. The vision presented to the management was that the MDSD solution would not only speed up the development, but it would also make the communication with the customer more efficient. The domain-specific language used to specify the model of an application would be readable also by customers (in this context they were domain experts). Moreover, the customer would be even able to *write* the input file by himself. This way *CrudComp* would not only spare the time and money for the development, but it would also gain more effective ways to communicate with the customer. They have started with the application of the MDSD in a small scale (generating just small parts of the system) not to hamper the development of currently developed applications. And so he with the rest of the team decided to iteratively build a full MDSD solution with each iteration covering just a small portion of the whole CRUD application. Until the whole solution would be ready the programmers would have to implement the rest of the system manually to meet the deadlines.

The input of *CrudComp* MDSD solution was a simple model of the domain in terms of entities, their properties and relations. The output was supposed to be a part of a CRUD application. They decided to start with entity classes generation since the entity classes are the simplest artefacts of a CRUD application source code. Entity classes define the data structures manipulated in a CRUD application. Later they wanted to generate also data-access objects implementations, validators, etc. The only thing the programmers would need to do to get entity classes or later even the complete CRUD application is to write a simple input file that models the domain for a given customer. After running the generator they only needed to add a hand-written specific code to the generated source code to finish the application so that it would be fully functional and tailored for the specific customer. Thus they were able to reduce the amount of their repetitive work.

CrudComp presents a simple case of possible MDSD adoption candidate. As the reader can see we use the case study to motivate and explain the adoption of the MDSD technique. However, on the other hand we do not avoid development process issues. The case study context puts students in the role of *CrudComp* developers that need to iteratively and incrementally build an MDSD solution for a CRUD application family. Incremental MDSD adoption is a necessity to fit into the agile development processes.

We selected a CRUD application software family for our case study because it is the most common information system type in practice. It is also very similar to common project assignments at our university that our students are already used to. Moreover, examples in many tutorials (e.g. Spring, NetBeans JSF) are illustrated on a CRUD application.

During the course, each student works individually on his/her *CrudComp* project at home or in the class. Their progress is controlled in the class on a week basis to prevent procrastination and to help them with issues that raise during the development of the case study.

IV. Teaching MDSD Iteratively

The *CrudComp* case study is divided into 4 relatively self-contained incremental iterations. They all solve problems in the same problem domain – the implementation of CRUD applications. However, rather than solving the whole problem at once, each iteration solves a smaller sub-problem of the CRUD application generation. The first iteration starts with generating entity classes and DAO implementations, and each next iteration adds generation of some new functionality. This iterative approach allows us to teach 4 different approaches to MDSD while keeping the case study quite simple[1]. Thanks to the variety of the MDSD techniques used in the case study we can give the students a brief insight into the problems, advantages and disadvantages of these techniques and the students can compare them by themselves. Multiple approaches also enable us to introduce the problem of language composition.

While each iteration uses a different technique they all share the same tooling infrastructure used in MDSD (see Figure 2).

[1]Of course, this iterative approach is not only about showing multiple techniques. As we argued in Section II, its main objective is to explain (and illustrate, too) to the students that MDSD can be applied just to small portions of the whole system and one can even combine multiple approaches in context of the same system. Moreover, iterative approach nicely fits into agile development.

As the reader can see from the scheme in Figure 2 we accent the importance of the model that connects the problem domain with the implementation.

The case study is divided into 4 iterations that introduce the following techniques:

1) *Entities DSL* processed by a simple parser implemented in an ad hoc manner (delimiter-directed parser). This iteration solves the entities definition problem and enables the user of the generative system to generate the data tier for the CRUD application. Source code artefacts are generated by direct transformation and using templates.
2) *Constraints DSL* implemented as a Java-based internal language. It solves the problem of defining constraints upon entity properties and introduces the technique of language composition. Templates composition is introduced.
3) *Entities DSL with references* processed by a generated parser. The language adds a new functionality to the generated CRUD applications that allows to specify relations between entities.
4) And finally, *UI specification language* parsed by a standard XML parser. The UI specification language enables *CrudComp* to generate a standard user interface for a CRUD application. This iteration introduces templates reuse.

Each iteration ends with a full MDSD solution to a subproblem of the whole CRUD application generation. They all follow the whole scheme in Figure 2. The students can see that MDSD can be applied in a small scale and that it can be done relatively easily and quickly (they can see that even MDSD can be done in agile manner). The following sections discuss the iterations in detail and explain our motivation for each of the chosen approach.

A. Entities Language

The first iteration starts with a simple external DSL. From the viewpoint of the parsing approaches the objective of this iteration is to show the students that writing an ad hoc delimiter-directed parser for a very simple language can be the right choice – in some simple situations the "big guns" such as parser generators could just complicate the matter. To make the implementation of the entities language as simple as possible we exploit the file system for the concrete syntax (see Section IV-A2). On the other hand, the students can also see that if the language would get a little bit more complex, the parser implementation complexity could raise much more (thus we are preparing the ground for introducing other approaches).

Another reason why we start with an ad hoc parser is that students are often scared of parser generators. Usually they think parser generators are complicated and therefore can be used only by experts in language theory. We start with a simple ad hoc implementation to gain the students' attention and enthusiasm.

From the viewpoint of code generation we use both template-based generation and direct transformation. Again, we want the students to understand when a direct transformation generation is enough and when we can simplify generation with templates. To emphasize incorporating multiple approaches in one project we also generate multiple outputs from the same model.

1) Abstract Syntax: In the first iteration we start with a domain model that considers entities and their properties as the data structures handled by CRUD operations. Entity has a unique name and a set of its properties. Each property has a name too (that is unique in scope of one entity) and a type. For the purposes of the project string, integer and floating point number types suffice. The result of the first iteration is a language that covers the domain of CRUD entities.

The abstract form of a language sentence is represented by an in-memory object-oriented model – semantic model using Fowler's words [4]. For each entity there should be an in-memory object that would have a reference to a string with an entity name and a reference to a list of objects representing its properties, etc. The in-memory model is defined by GPL classes (Java classes in our case study). The language model for the problem domain of this iteration is shown in Figure 3.

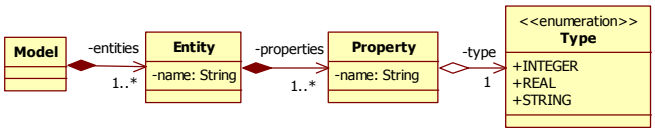

Fig. 3. Object-oriented language model of the entities language

2) Concrete Syntax: The first parsing approach we want the students to use is an ad hoc delimiter-directed parser. To keep the implementation effort manageable we chose a simple pragmatic syntax. The whole model is defined in a single directory in a file system. In this model directory there is a set of files that define entities. One file specifies one entity. The name of the entity is derived from the name of the file. This way we mimic the Java programming language that requires the name of the file to be the same as the name of the class specified by that file. Since we use standard file system to specify the set of entities in the domain model we can keep the internal structure of the entity files simple. The internal structure of the entity files is used to specify entity properties, each on a single line. An example of a language sentence is shown in Listing 1.

Listing 1. Two entities specified in a file-based entities language

```
<model>
  |———— <Department>
  |            name : string
  |            code : string
  |———— <Employee>
               name : string
               age : integer
```

The students have to implement a simple parser `LineParser` that scans a given directory for files and parses them to create in-memory objects representing entities. File system scanning is done using standard Java File API. Files are

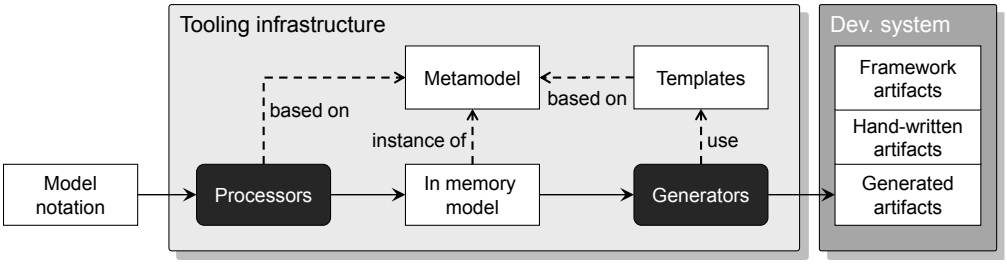

Fig. 2. Tooling infrastructure of our MDSD case study solution

text based and are parsed using just the `String` class and its methods and regular expressions. The syntax of an entity file is very simple. Each line in the file specifies a single property of the entity. The property definition starts with property name and ends with its type that is separated from the property name by a ':' character. Entity files support single line comments starting with '#'.

3) Semantics: Once the students have the in-memory model they use it to generate source code artefacts. In the first iteration they generate just a part of the whole system – the data tier of the CRUD application (simulating small-scale MDSD). For example, for the Employee entity from Listing 1 they are supposed to generate a Java entity class and a data-access object with appropriate CRUD operations. In the standard line of the case study we use JDBC to prepare SQL statements and run them on a database, but students are encouraged to use other technologies (such as Hibernate) if they have experience with them. To show to the students that we can generate multiple output artefacts from the same model the case study requires that the students would also generate a database schema creation script for a specific database (e.g. Java Derby).

We chose templates as the basic generative approach, in particular the Velocity templating engine. Both entity and DAO classes are written as templates that are instantiated using the in-memory model obtained by parsing the DSL. However, we require the database schema script to be generated using the direct transformation approach. We want the students to realize that sometimes (for very simple output artefacts or when the static portion of the generated source code is relatively small) the template-based approach is unnecessary complex and it is more appropriate to use program transformation.

B. Constraints Language

The second iteration introduces another pragmatic solution – internal language based on a host GPL. We want to show to the students that if syntactic restrictions posed by the host GPL are not a problem, an internal DSL can significantly decrease parser implementation costs.

In this iteration the students define a new language that have to be composed with the entities language implemented in the previous iteration. Since the new language models an extension of the entities domain the two languages need to be composed. Thus the students are introduced to language composition on models. And finally, in the process of code generation we show them that templates can be composed, too. Template composition can be used to modularize and simplify the templates.

1) Abstract Syntax: The second iteration extends the problem domain with property constraints. In addition to property name and type, we want to be able to specify constraints about properties. For example, the value of a particular property might be required, it might have restrictions on range or length, etc. Students will use Java-based internal domain-specific language for constraints specification. Instead of extending the LineParser they will implement a new constraints language that will be composed with the entities language.

Since the constraints internal language is a new language, it has its own model. The model of the constraints language is shown in Figure 4. Classes highlighted in red represent references to the entities language. `EntityRef` and `PropertyRef` classes have both a `name` attribute that refers to an Entity concept and to a Property concept of the original entities language, respectively. For the purpose of the composition the entities language model has to be extended, too. The `Property` class representing the Property concept of the language gets a new attribute with a list of its constraints (similarly as the `PropertyRef` class).

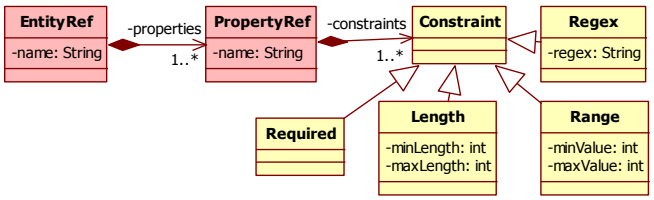

Fig. 4. The constraints language model

In addition to parsing, the constraints language have to be composed with the entities language. Students have to implement a method that validates references from the constraints language so that they refer to existing entities from the entities language model. After the validation they have to compose both models. That basically means that they have to assign constraints from the constraints language model to the appropriate properties objects from the entities language model.

2) Concrete Syntax: The second iteration of the teaching process is aimed at internal languages. Instead of imple-

menting their own parser, the students are shown how to reuse the compiler of the host general purpose language. This pragmatic solution is a façade to the language model that can be used to build constraints language expressions using domain-specific concrete syntax. In Listing 2 there is an example of a sentence specifying constraints on the name property of the Employee entity from Listing 1. The example specifies that every Employee must have a name and it cannot exceed 30 characters.

Listing 2. Constraints for the Employee entity in the constraints language

```
public class Constraints extends ConstraintBuilder {
  protected void define() {
    entity_ref("Employee",
      property_ref("name",
        required(),
        max_length(30)));
  }
}
```

The façade to the language model is called expression builder. Expression builder in the *CrudComp* case study is implemented as a Java class that provides creation methods with names from the problem domain. Part of the implementation for constraints expression builder is shown in Listing 3. It is implemented using the *nested methods* design pattern of internal languages inspired by Fowler [4].

Listing 3. Expression builder for the constraints language

```
public abstract class ConstraintBuilder {
  private List<EntityRef> entities = new ArrayList<EntityRef>();
  private Model model;

  protected abstract void define();

  protected void entity_ref
      (String name, PropertyRef... properties) {
    entities.add(new EntityRef(name, properties));
  }

  protected PropertyRef property_ref
      (String name, Constraint... constraints) {
    return new PropertyRef(name, constraints);
  }

  protected Required required() {
    return new Required();
  }
  :
}
```

3) Semantics: From the viewpoint of the constraints language semantics the students have to extend the DAO implementation to add a test method that validates objects of entity classes to match the specified constraints. Here we introduce another concept – template composition. For each constraint there should be a template just with the corresponding test. For example, in Listing 4 there is a Velocity template for the *required* constraint that tests whether an attribute of an entity class is not null (the `toUCIdent` method transforms the name into upper case identifier). In the test method of the DAO template there is a loop that goes through all the constraints assigned to the properties of the current entity class and instantiates and includes the appropriate template for each found constraint. This way we can avoid multiple 'if-else' conditional branches in the DAO template.

Listing 4. Test template for the required constraint

```
if(object.get${generator.toUCIdent($property.name)}() == null) {
  throw new ValidatorException("Property '$property.getName()'"
      + " of entity '$entity.getName()' is required.");
}
```

C. Entities Language with References

The third iteration moves the focus to the traditional MDSD tools. Now a new parser is not implemented in an ad hoc manner, but the students are supposed to work with a parser generator. The previously used approaches were supposed to show to the students that a simple DSL can be easily built without a lot of knowledge about the language theory. This iteration is used to show them that with modern approaches to parser generation, generating a parser is not difficult and for a non-trivial language it is much more effective than writing an own implementation.

To keep the course pragmatic we favoured model-based approach to parser generation (introduced in [5]). Students use the YAJCo [5] model-based parser generator that considers the object-oriented model of the entities language to be the specification of the language abstract syntax. Thus the students do not have to explicitly worry about the language grammar (although we show them the correspondence between the EBNF-based and model-based grammar specification). Using model-based parser generation does not necessarily require extensive knowledge of language and grammar theory.

1) Abstract Syntax: In the third step the problem domain is extended with relationships between entities. An entity uses a reference to other entity to express a relationship. For example, an employee works in a specific department. This relationship will be expressed by a reference from the Employee entity to the Department entity.

In this iteration we create a new parser for an external DSL that supports entities, constraints and references. The language model from previous iterations is reused thus mimicking agile evolution of the MDSD solution. Prototype parsers implemented in previous iterations are discarded, but the model and the generators are still used. A new parser populates the same `Model`, `Entity`, `Property`, and `Constraint` classes that were previously instantiated by the `LineParser` and the `ConstraintBuilder`. From the viewpoint of the language model, only the `Reference` class is an addition. Figure 5 shows the new `Reference` class with relations to the existing `Entity` class.

2) Concrete Syntax: The new entities language with references is an external language that is parsed by a generated parser. YAJCo parser generator uses the language model expressed by Java classes as a definition of the language abstract syntax. In addition to the model, students have to specify the concrete syntax of the language so that sentences like the one in Listing 5 can be processed.

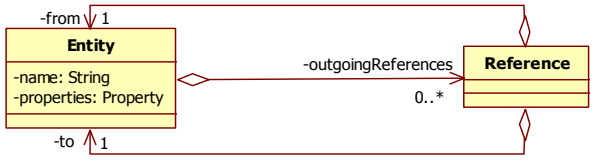

Fig. 5. `Reference` class and its relationship with the `Entity` class

Listing 5. Sentence in the entities language with references

```
entity Department {
  name : string required, length 5 30
  code : string required, length 1 4
}
entity Employee {
  name : string required, length 2 30
  age : integer
}
reference from Employee to Department
```

YAJCo uses Java annotations to associate concrete syntax patterns with the language abstract syntax expressed by Java classes. Each constructor of a language model class is considered an alternative in the grammar rule for expanding the language concept represented by that class. A constructor is a mean for creating an object from formally defined input. Annotations are used to associate concrete syntax to these rules, e.g., keywords with `@Before`/`@After`, number of occurrences with `@Range`, etc. Listing 6 illustrates modelling an expansion rule for the Entity concept of the class by annotating parameters of the constructor (for illustration of the duality there is an EBNF-based version of the rule).

Listing 6. Entity concept concrete syntax expressed by YAJCo annotations

```
public class Entity implements Named {
  :
  // Entity –> 'entity' NAME '{' Property+ '}'
  public Entity(@Before("entity") String name,
                @Before("{") @After("}") @Range(minOccurs=1)
                Property[] properties) {
    this.name = name;
    this.properties = properties;
  }
  :
}
```

In this point the students already have the abstract syntax of the language – they have the language model. To generate a parser they only need to properly annotate constructors of the model classes to specify the concrete syntax of the language.

3) Semantics: This iteration introduces only small additions to the generated artefacts. The students have to alter the database schema script generator, entity class template and DAO template to support references between entities.

D. User Interface Specification Language

The last iteration we use to teach the concept of generic languages (called Commercial-Off-The-Shelf by Kosar et al. in [6]). If a language designer keeps the syntactic restrictions defined by a generic language he/she can then reuse its generic parser. Generic languages (XML, YAML, .properties, etc.) are currently very popular in industry, especially for configuration languages [7]. This popularity is the reason why we believe that generic languages should be a part of an MDSD course. From the viewpoint of code generation and templates we use this iteration to show how the templates can be reused.

1) Abstract Syntax: In the last iteration the problem domain is extended to consider the user interface of the CRUD application. Entity objects are presented to application users in tables, each of which has a set of columns corresponding to entity properties. Not all the properties of a particular entity have to be presented and therefore there does not necessarily have to be a column for each property. To support creating and editing entity instances, a form has to be specified. Again, for each property, a field in the form can be defined.

The language model for the UI specification DSL includes new classes that describe concepts of a CRUD user interface. In Figure 6 there is a class diagram showing the language model of the UI specification language. A user interface consists of tables and forms for the entities. Tables and forms are special cases of a dialog. Each dialog has its components; in case of tables those are columns and in case of forms the components are fields. The `Dialog` and the `Component` classes have attributes prepared for composition with the entities language.

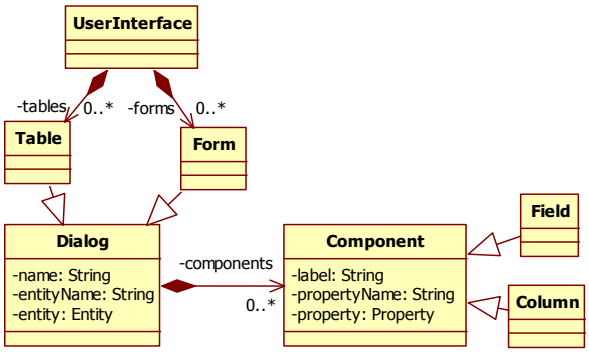

Fig. 6. User interface specification language model

2) Concrete Syntax: The concrete syntax of the UI specification language is XML-based. For parsing the language we chose the Java Architecture for XML Binding (JAXB). JAXB enables to marshal (serialize) a Java object tree into a corresponding XML document and to unmarshal (deserialize) an XML document into its in-memory object oriented representation. The classes that JAXB works with are indeed the model of the XML-based language that specifies its abstract syntax. JAXB uses *convention over configuration* design pattern to assume a concrete XML-based syntax of the language. For example, by default, JAXB maps class attributes to XML elements with the same name (mapping options between XML format and object trees are discussed in detail in [8]). The JAXB schemagen tool that can be used to generate XML Schema Definition for the XML language.

Listing 7 shows a simple user interface specification for the CRUD application with Employee entities using an XML-

based notation. Again the students' task is to annotate the language model (Figure 6) so that the JAXB would be able to marshal and unmarshal instances of the model to XML documents with the format shown in Listing 7.

Listing 7. XML-based user interface specification language

```
<ui>
  <form name="EmployeeForm" entity="Employee"
        label="Employee">
    <field property="name"/>
    <field property="age"/>
  </form>
  <table name="EmployeeTable" entity="Employee"
        label="Employee" editFormDialog="EmployeeForm">
    <column property="name"/>
    <column property="age"/>
  </table>
</ui>
```

JAXB annotations are used to specify deviations from the default mapping. An excerpt from the `Dialog` class with JAXB annotations in Listing 8 represents an example of a mapping definition. `@XMLTransient` annotations exclude program elements from mapping. E.g. the Dialog class itself is excluded since its descendants will suffice. `@XmlID` annotation specifies that the `name` attribute is an identifier of `Dialog` (or its subclasses) objects. `@XmlAttribute` overrides mapping to XML element and specifies that the `name` attribute of the `Dialog` class will be mapped rather to XML attribute.

Listing 8. Dialog class annotated with JAXB annotations

```
@XmlTransient
public abstract class Dialog implements Named {
  @XmlID @XmlAttribute(required=true)
  private String name;
  @XmlAttribute(name="entity", required=true)
  private String entityName;
  @XmlTransient
  private Entity entity;
  @XmlAttribute(required=true)
  private String label;
  @XmlTransient
  private Component[] components;
  :
}
```

3) Semantics: The last iteration finishes the CRUD application generator. The students will implement generators that will provide a user interface for the data tier generated by the generator implemented in the previous iterations. Currently as the standard line in the case study we use a console-based user interface so that the project would be simpler and at least partially manageable even for under-average students. The standard console-based UI solution requires providing templates for forms and tables. In addition, the students have to write a simple template for the main class of the application that provides the main menu for using it. Of course, we encourage the students to rewrite the project to support other types of user interfaces – we have seen multiple web-based UIs (e.g., HTML+JavaScript, Java Server Faces), desktop UIs based on Swing and also mobile clients (e.g., Windows Phone 8 communicating with server through web services, Blackberry) developed by our students.

From the viewpoint of generation techniques we ask the students to reuse the templates. The UI has to validate users input to avoid violating constraints on entity properties[2]. Here they have to reuse the constraints validation templates written in the second iteration (e.g. the template shown in Listing 4). This way they can see that a good decomposition of templates can also support template reusability.

V. Evaluation

To determine the impact of using MDSD in our course, we administered a survey to the students in our classes. 58 students responded the survey. Following questions were used in the questionnaire

A Single choice questions:

1. What were your experiences with model-driven software development (MDSD) before this course? *(a) I have not heard of it before, (b) I have heard of it before but I have never used it, (c) I have already used this approach before this course.*
2. Do you think you understood MDSD? *1 - Strongly agree, 2 - Agree, 3 - Disagree, 4 - Strongly disagree.*
3. Would you use the techniques learned in this course in practice? *1 - Strongly agree, ..., 4 - Strongly disagree.*
4. Were you satisfied with the iterative way of development used in the course? *1 - Strongly agree, ..., 4 - Strongly disagree.*
5. Rate the amount of work needed to complete the project solved in the course. *(a) Significantly more than in other courses, (b) More than in other courses, (c) Less than in other courses, (d) Significantly less than in other courses.*
6. The course belongs to your: *(a) favourite subjects, (b) rather favourite subjects, (c) rather not favourite subjects, (d) not favourite subjects.*

B Open text questions:

7. What did you like about the course?
8. What is the biggest problem you had during the course?
9. What would you change about the course?
10. Which of the learned techniques would you use and in what situations/projects/platforms?

As the reader can see, the first two questions of the questionnaire are oriented to students' knowledge about MDSD before and after the course. The 2nd and 10th question are targeted to practical usage of the learned knowledge. The rest

[2]In this simple console-based application the validation both in data tier and in UI is redundant, but we want the students to have an opportunity to reuse the templates written for constraints. In the real world, most of the common CRUD applications are web based. In web input, validation in UI forms is important for user experience. And duplicate validation on server is necessary if the server exports services that can be used to create or update entities.

of the survey addressed the course, it's form and the problems that the students might have had during the course.

Results

The results we obtained from the first two questions revealed that most of the students (57%) have never heard of MDSD and only 5% have used an MDSD approach before the course. After finishing the course, almost 86% of the students think they understand MDSD and only one student feels s/he does not understand MDSD at all.

More than a half of the students (almost 58%) think that they will use the MDSD techniques in practice. Here we have to note, that not all of our students are programmers and many students are focused on computer networks for example. According to the answers of the 10th question, more than a half of all students (51%) specified also relevant examples of using specific techniques in practice. This fact implies that *more than a half of the students sufficiently understood MDSD principles and techniques, they can distinguish between them and know how to use them in practice*.

The results of the 4th question shows that majority of the students (93%) liked the iterative approach used in our course.

It was surprising and gratifying for us to learn that although 88% of students thought the course puts an excessive amount of work on them, however 70% marked the subject as their favourite or rather favourite.

The problems that our students encountered most frequently were mainly misunderstanding of several tasks in the course materials (30%), technological issues (IDE, operating system compatibility, etc.) or Java (25%). *17% of students had no problem with the course*. Only a little number of students had problem with the techniques used - YAJCo (3 students), annotations (2 students) or velocity (7 students).

Although the students had issues, the results of the 9th question show that *more than a half* of them (52%) felt that they *would not change the course materials at all*.

The results obtained in the open text section showed that the students liked the iterative approach very much and they are satisfied with the consultation during exercises. Many of them marked the exercises as useful and they liked the implementation. Some of them like the various techniques used and favour the possibility of using the learned techniques in practice.

We can conclude that the course is successful and orientation to the practice had motivating impact on the students. Problems lied mainly in the formulation of several tasks, which were hard to interpret for weaker programmers. For this reason, we introduced discussions and evaluations of concrete tasks into our course materials, to be able to obtain task-specific feedback and improve the course materials in the future.

VI. Related Work

The motivation for teaching MDSD at our university is based on its promises of narrowing the semantic gap between problem and solution domains. Selic [9] argues that these benefits of using models are even greater in software than in other engineering disciplines (due to less diversity in skills needed for the complete MDSD implementation). Introduction of the MDSD course at our university was a response to the studies and works that on the one hand proclaim the benefits of MDSD, but on the other hand state that MDSD is given little attention in education (e.g., an early work by Cowling [10]). The main problem with MDSD teaching at our university is that myths discussed in Section I were and still are strongly rooted among our students. Although there are numerous articles describing research challenges in MDSD (e.g., work by France et al. [11]) we faced the problem of MDSD unpopularity among the students. And our students considered most of the scientific papers on the topic as just proofs of those myths (they usually deal with the highly specific problems). In our teaching approach we tried to extract the fundamental MDSD principles and show them to the students on simple pragmatic examples. The principles had to be directly applicable in practice (considering the small scale application, application in the agile methodologies, etc.).

Considering taught principles we explain the MDSD topic from the viewpoint of the language-oriented programming (see Section II). Although this viewpoint covers basically the same challenges and benefits as rather "classic" MDSD teaching approaches such as the one by Clarke et al. [12], our approach is more language-centric. We decided to extensively cover also the topic of formal languages, since currently in the industry there is ubiquitous need for developing and working with little languages (especially configuration languages [7]). Not only this course teaches the students useful knowledge, but it also serves as a motivational factor; the most important attribute of a course for students is whether they will be able to apply the learned topics in their future career.

Problem with used tools in MDSD teaching was discussed in multiple scientific works. There are cases in which teachers chose complex MDSD tools and they do not report any significant problems with students using complex solutions. For example, Tekinerdogan [13] and Clarke et al. [12] used Eclipse Modeling Project (EMP) tools, Pareto [14] used Microsoft DSL toolkit. However, there are reports of students having problems with working with such complex tools. For example, Batory et al. [15] tried to use the Eclipse Modeling Framework (EMF), but their students were overwhelmed by the technology. The failure to successfully understand and work with the EMF resulted in, using words of Batory et al., "a bitter taste" for them, and worse, even their students. We did not use a single complex tool to defy the myths about the solely large scale MDSD application and the need of massive tool support.

Schmidt et al. [16] identified three approaches to MDSD teaching:

- *Purely theoretical approach* that focuses on theoretical knowledge and neglects the practical exercise of the MDSD principles by students themselves.
- *Tool-supported approach* is a teaching approach that uses a single complex MDSD tool (e.g., EMF in [12]).

- *Practical approach* that focuses on underlying concepts rather than the use of a concrete tool.

Schmidt et al. use the practical approach in which they ask students to implement the generator tool themselves. They favoured this approach to the tool-supported approach since with the practical approach students have to directly apply the MDSD elementary principles themselves. Using a complex MDSD framework risks that some of the basic principles might be encapsulated by the framework and thus hidden from the students. Although this motivation differs from ours (we did not use a complex tool to show that MDSD can be applied without a massive tooling support) we ended with the very similar approach focused rather on principles than on tools.

Considering the domain of the course project, the used domain usually differs from work to work. For example, Mosterman [17] uses the domain of embedded systems, Clarke et al. [12] use the domain of communication services, or Batory et al. [15] let the students choose a domain of their interest. For the case study in our course we selected the domain of CRUD applications for two reasons, (1) it is a well-known domain for our students, and (2) it is widespread in practice (considering frameworks such as Spring Roo or Ruby on Rails). While the usage of a well-known domain does not bother the students with unnecessary learning load, the fact that the domain is widespread in the industry serves as a motivational factor.

From the viewpoint of the teaching approach, most of the articles report using classic development with a single iteration (e.g., Clarke et al. [12]). We use iterative approach to show the options in using MDSD for incremental, agile development and also to reduce the focus on a complex MDSD tool and to rather move it to MDSD principles. Iterative teaching approach is also used by Schmidt et al. [16]. They use the iterative approach for the same reason as we do; they want to focus on MDSD principles rather than on tools. In the first iteration their students implement their own generator tool, in the second iteration they extend the tool, and only in the last iteration they implement a language using a complex MDSD tool.

VII. Conclusion

In this paper we have presented our approach to teaching model-driven software development. The goal of our course is to explain the basic principles and concepts of model-driven and generative development. These concepts are illustrated using several different practical tools and techniques that can be used in different combinations and in projects of different scale. The presented approach could be also inspirative when adapting the model-driven approach in a software project. Thanks to the case study students can acquire practical experience with each of presented techniques during the course. Iterative character of development also provides insight into the use of MDSD as a part of the development process.

***Abstract*—Nowadays, complex systems are distributed over several levels of Information and Communications Technology (ICT) infrastructures. They may involve very small devices such as sensors and RFID, but also powerful systems such as Cloud computers and knowledge bases, as well as intermediate devices such as smartphones and personal computers. These systems are sometimes referred to as multiscale systems. The word "multiscale" may qualify various distributed systems according to different viewpoints such as their geographic dispersion, the networks they are deployed on, or their users' organizations. For one entity of the multiscale system, communication technologies, non-functional properties (for persistence or security purpose) or architectures to be favored may vary from one scale to another. Moreover, ad hoc architecture of such complex systems are costly and non-sustainable. In this paper, we propose a scale-awareness framework, called MuSCa. This framework includes a characterization process based on the concepts of viewpoints, dimensions and scales. These concepts constitute the core of a dedicated metamodel. The proposed framework allows multiscale software designers to share a taxonomy for qualifying their own system. At system design time, the result of such a qualification is a model from which the framework produces scale-awareness artifacts. As an illustration of this model-driven approach, we show how multiscale probes are generated to provide multiscale components with an embedded scale-awareness ability.**

***Index Terms*—Multiscale Distributed systems, Model Driven Engineering**

I. Introduction

SEVERAL recent research works [1], [2], [3] consider complex distributed systems that include both very small systems such as objects from the Internet of Things (IoT) paradigm, and powerful systems such as those found in the Cloud. This collaboration enables each system to benefit from the capabilities of the others. Some of these systems also involve intermediate computers such as mobile devices or proximity servers. Those complex systems could also be viewed as *multiscale distributed systems*.

As stated in [4], a "complex system" is any system comprised of a great number of heterogeneous entities, where local interactions among entities create multiple levels of collective structure and organization. Identifying underlying superstructures of complex systems is a challenge. A multiscale analysis of complex systems provides reduced views of those systems with simplified structures, such as presented in [5].

Multiscale distribution is a different concept from large-scale distribution. Large scale has a quantitative meaning, whereas multiscale has an heterogeneity meaning [6], [7]. The system heterogeneity may come from differences of latency or protocols of involved networks, from differences of storage capacity or nature of devices, or from dispersion variations between entities. We propose to study the multiscale nature of a complex system at design time. Approaches that allow developers to work at a high level of abstraction are needed. Model-Driven Engineering (MDE) approaches may help to describe complex systems at different levels of abstraction and from a variety of perspectives [8].

The contribution of this paper is a multiscale characterization framework, called MuSCa (***Mu**lti**S**cale **Ch**a**r**acterization framework*). This framework provides a multiscale taxonomy to describe at design time the multiscale nature of complex distributed systems. The first contribution is a multiscale characterization process. It is based on the concepts of viewpoints, dimensions and scales. We follow a model-driven approach to produce a multiscale characterization editor to qualify complex distributed systems. As a second contribution, multiscale probe artifacts are generated for runtime scale-awareness purpose. With those artifacts, system entities become aware of their place in the organization of the system. In the future, multiscale characterization, and multiscale probes may enable software stakeholders to build, deploy, and manage complex distributed systems.

This paper is organized as follows. Section II presents the motivations for a multiscale characterization framework. Then, Section III proposes a generic characterization process for multiscale systems. The MuSCa framework is presented in Section IV. Finally, Section V presents related works, and Section VI concludes the paper.

II. Motivations for a multiscale characterization framework

This Section presents the motivations for a multiscale characterization framework. Section II-A discusses the heterogeneity of complex distributed systems from the ICT infrastructure viewpoint. Afterwards, Section II-B details some motivating examples for multiscale characterization. Finally, based on these motivations, Section II-C outlines our contribution.

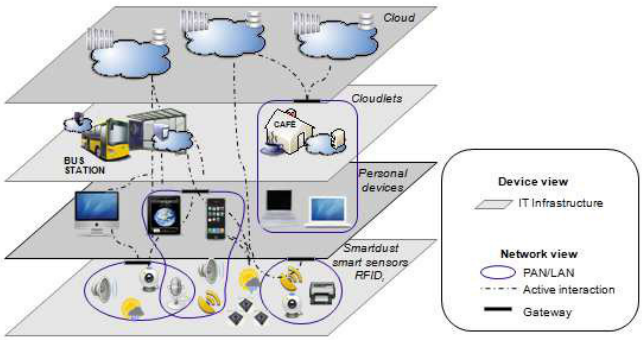

Fig. 1. ICT infrastructure levels of a multiscale distributed system

A. Complex distributed systems and multiscale distributed systems

Fig. 1 depicts our vision of various ICT infrastructure levels that compose complex distributed systems. This figure considers four ICT levels: at the bottom, the smartdust, Radio Frequency Identification (RFID), smart sensors level; at the top, the Cloud computing level; and two intermediate infrastructure levels: firstly personal devices and secondly cloudlets [9] in cafes and bus shelters.

A system, such as the one depicted in Fig. 1 has the topology of a complex system. The interactions between the system entities are decentralized. Many interactions are local but some of them take place between levels. Therefore, the interaction graph between the entities is non trivial, and is difficult to simplify. Moreover this kind of complex systems is composed of a great number of heterogeneous entities, collaborating through different networks, protocols, rules, depending on their respective organizations, geographical distance for instance.

In order to better understand and master the inner complexity of such highly heterogeneous systems, the study of the multiscale nature of a complex system may help to obtain meaningful organizations of a complex system.

B. Motivating scenario

This section presents a motivating scenario that is used throughout the paper in order to illustrate and to evaluate our contribution. This scenario involves a context management system, which is a complex distributed system. This system is deployed through many entities in the city of Toulouse in France. This system aims at enabling a large number of end-users and connected objects to share their context information, such as their location. This scenario is studied through two different aspects: the deployment aspect and the context data filtering aspect.

Considering the deployment aspect, in this scenario it is required that for each local network (LAN) containing at least one context-aware object, one software component dedicated to filter context management data must be installed in the same LAN, on any device having a bandwidth greater than 50 MB/s. Moreover, to get a scalable architecture, another software component dedicated to route context management data must be installed in a hierarchical way, one for each geographical dimension of the city of Toulouse (one for each building, one for each district and one for the city). At last, the routing component for the city of Toulouse must be installed in a cloud and end-user context-aware components must be installed on smartphones.

The second aspect is the context data filtering aspect. In the studied scenario, the user should be able to express constraints about the information he or she wants to receive and about the users that are allowed to receive his or her context information. The two following use cases are studied in this paper. In the first use case, a user, called Sophie, is going to the theater and wants to find a place to park her car. She wants to use the context management system with her smartphone to see the parking places available at foot distance from the theater, where she has just arrived. In the second use case, Sophie wants to share her location, but only with her friends located in her neighborhood.

In this scenario, it is required to express scales of distances (e.g., foot distance, same neighborhood) between system entities—i.e., users and parking places—but also scales of devices (e.g., smartphone, super-computer), network topology, or even geographical administration. These scales constraints drive interactions between entities.

C. From motivations to our contribution

All these use cases motivate the need for a multiscale vision of complex distributed systems. This vision enables a system designer or a user to express constraints concerning different points of view (e.g, geographic dispersion of system entities, network organization, social organization, devices). The solution proposed in this paper is a multiscale vocabulary on which is based a multiscale characterization process for complex distributed systems. This process is then formalized and applied through a MDE approach. The main results of this approach are, firstly, a shared extendable multiscale taxonomy, which can be used to characterize a system or express configuration and behavior constraints, and secondly, generated artifacts, which enable to enforce the constraints at runtime.

III. Multiscale characterization process of complex distributed systems

The MuSCa approach is presented in Section III-A. Then, Section III-B defines a multiscale vocabulary. This vocabulary is illustrated for the geography viewpoint in Section III-C. Other multiscale viewpoints are discussed in Section III-D. Finally, Section III-E presents the full characterization process.

A. MuSCa approach

Fig. 2 depicts the general approach followed by the MuSCa framework. The design process, which is detailed with a SPEM [10] diagram, is composed of two main activities. The first activity is the multiscale characterization to render a multiscale analysis of a complex distributed system. In order

to guide the system designer and to capitalize on previous characterizations, this activity takes the MuSCa taxonomy as an input. This taxonomy contains all the multiscale characterization terms that have already been used in previous characterizations. The result of this activity is a MuSCa model, which is a restriction of the MuSCa taxonomy. If a system designer wants to use new multiscale terms when describing the model, these terms are added to the taxonomy and will be available for the next characterization. In the second activity, multiscale probe artifacts are generated from a MuSCa model. Those probes consolidate data provided by lower level probes, called basic probes. They enable to identify the scales of the system entities at runtime.

B. Multiscale vocabulary

The multiscale characterization process must be based on a precise vocabulary. In the following the concepts of viewpoint, dimension, measure, scale, scale set are defined. These concepts will constitute the structure of the MuSCa metamodel presented in Section IV-B.

The architecture of a system is obtained by studying this system from different *viewpoints*, each viewpoint leads to a view of the system [11].

Each viewpoint is studied through *dimensions*. A multiscale dimension is a measurement of a particular characteristic of a system view for a particular viewpoint.

A dimension is associated to a *measure*, which can be either numeric or semantic.

Using a measure, a dimension can be divided into *scales*. A scale matches, respectively, orders of magnitude for numeric measures, or sets of elements that share common semantic characteristics for semantic measures.

A *scale set* is the set of scales chosen for a given dimension and measure couple.

C. Geography viewpoint

To illustrate the MuSCa vocabulary, Fig. 3 presents possible dimensions and scales for the geography viewpoint. The study of other viewpoints is available for download[1].

For the geography viewpoint, we have chosen to study the multiscale nature of a system through two dimensions, respectively associated with one numeric measure and one semantic measure. The *distance* dimension measures in meter the maximum distance between a set of entities. A set of four scales has been selected for this numeric measure: *local* under $10m$, *footdistance* between $10m$ and 10^3m, *cardistance* between 10^3m and 10^5m, and *planedistance* above 10^5m. For this dimension, the center of each scale is distant from several orders of magnitude from the center of the other scales. The *administrative division* dimension is associated to a semantic measure. It is also applied to a set of entities. It measures their smallest common division. For this analysis, we have selected a set of six scales: *Building*, *District*, *City*, *Region*, *Country* and *World*. One can notice that according to the chosen dimension and scales to study a geography view of the system, the possible organizations and interactions between entities of the system differ.

[1]http://anr-income.fr/uploads/MultiscaleViewpoints.pdf

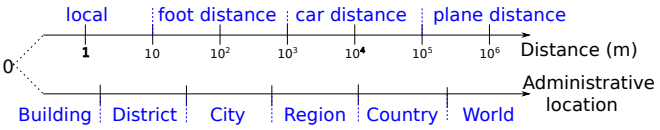

Fig. 3. Dimensions and scales for the geography viewpoint

D. Other multiscale viewpoints

The geography viewpoint is not the only viewpoint to analyze during the multiscale characterization of a distributed system. There are other fundamental viewpoints to consider such as the study of the devices of the system (device viewpoint), the social organization (user viewpoint), the administration organization (administration viewpoint), the network connections between the system entities (network viewpoint). Indeed, they are related to the main issues at stake in the design, implementation and deployment of such complex systems: the need of computing power or storage capacity (device viewpoint), of interaction between distant entities (network viewpoint), and of social organizations (user viewpoint).

However, the above viewpoint list is not exhaustive and other viewpoints, such as data, or time, could also be considered. Depending on the properties to be highlighted for the systems, one may choose to study different viewpoints and dimensions; this is the reason why we propose an open multiscale characterization process.

E. Multiscale characterization process

The multiscale nature of a distributed system should be studied independently from each considered viewpoint. For each viewpoint, a restricted view of the system is considered. Then, for this view, one or several dimensions are chosen. To identify scales for a given dimension, each dimension is associated with a numeric or a semantic measure. Depending on the type of the measure, the resulting scales match, respectively, orders of magnitude for numeric measures, or sets of elements that share common semantic characteristics for semantic measures. The choice of the viewpoints, dimensions/measures and of the scales relevant for a multiscale characterization, is left open depending on the properties of the system one wants to highlight. The objective of these choices is to put to the fore specific characteristics to deal with during the system design, or the system runtime.

The multiscale nature of a system is relative to a multiscale characterization; it is studied independently from each viewpoint. For a given viewpoint, and for a couple dimension/measure, each element of the restricted view of the system is associated with a scale. For a given characterization, and a given viewpoint, a distributed system is qualified as multiscale when, for at least one dimension, the elements of its view are associated with different scales.

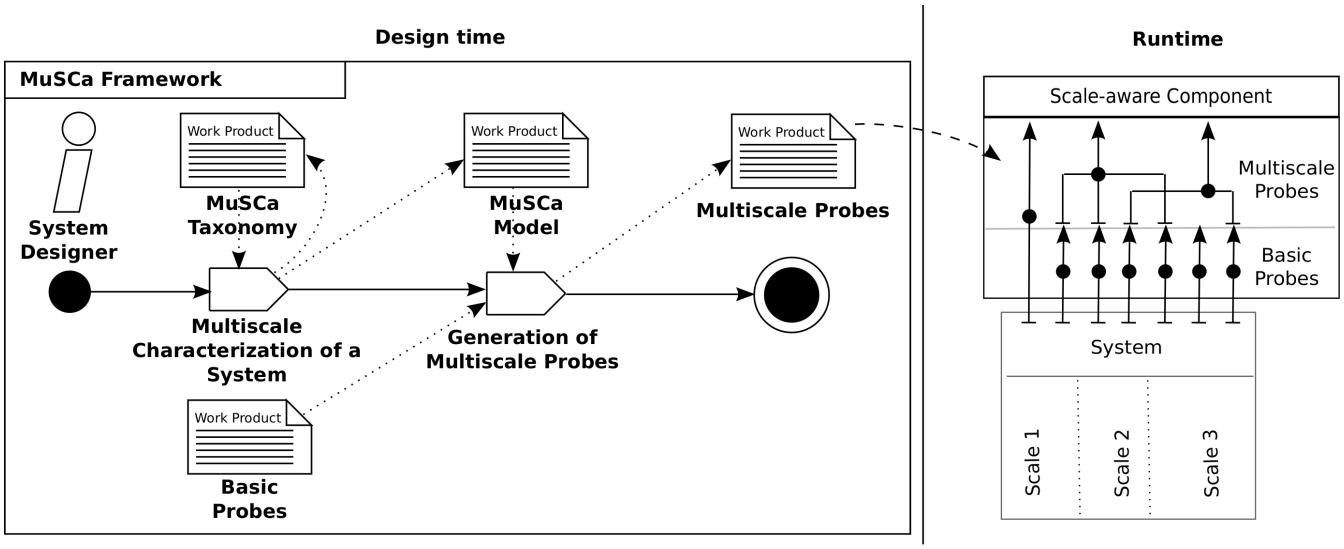

Fig. 2. MuSCa framework approach

IV. MuSCa framework

This section presents the MuSCa framework. Firstly, Section IV-A presents the model-driven approach. Then, Section IV-B formalizes the characterization process with the MuSCa metamodel, and Section IV-C gives an example of a MuSCa model. Thereafter, Section IV-D describes the generated artifacts —i.e., multiscale probes. Finally, Section IV-E presents some MuSCa implementation details and different utilizations of MuSCa are given in Section IV-F.

A. Model-driven approach

In order to formalize the multiscale characterization process, and to use it in the design and deployment of scale-aware distributed systems, we have chosen to follow a model-driven approach (using the four OMG meta-modeling layers [12]). Fig. 4 shows the mapping between the model-driven architecture levels and the MuSCa levels. The MuSCa metamodel (M2 level) is defined with the Ecore meta-metamodel (M3 level). The classes of the MuSCa metamodel represent multiscale concepts. This metamodel is used to define characterization models (M1 level). This characterization may be used for one or several real world systems (M0 level). We also follow the model-driven approach in order to automatically produce artifacts, for instance, producing probe artifacts for scale-awareness.

B. MuSCa metamodel

The MuSCa metamodel is shown in Fig. 5. This metamodel is based on the vocabulary used in the multiscale characterization process.

An instance of MSCharacterization is the result of a characterization process. A characterization considers several Viewpoints —e.g., Geography, User, Device and Network viewpoints (M1 level classes). Each viewpoint determines a restricted view of the system that is studied independently. A

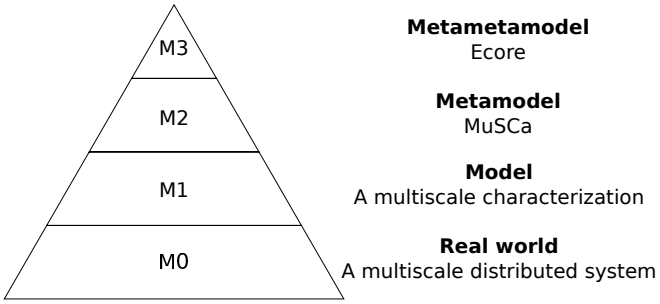

Fig. 4. MuSCa: Model-driven architecture levels

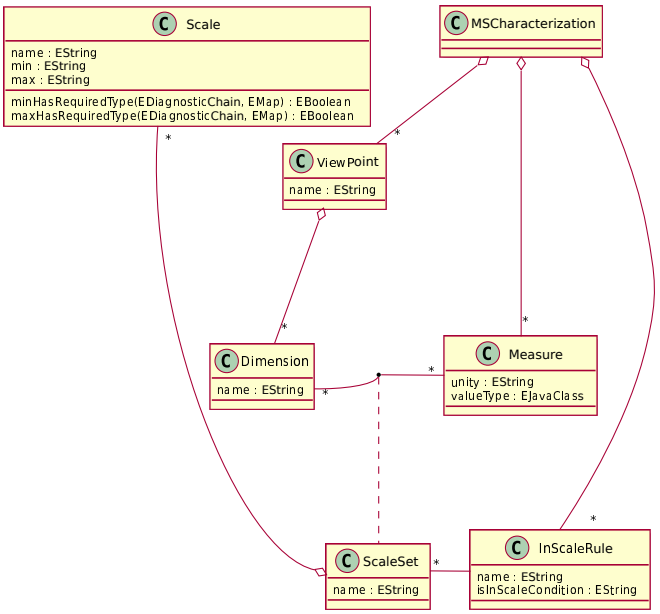

Fig. 5. MuSCa: Multiscale characterization metamodel

view of the system from a given viewpoint is studied through several Dimensions, which are measureable caracteristics of the elements of the view. For example, the Device viewpoint can be analyzed through the StorageCapacity (M1 level) dimension of the system devices. As previously mentioned, a Dimension is measurable, meaning that it can be associated with one or several Measures. For example, at M1 level, the StorageCapacity dimension may be measured with the Bytes measure or the KiloBytes measure. For the association of one dimension with one measure, the designer defines a ScaleSet, which is an ordered set of scales relevant for the system. Each scale set is associated to an InScaleRule, which determines the condition that the measured dimension of an entity, for this scale set, must satisfy so that the entity is associated to a scale. For example, for numeric measures, a Scale is defined by its min and max bounds and a rule can express that an entity is associated to a scale because its measured value is strictly between min and max. Finally, for some viewpoints, the system may present several instances of one scale. For example, if we take the Geography viewpoint, in the AdministrativeLocation dimension, the City scale (M1 level) often has several instances (M0 level) —i.e., the different cities where entities of the system are present.

C. MuSCa model as a multiscale characterization

Fig. 6 illustrates an extract of a MuSCa model that is the result of a characterization process applied to the scenario presented in Section II-B. As mentioned in Section III-A, this model is a restriction of the MuSCa taxonomy. Four viewpoints have been selected: device, network, geography and user viewpoints (the figure only shows the geography viewpoint scales).

We study the geography viewpoint through two dimensions. The first dimension, which we call the "smallest common location" dimension, measures the distribution of the system by studying the smallest common administrative location of a set of scale-aware entities. For this dimension, measured in what we call the "smallest common location measure" (semantic measure), we identify the following scales: building, district, city, region, country, and world. The second dimension, called the "smallest common distance" dimension, studies the distribution of system entities in terms of distances between each other. For this dimension, measured in meters (numeric measure), we identify the following scales: local, foot distance, car distance, and plane distance. Scales are characterized by the min and max bounds in meters. An illustration of these two geography dimensions can be found in Section IV-F, Fig. 7.

D. From MuSCa model to multiscale probes

From a MuSCa model, multiscale probe artifacts are automatically produced. These probes are monitoring programs that are to be deployed on each entity of a multiscale system. One probe is generated for each viewpoint. Each probe exposes at least one method by dimension. This mandatory method returns a scale for a set of entities (e.g., the smallest

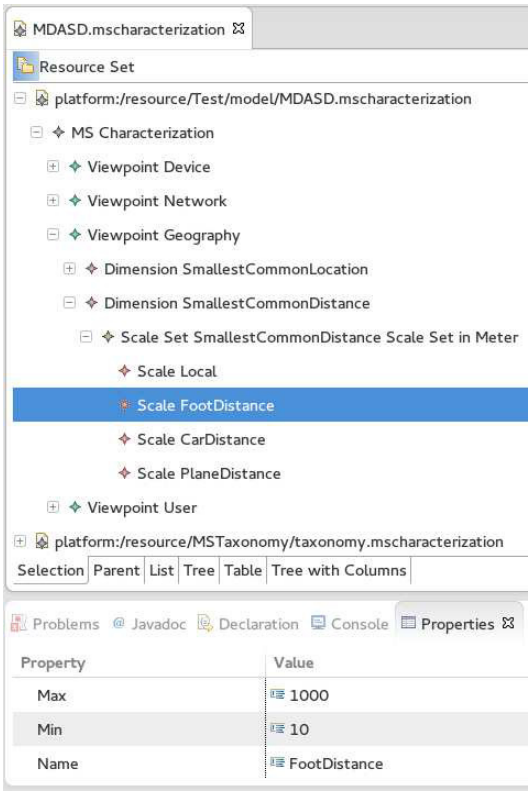

Fig. 6. Example of a MuSCa model

common location measure may return the City scale). For some dimensions, MuSCa also generates one method, which returns the scale instance for a set of entities (e.g., the name of the city). For numeric measures, the methods are automatically generated. The generated methods can be completed to implement a specific logic, in particular to call basic probes, as shown in Fig. 2, or to implement specific semantic measures.

An extract of an automatically generated probe is presented in Listing 1. This probe exposes the getScale method line 5, which uses the getValue method line 3 to call the basic probe. The getScale method returns one of the scales listed between lines 2 and 5 in Listing 2. This last listing contains two generated methods: isInScale method at line 26, which tests if a given measure value is between min and max bounds of a given scale, and getScale method at line 15, which returns the first scale corresponding to a measure value.

```

2    LOCAL("0", "10"),
3    FOOTDISTANCE("10", "1000"),
```

```
4     CARDISTANCE("1000", "100000"),
5     PLANEDISTANCE("100000", "Infinity");

7     private final Meter_Value min;
8     private final Meter_Value max;

10    SCD_In_Meter_Scale(String min, String max) {
11      this.min = new Meter_Value(min);
12      this.max = new Meter_Value(max);
13    }

15    public static SCD_In_Meter_Scale
16      getScaleFromMeasureValue(Meter_Value value) {
17        for (SCD_In_Meter_Scale scale :
18          SCD_In_Meter_Scale.values()) {
19            if (scale.isInScale(value)) {
20              return scale;
21            }
22        }
23        return null;
24    }

26    private boolean isInScale(Meter_Value value) {
27      return (value.compareTo(this.min) >= 0)
28        && (value.compareTo(this.max) <= 0);
29    }
30  }
```

Listing 2. Extract of generated SmallestCommonDistance_In_Meter_Scale enumeration

This probe has been generated with the Acceleo[2] code generator. As an example, Listing 3 shows an extract of an Acceleo template. When this template is applied to the MuSCa model presented in Fig. 6, it generates the scales listed between lines 2 and 5 of Listing 2.

```
1 [for (scale : Scale | aScaleSet.scales) separator(',\n')]
2   [scale.name.toUpper()/]("[scale.min/]", "[scale.max/]")
3 [/for];
```

Listing 3. Extract of a MuSCa Acceleo template

E. MuSCa implementation

We have implemented MuSCa with the Eclipse Modeling Framework Project[3] (EMF). The MuSCa metamodel is defined as an instance of the Ecore metametamodel. EMF generates a specialized model editor. We have extended the editor for validation purpose. This editor has been used to define the MuSCa model presented in Fig. 6. Then, the Acceleo code generator is used to produce multiscale probes implemented in Java.

For illustration purpose, we have detailed in this paper the multiscale probe generated for the geography/smallestCommonLocation viewpoint/dimension couple. The probes corresponding to the device/storageCapacity and geography/smallestCommonDistance couples have also been implemented. Moreover, other multiscale probes can be generated through the same process, for any given viewpoint/dimension couple, provided there is an available basic probe for the corresponding dimension.

F. MuSCa in action

So far, this work is used through three aspects. First, MuSCa has been used to study different IoT scenarios in the INCOME[4] project. Then, MuSCa is used to specify and implement multiscale deployment requirements in a multiscale software deployment tool. At last, MuSCa is used to add multiscale requirements between data producers and consumers and generate the multiscale probes used in the implementation. This section presents a synthesis of these three aspects.

1) Multiscale IoT Scenarios analysis: In the INCOME project, in order to characterize the multiscale nature of several IoT scenarios, the MuSCa vocabulary has been used as a reading grid. The scenarios have been analyzed through different viewpoints and dimensions to highlight their revelant scales. This approach enabled the INCOME project members to compare a great variety of scenarios. This work helped to build the MuSCa taxonomy, which was based on the viewpoints, dimensions, measures and scales identified during the study of the scenarios.

2) Multiscale deployment: Deployment of software entities on devices in a multiscale system is another concern of the INCOME project. For this purpose, MuSCa has been used to define MuScADeL [13], a domain-specific language (DSL) dedicated to multiscale and autonomic software deployment. MuScADeL allows deployment designers to abstractly define deployment properties without exact knowledge of the devices and networks the system will be deployed on. MuSCa helps deployment designers to characterize the multiscale nature of a system from several viewpoints such as device, network, administration and geography. An example of the language (deployment of the motivating scenario) is presented in the Listing 4.

```
2   // Definition of probes
3   Probe Network {...}
4   MultiScaleProbe MSNetwork {..}
5   MultiScaleProbe Geography {..}
6   MultiScaleProbe Device {..}
7   // Definition of a criterion
8   BCriterion Crit50MB { Network.bandwidth > 50; }
9   // Definition of deployment requirements
10  Deployment {
11    // deployment of filter components
12    F @ Crit50Mb, Each MSNetwork.Type.LAN;
13    // deployment of hierarchical routing components
14    R @ Each Geography.Location.Building,
15        Geography.Location.City("Toulouse");
16    R @ Each Geography.Location.District,
17        Geography.Location.City("Toulouse");
18    R @ Geography.Location.City("Toulouse"),
19        Device.PowerProcessing.Cloud;
20    // deployment of end-user context-aware components
21    C @ All Device.Type.Smartphone,
22        Geography.Location.City("Toulouse");
23  }
```

Listing 4. Multiscale deployment constraints

As a MuScADeL code is linked to a MuSCa specific model, the MuScADeL editor can check that dimensions and scales conform to the ones defined in the MuSCa model associated with it. In addition, multiscale requirements are verified at runtime by the multiscale probes generated for this MuSCa model.

MuScADeL runs alongside MuSCa, as an Eclipse plugin, allowing the deployment designer to be able within the same

[2]http://www.eclipse.org/acceleo/

[3]http://www.eclipse.org/modeling/emf/

[4]http://anr-income.fr

engineering tool (Eclipse) to define new multiscale viewpoints, dimensions or scales, before using them in the deployment DSL.

3) Multiscale context data filtering: Concerning context data filtering, there are ongoing works in the INCOME project to extend context data routing and filtering with expressions that use the multiscale vocabulary. These scale-aware routing requirements can be added to context data producer and consumer contracts [14]. The aim of these works is to express privacy and quality of context constraint based on multiscale concerns —e.g., to get context data from parking places located at foot distance, or to share context data with user located in the same neighborhood. These constraints are defined from a model of the multiscale characterization of the deployed system, which gives to the contract designers a shared vocabulary restricted to the existing scales in the system.

Once the constraints are defined, they can be enforced thanks to the multiscale probes generated with the model-driven approach. These probes, which are generated from the same MuSCa model as the one used to define the constraints, can characterize a system entity at runtime in order to decide if this entity matches a constraint or not. For example, Fig. 7 illustrates the areas that match the context data filtering constraints presented in Section II-B —i.e., Sophie's neighborhood and foot distance scale instances. This figure was produced with the help of a generated geography multiscale probe, which has been implemented by calling the reverse geocoding API of the OpenStreetMap[5] Nominatim[6] service, and the map has been produced using the JMapViewer[7] API (also part of the OpenStreetMap project).

This example illustrates the interest of the MuSCa metamodel. The multiscale characterization of the system, which contains rules to associate system entities to scales, is expressed in a MuSCa model with a shared vocabulary, in a declarative way. The MDE approach allows to automatically generate the appropriate probes depending on the rules and scales declared in the MuSCa model. As the same MuSCa model is used to express context data routing constraints, the probes can be used to identify the areas that match these routing constraints.

V. Related works

We have noticed the rising presence of complex distributed systems in several recent research studies [15], [1], [2], [3], [16]. Some of these systems are explicitly described by their authors as multiscale [15], [3], [16]. However, we did not find any definition of the *multiscale* vision of distributed systems and when it should be applied. We propose a framework to characterize the multiscale nature of distributed systems.

To obtain a multiscale analysis of a complex distributed system, two methods may be applied. The first one is a bottom up approach, it studies at runtime real complex distributed system. Some recent works propose algorithms to study collaboration patterns of real complex systems. For example, in [5], the authors propose a community detection algorithm to find structures of communities to partition a complex system. These families of algorithms study the hierarchical structure of real complex systems. Due to the dynamic nature of complex systems, multiscale runtime analysis is unachievable. The second one is a top-down approach, it studies complex distributed systems at design time. New generations of approaches that allow developers of complex systems to work at a higher level of abstraction are needed [8]. Developing complex systems without such approaches increases the use of code-centric technologies, hinders developers from focusing on functional, non-functional and architectural needs, and requires herculean efforts. It produces hand-crafted systems, strongly coupled with technologies, that are neither maintainable nor upgradable. The use of MDE may help to describe systems at multiple levels of abstraction and from a variety of perspectives [17], [8]. MDE facilitates developers' work at design time, by providing specialized modeling languages, metamodels and code generation tools. Moreover, MDE can also be used at runtime to maintain a model of the running system. The interest of MDE is demonstrated in several research areas, as for context-aware pervasive systems [18], [19], runtime adaptation [20], or multi-cloud systems management [21]. Concerning the multiscale vision of complex systems, a multiscale UML profile for the deployment of complex systems is proposed in [22]. The model proposes three fixed scales: infrastructure, communication and deployed entities. In this approach, scales are rather views of a system. There is no distinction of levels in a given view —i.e., scales.

This study highlights the need for a top-down approach to study the multiscale nature of complex distributed systems. Model-driven approaches are interesting as they propose different levels of abstraction, and model transformations. It also identifies the lack of a shared multiscale taxonomy and scale-aware framework. We believe that the MuSCa framework fills these needs by helping system designers to build a multiscale vision of their complex systems. This framework is open : one

can add new viewpoints and associated dimensions, measures, scale sets and scales as needed.

VI. Conclusion

Multiscale distributed systems raise new kind of issues such as heterogeneity management, granularity variations, and distribution over the scales. This paper presented MuSCa, a framework to study multiscale nature of complex distributed systems and to provide them with scale-awareness capability.

The framework is based on a characterization process, which helps designers to study the multiscale nature of a given system. We have analyzed many scenarios and use cases for multiscale systems for the INCOME project. The characterization process enables the designer either to select—among existing ones—the viewpoints, dimensions and scales relevant for a given system, or to define new ones. For one characterization, MuSCa generates probes for runtime scale-awareness. Each characterization enables the framework to extend its multiscale taxonomy and its multiscale probes. Thus the framework learns and memorizes new viewpoints, dimensions and scales to be proposed for a later characterization.

MuSCa is helpful to build multiscale distributed systems that cope with some of the previously mentioned challenges. A good knowledge of the multiscale nature of a system contributes to choosing appropriate architectural patterns for each multiscale distributed system.

Currently, MuSCa is used the INCOME project. A DSL for software deployment was successfully designed using MuSCa. We also plan to use the scale-awareness capability to filter the distribution of the events in a distributed event based system.

Acknowledgments

This work is partly funded by the INCOME ANR project (ANR-11-INFR-009, 2012–2015) in which the following French partners are taking part: IRIT (Institut de Recherche en Informatique de Toulouse), Télécom SudParis, and ARTAL Technologies. The authors thank all the members of this project.

***Abstract*—Increasing demands on web user interface (UI) usability, adaptability, and dynamic behavior drives ever growing development and maintenance complexity. Conventional design approaches scale poorly with such rising complexity, resulting in rapidly increasing costs. Much of the complexity centers around data presentation and processing. Recent work greatly reduces such data complexity through the application of Aspect-Oriented UI (AOUI) design, which separates various UI concerns; however, rendering in conventional and even AOUI approaches fails to maintain this separation, often resulting in high repetitions of concern fragments due to tangling. Even worse, mixing of dynamic and immutable components greatly limits caching efficacy as each have differing lifetimes. We extend AOUI design to push down concern separation to rendering, which reduces description size, through repetition reduction, and enables separate caching of individual concerns. Our results show considerable size reduction of UI descriptions for data presentations, faster load times and extended caching capabilities.**

I. Introduction

ENTERPRISE web applications have became common for domestic and international business in the last two decades. Users expect that enterprise applications support various browsing devices and provide attractive, usable, and fast UIs. Usability and speed often work in contradiction for web applications. Features to enhance usability often increase application size, which slows responsiveness, particularly in low bandwidth network such as those used for mobile access.

Despite clear expectations from UIs of enterprise web applications, conventional design approaches struggle from multiple deficiencies. For example, the UI descriptions for data presentations must restate information [18] from lower layers of the application, in order to extend them. This brings the risk of mistype errors caused by inconsistencies. Furthermore, modifications to the application data definitions require manual changes to the UI. The complexity is mostly evident when the UI description uses Domain Specific Languages (DSLs) [26] with limited type-safety. Furthermore, conventional approaches realize multiple UI concerns tangled together in a single component [5]. This not only limits component readability, but mostly limits its reuse, since such the component is strongly specialized. This "multi-concern component solution" results from the inability of conventional approaches to capture different concerns separately [33]. Such inability is also evident in object-oriented (OO) design [20]. Providing UI for given data in two slightly different situations (e.g., normal and mobile version of a website) may require to implement two similar UI components that differ only in details [5], [24], but requiring their separate maintenance. The UI development efforts are apparent from research [5], [18], which shows that approximately 48% of application code and 50% of development time is devoted to implementing UIs. This percentage grows with UI abilities and context-specificity.

Next, consider UI delivery to remote clients. In most cases, the UI is expressed as HTML and streamed to clients over the Internet. Although, supplemented with immutable resources such as images, stylesheets or JavaScripts the description itself is provided as a single piece of information. Such a single block of information has limited caching options and its size might be extensive. As stated above, UI components that present application data tangle multiple concerns together. This concern mix is also evident in the HTML streamed to a client. For example, an HTML data form mixes together field presentation, form layout, data binding, field validation, etc. Client web browser interprets the delivered HTML to present the UI description to the user.

Aspect-oriented design for UIs [5] reduces information restatement and supports separation of UI concerns for components presenting data [24]. The reduction of restatement is addressed through automated code-inspection [19] that supplies information for transformation to the UI. The aspect-oriented transformation involves integration of various UI concerns. This approach works at runtime and thus considers both static and contextual information. Each data presentation is assembled on demand, based on a given data instance. Concerns are captured individually and integrated based on contextual conditions. Individual concerns can thus be reused across different presentations and data. The outcome is significant UI code reduction and an assurance of correlation between the data definition and the UI presentation, which eliminates errors introduced by human factor [5], [9].

978-83-60810-58-3/$25.00

Since it is possible to capture UI concerns separately at the server-side, they can be also delivered individually to the client. The benefit at the server-side is the increase of concern reuse and thus UI code reduction. The delegation of the UI component assembly to the client-side could considerably decrease the amount of transferred information.

Efficient client-side caching of "tangled" HTML is complicated or even impossible. When only a single concern changes, the entire fragment must be transmitted again. Individual delivery of concerns to clients addresses reduction of replicated information in UI descriptions and makes it possible to cache certain concerns at the client. In this paper, we apply aspect-oriented UI (AOUI) design and research the impact of split concern streaming on the UI load time, transmission size and content caching. Our empirical results show considerable reduction of the UI description size, and the ability to cache individual concerns, which significantly reduces page load times for repeated visits. We evaluate our work by comparing the proposed approach with the conventional approach with respect to transmission content size, load time and caching.

The remainder of this paper is organized as follows: Section 2 describes the background of user interface designs. Section 3 provides an overview of existing work. AOUI approach is presented in detail in Section 4. Section 5 introduces distributed version of the approach. Its evaluation is discussed in Section 6. The final section presents our conclusion and future work.

II. Background

Enterprise system architecture [15], [22], [13] divides responsibilities into layers. For example the Java Enterprise Edition (Java EE) specification [10] divides the application into persistence, business logic and presentation layers. Developers implement each layer using a General Purpose Language (GPL). It is common practice for the presentation layer to use component-based UI approaches [2], which may involve a DSL to better describe a UI; unfortunately, such languages have limited type safety. Each layer has well defined responsibilities, and provides mechanisms to capture certain concerns. A concern [14] [20] can be understood as a set of information, which has some effect on the source code. For example, consider the concerns of data persistence, UI presentation, security, etc. Even though each layer has defined responsibilities and captures given concerns, there exist concerns that do not fit into a single layer but instead cross-cuts multiple layers. These cross-cutting concerns are responsible for tangled source code [20], and GPL languages, including OO, do not have mechanisms to effectively handle them [20], [21] so as to provide readability, maintenance or centralization. The result is that an individual concern, spreads throughout the source code and cross-cuts other concerns. Common examples of such concerns are exception handling, logging, and security as illustrated at Figure 1.

Aspect-Oriented Programming (AOP) provides an effective solution to this problem. [20], [21]. AOP suggests that, in addition to GPL components, there exists an additional concept

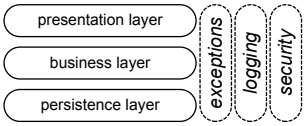

Fig. 1. Cross-cutting concerns in 3-layer enterprise system architecture

called an aspect. A particular program is then implemented using GPL and aspects. An aspect captures cross-cutting concerns separately from the GPL components. The way GPL components are connected with aspects is the main AOP contribution. An aspect consists of two parts: pointcut and advice. The pointcut specifies a situation, location or context under which the aspect is woven into the GPL component. The advice is the concern definition specified either in GPL or a custom DSL. In order to effectively address location in GPL components, AOP defines the concept of join-points. A join-point can range from code location specified by name or a wildcard, method invocation based on method name, annotation, or even a particular application context. Naturally, we can divide join-points into static and dynamic, with the difference based on whether they are activated only by location in the code or whether a runtime condition must hold to activate it. An example can be seen in enterprise systems when handing security with an AOP approach. When a user invokes an action from the UI, this action goes through an action controller [22], which has a method to implement the action. Often, this method has a security annotation determining user access, such as a user security role. Before the actual method is called, the security annotation acts as a join-point that activates a security aspect. This join-point is specified in the security aspect point-cut, and its advice looks into the application context to determine whether the actual user is logged into the system and whether he/she has sufficient permission, given by the security annotation, to be eligible to call the action. If not, the advice throws a security exception; otherwise it delegates the call to the controller method. The same security aspect applies in the UI to determine whether or not to render a given action button for a particular user, etc.

Tangled concerns can be found in the UI as well [5], [4]. Conventional design approaches do not address them separately but together in a single source code. This is directly responsible for low code reuse and readability as well as for high development and maintenance efforts. Various concerns that play a role in the UI can be considered independently as shown by Figure 2a. Unfortunately, because of limited GPL and DSL constructs, all concerns must collapse together into a single UI component, a single source code as depicted at Figure 2b. This results with tangling of all involved concerns, which makes individual concern localization difficult. Consider the concern collapse in Figure 2b at the sample code in Listing 1 while considering concerns from Figure 2a. Its graphical representation sketch is shown in Figure 3. The resulting source code is very specialized with limited reuse. At the same time, we must consider that such UI code restates information from the data definition [19], which introduces interdependencies that must be maintained. Because of limited

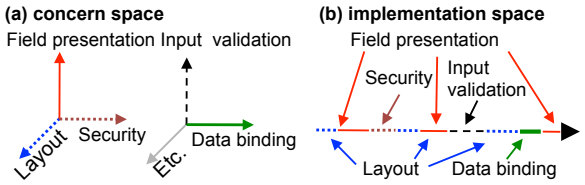

Fig. 2. (a) Concerns as orthogonal dimensions / (b) Implementation space in a single dimension with tangled concerns

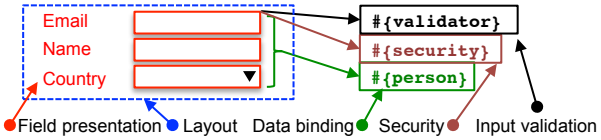

Fig. 3. Graphical sketch of Listing 1 denoting concerns from Figure 2

type safety in DSLs, it is easy to introduce an error while restating information [9]. The situation becomes worse when multiple presentations exist for given data [4]. The limited reuse forces us to maintain multiple, very similar components. Moreover, when we consider conventional approaches and aim to design adaptive or context-aware UIs, we end up with even more similar UI components that we must manage and update each time the data change [24].

The AOP approach for UIs [5] considers the data definition to be the GPL component that is being presented in the UI. In order to present data in UI, it considers individual UI concerns (e.g., Figure 2a) and weaves them together at runtime upon request to assemble the UI presentation. Such data presentation reflects the actual data definition and the particular application/user context. Data definitions, normally OO classes, define data fields and their constraints that act as static and dynamic join-points for the "data to UI" transformation. Dynamic join-points are further extended with the application context. A particular base presentation for each data field is selected based on these join-points. Subsequently, this base presentation is extended with field-level concerns through various aspects. Once all data fields have determined the presentation integrated with other concerns, the layout is woven through the fields. The resulting component reflects the data definition, context and considered concerns. Thus issues, such as information restatement or multi-component management, are eliminated. The result is that no physical UI component for data presentation exists; they are assembled on demand where each concern can be maintained and vary individually based on the user/application context. The advantage comes when we want to present novel data in the UI. All concerns are be reused and thus scaling-up the data model size does not impact the UI concern size or the UI management. What impact the size of the individual concern space are custom presentation layouts for given data, although it is possible to design generic set of layouts reusable among data.

When we consider client-server communication over HTTP, we must be aware that all the concern assembly to receive data presentation takes place at the server-side. Basically, at the server-side all concerns tangle together through an aspect-

Listing 1. Sample source code for UI form reflecting Figure 2 (b)

```
<table><tr>
 <td>Email:</td>
 <td><h:input id="email" value="#{person.email}"
     render="#{security.hasAccess('email')}"
   validate="#{validator.validate('email')}"/></td>
</tr><tr>
 <td>Name:</td>
 <td><h:input id="name" value="#{person.name}"/></td>
</tr><tr>
 <td>Country:</td>
 <td><a:smenu id="country" value="#{person.country}"/></td>
</tr></table>
```

weaver that produces UI descriptions, eventually translated to HTML. This tangling may produce large and complex HTML, containing repetitive information impacting the content size. The server transmission outcome of conventional approaches is similar, if not the same, to the outcome of AOP-based UIs. While compression as well as caching of static resources can be applied, there are two issues. First, compression, although addressing repeating patterns, is not aware of the content logical structure, and thus it addresses small repetitive fragments rather than large concerns. Second, it does not allow to cache immutable information occurring in the delivered UI description. In this work, we show that it is possible to improve the transmission content size and caching with AOP-based UIs. Since AOP has constructs to separate individual concerns, it is possible to stream separately to the client and let the client perform the assembly at the client-side. This reduces the repetitive information from the transmission and, at the same time, an individual decision on concern caching and reuse can be made. Such changes in the UI delivery impact the UI transmission and presumably reduce the delivery time.

III. Related Work

A. UI design approaches

Various approaches have been introduced to simplify development of complex UIs. These approaches can be divided into model-based, generation-based, inspection-based, and AOP-based. Each of these offers certain advantages for UI development; however, they typically fail to address UI maintenance or complex situations, such as context-based UIs adapting during the runtime. In terms of client-server communication, conventional approaches transfer large, perhaps unnecessary, amounts of data, which negatively impacts the communication and response times.

Model-driven development (MDD) [29] suggests that a model is the source of information, and the resulting source code is generated using this model together with a set of transformation rules. The main advantage should be reduction of information restatement that must be handled manually [9] for different perspectives. In [23] MDD is applied to distributed UIs, with description of a workflow that uses a task-centred approach described through the Concur Task Tree (CTT) notation [1]. This allows the description of environment and given context. MDD can handle multi-context UIs, for example, in [3] authors split the context into user, platform and environment parts. At the same time when we aim to

describe different concerns through multiple models, MDD does not provide any standard integration mechanisms to do so [31]. Sottet et al. [31], [32] provide a deep explanation of model-to-code and model-to-model transformations relevant to UI MDD. Although, MDD can be used to capture complex UIs, various contexts, and adaptive features, the model-to-code transformations may struggle in the performance perspective [24]. Transformations are usually performed at compile time as they tend to be time consuming [24]. Compile-time transformations produce source code and descriptions for all possible context states, which might not be fulfilled by the user [27]. Next, the transformation takes place at the server-side, and thus the result may contain tangled UI descriptions possibly containing repetition. The MDD-based UI design may struggle from further issues. In [27], the authors observe that it suffers during adaptation and evolution management. Such design handles base situations well, although when context variations or customizations are needed, the modification often take place in the UI code [9] rather than in the model. Manual changes are lost the next model-to-code transformation, which then leads to difficult maintenance [9]. Another issue, presented by [5], arises when the MDD applies solely to the UI but not to other parts of the system, such as persistence or business logic subsystems. In such cases, information captured by the model must match to information captured by the rest of the system. When only one part of the system changes, another part may lose compatibility and may need to address the changes manually. Such an approach is unfortunately very common in the research discipline of human-computer interaction [24].

The use of DSLs [26] for the UI model description is common, although, DSLs tend to provide weak type safety, which extends maintenance efforts, since information change propagation becomes tedious and error-prone in a manual process. DSLs are often used to directly specify UIs [26] [17]; a practical example is the Java EE standard for component-based development called JavaServer Faces (JSF) [2]. The DSL brings simplification to the UI description [5], as oppose to GPL. It is transformed to the target UI language, such as HTML. DSLs naturally fit to UI descriptions, but through their weak type-safety, it is easy to introduce errors related to restated information from lower application layers [18]. For example a DSL description may reference data, their fields and constraints that are already described in the application through GPL [12]; however, referencing a GPL component from DSL requires certain restatement with a negative impact on maintenance. Similarly to MDD, the DSL-to-native code transformation takes place at the server-side, thus the transmission streams the produced tangled code.

Another approach addresses information restatement by utilizing code-inspection and meta-programming [18], [5], [24]. It inspects data GPL definitions and from the result composes a structural model. This model is transformed to UI descriptions with all data/constraint references resolved through the model; this avoids human-errors related to inconsistencies. The output can be in the form of DSL, such as JSF. In comparison to the above approaches, this one works at runtime, although, it does not address cross-cutting UI concerns. Similarly, the product generated at the server-side is not different from the product produced through DSLs or MDD.

One possible solution that addresses tangled code and cross-cutting UI concerns is Generative Programming (GP) [11], [30], which emphasizes domain methods and integration with GPL. GP can be seen as programming that generates source code through generic code fragments or templates. The goal is to address gaps between program code and domain concepts, support reuse and adaptation, simplify management of component variants and increase efficiency. The generation, although, happens at compile time. The use of GP for UI is demonstrated at [30] through abstract UI specifications. An application that uses this concept consists of three parts: a DSL for UI description, configuration generator that automates the product UI assembly and an extensible collection of elementary components available for the assembly. The configuration generator takes the DSL specification and assembles implementation components from them and from the available components. Such an approach allows production of a large number of system variants for specific requirements. In a presented case study, a system combined two hundred features in the UI, with a resulting variability of 5×10^{17} prototypes. It is questionable whether such a large number of feature components is reasonable and could be ever used, although all states are physically generated at compile time and statically allocated. The nature of the compile-time assembly makes it hard for use with future adaptive systems that need runtime information to base its decisions on [27].

The AOP approach has been applied to extend capabilities of existing approaches. In [27] the authors apply AOP to MDD to support adaptive features at runtime. This work suggests that MDD approaches do not naturally fit into adaptive systems because they lack the runtime information, which should be considered to influence model-to-code transformation. As mentioned in [32] the MDD runtime transformation might be performance inefficient for complex situations [24]. Some suggest that MDD UI transformations may generate all possible application states and configurations for hypothetical/possible situations. In complex systems, this can grow exponentially. Also, MDD-based systems suffer and become impractical in evolution management of system adaptation. [27] thus suggests using four runtime models that represent main system data that are manipulated at runtime. These models are responsible for system runtime adaptations and generation of application components. The work describes the aspect-oriented conceptual model [33], weaving process and context very sparsely, and no performance consideration is given to the manifest approach effectivity for production systems. Alternative aspect-oriented UI design, based on conventional UI designs and enabling both code inspection and separation of concerns for data representations, is given at [5]. Similar to inspection-based approaches, meta-programming determines a structural model (join-point model). Subsequently an aspect-oriented transformation of the model to the UI enables integration of various, separately defined, UI concerns. Although, the

aspect weaving happens at runtime, it takes place at the server side and thus the UI transmission to clients is no different from the above approaches.

As shown above, existing research in UI fails to address effective UI transmission to clients or optimization of client-side caching. One of the contemporary UI frameworks, although, does address caching by compiling the GPL UI descriptions to client cacheable resources. The Google Web Toolkit (GWT) [16] suggests describing the UI in the type-safe Java language and compile it to a JavaScript (JS) UI description. Note well, that even GPL UI description consists of restated information from application lower layers, such as data field descriptions and their constraints. For example, to design a UI representation for a given data field, the developer must select an appropriate component, bind it with the field and manually restate the component constraints already defined at the field, through annotations [12]. As mentioned in [33] and [20], GPL languages do not effectively handle cross-cutting concerns; consequently, GWT tangles them together. The GWT produces a JS UI description at compile time, which is similar to the MDD approach. It produces multiple versions of those descriptions to support various end-devices. It consists of code fragments that can be cached as well as these that cannot. GWT struggles from the same disadvantages as MDD, and thus it does not fit to adaptive UIs. For instance a UI page that presents many context-based variations compiles all possible states to a single description and ships it to the client not matter whether the user uses a single UI state or multiple. This becomes obvious with complex adaptive systems [27] with combinations of states and configurations that grow exponentially. In our work, we suggest transmitting UI concerns separately to clients. This allows transmitting only the actual state needed by the client, and at the same time, each concern may change individually, avoiding exponential grow.

B. UI delivery to the client

The standard client-server communication for web systems is based on the HTTP protocol that provides the core mechanisms to improve the transmission. First, the TCP-based protocol supports connection persistence so multiple resources can be loaded from a single server. Connections are reused, rather than reopened, which requires additional overhead. Multiple connections may exist from a client to a single server. HTTP supports content compression to reduce the transmission content size. Furthermore, it supports content caching at the client-side with time-based invalidation. The caching applies mostly to static resources such as CSS, images, and JS. In [7] authors show that the average contemporary web systems consists of about 90% static and cacheable resources. To further reduce the transmission, UI developers may apply content obfuscation and resource merging [6]. To mitigate the impact of client distance, servers often apply geo-distributed caching of static resources called content-delivery networks (CDNs), such as Akamai [28].

Structured Hypertext Transfer Protocol (STTP) [34] extends HTTP to include new messages to control the resource transmission for a particular web page. A similar approach, HTTP-MPLEX [25], employs a header compression and response encoding scheme for HTTP. Similar to STTP, it multiplexes multiple responses to a single sustained stream of data to speed response times and improve application layer use of TCP. While experiments show performance improvements with these protocols, they do not consider resource distribution through CDNs, caching, or variations. Another optimization approach is brought by cooperative-web cache [7], [8]. It involves clients with cached resources in participation in an overlay peer-to-peer network, which allows clients to share these resources in the overlay. Unlike CDNs it supports natural scalability and free P2P services; however, it must deal with content invalidation in the overlay and mechanisms to disable and prevent malicious clients from sharing corrupted data.

IV. AOP-BASED UI ASSEMBLY

The development and design approach of aspect-oriented UIs (AOUI) [5] is considerably different from conventional approaches. In order to describe the AOUI design, we first illustrate the UI design with conventional approaches and describe its dependencies to data definitions. Next, we sketch the AOUI design differences and describe it genericity and relaxed dependencies.

Figure 4 demonstrates the conventional UI design with the data model at the top with individual data classes with fields and given constraints as well as application context. The bottom presents a sketch of various presentations of given data. These presentations are rendered in the application based on the context. Each presentation has physical code representation and consists of multiple elements that bind to a particular data field or its constraints. The UI presentation has to restate field names as well as the constraints in its source code, which increases UI component coupling. Each such component is specialized to display specific data, and we can hardly assume that such UI component could be used for another data class. Such coupling must be seen from the perspective of system maintenance, thus when a given data class changes, for example a new field occurs, we must manually reflect it in related UI components. When the UI component description uses DSL, limited type safety may not provide any enforcement mechanism on the compatibility with data. We can summarize the disadvantages as follows: no automated data change propagation to the UI, limited type safety does not prevent human errors, limited separation of concerns and limited reuse, data class presentation requires to design a custom UI component. To see the difference with the AOUI design, consider the case when we aim to render data in the UI. In order to do that, we need to know the physical location of a particular UI component (denoted via UI render start mark at Figure 4), and this components then uses its configuration to cooperate with the data class, and its fields based on matching names.

Next, consider the AOUI design in the same illustration of data classes and the application context at the top and data presentations at the bottom Figure 5. First, note that with AOUI

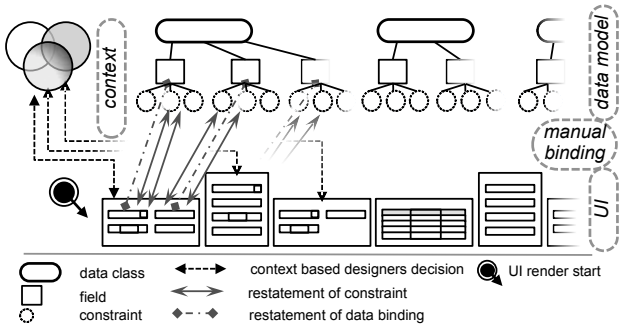

Fig. 4. UI design with conventional approach

there is no physical location of the UI presentation, because it does not exists. Instead it is generated on request by passing a data instance reference to an aspect weaver (denoted via start mark in Figure 5). The AOUI aspect weaver inspects the given instance data class, denoted by ①, and produces its structural (join point) model for given data. This model is created once upon the first use and consists of class and field information and their constraints. Upon each use, a clone model is made and modified/restricted according to user context. For example fields not relevant to given context in the UI are eliminated or restricted based on security rights. Additional elements from the application context can be exposed to this model as well. Each model element then acts as a join point for the subsequent transformation stages. In the next stage ②, the aspect weaver considers generic mapping rules that select a presentation for each particular data field based on its properties in the structural model. These rules are not specific for a given data class or a field; instead they only bind to model elements, which may occur at any data field. This brings genericity and reusability among fields and data classes. These rules become reusable among data classes or even among different systems. Each rule consists of two parts, a specification of structural model elements in a query (a point-cut) and an advice in the form of a presentation template. A rule applies to a field, which has a given constellation of specified elements. For example a query specifies a text-typed field with maximum length greater than 255 letters. The selected rule then applies an advice that selects a presentation template for the field matching the given query. This presentation template consists of a description for a basic field presentation in the target UI language. It also contains extensions in the description through which it is possible to integrate other aspects to it, providing concerns weaving. Each template aspect consists again of a point-cut that uses the same constructs as mapping rules referencing the structural model and advising how to integrate the concern. Often it embeds selected structural model element values to the output. In the stage ③, after all data fields have resolved presentation, a layout template is selected based on the context and integrated to the field presentation. This results with stage ④ that provides the presentation for given data instance and current application context and renders it to the UI. The most important benefit is that rules and presentation templates are generic and not dependent on specific data, which allows us to scale-up the

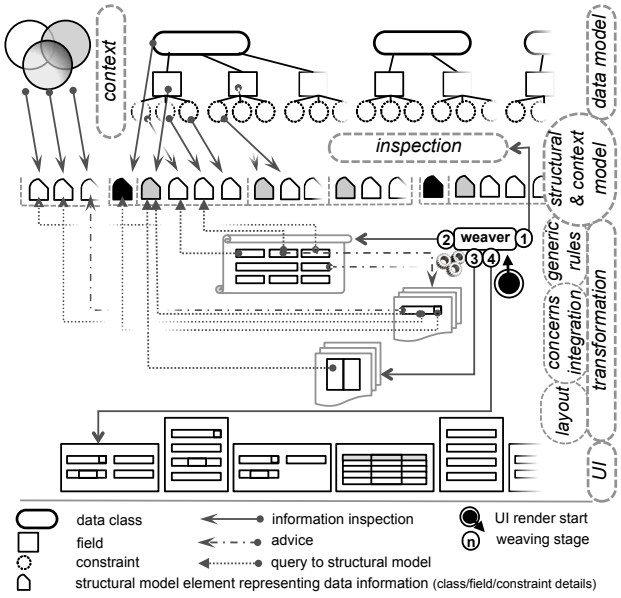

Fig. 5. UI design with AOUI

data model without an impact on the size or efforts related to the UI. In other words, a new data class passed to the AOUI aspect weaver is displayed based on the existing rules and templates. Data changes do not cause inconsistency in the UI because the change is reflected in the ad-hoc structural model that influences the selection of a given transformation rule as well as it subsequent aspect integration in the presentation template. Novel constraints apply to the UI according to the their occurrence in templates. In the [5] authors show that among 63 data classes in a production system with about 473 fields, only 28 transformation rules and presentation templates are needed. They are reused, and various concerns integrate to it based on given context. The benefits can be summarized as: Code volume reduction, constraint enforcement, separation of concerns, data independence, concern reuse, reduction of restatement. Furthermore, it is easy to integrate new concerns and thus support context-aware or adaptive UIs while not introducing complexity to the UI design.

V. Distributed AOP-based UI assembly

Conventional design approaches stream the UI description as a single block of information. The AOUI design untangles UI concerns for components reflecting data and reduces development and maintenance efforts. Such weaving takes place at the server-side and its product, with weaved-concerns, is streamed to clients. This is equivalent to conventional approaches. One may assume that content compression over HTTP solves the inefficiency, although with no doubt, it does not improve caching options. To the contrary, consider a solution where concerns (such as these from Figure 2 a) are streamed separately to clients. This might seem as an addition overhead as we need to handle multiple connections. On the other hand, this may eliminate repeating patterns in the transmitted content and enable caching for given immutable concerns.

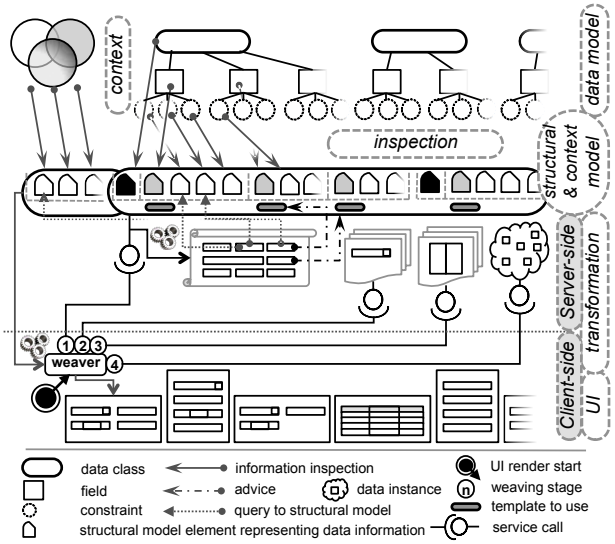

Fig. 6. UI design with dAOUI

In order to design distributed AOUI (dAOUI), the process of concern weaving should be partially pushed to the client-side. The application data model (or data transfer objects [15]) and application context are part of the server-side, and thus the inspection part takes place there. This gives a structural and context model, which could be streamed to the client. Some model elements might not be relevant to presentation or to a particular user. For example, there might be internal fields such as primary key, version field, etc., and these might not be relevant to the UI or to a particular user rights/tasks. AOUI handles this through data model constraints as well as through the context. To provide a particular user only the model elements relevant to his session and rights, the context is applied to the requested subset of structural model. This eliminates elements that would not apply for the UI composition, and this subset is streamed to the client. The selection of a particular presentation template for given data field could be done at the client-side. This increases the complexity of the client weaver since it must be aware of transformation rules and these may need to have access to internal server-side information to resolve rules to and make a decision. Thus keeping this responsibility at the server-side and providing the result to the client reduces the client weaver design complexity. Figure 6 depicts the responsibility assignments between server and client sides through service calls. Each client needs to have access to the structural and context model for the given data it represents in the UI ①. It also needs access to presentation templates ②. The decision on template selection made on the server-side is delivered together with the structural and context model ①. The client uses a particular presentation template suggested by server. Each template content is resolved towards the structural and context model of a given data field. Layouts ③, similar to presentation templates, are provided to the client-side for integration to the data UI presentation. Other concerns might be provided as separate services and integrated either at the server-side through transformation rules or via client-side presentation templates. Each client composes the UI data component based on provided concerns that are influenced by system context. The server also provides the actual data instances to the client ④. These data are displayed in the assembled UI component. The data submission uses HTTP POST or GET mechanisms or a web service.

The life-cycle for the web systems works as follows. First, the user requests navigation to a particular page or a dialog. This page consists of description elements from conventional UI design. The difference is for components representing data. Such components are replaced by custom tags interpreted at the client-side (for example a JS call). The tag indicates which data to display and what settings (context) should apply for the UI component assembly. Such content, with no data physical representation in it, is transmitted to the client-side. When client interprets the delivered content, it interprets it ordinarily. Custom tags are interpreted through a client-side weaver that requests given concerns from the server-side. Provided responses consider user rights and security. As depicted at Figure 6, the weaver assembles the UI representation of a data instance (given by the custom tag) conforms the structural model, application context and settings provided together with the data reference. The weaver may either request a particular concern from the server-side or may reuse it from its cache. For example, presentation templates will hardly change throughout a long period of time, or given data fields are immutable in given context over the time or throughout a user session/conversation.

VI. Evaluation

In order to evaluate our approach, we consider existing production level enterprise web application based on Java EE 6 platform with JSF [2] framework for the UI design. For our evaluation, we consider a subsystem for user account management. We evaluate the existing solution regarding data transmission, page load time and caching. Next, we implement the same subsystem with dAOUI design. Specifically, we design REST services at the server-side and a JS library responsible for UI component assembly, interacting with these services. These services include a service to obtain structural and context model for given data, a service to obtain the actual data from a given instance conforming system security and finally a service to handle data manipulation from the client-side. Next, we provide a JS package with presentation and layout templates and the client-side aspect-weaver. The dAOUI prototype is evaluated using the same criteria.

Figure 7 at outer left shows a sample UI subsystem considered in the evaluation. The same result can be designed with both conventional and AOUI approaches [5]. The difference relates solely to the server-side design; the content transmitted to the client-side is equivalent for both approaches. The dAOUI prototype is shown at inner right of Figure 7. The differences are that the conventional UI uses JSF, which is transformed to HTML through the framework and transmitted to the client-side all together. The second UI consists of JSF for the page without components representing data. Instead it uses a JS library that interacts with the server REST services

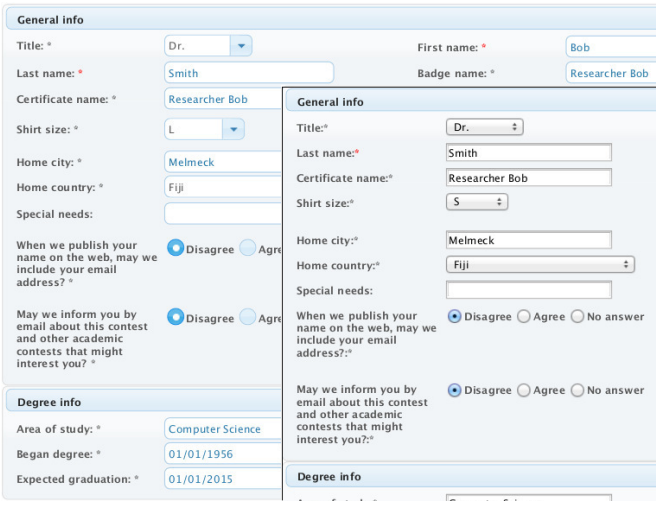

Fig. 7. Evaluated UI subsystem designed with conventional/AOUI approach in the outer left position, the dAOUI approach in the inner right position

through JSON format to assemble the data presentation components and embeds them to the UI. In both cases UI panels, controllers and page navigation logic are equivalent.

A. Network transmission and page load times: The base case

To evaluate network transmission size and page load times, we use the UIs described above. In the evaluation of page loads, we consider complete page rendering. We must emphasize that both UIs utilize equivalent static web resources (JS, CSS and images). These same resources are part of the production system, so with the outcome we can consider a realistic impact on a production system. The dAOUI version has additional JS libraries, but on the other hand, the initial HTML page does not contain descriptions for data components. Instead, it consists of a JS initiation calls to assemble data components based on settings given in the HTML page. The considered data components at the page at Figure 7 consist of 23 fields of various data types given by the production system.

The conventional approach page produces 1458 KB to render the UI, although with HTTP compression the transmitted content reduces to 329 compressed KB (cKB). The main HTML document is 86 KB (11.1 cKB), and the rest 1372 KB are static resources. To download and render the UI page with compression takes 2.3 sec (average over 10 samples with standard deviation $\sigma = 0.23$). The download uses gzip compression with no network restrictions. The dAOUI page produces 1368 KB (311 cKB). The main HTML document has the size only 2.9 KB (1.2 cKB); additionally there is 10 KB (3 cKB) of JS and four calls to REST services with a total size of 13.6 KB (4.9 cKB). The page load reduces to 1.73 sec ($\sigma = 0.14$), an almost 0.6 second (or 25%) time reduction.

Next, we consider caching. All static resources are cached at the client-side. The conventional approach page with cached resources requires 86 KB (11.1 cKB) to be loaded from the server, and the page load time reduces to 1.67 sec ($\sigma = 0.24$). The dAOUI allows us to cache the weaver, presentation and layout templates, as well as the data structure, which is immutable. This reduces the transmitted content down to 3.9 KB (2.1 cKB), and the page load time needs only 0.79sec ($\sigma = 0.07$), representing reduction of almost 0.9 sec, which is less than 50% of the original wait time. The summary can be seen from Table I.

B. Increasing the UI size: The larger case

The production system on which our study is based has the person account page considerably larger than what we considered above. Next, we consider the impact related to data size extension. The extended UI has 42 fields at the page.

The conventional approach page extends to 1484 KB (331 cKB) out of which 110 KB is the HTML document (13.9 cKB). The page load time is 2.54 sec ($\sigma = 0.33$). The dAOUI size has in total 1394 KB with the HTML document 5 KB (1.4 cKB) and JSON calls 19.3 KB (8.4 cKB). The compressed transmission size has 315 cKB. The page load time for dAOUI is 1.89 sec ($\sigma = 0.17$), representing a reduction of 0.65 sec, which is similar to the previous evaluation with reduction to less than 75% compared to the conventional approach.

The cached-enable evaluation of the conventional approach design consists of the total transmitted size of 110 KB (13.9 cKB) with load time 1.99 sec ($\sigma = 0.38$). The cached dAOUI has 6.9 KB (3.8 cKB) and a load time of 1.01 sec ($\sigma = 0.15$). Similar to the previous evaluation, the reduction of wait time is almost 1 second and represents almost 50% of the load time. The summary can be seen in Table II.

C. Throttling the network: 3G/DSL users case

The next evaluation throttles the network conditions to evaluate behavior for both mobile users with a 3G network and DSL users. For the 3G evaluation, we restrict the network bandwidth to 384 kbit/s and set network delay to 20ms. Such network restrictions allow us to emulate network conditions for users with mobile devices. We evaluate the base page with 23 fields. The load time significantly grows to a barely usable system. The page using the conventional approach requires

TABLE III
3G AND DSL CASE, TRANSMISSION OF UIS WITH 23 FIELDS

	Load time (using compression)			
	(sec)	(relative)	(sec)	(relative)
384kbit/s 20ms delay	*No-cache*		*Cached*	
Convent. approach (sec)	18.89	1	2.72	1
Distrib. AOUI (relative)	15.88	0.84	1.07	0.39
768kbit/s 10ms delay	*No-cache*		*Cached*	
Convent. approach (sec)	9.45	1	1.79	1
Distrib. AOUI (relative)	8.28	0.88	1	0.49

TABLE IV
GWT COMPARISON, TRANSMISSION OF UIS WITH 23 FIELDS

	No-cache	**Size (KB)**		*Cached*
		Compressed		Compressed
GWT	379	102	11.9	5.8
Distrib. AOUI	161	41.8	3.9	2.1

18.89 sec to load ($\sigma = 2.16$). The dAOUI requires still a long time 15.88 sec ($\sigma = 0.57$). The reduction represents 3 sec, which is around 85% of the original load time. Caching becomes a "must have" for these kinds of mobile users. With caching, the conventional page loads within 2.7 sec ($\sigma = 0.42$) compare to the dAOUI with 1.07 sec ($\sigma = 0.19$). This represents a reduction of 1.6 sec, which is less than 40% of the original load time. The summary is at the top of Table III.

Next, we evaluate the situation for DSL users with bandwidth to 768kbit/s and delay 10ms. The conventional page needs 9.45 sec to load ($\sigma = 0.84$). The dAOUI reduces the load time by 1.1 sec, down to 8.28 sec ($\sigma = 0.36$). The reduction in percentage is similar to the 3G version and represents slightly less than 85% of the original load time.

Caching significantly helps for consequent page loads. The conventional page loads within 1.79 sec ($\sigma = 0.24$) compared to the dAOUI with 0.87 sec ($\sigma = 0.08$). The dAOUI is 0.9 sec faster and less than 50% of the load time. The summary can be seen at the bottom of Table III.

D. Comparison with GWT

The GWT introduced in the related work targets improvements to UI caching. To compare it with our approach, we implemented the 23-field prototype application with GWT. Note well, that the evaluated dAOUI page at Figure 7 is based on a production system, while the GWT is just a prototype. This results with differences in both prototypes regarding linked JS libraries. While the dAOUI prototype links JS resources related to given JSF component provider, the GWT prototype does not link to any generic JS library. Although, this does not impact the caching statistics, we modify the dAOUI prototype as follows: We reduce the linked JS libraries and only consider libraries related to the functionality of the dAOUI, which makes it equivalent regarding the comparison with the GWT prototype. The dAOUI prototype needs to transmit 161 KB of data to build the UI at the client (41.8 cKB). The GWT version needs 379 KB (102 cKB). The main document in GWT is converted to into JS with cacheable fractions with 141KB (50 cKB) and non-cacheable fraction with 7.2 KB (3.4 cKB).

The cached-enabled evaluation stays the same for dAOUI with transmitted content 3.9 KB (2.1 cKB). The GWT version needs to download the HTML page, displayed data and the non-cacheable JS fragment, which is in total 11.9 KB (5.8 cKB). The results are summarized in Table IV. From the results, we see that UI construction in the form of JS can considerably improve caching at the client-side. The JS presents tangled code through mixed concern, which extends its size. Separately streamed UI concerns can reduce the UI description, and improve caching.

E. Summary

Streaming various concerns separately from server to clients brings reduction to the overall transmitted content, page load times (considering complete UI rendering) and improved caching. In the evaluation, we streamed presentation and layout templates, data structure with applied security as well as the actual data. The dAOUI enables to use cache for concerns that are normally tangled together in conventional approaches. The study on a production system shows the reduction of content size in the range of tens of KBs even when compressed. Even though the dynamic content represents only around 6% (3.5% compressed) of the total content, the transmission size of uncached UI content reduced in total by 5%. With caching that strips the static content, it reduces transmission by 72-81% compare to JSF. With GWT the transmission content with cached resources improves by around 63%. The dAOUI managed to reduce the page load time to the range of 75-90% of what it takes with a conventional approach. This turns even better with caching, which gives reduction in the range of 40-50% compared to the conventional approach. The exact reduction is, although, influenced by many factors including network conditions and the UI itself.

In our evaluation, we reduced the transmitted content sometimes by an order of magnitude compare to the JSF approach. While the GWT approach compiles the UI into a JS and provides a solution with extended caching capabilities, such a solution can be further improved with dAOUI.

VII. CONCLUSION

In this paper, we suggest an alternative design approach for presentations of data in enterprise software systems. Conventional designs mix various concerns together, which results in code that is hard to maintain and reuse. We show that some of the UI concerns do not change over the time, and we may cache them at the client-side to reduce network traffic. Conventional designs fail to offer this ability, so given concern might be tangled with others without the possibly of variability and reuse. AOUI design separates concerns for UI components presenting data and thus reduces maintenance efforts as well as improves reuse of these concerns. With an extension of such design, it is possible to deliver concerns separately over the network to clients and delegate the component assembly to the client-side. This may reduce the transmitted content size that needs to be delivered to the client over the network, but mostly it enables caching and reuse of specific UI concerns at the client-side. From a case study based on a subset of a production system, we provide results showing a reduction of the total transmission size from the server to the client

and the page load time. Furthermore, we extend capabilities for caching of UI concerns at the client-side, which further reduces the data transmission as well as page load times.

Although the results from the study are promising, we must consider its limitations. The design approach fits well for data presentations; it builds on the top of other approaches that deal with interaction, page-flow, etc. AOUI easily adapts to development standards and allows integration of third parties for security, context-awareness, etc. The approach does not aim for complete design of UI pages but targets only data presentations. Existing approaches provide a large palette of various field components, suggestion boxes and data manipulations. With this approach, it is necessary to design them as no component library exists. On the other hand, it is easy to integrate HTML5 components or custom presentations for fat-clients. The interaction is not limited to only frontend and backend parts of systems, but it possible to consider middleware communication. Considering AOP's natural ability of concern separation, the design fits well to context-based UIs. At the same time, the AOP development pushes towards different development practices, and designer transition from conventional habits might be difficult. In addition there is a lack of tool and framework support as well as a missing standard for AOUI.

In future work, we aim to extend concerns with business rules integration. Our preliminary work [4] shows that it has large potential. We also look at integration of aspect-oriented design to service oriented architecture (SOA).
